Paranoid delusions are very common in patients with a first-episode of psychosis; in a large-scale clinical trial of patients who were offered psychological interventions soon after being diagnosed as suffering from a schizophrenia spectrum disorder, 250 (98%) of 255 patients who were suffering from a first episode and were assessed within 2 weeks of becoming known to services scored above the clinical cutoff of 3 on the Positive and Negative Syndrome Scale P1 item (delusions), and 235 (98.1%) scored above the clinical threshold for suspiciousness (P6) (Moutoussis et al., 2007). Persecutory delusions are also found, although less often, in patients with other diagnoses such as depression (Bentall, Kinderman, Howard et al., 2008) and both the depressive and manic phases of bipolar disorder (Smith et al., 2017).

A complication in classifying delusions is that people, particularly when severely psychotic, often report multiple beliefs. However, a recent metaanalysis of 99 studies of the prevalence of different delusional system in different psychiatric populations around the world, all of which allowed more than one delusional theme to be recorded per patient, found that paranoid delusions were the most common (64.4% of patients), followed by delusions of reference (the belief that innocuous events; e.g., a casual glance from a stranger in the street or a news bulletin on the radio, have special significance for the individual; 38.9%), grandiose delusions (28.4%), delusions of control (the belief that the body, emotions, or thoughts are being controlled by someone else; 21.3%), and religious delusions (18.0%) (Collin et al., in submission). A wide variety of political and socioeconomic variables relating to the countries in which the studies were conducted were examined in this study, but these had very little impact on the distributions; for example, paranoid delusions were the most common in both the industrialized, developed nations and also in poorer developing nations, and this was true when individualist and collectivist cultures were compared.

The covariation between these different kinds of delusions has not been comprehensively studied. However, some studies have addressed the comorbidity between paranoid beliefs and grandiose delusions, and others have addressed the relationship between persecutory delusions and delusions of reference. Patients with both paranoid and grandiose delusions are quite common, and it is common in clinical practice to encounter delusional systems in which both types of belief are intertwined, as in the case of a patient who believed that he had invented the helicopter and pop-up toaster and blamed his doctors for stealing the revenues that should have accrued from these achievements (Bentall, 2003). In a British study of 301 chronically ill (at least two episodes) patients with schizophrenia or related diagnoses, 63.8% were found to have persecutory delusions, 32.2% had grandiose delusions, but a further 19.3% had both (Garety et al., 2013).

The relationship between persecutory delusions and delusions of reference has been more contested. For example, as noted above, Freeman and Garety's (2000) criteria for classifying a delusion as persecutory explicitly excluded delusions of reference and yet the same research group, a few years later, included a subscale measuring ideas of reference ("People definitely laughed at me behind my back," "People have been dropping hints for me") in a questionnaire measure of paranoia (Green et al. 2008; see below). Startup and Startup (2005) attempted to clarify this issue by showing that delusions of reference fall into two separate types: *delusions of observation* (patients believe that they are being spied on or gossiped about) and *delusions of communication* (patients believe that some kind of general sign or message, e.g., a bulletin by a television news announcer, is being directly addressed to them); they found that only the former type cooccurs with persecutory delusions.

In most accounts of delusional paranoia, the patient considers him- or herself to be an innocent victim of persecution. However, Trower and Chadwick (Chadwick et al., 2005; Trower & Chadwick, 1995) have argued that two distinct types of paranoia can be identified, which they termed poor me and bad me. In the poor me variety, the patient considers herself to be the target of unfair victimization, but, in the bad me variety, he or she believes that the persecution is warranted in the light of some personal flaw or misbehavior. However, longitudinal studies in which patients have been asked to report the extent to which they deserve persecution at different time points suggest that they often fluctuate between the two types of beliefs (Melo et al., 2006; Melo & Bentall, 2013). An experience sampling study, in which schizophrenia spectrum patients with paranoid symptoms reported their beliefs up to 10 times a day, found that patients who were classified as bad me at the onset showed especially marked fluctuations between poor me and bad me beliefs (those who were classified as poor me at the outset were more stable), and these fluctuations were accompanied by changes in self-esteem (Udachina et al., 2012). This finding has been interpreted in terms of a model that argues that paranoid beliefs are the consequence of dynamic attempts to regulate self-esteem (Bentall et al., 2001; see below).

# The Continuum Hypothesis

One way of resolving the difficulties in defining whether a belief is delusional is to propose a continuum between abnormal and normal beliefs so that, for example, paranoid delusions are viewed as an extreme variant of more common paranoid ideas and beliefs, such as suspicions about the intentions of others or the sense of being viewed critically by colleagues and neighbors. This idea has been particularly advocated by psychologists, who have not been convinced by the phenomenological studies (reviewed above) that have claimed to identify abnormal modes of experience that make delusions qualitatively different from other kinds of beliefs.

One type of evidence that is sometimes cited in this regard is the surprisingly high rate at which apparently delusional beliefs are endorsed by ordinary people who take part in epidemiological surveys. For example, when a large sample of general practice patients in the Aquitaine region of Southwest France were asked to complete a questionnaire measuring types of delusional beliefs commonly reported in the psychiatric literature, 69.3% of those with no history of psychiatric disorder reported that people were not who they seemed to be; 46.9% reported telepathic communication; 42.2% reported experiencing seemingly innocuous events that had double meanings; and 25.5% reported that they were being persecuted in some way (Verdoux et al., 1998). In a study of the 7,000 adults interviewed in the Dutch NEMESIS epidemiological study, 3.3% were classified as having "true" delusions and 8.7% were judged to have delusions that were not clinically relevant (i.e., which were not associated with distress and did not require treatment) (van Os et al., 2000). A recent critical systematic review by Heilskov, Urfer-Parnas and Nordgaard (2020), identified 17 studies of this kind and pointed out that the reported prevalence rates of delusions in the general population varied very considerably from study to study. They attributed this variation to the use of self-report instruments or brief interviews conducted by lay interviewers and recommended that future studies should include detailed interviews of subsamples of participants conducted by experienced clinicians.

A small number of studies have explicitly tested the continuum hypothesis, focusing specifically on paranoid ideas. Freeman et al. (2005) administered a questionnaire measure of paranoid thoughts to an online convenience sample of more than a thousand (predominantly female) students at three UK universities. Participants were asked to rate each item (e.g., "People communicate about me in subtle ways," "People would harm me if given an opportunity") for frequency over the last month, conviction, and distress. The three scales were highly correlated, and total scores fitted a mathematical distribution (an exponential decay curve) in which the most common scores were close to zero, after which there was a smooth decrease in the number of people with increasing scores so that very few

participants scored at the extreme. Large numbers of participants endorsed the least pathological items on the questionnaire, but the rarer items were endorsed only by those had very high total scores, who were therefore judged highly paranoid. A later study by the same group (Bebbington et al., 2013) used data from the UK Adult Psychiatric Morbidity Survey, a face-to-face interview study of 7,000 UK adults, and picked out items from the Psychosis Screening Questionnaire (Bebbington & Nayani, 1995) and other survey items which related to paranoid thinking. The analysis, using a complex type of factor analysis, identified four separate components of paranoia-interpersonal vulnerability, ideas of reference, mistrust, and fear of persecution-and again found that total scores on the items were distributed along an exponential decay curve.

A limitation of these studies is that they did not include clinical samples. Recently, Elahi et al. (2017) compiled data on more than 2,000 healthy participants (mainly students and predominantly female), 157 patients with prodromal psychosis, and 360 patients with psychosis from various studies that had used the same paranoia measure. Three separate taxometric techniques designed to discriminate between continua and taxons (classes of individuals with unique characteristics) were used to interrogate the score distributions from the entire sample and the nonclinical participants alone, with the findings from all six analyses strongly supporting a continuum model.

The continuum approach carries the implication that we can further our understanding of the psychological mechanisms involved in paranoia by studying subclinical variants in the normal population; we shall see later that this approach has been quite fruitful. However, phenomenologically inclined researchers such as Feyaerts et al. (2021) have remained skeptical because they argue that this approach is focused entirely on the content of beliefs and ignores more subtle mental phenomena associated with paranoia of the kind discussed earlier. Indeed, it can be argued that much of the psychological literature on delusions assumes an inner list model in which an individual's beliefs are a list of propositions that can be simply read off by asking the right questions; although this idea has deep roots in Western culture, it is philosophically hard to justify and underestimates the dynamic aspects of belief systems (Bentall, 2018). Future research addressing the continuum hypothesis would benefit from integrating the phenomenological and psychological approaches by investigating nonpropositional

aspects of belief alongside belief content in both clinical and large, representative samples.

# The Assessment of Paranoia

Many paranoia measures have been developed over the years, and each has advantages and disadvantages depending on the purpose of the assessment and the resources available (Freeman, 2008).

In clinical samples, paranoid beliefs are usually assessed using instruments designed to measure psychotic symptoms or assign diagnoses. For example, the Schedules for Clinical Assessment in Neuropsychiatry (SCAN; World Health Organisation, 1999) is a comprehensive psychiatric interview schedule designed primarily for diagnostic purposes. It includes a section on delusions, which includes questions about paranoid delusions, beliefs about conspiracies, and also many other types of abnormal belief. Each is rated on a 4-point scale of severity, either over the lifetime of the individual, during the present episode or the past month. The main disadvantages of this assessment, aside from the requirement for training before administering it, is that each type of delusion is identified by a single question and the severity range is restricted.

The Positive and Negative Syndrome Scale (PANSS; Kay & Opler, 1987) is specifically designed to assess the severity of psychotic symptoms, rather than for diagnostic purposes, and is widely used in clinical trials. It includes separate scales for *delusions* and *suspiciousness*, each rated on 7-point scales of severity. Its advantage is that it is possible to take either the suspiciousness scale alone, or both scales together, to generate a measure of paranoia severity, but it lacks the fine-grain analysis of other delusions which is possible with the SCAN.

A number of questionnaire measures of paranoia have been developed. For example, Fenigstein and Vanable (1992) developed a 20-item paranoia questionnaire primarily for the purposes of social psychological research; each item is scored on a 5-point scale. Although the scale was designed to assess subclinical paranoid beliefs, it was subsequently shown to correlate with clinically assessed paranoia in a sample of schizophrenia patients (Smari et al., 1994).

The 21-item Peters Delusions Inventory (Peters et al., 1999) uses items derived from the SCAN to measure a wide range of beliefs and hence is designed to detect clinically relevant delusional beliefs. However, only two items refer specifically to paranoid ideas ("Do you ever feel that you are being persecuted in some way?" "Do you ever feel that there is a conspiracy against you?"). Other items sample delusions of reference, grandiose and religious delusions, and a wide variety of less common (e.g., being influenced by computers or electrical devices, or believing that the world is going to end) and less pathological beliefs (e.g., believing in witchcraft or telepathy). Respondents first of all answer each question "yes" or "no" and then, if the answer is "yes," proceed to rate whether the belief is distressing or preoccupying, and also their conviction, on 5-point scales.

Freeman et al. (2005) developed an 18-item paranoia checklist to assess paranoid beliefs in the general population, but then went on to develop a more widely used scale designed for both clinical and healthy samples, the Green Paranoia Scale (Green et al., 2008). This scale originally had two 16-item subscales: Part-A measuring ideas of reference and Part-B measuring ideas of persecution. However, the scale has recently been revised (Freeman et al., 2021), and the subscales have been cut down to 8 and 10 items, respectively, each rated on a 5-point scale ranging from "not at all" to "totally." The questionnaire has very good psychometric properties and discriminates well between subclinical and clinical paranoia; recommended cutoff scores are provided.

For the purpose of measuring very rapid fluctuations of paranoia, for example, in experimental studies, Schlier et al. (2016) have published very short (3- and 5-item) versions of Freeman's original Paranoia Checklist, selecting items (e.g., "People try to make me upset") that had proved most sensitive to change in previous studies and adapting them so that respondents reported the extent to which they applied "at the moment."

Finally, inspired by Trower and Chadwick's (1995) theory of two types of paranoia, Melo et al. (2009) adapted items from Fenigstein and Vanable's (1992) scale to create a 10-item measure in which respondents first indicated whether they agreed with a series of paranoid beliefs ("There are times when I worry that others might be plotting against me," with responses ranging from "certainly false" to "certainly true") and then, if they score 2 ("unsure") or higher on an item, whether they deserved to be persecuted ("Do you feel like you deserve others to plot against you?" with responses ranging from "not at all" to "very much"). Scores on persecution (P subscale) were calculated as the sum of the relevant items, and for deservedness (D subscale) as the mean of those items they completed. The scale had good psychometric properties and discriminated

between healthy and clinical participants. An interesting difference between the two groups was that P and D scores were positively correlated in the healthy participants but nearly all of the clinical participants had very low D scores (they were "poor me"). A shortened 5-item version of the P subscale has subsequently been developed for epidemiological studies and shown to have good psychometric properties (McIntyre et al., 2018).

# Genetic and Social Determinants of Paranoia

It is fair to say that, over the past two decades, there has been a dramatic reappraisal of the relative contributions of genetic and environmental factors to severe mental illness, and any analysis of the role of these factors in paranoia must be seen in this context. For example, until quite recently, the high heritability estimates, typically around 80% (Sullivan et al., 2003), calculated for schizophrenia in family, twin, and adoption studies was assumed to preclude the importance of life experience (van Os & McGuffin, 2003). A conceptual error, in many interpretations of these findings, has been the assumption that heritability is a measure of causation that applies to the individual, whereas, in fact, it is an estimation of the correlation between genes and outcomes within a specific population and therefore subject to all the usual caveats about the meaning of correlations (Bentall, 2021).

Molecular research has shown that the genetic risk of schizophrenia and other related forms is massively polygenic, although there are rare genetic mutations that confer a high level of risk in a small number of cases (Kendler, 2015; Owen, 2012). At the same time, population, clinical, and even a small number of prospective studies have shown a very strong association between various types of environmental exposures, especially in childhood, and the development of psychosis in adulthood. These include both forms of collective adversity, such as poverty (Wicks et al., 2005), social inequality (Johnson et al., 2015), exposure to urban environments (Vassos et al., 2012), ethnic minority status (Bosqui et al., 2014), and the experience of migration (Castillejos et al., 2018), but also specific interpersonal traumas such as sexual and physical abuse and victimization by peers. The effects of interpersonal trauma have been particularly well-replicated and supported by meta-analyses, with a doseresponse effect suggestive of causation (McGrath et al., 2017; Varese et al., 2012). A small number of studies that have assessed the impact of childhood

adversity and genes at the same time, using either classical (Alemany et al., 2013; Arseneault et al., 2011) or molecular methods (Trotta et al., 2016), have pointed to independent and additive effects of the two types of risk factors.

Genetic studies of paranoid phenomena have been few and far between. Some studies have attempted to assess the heritability of paranoid personality disorder, usually in the context of a broader genetic investigation of personality disorders in general, and have reported modest to moderate heritability estimates (Reichborn-Kjennerud, 2010). Even fewer investigations have specifically examined the heritability of paranoia considered as a symptom. In a recent study of a large sample of adolescent identical and nonidentical twins who were assessed using dimensional measures of a range of specific psychotic experiences, the heritability of paranoia was estimated at 50% when using traditional methods based on the comparison of the two types of twins (Zavos et al., 2014); this estimate was little affected when only extreme scorers on the dimension were considered, suggesting that the genetic architecture of paranoia remains the same across nonclinical and clinical variants. A later analysis using molecular methods yielded a heritability estimate of 14% (Sieradzka et al., 2015), a finding that is consistent with many other observations of discrepancies between the estimates derived from the two methods (the *missing heritability* problem), which is especially marked in child and adolescent samples and which has yet to be adequately explained (Cheesman et al., 2017).

Most of the research on the role of adverse environmental factors in psychosis has not considered the relationship between particular types of exposures and specific symptoms, and so research focused on the environmental determinants of paranoia has been limited. Perhaps the strongest evidence for the influence of collective adversity concerns socioeconomic factors. One of the earliest studies of the relationship between urban environments and psychosis was conducted in Chicago by Faris and Dunham (1939), who reported a higher prevalence of schizophrenia in inner-city areas and also noted that patients in those areas often showed paranoid symptoms. In a later survey of residents of El Paso in the United States and Juarez in Mexico, Mirowsky and Ross (1983) found that paranoia was associated with circumstances which they characterized as victimization and powerlessness; specifically, low social status interacted with an external locus of control to lead to mistrust and paranoia.

Using epidemiological data from the United Kingdom, Wickham et al. (2014) found that a global index of neighborhood deprivation predicted the likelihood of paranoid and depressive symptoms but not hallucinations or manic symptoms. A later study using a different epidemiological dataset found, again, that people reported more severe paranoid beliefs if they were living in deprived neighborhoods and, using network analysis, found that paranoia was a possible bridge symptom (pathway) between specific neighborhood characteristics (e.g., exposure to incivilities and mistrust of neighbors) to symptoms of depression and anxiety (McElroy et al., 2019). If replicated, this finding suggests that subclinical paranoid beliefs may have much greater public health implications than is widely recognized. The finding that harsh neighborhood environments foster paranoia has been further supported by studies in which people, either drawn from the general population (Corcoran et al., 2018) or who suffer from paranoid symptoms (Ellett et al., 2008), are asked to walk around urban environments and report their thoughts and feelings; in deprived neighborhoods, people feel more paranoid.

It is difficult to disaggregate the many factors that could explain these effects. For example, one possibility is that people are more likely to experience victimization and other kinds of adverse interpersonal interactions in deprived areas, and another is that these areas are not rich in social capital and networks of supportive relationships. These hypotheses are not mutually exclusive, and there is evidence for each of them.

For example, a Dutch longitudinal epidemiological study reported by Janssen et al. (2003) found that, in those individuals who showed no evidence of paranoid ideation at baseline, reports of discrimination on the basis of age, gender, disability, appearance, skin color, ethnicity, or sexual orientation predicted the onset of delusions but not hallucinations in the following 3 years. In a more recent British epidemiological survey, experiences of bullying and lack of social support also partially explained a specific association observed between sexual minority status and paranoia but not hallucinations (Qi et al., 2020).

The sense of belonging to a neighborhood was shown to protect individuals against both paranoia and depression (but not hallucinations) in a British epidemiological survey; a follow-up study with UK students, in which the sense of belonging to their university was measured, obtained comparable results (McIntyre et al., 2018). In a further analysis of the same datasets, Elahi et al. (2018) found that a strong sense of social identity moderated (reduced) the relationship between financial difficulties (a fairly objective measure of stress) and the same mental health symptoms. This finding is consistent with research by social psychologists, who have argued that having multiple social identities (not only belonging to groups but defining oneself in terms of those group memberships) is protective against mental ill-health (Haslam et al., 2009).

It has been hypothesized that, because ethnic minority and migration status are associated with victimization and sometimes with the inability to identify with the majority population, these groups should be especially likely to experience paranoid symptoms (McIntyre et al., 2016). However, specific evidence in support of this hypothesis is limited to a few, relatively small-scale studies. Combs et al. (2002) found that African Americans scored higher on a paranoia scale than White Americans and, later, that perceived racism in African Americans predicted a measure of subclinical paranoia but not scores on a clinical measure (Combs et al., 2006). In a small sample of Muslim Americans, it was also reported that perceived religious discrimination was associated with subclinical paranoia (Rippy & Newman, 2006), and, in a study of female Emirati students, it was found that identification with US culture in preference to Arab culture (measured using an implicit technique based on reaction times when making judgments about national symbols such as flags) was associated with paranoid beliefs (Thomas et al., 2016). It is likely that the two factors considered here-discrimination and identity—interact. McIntyre et al. (2019) examined the relationship between social identity and paranoia in UK Afro-Caribbeans, finding that, in those who reported positive relationships with the White majority, identifying as British was associated with low levels of paranoia whereas in those who had experienced negative relationships with the White majority, identifying as British was associated with high levels of paranoia.

Some studies have examined the role of adverse childhood experiences in paranoia. An analysis of epidemiological data from the United Kingdom found a particularly strong association between being raised in institutional care (a strong indicator of damaged relationships with caregivers) and paranoid symptoms in adulthood, whereas hallucinations were strongly associated with childhood sexual abuse (Bentall et al., 2012); the same relationship did not hold for children raised in foster care. These findings were subsequently replicated in a large sample of UK prisoners (Shevlin et al., 2015).

An analysis of a US epidemiological dataset found that neglect by parents was the type of childhood adversity most associated with paranoid beliefs, whereas, again, hallucinations were associated with sexual abuse (Sitko et al., 2014). A more recent study used data from a US epidemiological sample of adolescents and also a replication dataset collected from UK adults; in both samples, reports of verbal abuse and physical abuse were associated with a higher likelihood of reporting paranoia, whereas reporting a high level of care from parents was associated with a low likelihood of reporting paranoia (Brown et al., 2021). A network analysis of the UK dataset allowed these associations to be studied in more detail, and it was found that all of the parenting variables were closely connected but that the variable most closely linked to paranoia was maternal indifference.

These findings have been mirrored by the results from a small number of studies with clinical samples. Rankin et al. (2005) found that both currently ill and recovered paranoid patients reported adverse relationships with their parents during childhood; the fact that the recovered patients' reports matched those of the patients who were currently ill was taken as indicating that these reports were unlikely to be caused by the patients' paranoid symptoms. In an analysis of data from a group of UK psychotic patients, it was found again that paranoid symptoms were specifically associated with childhood emotional neglect (Wickham & Bentall, 2016). Studies of patients diagnosed as suffering from paranoid personality disorder have also generated parallel findings. For example, Bierer et al. (2014) studied a large sample of patients with personality disorders and found a high level of childhood trauma overall but, in the cluster A (schizotypal, schizoid, and paranoid) group, paranoid personality disorder alone was predicted by sexual, physical, and emotional abuse.

There are some important limitations of this research that should be noted. All have employed retrospective reports of childhood experiences by either adults living in the community or patients. In the wider psychosis literature, this limitation has been addressed by showing similar findings from prospective studies (Varese et al., 2012) or by conducting investigations to verify the validity of patients' retrospective reports (Fisher et al., 2011) but these kinds of investigations are absent in studies focusing specifically on paranoia. However, cautiously, it is reasonable to say that the development of both clinical and subclinical paranoia in adulthood seems to be related to disrupted early attachment relationships with caregivers and exposure to harsh environments and victimization in later life. These findings, which point to the importance of the individual's history and social context, obviously have important implications for how paranoia is conceived by clinicians and researchers, as is evident in the account of Zeppi discussed earlier. Specifically, although research to be reviewed below shows that various cognitive and emotional processes contribute to paranoid thinking, it is a mistake to assume that these kinds of beliefs never have a foundation in real-life events.

### **Psychological Models of Paranoia**

Psychological models of paranoia are of broadly three kinds, although they to some extent overlap. Some researchers following Maher and Ross (1984) have seen paranoid beliefs and delusions in general as attempts to construct meaningful explanations of anomalous experiences. Others, particularly Freeman and his colleagues (Freeman et al., 2002; Freeman, 2016), have argued that cognitive abnormalities of one kind or another play a direct role in generating paranoid beliefs. Still others, notably Frith (1992), have proposed that paranoia arises from a difficulty in understanding the intentions of others. Finally, some researchers, sometimes inspired by psychoanalytic theory, for example Colby (1977), have argued that paranoid beliefs emerge as a dynamic process as a consequence of the individual's attempts to avoid threats to self-esteem (Bentall et al., 2001) (sometimes called the paranoia as a defense model). These theories have led to rich avenues of empirical research, and the literature on the psychological mechanisms underlying paranoia has grown from a smattering of studies in the 1990s to an enormous number today. Hence, the following review can only focus on the most widely studied processes.

### Paranoia and Anomalous Experiences

Maher and Ross's (1984) original formulation of the anomalous experience model of delusions consisted of two separate propositions: first, that delusional beliefs were invariably preceded by experiences which seemed anomalous to the individual and, second, that people with delusions did not suffer from cognitive abnormalities. Hence delusions were seen as more or less rational attempts to explain anomalous experiences. It is important to note that the two parts of this theory (the role of anomalous experiences and the idea that reasoning is unimpaired in deluded patients) are logically independent of each other; one could be true and the other remain false.

On the first proposition, Maher cited examples of patients whose delusions appeared to be responses to hallucinatory experiences. Also, factor analytic studies have consistently shown that delusions and hallucinations tend to co-occur, with both belonging to the positive syndrome of psychosis (Safer & Dazzi, 2019). However, this co-occurrence might, in principle be caused by shared underlying processes, by hallucinations leading to delusions, or by delusions leading to hallucinations. The fact that delusions often (although not always) precede hallucinations during the early stages of psychosis (Compton et al., 2012) suggests that the last of these pathway is the most likely one, and this explanation for the covariation of the two symptoms is supported by the fact that exacerbations in paranoid thinking often precede the onset of hallucinations in patients' daily lives (Oorschot et al., 2012) and by experimental studies which have shown that hallucinatory experiences in patients (Haddock et al., 1995; Mintz & Alpert, 1972), people with schizotypal traits (Alganami et al., 2017), and even ordinary people (Barber & Calverley, 1964) can be influenced by simple suggestions (the manipulations of expectancies about what participants expected to see or hear). An epidemiological study using directed acyclic graphs (a technique that can increase the confidence in causal effects, even in cross-sectional data) also found support for a pathway from persecutory beliefs to hallucinations but not vice versa (Moffa et al., 2017).

But this does not mean that other kinds of anomalous experiences do not play a role in paranoia. Early studies suggested that paranoid beliefs, particularly in elderly patients, are often associated with the slow onset of deafness, with the possible explanation that hearing loss can prompt individuals to believe that those around them are either not communicating with them or speaking in whispers (Cooper & Curry, 1976). One study claimed to induce paranoia in healthy persons by using a hypnotic induction to simulate deafness (Zimbardo et al., 1981). More convincing are recent epidemiological studies which have also shown an association between hearing loss and paranoid beliefs (Stefanis et al., 2006; Thewissen et al., 2005).

Several additional recent observations about the factors relating to paranoia can also be

accommodated within the anomalous perception model. For example, it may explain the possible role of cannabis consumption in paranoid symptoms (Freeman et al., 2014). On the assumption that sleep disturbance may lead to anomalous perceptual experiences, it may also explain the likely association between insomnia and paranoia (Freeman et al., 2009; Freeman et al., 2011), although the findings from different kinds of sleep investigations have been varied, with cross-sectional studies showing a more consistent association than sleep interventions designed to detect a causal effect (see Barton et al., 2018, for a review).

One further type of anomalous experience that should be considered in this context is dissociation, which is a common consequence of severe psychological trauma and involves a disturbance in the integration of cognitive functions and emotional processes, leading to a sense of detachment from self (depersonalization) and/or the environment (derealization) (Dalenberg et al., 2012). It is worth noting that these experiences are not dissimilar to the subtle alterations in experience reported in phenomenological investigations of delusions, for example by Conrad (1958/2012). Many studies have reported that dissociation at least partially mediates the relationship between trauma and hallucinations (Pilton et al., 2016; Varese et al., 2011), but a recent meta-analysis reported that dissociation was associated with all of the positive symptoms of psychosis, including paranoia (Longden et al., 2020).

These findings, of course, do not show that anomalous experiences are a necessary condition for paranoid beliefs. Nor do they address the second proposition in Maher's model, which is that reasoning in deluded patients is normal. In support for this claim, Maher cited studies of syllogistic reasoning in psychiatric patients, but these are not convincing because healthy performance on syllogistic reasoning tasks is often poor and because subsequent studies have revealed many ways in which the reasoning of paranoid people appears to be abnormal.

# Cognitive Factors and Delusional Beliefs

A number of researchers have attempted to identify psychological processes that contribute directly to paranoid thinking, but much of this work has been inspired by a theoretical framework developed by Freeman and colleagues (Freeman, 2016; Freeman et al., 2002). This model encompasses Maher's anomalous perception model to the extent that unusual experiences are seen as setting the occasion for the individual to search for the meaning of events, but a number of cognitive deficits and emotional biases are hypothesized to shape the explanation eventually arrived at. It attempts to explain not only the onset of paranoia as a consequence of this interaction between experience and psychological biases but also the subsequent maintenance of the resulting delusional beliefs by safety (avoidance) behaviors (e.g., avoiding areas where threats are thought to be most likely) which prevent the individual from discovering new information that is contrary to their delusional beliefs (Freeman et al., 2007).

One of the most widely studied cognitive abnormalities thought to influence delusion formation is known as the jumping to conclusions (JTC) *bias* although it is probably more correctly described as a deficit than a bias. This phenomenon is usually assessed with the beads in a jar task, in which the individual is asked to observe a sequence of blue or red beads and decide whether they are drawn from a jar with a majority of red beads or a jar with a majority of blue beads. After each draw, the individual can either make a decision or ask to see another bead. In early studies, Huq et al. (1988) and Garety et al. (1991) reported that patients with delusions ask to see fewer beads before making a decision in comparison to controls, and this has been replicated many times, including with patients suffering from paranoid delusions (Corcoran et al., 2008) and with ordinary people with high levels of paranoid conviction (Freeman et al., 2008). Several metaanalyses have shown that this effect is robustly related to psychosis (So et al., 2016) and delusion severity (Dudley et al., 2016), although it is probably not specific to paranoid beliefs.

A second type of reasoning bias which has been explored in relation to delusions is the bias against disconfirmatory evidence (BADE) effect, which was first demonstrated by Woodward et al. (2006). In this study, patients with psychosis were asked to rate the plausibility of four possible interpretations of the events shown in a picture; they were then asked to adjust their ratings as pictures with further relevant information were shown to them. A BADE was demonstrated by the unwillingness to adjust ratings in response to new information that was inconsistent with formerly plausible interpretations, and this effect was shown to be greatest for patients suffering from delusions. This finding has been replicated a number of times, using variations in methodology (e.g., using sentences instead of pictures as

stimulus material) and in studies with nonclinical participants scoring highly on a measure of delusion proneness (Woodward et al., 2007; see McLean et al., 2016, and Zhu et al., 2018, for meta-analytic reviews). In a factor analysis of BADE responses in a large group of schizophrenia and bipolar patients, Speechley et al. (2012) found that the patients' performance could be accounted for by two factors: a failure to integrate new evidence and a more general conservative response bias (a general unwillingness to make high ratings); only the former component distinguished between deluded and nondeluded patients.

Like the JTC bias, the BADE effect is probably not specific to paranoid as opposed to other kinds of delusional beliefs. An interesting feature of the BADE task is that the scenarios are unrelated to patients' delusions and hence the task appears to demonstrate a bias in general reasoning. However, Woodward et al. (2008) found a BADE effect only when schizophrenia patients were provided with evidence against strongly held initial beliefs-they were as willing to change weakly held initial beliefs as controls-and the BADE effect has also been shown to modestly predict political dogmatism and racial prejudice in healthy people (Bronstein et al., 2017). Indeed, as noted earlier, similar effects have been observed in other studies of political reasoning (Taber & Lodge, 2013; Westen et al., 2006). Further research is therefore needed to establish the extent to which the BADE effect is specific to delusions or also is found in people with other kinds of very strongly held beliefs.

Another question that remains unresolved is whether the JTC and BADE tasks measure a specific domain of cognitive functioning or whether poor performance on these tasks reflects a more general impairment. Several studies have reported that performance on the JTC task closely correlates with measures of executive function (Bentall et al., 2009; Ochoa et al., 2014), and detailed, trial-by-trial analysis of patients' responses on the task has shown that impaired performance more likely reflects impulsive or even random responding rather than a preference for making an early decision (Moutoussis et al., 2011). (In most versions of the task, the first two beads are alternative colors so that, at the second trial, the patient has no information whatsoever to indicate which jar the beads might have been drawn from; nonetheless, many patients make a decision after the second draw.) Similarly, BADE performance has been found to correlate with more general cognitive abilities (Eifler et al., 2014).

# Theory of Mind

The term "theory of mind" (ToM) was coined in a celebrated paper by the primatologists Premack and Woodruff (1978), which asked whether chimpanzees had an ability to understand the mental states of other chimpanzees. This question had two consequences. First, it established the slightly misleading term (ToM), which ever since has been used to refer to the human ability to understand the thoughts and feelings of other people. Second, it stimulated a vast research literature by cognitive psychologists, comparative psychologists, and developmentalists to attempt to understand the origins of this ability (Wellman, 2017). An important discovery, which created great impetus in this respect, was that autistic people suffer from severe ToM impairments (Baron-Cohen, 1995; Baron-Cohen et al., 1985).

Frith (1994) suggested that ToM impairments could explain the paranoid symptoms of psychotic patients. The idea behind this hypothesis was that individuals who had difficulty in understanding the intentions of others might assume those intentions were malign. Frith argued that patients might be especially likely to make this assumption if their psychotic breakdown had been preceded by a period of good mental functioning in which the ability to understand the intentions of others was unimpaired. Several studies appeared to provide support for this hypothesis (Corcoran et al., 1995, 1997), and ToM impairments have been reported specifically in paranoid patients (Corcoran et al., 2008). In one study, which compared Asperger's syndrome patients (adults with less severe autistic traits) with paranoid patients, the two groups were found to be comparable on a ToM measure, but only the paranoid patients showed an attributional bias (see below) (Craig et al., 2004).

However, other studies have reported that impaired ToM is associated with a wide range of psychotic symptoms, including thought disorder (Grieg et al., 2004; Sarfati & Hardy-Bayle, 1999) and lack of insight (Langdon et al., 2006). Indeed, impaired ToM has been reported in both bipolar (Bora et al., 2016) and depressed patients (Bora & Berk, 2016) (although, as noted earlier, paranoid delusions are sometimes reported by patients in both of these groups). A study which divided paranoid patients between those with and without ToM deficits found that the latter scored high on a measure of social anxiety, suggesting that impaired ToM and social anxiety separately contribute to paranoid beliefs (Lysaker et al., 2016). In a recent study using two British epidemiological samples, autistic traits assessed using a questionnaire screening instrument were strongly associated with not only paranoia but also with all other psychotic symptoms with the exception of mania (Martinez et al., 2021). This finding is consistent with a birth cohort study which found that autistic traits in children predicted the development of psychotic (but not specifically paranoid) experiences in adolescence (Jones et al., 2012).

A further issue concerns whether ToM deficits in psychosis reflect a specific domain of cognition or more general deficits; a recent meta-analysis of 91 studies found strong evidence that the latter is the case (Thibaudeau et al., 2020).

### Emotional Biases and Paranoid Beliefs

Much of the research on emotional processes in relation to paranoia was stimulated by the paranoia as a defense model. This model was based on the observations by Kaney and Bentall (1989, 1992) of abnormalities in the way that paranoid patients explained events. Previous research had shown that depressed patients tended to make internal (self-blaming), stable (the cause was unchangeable), and global (it affected all areas of life) attributions (explanatory statements) about negative events (Abramson et al., 1978). Kaney and Bentall found that paranoid patients also made global and stable explanations for these kinds of events, but their explanations were, by contrast, highly external (they attributed the cause to factors other than themselves). Subsequent studies showed that these external explanations typically implicated other actors rather than circumstances (Kinderman & Bentall, 1997).

To account for these findings Bentall et al. (1994) proposed that this attributional style protected the individual from the unpleasant experience of discrepancies between their actual selves (themselves as they thought they really were) and their ideal selves, thereby maintaining their self-esteem. A subsequent iteration of the model (Bentall et al., 2001), made to accommodate the distinction between poor me and bad me paranoia (Trower & Chadwick, 1995), proposed a dynamic process by which the interpretation of events was influenced by current selfesteem (someone with low self-esteem should tend to attribute a negative event to themselves) but that attributions should, in turn, influence future selfesteem (an external explanation for a negative event would have less psychologically damaging consequences than an internal explanation). This version

of the model had the implication that self-esteem should be highly unstable in paranoid patients. The model also predicted that paranoid patients should show discrepancies between implicit (indirect) measures of self-esteem, which should reveal a negative appraisal of the self, and explicit (direct measures), which should show a positive appraisal.

An important objection made to the defense model is that self-esteem is often low in paranoid patients. Indeed, numerous studies have shown that paranoia is associated with low self-esteem (Bentall, Kinderman, & Moutoussis, 2008) and negative beliefs about the self (Fowler et al., 2006), and, indeed that, longitudinally, negative beliefs about the self predict a poor recovery from paranoia (Fowler et al., 2012). These findings have been supported by a recent meta-analysis (Humphrey et al., 2021) although the authors noted that a complication was the effect of depression, which often co-occurs with paranoid symptoms. Studies in which implicit and explicit measures of self-esteem were used have also failed to support the defense model (Murphy et al., 2018), although recent meta-analyses have supported the prediction of an extreme self-serving attributional bias (Müller et al., 2021) and also high self-esteem fluctuations in paranoid patients (Müller et al., 2021; Murphy et al., 2018).

Recently, researchers have begun to investigate whether the emotional negativity found in paranoid patients might be associated with more general interpersonal processes and specifically attachment styles. Bowlby (1969) proposed that experiences with caregivers led young children to create internal working models of their relationships, which then affected their interactions with other people throughout adult life (Mikulincer & Shaver, 2007). The internal working models of the majority of children-based on their confidence that the caregiver will always be available when needed—incorporate a positive model of the self, a positive model of others, and the expectation that others can be trusted. However, insecure ways of relating to others were explained in terms of two dimensions of insecure attachment: anxious attachment, reflecting negative beliefs about the self, need for approval, and fear of rejection, and avoidant attachment, reflecting fears about the intentions of others and a preference for emotional distance.

Bentall and Fernyhough (2008) proposed that these styles might explain the relationship between early childhood adversity and paranoia. Empirical studies of healthy individuals varying in trait paranoia (Pickering et al., 2008) and patients differing in the severity of their persecutory delusions (Wickham et al., 2015) confirmed that paranoid beliefs were associated with both the anxious and avoidant styles, a finding that has subsequently been replicated by other researchers (see Murphy et al., 2020, for a meta-analysis). In an experience sampling study, in which patients with persecutory delusions and healthy controls recorded their thoughts and feelings up to 10 times a day for 6 days, it was also shown that fluctuations in attachment-related cognitions predicted changes in paranoid symptoms (Sitko et al., 2016).

Several mediators of this relationship have been identified, including low self-esteem (Pickering et al., 2008; Wickham et al., 2015), fear of powerful others, and anticipation of threat (Pickering et al., 2008). In a recent study with a large population sample, Martinez et al. (2021) asked participants to complete measures of attachment and self-esteem and also to judge the trustworthiness of a series of computer-generated faces that had been previously classified as appearing trustworthy or untrustworthy. Signal detection analysis was used to distinguish between the general ability to discriminate between the two types of faces (sensitivity) and a response bias toward judging the faces as untrustworthy. The pathway from both avoidant and anxious attachment to paranoia was mediated by low self-esteem, but the pathway from avoidant attachment to paranoia was also uniquely mediated by response bias (but not sensitivity) when making the trustworthiness judgments.

### Conclusion

Despite some disagreement between the models, it is striking that there has recently emerged a consensus about the psychological origins and mechanisms involved in paranoia. First, the continuum model, although leaving some questions unanswered (particularly with regard to some unusual phenomenological characteristics of delusional paranoia), has been very fruitful in generating research and progressing theory development. Second, it now clear that paranoid beliefs, like other psychotic phenomena, are associated with adverse life experiences. Disrupted early attachment relationships, exposure to harsh environments, victimization by others, the absence of social bonds and the sense of belonging are all circumstances that create a high risk of paranoid beliefs. Third, a number of psychological mechanisms that contribute to paranoia have been identified, particularly problems in reasoning about sequential information, insecure attachment styles, negative beliefs about the self, an exaggerated self-serving bias, and (less certainly) an impaired ToM.

The four psychological models discussed in this chapter differ in the extent to which each of these factors is given precedence and also in how these mechanisms are thought to interact. Maher and Ross's (1984) anomalous experience model has stimulated some important discoveries about factors that influence paranoia, but it is clear that unusual experiences are not sufficient to explain the development of persecutory delusions. Frith's (1994) proposal that impairments of ToM are central to paranoia is only very weakly supported because ToM deficits do not seem to be specific to paranoid symptoms, and some paranoid patients have preserved ToM. The remaining two theories, the model of Freeman and colleagues (Freeman, 2016; Freeman et al., 2002) and the defense model of Bentall et al. (2001), both emphasize the role of cognitive and emotional processes (e.g., difficulties in reasoning about sequential information, negative beliefs about the self that are related to interpersonal vulnerabilities, and insecure attachment styles). Of the two models, the model by Freeman and colleagues is currently the most strongly supported, with some of the predictions arising from the defense model (e.g., about discrepancies between implicit and explicit self-esteem) lacking empirical support.

The development of these psychological models has emboldened clinical researchers to develop psychological interventions for paranoid patients who, not many decades ago, were thought to be beyond the reach of psychotherapy. As noted earlier, there is evidence that conventional cognitivebehavior therapy interventions, in which patients are encouraged to evaluate their beliefs and the evidence pertaining to them, are modestly effective (Mehl et al., 2015; Sitko et al., 2020). However, more recent trials have begun to target processes and psychological mechanisms which are thought to exacerbate paranoid thinking, such as sleep abnormalities (Myers et al., 2011) and over-hasty reasoning (Garety et al., 2021). In many ways, therefore, research on paranoia is a model of how clinical psychological science can progress from small-scale experimental studies to interventions that make a real difference to the lives of vulnerable people. It is to be hoped that this progress will continue in the years ahead.

# Sexual Dysfunction

Cindy M. Meston, Bridget K. Freihart, and Amelia M. Stanton

Sexual problems can be broadly conceptualized as the inability to exhibit a sexual response or experience sexual pleasure. For such problems to be diagnosed as a sexual dysfunction, the concerns need to be further identified as personally distressing. Moreover, two additional morbidity criteria were added with release of DSM-5: (1) the problem must be persistent, recurrent and/or present during 75-100% of sexual encounters (i.e., a severity criterion), and (2) the individual must have experienced the problem for at least 6 months (i.e., a duration criterion). Each sexual dysfunction is subsequently categorized as lifelong versus acquired and generalized versus situational. A lifelong disorder refers to a sexual dysfunction that is chronic and has always been present, whereas an acquired disorder refers to a sexual dysfunction that developed after an identified period of unimpaired function. A generalized sexual dysfunction refers to a sexual problem that reliably occurs in all contexts; a situational sexual disorder refers to a problem that only occurs in certain contexts, such as with specific partners, in specific locations, or while engaging in specific sexual activities. These criteria apply, with some minor variation, to each sexual dysfunction mentioned in this chapter.

Although individuals may present with a range of sexual problems, *DSM-5* recognizes only three major categories of sexual dysfunction: interest/arousal, orgasm, and pain. This chapter provides an overview of the definition, prevalence, and etiology of each of the sexual disorders within these three categories.

### **Sexual Interest/Arousal Disorders**

Sexual interest, commonly referred to as "desire" or "sex drive," refers to the motivation to engage in sexual activity and/or the feelings that motivate a person to seek sexual activity in both partnered and individual contexts. Sexual arousal, on the other hand, is characterized by readiness for sexual activity. Arousal includes physiological changes that prepare the body for a sexual interaction (e.g., erection, vaginal swelling and lubrication), as well as cognitive shifts (e.g., experiencing positive mental engagement with a sexual stimulus).

# Female Sexual Interest/Arousal Disorder DEFINITION, DIAGNOSIS, AND PREVALENCE

In DSM-5, female sexual interest/arousal disorder (FSIAD) is defined as a significantly reduced or totally absent sense of sexual interest and/or arousal. To receive a diagnosis, a woman must have three of the following six symptoms: absent or reduced interest in sexual activity, absent or reduced sexual thoughts or fantasies, no or reduced initiation of sexual activity, reduced receptivity to a partner's attempts to initiate, absent or reduced sexual excitement or pleasure in almost all or all sexual encounters, absent or reduced sexual interest/arousal in response to any internal or external sexual cues, and absent or reduced genital or nongenital sensations during sexual activity in all or almost all sexual encounters.

Abbreviations	
DE	Delayed ejaculation
ED	Erectile disorder
FOD	Female orgasmic disorder
FSAD	Female sexual arousal disorder
FSIAD	Female sexual interest/arousal disorder
GPPPD	Genito-pelvic pain/penetration disorder
HSDD	Hypoactive sexual desire disorder
MHSDD	Male hypoactive sexual desire disorder
PE	Premature (early) ejaculation
PVD	Provoked vestibulodynia

FSIAD is relatively new to the *DSM*. *DSM-IV-TR* included separate diagnoses for hypoactive sexual desire disorder (HSDD) and female sexual arousal disorder (FSAD). HSDD was characterized by the lack of desire for sexual activity, whereas FSAD was characterized by an inability to maintain or develop a sufficient lubrication/swelling response. The *DSM-5* Sexual Dysfunctions subworking group chose to combine these disorders, citing a number of studies that failed to reliably distinguish between desire and arousal in women (Brotto et al., 2009; Graham et al., 2004).

Given that FSIAD is a relatively new diagnosis, few prevalence studies on the disorder have been published. Available evidence suggests that the new morbidity criteria (duration and severity) may reduce the number of women who will meet diagnostic criteria for FSIAD. A recent probability sample found a 1-year prevalence rate of 6.5% for interest/arousal concerns in women, with only 0.6% of women meeting criteria for the disorder when considering the duration and severity criteria (Mitchell et al., 2016). Notably, the authors specify that their classification only included women who reported both interest and arousal problems and may thus be a poor proxy for FSIAD prevalence in the general population, given that women can meet criteria for the disorder by endorsing exclusively interest- or exclusively arousal-related concerns.

To that end, it is important to consider previous prevalence estimates for FSAD and HSDD to effectively estimate FSIAD rates. HSDD prevalence rates have been estimated to range from 7.3% (Bancroft et al., 2003) to 23% (Witting et al., 2008), and FSAD has been estimated between 2.6% (Mercer et al., 2003) to 28% (Dunn et al., 1999), varying as a function of age, cultural background, and reproductive status.

# FACTORS ASSOCIATED WITH FEMALE SEXUAL INTEREST/AROUSAL DISORDER

Research on the etiological factors associated with both reduced sexual interest and arousal in women is reviewed here. These elements are broken down into biological factors (e.g., physical health, hormones, medications) and psychological factors (e.g., stress, relationships, comorbid mental illness, history of sexual abuse).

*Biological Factors.* With regards to low sexual interest, the most commonly discussed biological factor is endocrine function. A wide range of studies have found a close association between hormone levels and overall sexual desire. The onset of menopause is closely associated with low sexual desire, in part due to decreased ovarian function that, in turn,

results in decreased estrogen production. Similarly, an oophorectomy (i.e., surgical removal of the ovaries) results in notable estradiol and testosterone decrements that reflect a more prominent risk factor for sexual interest concerns than natural menopause, particularly among younger women (Dennerstein et al., 2006; Leiblum et al., 2006). Conversely, higher levels of sexual desire have been found in women nearing ovulation (e.g., Diamond & Wallen, 2011; Pillsworth et al., 2004), while decreased sexual desire follows the chemical suppression of ovarian hormones (Schmidt & Rubinow, 2009).

As is the case with sexual interest, there is a close link between endocrine function and arousal levels in women. In particular, there is evidence to suggest that estrogen plays a structural role in tissue function and may govern blood flow into genital tissue through vasodilatory and vasoprotective effects (Sarrel, 1998). Menopause and lactation both result in decreased estradiol levels, and both are associated with reduced blood flow into the vaginal walls (and, as a consequence, reduced lubrication) (e.g., Graziottin & Leiblum, 2005; Simon, 2011). While menopause has been closely associated with reductions in arousal and lubrication as a function of decreased estrogen (Sandhu et al., 2011), there is no specific threshold at which one's level of estrogen is sufficient for sexual arousal. It is therefore difficult to determine whether estrogen deficiency itself can be deemed a cause of sexual arousal problems.

While it is clear that sex hormones, including androgens, estrogens, and progestins, impact female sexual interest and arousal, questions remain as to which of these hormones plays the most critical role in sexual function (Sandhu et al., 2011). The structure and function of the cervix, vagina, labia, and clitoris are governed by androgens and estrogens. Androgens may be most influential factor impacting levels of sexual desire, as they immediately precede estrogen synthesis and thus impact sexual desire, mood, and energy (Goldstein et al., 2004). Notably, the theory that androgen insufficiency causes low sexual desire in women is controversial. It was originally thought that androgen depletion occurred in response to an age-related decline in adrenal and ovarian androgen production. More recently, the field has recognized that declines in female androgen production begin in the early 20s, suggesting a phenomenological decoupling with natural menopause (Sandhu et al., 2011).

Interestingly, testosterone is most closely linked with solitary sexual desire in women. Whereas dyadic sexual desire refers to the desire to be sexual with another person, solitary desire (i.e., the desire to engage in sexual activity with or without another person) is thought to be a more "true" measure of desire as it is less influenced by relational context and more responsive to endogenous physiology (Van Anders, 2012). Several studies have indicated that higher levels of testosterone are associated with increased solitary desire, while dyadic desire has shown either no association with testosterone levels, or in some cases, even a slight negative correlation (Van Anders et al., 2009; Van Anders & Gray, 2007). To that end, masturbation—a behavioral index of solitary desire—has been closely associated with testosterone levels in women (Van Anders, 2012).

Given the evidence for hormonal modulation of female interest and arousal, there has been research interest in the relationship between oral contraception use and sexual function. Oral contraceptives, which include a combination of estrogens and progesterone, cause an increase in sex hormone-binding globulin (SHBG) levels. SHBG, in turn, has been known to lower testosterone levels; thus, it is feasible that this decrease in testosterone could contribute to lower sexual desire in women taking oral contraceptives. Research on the relationship between oral contraceptives and sexual desire has yielded mixed results, and despite the fact that oral contraceptives have been shown to decrease androgen levels, they have not been consistently associated with decreases in sexual desire (Burrows et al., 2012). Indeed, a recent meta-analysis found no differences on various domains of sexual function (i.e., desire, orgasm, lubrication, pain) between women currently taking oral contraceptives and women who were not engaged in oral contraceptive usage (Huang et al., 2020). Similarly, when McCall and Meston (2006) assessed cues for sexual desire, they determined that contraceptive use did not influence sexual desire in women with and without sexual desire concerns.

At the same time, other research has found a negative association between oral contraceptives and sex drive. One study found a significantly lower rate of sexual thoughts and interest among women taking oral contraceptives compared to nonusers (Davison et al., 2008). Similarly, a relatively large-scale study found that oral contraceptive users demonstrated notably lower scores on the desire subscale of the Female Sexual Function Index relative to women who were not currently using oral birth control (Wallwiener et al., 2010). Importantly, these studies are cross-sectional and do not necessarily suggest that oral contraceptives play a causal role in decreased desire. It is also worth noting that the benefits accompanying oral contraceptive use (i.e., reduced fear of pregnancy, reduction in menstrual side effects) may serve to enhance, rather than inhibit, sexual desire. This effect may obscure any possible decrements in sexual desire and arousal that occur as a function of testosterone levels.

More recent research suggests that several neurochemical factors may affect both interest and arousal concerns. A recent study found two distinct, neurologically modulated pathways to FSIAD: (1) insensitivity in brain systems associated with sexual excitation and (2) a phasic increase in serotonergic activity following sexual stimulation, leading to an inhibitory response to sexual stimuli (Tuiten et al., 2018). Relatedly, psychoactive medications that act on these brain systems, including antidepressants, are implicated in FSIAD. With regards to antidepressants specifically, there is a large amount of variability in these effects depending on neurotransmitter receptor profiles (Clayton, El Haddad et al., 2014). The most commonly used antidepressants, selective serotonin reuptake inhibitors (SSRIs), function by increasing serotonin levels. This process increases activation in the serotonin-2 receptor, which confers a variety of sexual side effects in both men and women, including decreased desire. More modern classes of antidepressants act as antagonists at the serotonin-2 receptor level and are thus linked to fewer sexual side effects (Keks et al., 2014). In addition to variations in neurotransmitter profiles, it is also possible that the sexual side effects of antidepressants may differ due to larger genetic variations. Clayton and colleagues (2014) suggest that future research should seek to examine genetic factors associated with antidepressant medication usage, including side-effect profiles, to ultimately facilitate the advancement of individualized medicine in this area.

Both branches of the autonomic nervous system, the sympathetic and the parasympathetic (SNS and PNS), have been shown to impact female genital arousal specifically. With respect to SNS involvement, norepinephrine (NE) plays an important role. The neurotransmitter that facilitates SNS communication, NE increases after exposure to sexually arousing content (Exton et al., 2000). Strong support for the role of the SNS in female sexual arousal comes from the spinal cord literature, as women with spinal cord injuries in areas associated with sympathetically mediated vasocongestion (i.e., between areas T11 and L2) show a lack of lubrication during sexual arousal (Sipski et al., 1997).

Laboratory studies have also demonstrated the role of SNS involvement in female sexual arousal. For instance, Meston and colleagues found that moderate activation of the SNS using exercise (Meston & Gorzalka, 1995, 1996a, 1996b) or ephedrine (Meston & Heiman, 1998) facilitates genital sexual arousal, whereas genital arousal is inhibited by suppression of the SNS (Meston et al., 1997). Consequently, an optimal level of SNS activation has been proposed to facilitate genital arousal in women (Lorenz et al., 2012). Indeed, Lorenz and colleagues found a curvilinear relationship between SNS activation and sexual arousal such that moderate increases in SNS activity were associated with higher sexual arousal levels, while both very low and very high levels of SNS activation were associated with lower levels of sexual arousal. Moreover, resting state heart rate variability (which indexes the relative balance of the SNS and the PNS) has been identified as risk factor for sexual arousal problems (Stanton, Lorenz et al., 2015; Xhyheri et al., 2012). Therefore, factors that disrupt normal SNS activity, such as stress, may negatively affect women's sexual arousal.

Psychological Factors. Psychosocial factors are also implicated in low sexual interest and arousal. For instance, relationship duration is a significant, negative predictor of sexual desire, even after controlling for related variables including age, relationship satisfaction, and sexual satisfaction (Murray & Milhausen, 2012). Other research has examined the mechanisms underlying this association, finding that married women experience decreases in sexual desire accompanying feelings of overfamiliarity in their relationships (Sims & Meana, 2010). Sexual desire might also be impacted by daily stressors (i.e., childrearing, financial stress) and professional concerns (i.e., long hours, deadlines), as well as a range of partner-level issues. Women who report lower levels of intimacy and affection in their relationships, as well as lower levels of relationship satisfaction overall, also tend to report decreased sexual desire. The mechanism driving these associations has been theorized to be related to communication. as couples who communicate more openly have a better forum for learning about their partner's sexual preferences (for a review, see Freihart et al., 2020). Gender roles also impact sexual function, and women who subscribe to traditional gender roles may be at greater risk of experiencing sexual problems given a decreased sense of sexual agency (Nobre & Pinto-Gouveia, 2008).

Societal factors may also impact sexual interest and arousal levels in women. Sexual norms differ greatly as a function of culture, with broad implications for sexual function. For instance, women who are socialized to believe that sexual desire is shameful frequently report experiences of guilt and shame during sex. This pattern may result in lower levels of sexual desire and arousal longer-term (Woo et al., 2012).

Four distinct clusters of cues for sexual desire in women have been reported, including emotional bonding cues (e.g., experiencing emotional closeness with a partner), erotic/explicit cues (e.g., watching an erotic film), visual/proximity cues (e.g., being in close proximity to an attractive person), and romantic/implicit cues (e.g., giving or receiving a massage) (McCall & Meston, 2006). When compared to sexually healthy women, women with desire concerns report significantly fewer cues in each of these domains. Research has also identified cues for sexual arousal. When describing their sexual arousal experiences, women with sexual arousal problems reported relying less on physiological or genital arousal cues (e.g., heart racing, genital lubrication, genital warmth, etc.) and more on external, partner, or environmental cues than did women without arousal concerns (Handy et al., 2019). Perhaps without reliable physiological markers of arousal (i.e., lubrication), women with low arousal come to depend on their environmental context to enhance their sexual experiences.

Sexual interest concerns are frequently comorbid with different mental health disorders, including social anxiety disorder, obsessive-compulsive disorder, panic disorder, and major depressive disorder. With regard to depression, the mechanism underlying this comorbidity may be rumination about negative events. Individuals who present with depressive rumination may also maintain an exclusive focus on the negative aspects of a sexual experience. Moreover, individuals with depression may interpret negative experiences to stable, global causes (Hankin et al., 2005), resulting in feelings of hopelessness that could maintain sexual dysfunction. Similarly, FSIAD has been linked to poor emotion regulation skills, and decrements in sexual desire/arousal may be a function of difficulties in tolerating and reappraising difficult emotions (Dubé et al., 2019).

Finally, a history of nonconsensual sexual experiences may contribute to impairments in both sexual desire and arousal in women. Research has found that many women with a history of childhood sexual abuse may, in adulthood, come to fear sexual intimacy, avoid sexual interactions with a partner, and present as less receptive to a partner's sexual approach (Rellini, 2008). Sexual self-schemas, or cognitive generalizations about sexual aspects of the self (Andersen & Cyranowski, 1994), have been shown to differ between women with and without a history of childhood sexual abuse (Meston et al., 2006; Stanton, Boyd et al., 2015). More specifically, women with histories of nonconsensual sexual experiences often view sex as risky or threatening, or alternatively, as a central component of overall self-worth. Perhaps as a consequence of these sexual self-schemas, a high proportion of women with a history of childhood sexual abuse engage in risky sexual behaviors (e.g., Bensley et al., 2000). It is currently unknown whether this pattern of behavior is a reflection of high levels of sexual desire, an inability to maintain or enforce physical boundaries, higher levels of sexual compulsivity, emotional avoidance, or some combination of the above.

# Male Hypoactive Sexual Desire Disorder DEFINITION, DIAGNOSIS, AND PREVALENCE

Male hypoactive sexual desire disorder (MHSDD) is defined in DSM-5 as persistent or recurrently deficient sexual or erotic thoughts, fantasies, and desire for sexual activity. One major shift with the release of DSM-5 is the gender specificity of the disorder; in past editions of the DSM the hypoactive sexual desire disorder diagnosis could be applied to men or women. Sexual desire and arousal problems in women have been collapsed into a single diagnostic category in DSM-5. Other than the shift in gender specificity, there are no major differences in MHSDD diagnostic criteria between DSM-IV-TR and DSM-5. Only one minor change was made: in DSM-IV-TR, hypoactive sexual desire disorder required "persistent" low interest in sex, whereas DSM-5 specifies that symptoms must be present for at least 6 months.

Men are much more likely to present with erectile disorder (ED) than MSHDD, perhaps due to cultural norms portraying men as extremely sexually desirous. Men may feel stigmatized when reporting symptoms of low sexual desire to healthcare providers, and therefore available prevalence estimates may underreport the true prevalence rate. Moreover, most epidemiological studies have not inquired about the full set of diagnostic criteria for HSDD (i.e., asking about lack of interest in sex but not the duration of those concerns or the degree to which they are experienced as distressing), making it difficult for researchers to determine accurate prevalence rates. One international study did examine the prevalence of low sexual interest in men over a 2-month period, finding that 14.4% of respondents reported a distressing lack of sexual desire (Carvalheira et al., 2014). These concerns were most common among men aged 30–39, per-haps as a consequence of professional or childrear-ing stressors.

A range of factors predict variation in prevalence rates for MHSDD. Self-reported prevalence rates vary by region, ranging from 4.8% in the United States (Laumann et al., 2009) to 17% in the United Kingdom (Mercer et al., 2003). MSHDD prevalence may also vary by age, with rates exceeding 40% in men older than 65 (Fugl-Meyer & Sjogren, 1999). Rates typically decrease when studies include information about the persistence of the problem; one study found that 4.8% of men reported an occasional lack of sexual desire whereas only 3.3% reported a frequent lack of sexual desire (Laumann et al., 2009). Finally, rates also vary depending on the type of sample (e.g., community vs. clinical). Men in community samples are more likely to report desire problems than are men in clinical samples, and reports of desire concerns exceed reports of erectile problems (Fugl-Meyer & Sjogren, 1999; Mercer et al., 2003). Men in clinical settings may feel more comfortable talking about erectile problems than desire problems, especially if they attribute their problems to biological rather than psychological mechanisms (Kedde et al., 2011).

# FACTORS ASSOCIATED WITH MALE HYPOACTIVE SEXUAL DESIRE DISORDER

Most research to date on the biological factors implicated in male sexual desire has focused on hormones and neurological disorders. Psychological causes of low sexual desire in men include relationship difficulties and psychopathology.

*Biological Factors.* Hormonal patterns are often associated with male sexual desire concerns. In men with intentionally suppressed androgen levels, low testosterone is linked to lower levels of sexual desire (Bancroft, 2005). Testosterone replacement has been shown to increase sexual desire among these men, but not among men with normal and/ or sufficient androgen levels (Corona, Jannini et al., 2011; Isidori et al., 2005; Khera et al., 2011). Hypogonadism (i.e., diminished functional activity of the gonads) has been observed in 3–7% of men between the ages of 30 and 69 and in 18% of men aged 70 and older (Araujo et al., 2007) perhaps accounting for age-related declines in sexual interest. Hyperprolactinema (i.e., clinically high levels of prolactin) and hypothyroidism have also been associated with low sexual desire in men (Carani et al., 2005; Corona et al., 2004; Corona, Restrelli et al., 2011; Maggi et al., 2013).

Certain psychoactive medications (e.g., SSRIs, selective norepinephrine reuptake inhibitors [SNRIs]) have been linked to low sexual interest in men (Clayton, El Haddad et al., 2014), as have neurological disorders and a range of other medical conditions. Atypical antidepressants may have lower incidence of sexual desire side effects (Clayton et al., 2013). With respect to medical conditions, one study found that 25% of men with multiple sclerosis reported low sexual interest (Lew-Starowicz & Rola, 2014). Low sexual desire has also been reported among men with inflammatory bowel disease (IBD), Crohn's disease, and ulcerative colitis. In such cases, decreased desire may be a side effect of the medications used to treat conditions like IBD, which have a demonstrated impact on testosterone levels. This association could also be mediated by depression levels; IBD is highly comorbid with depression, which may drive observed decreases in sexual interest (O'Toole et al., 2014). Coronary disease, heart failure, renal failure, and HIV have also been associated with low sexual interest in men (Bernardo, 2001; Lallemand et al., 2002; Meuleman & Van Lankveld, 2005; Toorians et al., 1997). Further research in this area is warranted, as it remains unclear whether decreases in desire are due to the conditions themselves, the medications used to treat the conditions, and/or the psychosocial stressors that often accompany the conditions.

Psychological Factors. Many psychological factors have been associated with low sexual desire in men, including relationship concerns, concerns related to sexual performance, and comorbid psychopathology (e.g., depression, anxiety). In fact, one study found that psychosocial symptoms were more predictive of low sexual interest than were biological factors, including hormone levels (Corona et al., 2004). Interpersonal factors, in particular, have been strongly associated with sexual interest. For example, men are more likely to experience low sexual desire if their partners also have desire concerns (McCabe & Connaughton, 2014). Desire problems have also been linked to partner-level factors, such as not finding one's partner attractive and being in a relationship for more than 5 years (Carvalheira et al., 2014). Individual factors, including mental health concerns, may also compromise sexual desire. In a survey of male outpatients seeking treatment for sexual dysfunction, 43% of men reported a history of psychiatric symptoms (Corona et al., 2004). To that end, many studies have highlighted the association between depression and low sexual desire (Carvalheira et al., 2014; McCabe & Connaughton, 2014; Pastuszak et al., 2013).

### Erectile Disorder

#### DEFINITION, DIAGNOSIS, AND PREVALENCE

ED is defined in DSM-5 as the recurrent inability to achieve an erection, the inability to maintain an adequate erection, and/or a noticeable decrease in erectile rigidity during partnered sexual activity. ED occurs in men of all ages but is most common among men aged 50 and older. Indeed, while only 7% of men between the ages of 18 and 29 have erectile concerns, almost 20% of men 50 to 59 endorse such problems (Laumann et al., 1999). Feldman and colleagues (1994) found that 10% of men under the age of 35 experience ED, compared to more than 50% of men over the age of 60. The Global Study of Sexual Attitudes and Behaviors reported that 18.8% of men over the age of 40 indicate occasional erectile problems, whereas only 3.5% report such problems consistently (Laumann et al., 2005; Nicolosi et al., 2004).

The prevalence of ED varies as a function of several factors other than age. Married men are less likely to report erectile problems compared to men who have never been married or are divorced (Laumann et al., 1999). Men with cardiovascular disease, diabetes, and metabolic syndrome are also more likely to have ED than are men without these diseases (Grover et al., 2006). Relatedly, health factors such as smoking, obesity, and lack of exercise have been linked to higher rates of ED (Rosen et al., 2014).

# FACTORS ASSOCIATED WITH ERECTION AND ERECTILE DYSFUNCTION

Over the past 30 years, a great deal of research has identified a number of key biological and psychological causal mechanisms in ED. Biological factors are largely related to changes in blood flow to the penis, while psychological factors most commonly involve anxiety and negative expectations for performance.

*Biological Factors.* Erection is caused by increased blood pressure in the corpora cavernosa, which occurs as a function of increased blood inflow and

decreased blood outflow. An overwhelming body of evidence suggests that the likelihood of ED increases with different types of vascular disease, such as hyperlipidemia, coronary heart disease, and diabetes (e.g. Kirby et al., 2005; Roumeguère et al., 2003; Seftel et al., 2004). In fact, the link between vascular problems and ED is so strong that ED is considered an early biomarker of vascular disease, especially when it presents in men under the age of 40 (Chew et al., 2010; Miner, 2009). To that end, some researchers favor conceptualizing ED as a vascular disorder rather than a sexual dysfunction (Schouten et al., 2008; Thompson et al., 2005).

ED can be caused by other medical conditions and procedures, including surgery, diabetes, alcoholism, infectious diseases (e.g., HIV), and pelvic pathologies. Drugs that decrease dopamine or reduce testosterone production are also implicated in ED. These include antihypertensive medications, antipsychotic drugs, anxiolytics, antiandrogens, anticholesterol agents, and drugs used to regulate heart rate. Conversely, antiparkinsonian medications increase dopamine and facilitate erection.

Psychological Factors. The sexual tipping point model, developed by Perelman in 2009, considers sexual function in terms of an individualized arousal threshold necessary to experience a sexual response. One's sexual tipping point, according to Perelman, is determined by a variety of complex factors that span physiological and psychosocial categories. Examples of psychosocial issues in men that may influence erectile function include performance anxiety, guilt and shame resulting from religious beliefs, and/or a history of sexual trauma (Perelman & Rowland, 2006; Waldinger & Schweitzer, 2005).

Barlow's (1986) feedback model of sexual dysfunction elucidates how these psychosocial factors work together to maintain ED. Men who experience anxiety related to their sexual performance tend to maintain focus on their own behaviors during a sexual encounter, leading to decrements in the ability to notice and experience pleasure. This pattern, known as spectatoring, serves to increase anxiety, which, in turn, inhibits the physiological relaxation of smooth muscles that is necessary for erection. This pattern then contributes to a negative mood state that drives future negative expectancies surrounding sexual experiences. Given that the result is impaired erectile responding, the man's performance-related fears are confirmed and reinforced, leading to an increased likelihood of repeating this process in subsequent sexual situations. In most cases of ED, performance anxiety is

also present, perhaps because the occurrence—or absence—of an erection is visible to both the man and his partner, which increases the focus on performance. According to Rosen and colleagues (2014), men experiencing performance anxiety engage in visual or tactile checking of the penis to ensure an erection is sustained.

Conversely, men without sexual concerns tend to approach sexual situations with positive expectancies and focus more closely on erotic cues. This sets the stage for a positive feedback loop: they become aroused, are able to obtain and sustain an erection, and then approach future sexual situations with positive expectations based on experience. While spectatoring can be detrimental for sexual function at any age, it appears to be particularly problematic when young men first begin engaging in sexual activity. Given the absence of sexual experience, young men are particularly vulnerable to the influence of negative expectations about erectile performance.

Other psychosocial factors can contribute to the development and maintenance of ED. According to Nobre and Pinto-Gouveia (2006, 2009), men are more likely to meet criteria for ED if they (1) endorse myths about male sexuality (e.g. "men always want to have sex"), (2) view themselves as incompetent, and (3) view their sexual problem as internal and stable over time. A range of mental health conditions, including depression, generalized anxiety disorder, obsessive-compulsive disorder, and paraphilic disorders, have been linked to ED. Last, a survey of college-aged men found that off-label Viagra use was correlated with erectile dysfunction (Harte & Meston, 2011). This study suggested that recreational Viagra use could lead to subsequent erectile problems by way of increasing psychological dependence on the drug for performance.

# **Orgasm Disorders**

The category of orgasm disorders refers to a broad collection of difficulties surrounding the presence or absence of orgasm during sexual activity. Both sexes can experience an inability to achieve orgasm. In men, the most frequent presentation is premature orgasm, or achieving orgasm too quickly. In women, the most common presentation is the inability to attain orgasm.

### Female Orgasmic Disorder

### DEFINITION, DIAGNOSIS, AND PREVALENCE

Female orgasmic disorder (FOD), as defined by *DSM-5*, refers to a reduced intensity, delay, infrequency, and/or absence of orgasm. Although not formally stated in *DSM-5*, the clinical consensus is that as long as a woman can obtain an orgasm through some mode—manual stimulation, stimulation with a sex toy, intercourse, or some combination of the above—she does *not* meet criteria for FOD (unless she is distressed by her orgasmic response).

Historically, the field has lacked a clear definition of female orgasm, making the operationalization of FOD difficult. In fact, one study cited more than 25 distinct definitions of female orgasm proposed by different authors (Mah & Binik, 2001). The following definition of female orgasm was derived by the committee on female orgasm and presented at the International Consultation on Urological Diseases in Official Relationship with the World Health Organization (WHO), in Paris, 2003:

An orgasm in the human female is a variable, transient peak sensation of intense pleasure, creating an altered state of consciousness, usually accompanied by involuntary, rhythmic contractions of the pelvic, striated circumvaginal musculature often with concomitant uterine and anal contractions and myotonia that resolves the sexually-induced vasocongestion (sometimes only partially), usually with an induction of well-being and contentment. (Meston, Levin et al., 2004)

Orgasms are the result of sustained erotic stimulation to both genital and nongenital zones of women's bodies, including the clitoris, vagina, other areas of the vulva, the breasts, and nipples. Female orgasm may also result from fantasy and/or mental imagery, and may occur during sleep, precluding the necessity of consciousness for an orgasm to occur. Orgasms generally do not occur spontaneously without some form of sexual stimulation (either physical or psychological); however, some psychotropic drugs have been reported to induce spontaneous orgasms in women. Interestingly, women experiencing orgasmic difficulties do not typically present with the same level of distress that has been reported in men with ED. This may be because women, unlike men, are able to replicate the appearance of orgasm, thus reducing performance-related anxiety concerns.

In the United States, orgasm difficulties are the second most common female sexual problem, with 22–28% of women (ages 18–59) reporting an inability to attain orgasm (Laumann et al., 1994). More recent research accounting for *DSM-5* morbidity criteria finds that approximately 16.3% of women report difficulties with orgasm over the past year, but only 1.9% meet diagnostic criteria (Mitchell et al., 2016). In particular, young women (18–24 years) have lower rates of orgasm, both with a partner and during masturbation, likely owing to levels of sexual experience (Laumann et al., 1994; Mitchell et al., 2016). Differences in research methodology and diagnostic criteria make it difficult to accurately determine prevalence rates for FOD. Indeed, in a review of 11 epidemiological studies, Graham (2010) found a low-end prevalence rate for FOD at 3.5% when *DSM-III* criteria were used and a high rate of 34% when women were simply asked whether or not they had difficulties experiencing orgasm.

# FACTORS ASSOCIATED WITH WOMEN'S ORGASM AND FOD

The female orgasm results from a complex interaction of biological, psychological, and cultural processes. The most common causes of FOD include disturbances to these processes, such as disruptions in the SNS response, different types of chronic illness (particularly spinal cord injury), sexual guilt, anxiety, and relationship concerns.

Biological Factors. Impairments in nervous system function, endocrine levels, and/or various brain mechanisms involved in female orgasm may cause orgasmic dysfunction (Heiman, 2002). With respect to the nervous system, studies examining blood plasma levels of neurotransmitters before, during, and after orgasm suggest that epinephrine and norepinephrine levels peak during female orgasm (e.g., Exton et al., 2000). Oxytocin levels are positively correlated with the subjective intensity of orgasm among orgasmic women, with elevated prolactin levels up to 60 minutes post orgasm (for review, see Meston & Frohlich, 2000). Studies in humans suggest that the paraventricular nucleus of the hypothalamus, an area of the brain that produces oxytocin, is involved in the orgasmic response (McKenna, 1999). Impairments in any of these systems may lead to FOD.

Medical issues and conditions impacting a woman's orgasmic ability include damage to the sacral/ pelvic nerves, multiple sclerosis, vascular disease, Parkinson's disease, epilepsy, hysterectomy complications, vulvodynia, hypothalamus-pituitary disorders, kidney disease, fibromyalgia, and sickle-cell anemia. Women with spinal cord injuries in the sacral region (interfering with the sacral reflex arc of the spinal cord) have shown difficulty attaining orgasm (Sipski et al., 2001). This is believed to be caused by interference with the vagus nerve, which connects the cervix to the brain (Whipple et al., 1996).

Several psychotherapeutic drugs have demonstrated orgasmic side effects in women. For instance, drugs that increase serotonergic activity (e.g., some antidepressants) or decrease dopaminergic activity (e.g., antipsychotics) have been shown to decrease, delay, or, in some cases, completely limit orgasmic capacity (Meston, Levin et al., 2004; Graham et al., 2010). Indeed, problems with orgasm have been noted in about one-third of women who take SSRIs (Stimmel & Gutierrez, 2006). There is interclass variability, however, in that some antidepressants have been associated with impaired orgasm more often than others, and these differences may be related to the specific serotonin receptor subtype being activated. As noted earlier, drugs that inhibit serotonin activity at the serotonin-2 receptor (e.g., nefazodone, cyproheptadine) cause fewer sexual side effects in women (for review, see Meston, Levin et al., 2004).

It has been reported that an increasing number of women believe the structure of their genitalia may contribute to difficulties in achieving or maintaining orgasm, leading to an increase in genital plastic surgery, including labiaplasty (reduction of the size of the inner labia and the outer labia), vaginoplasty (rebuilding the vaginal canal and its mucous membrane), hymenoplasty (reconstruction of the hymen), perineoplasty (tightening or loosening of the perineal muscles and the vagina and/or correcting clinical defects or damages of the vagina and the anus), and G-spot augmentation. While a few, relatively small studies have indicated that these surgeries resulted in increased sexual satisfaction (e.g. Goodman et al., 2010), little current evidence supports the efficacy of these procedures. Furthermore, many studies that examined the effects of these surgeries failed to (1) use standardized measures to formally assess for sexual dysfunction and (2) include control groups. For these reasons, the American College of Obstetricians and Gynecologists and the Society of Obstetricians and Gynecologists of Canada discourage physicians from performing genital plastic surgery.

*Psychological Factors.* Common psychological factors associated with FOD include sexual guilt, sexual anxiety, childhood loss, and relationship issues (for review, see Meston, Hull et al., 2004). Sexual guilt may arise from strict adherence to the values of Western religions, which sometimes view sexual pleasure as sin. This belief can influence orgasmic

abilities by increasing anxiety and discomfort during sex, by distracting a woman from what gives her pleasure, and by causing distressing thoughts during sexual activity. Conversely, women who initiate sex and/or are more active participants during sexual activity report more frequent orgasms. Their active role may allow for finding sexual positions that facilitate a greater level of stimulation and pleasure. Women who engage in sexual activity, both partnered and solo, more frequently report more orgasms than women with infrequent sexual activity. It is likely that women who engage in sex more often have a greater knowledge of what gives them sexual pleasure and are therefore more likely to experience orgasm. Finally, women are more likely to have orgasms when in romantic relationships that are characterized by a high degree of sexual and nonsexual communication (Mallory et al., 2019). To that end, women experiencing relationship discord might be at greater risk for FOD than women who are satisfied with their relationships. It is important to note that, because only a small percentage of women are distressed by their anorgasmia, prevalence rates of FOD are low (Graham, 2010).

A range of demographic factors are associated with FOD, including age, education, and religion. Women aged 18-24 are more likely to report orgasm problems, compared to older women, during both masturbation and partnered sexual activity (Laumann et al., 1994). Sexual experience may, as a consequence, be important for orgasmic ability, as might knowledge of one's body and preferences. Lower levels of education are associated with orgasmic difficulties, even during masturbation. Indeed, only 42% of women with a high school education report "always or usually" achieving orgasm during masturbation, as compared to 87% of women with an advanced degree (Laumann et al., 1994). It's possible that more educated women hold more liberal views on sexuality and might be more likely to center their own pleasure as a goal of sexual activity.

There is a negative relationship between high religiosity and orgasmic ability in women, such that religious belief may lead to experiences of guilt during sexual activity. Guilt, in turn, may impair orgasm through a number of cognitive mechanisms, including distraction. There is also a relationship between improved orgasmic ability and decreased sexual guilt (Davidson & Moore, 1994). Laumann and colleagues (1994) reported that a substantially higher proportion (79%) of women with no religious affiliation endorsed being orgasmic during masturbation compared to women with a religious affiliation (53–67%).

Last, it is possible that overarching societal notions of women's sexuality, including the cultural value placed on women's sexual pleasure, may play a role in female orgasmic capacity. Societies that value female orgasm have lower incidences of anorgasmia than societies that discourage sexual pleasure for women (for review, see Meston, Hull et al., 2004). Examples of societies that encourage sexual pleasure include the Mundugumor of Papua New Guinea and the Mangaia of the Cook Islands. Mangaian women are taught to have orgasms, with expectations of multiple female orgasms for each male orgasm, and specific attention is paid to mutual orgasm. In fact, Mangaian males who are not able to give their partners multiple orgasms are socially disparaged. At the opposite end of the spectrum are societies, such as the Arapesh of Papua New Guinea, that assume that women will have no pleasure from coitus and that the female orgasm does not exist. The Arapesh do not even have a word in their language for the female orgasm. It is feasible that women in societies that promote women's sexual pleasure are more likely to experiment and therefore learn about what facilitates their ability to have an orgasm. Moreover, women in such societies may be more likely to *admit* to experiences of orgasm, whereas orgasm rates may be underreported in societies that discourage sexual pleasure.

# Delayed Ejaculation

### DEFINITION, DIAGNOSIS, AND PREVALENCE

As defined by *DSM-5*, delayed ejaculation (DE) is a persistent difficulty or inability to achieve orgasm despite the presence of adequate desire, arousal, and stimulation. Most commonly, the term refers to a condition in which a man is unable to orgasm with his partner, even though he is able to achieve and maintain an erection. Typically, men with DE are able to ejaculate during masturbation or sleep.

Importantly, men experiencing retrograde ejaculation do not meet the diagnostic criteria for DE. Retrograde ejaculation occurs when the ejaculatory fluid travels backward into the bladder rather than forward through the urethra. It may result from prostate surgery complications or as a side effect of certain medications (e.g., anticholinergic drugs), and, in some cases, men may be unaware that this phenomenon can account for lack of visible ejaculate.

There is clinical consensus that DE is both the least common of the male sexual dysfunctions and

also the least understood. A key concern often associated with DE—and frequently missed by clinicians—is that partnered sexual activity may not be as sexually stimulating as masturbation. Stimulation techniques used during masturbation (e.g., pushing the penis against different objects, rolling the penis between one's hands), may create an intense sense of friction that is otherwise elusive during sexual activity with a partner. In addition, masturbation often contains a strong fantasy component, which may also be challenging to maintain when engaging in partnered intercourse.

Prevalence rates of DE in the literature are generally low, usually below 3% (e.g., Christensen et al., 2011; Líndal & Stefansson, 1993; Perelman & Rowland, 2006). Researchers have suggested that, over time, the rate of DE will rise as a function of age-related ejaculatory decline (Perelman, 2003) and widespread use of SSRIs (Georgiadis et al., 2007), which have been implicated in increased ejaculation latency.

The term "delay" in delayed ejaculation inherently suggests a normative amount of time from the start of sexual activity to ejaculation. In fact, only one study has addressed this question. Waldinger and Schweitzer (2005) measured intravaginal latency time in 500 heterosexual couples crossculturally. The median time to orgasm was 5.4 minutes, the mean was 8 minutes, and the standard deviation was 7.1 minutes. Though these values are empirically interesting, it is noteworthy that DSM-5 diagnostic criteria for DE do not include any objective measures of latency, which makes it challenging to determine overall prevalence. Furthermore, it is possible that some men may have unrealistic latency-to-orgasm expectations and may thus unfairly consider their ejaculation patterns to be delayed.

### FACTORS ASSOCIATED WITH DELAYED EJACULATION

Delayed ejaculation is associated with a number of biological and psychological factors. Biological factors include damage to nerve pathways that facilitate ejaculation, chronic medical conditions, and, potentially, age. Psychological etiologies of the disorder span from insufficient stimulation to assorted manifestations of "psychic conflict."

*Biological Factors.* When men ejaculate, nerve impulses on sympathetic fibers travel through the sympathetic ganglia and peripheral pelvic nerves, causing the efferent release of semen and closure of the bladder neck (Segraves, 2010). While damage to any of these pathways may compromise ejaculation,

spinal cord injury is the most common nerve-related cause of DE.

Several chronic medical conditions, including multiple sclerosis and diabetes, are correlated with DE (Perelman & Rowland, 2006; Waldinger & Schweitzer, 2005). Ejaculatory delay may also be caused by short-term, reversible medical conditions (e.g., prostate infection, urinary tract infection, substance use) and psychopharmacological agents (e.g., antipsychotics, antidepressants; Segraves, 2010).

There is conflicting evidence regarding the effect of age on ejaculatory function (Segraves, 2010). DE is more common in older males (Perelman & Rowland, 2006), and the disorder may be related to low penile sensitivity, which is itself associated with aging (Paick et al., 1998; Rowland, 1998). On the other hand, low penile sensitivity is not usually the primary cause of DE (Perelman, 2014). Rather, individual variability in the sensitivity of the ejaculatory reflex, which is exacerbated with age, may be driving the relationship between age and DE.

*Psychological Factors.* Althof (2012) reviewed the four leading psychological theories of DE. The first focuses on insufficient mental or physical stimulation (Masters & Johnson, 1970). Men with DE experience less sexual arousal than men without the disorder and therefore may have a diminished ability to experience penile sensations (Rowland et al., 2004). A lack of proper ambiance or environmental cues for sexual arousal may also contribute to insufficient mental stimulation (Shull & Sprenkle, 1980).

The second theory posits that DE is caused by a high frequency of masturbation or by a unique, idiosyncratic masturbatory style that differs greatly from the physical stimulation that occurs during partnered intercourse (Althof, 2012; Perelman, 2005; Perelman & Rowland, 2006). A large disparity may exist between the sensations that men with DE experience when masturbating to a specific fantasy and the sensations that they experience during sex with a partner.

A third theory centers on the idea of "psychic conflict" as the root cause of DE. While this theory was more common in the early stages of psychological treatment, some psychodynamically oriented therapists still conceptualize the disorder in these terms. Examples of psychic conflict include anxiety related to loss of self (due to loss of semen), fear that ejaculation may hurt the partner, fear of impregnating the partner, and guilt from strict religious upbringing (Friedman, 1973; Ovesey & Meyers, 1968). The fourth and final theory suggests that DE may be masking the presence of a desire disorder. In this case, the male may be overly concerned with pleasing his partner and, even when he is not aroused, may seek to ejaculate (Apfelbaum, 1989).

# Premature (Early) Ejaculation

### DEFINITION, DIAGNOSIS, AND PREVALENCE

Premature (early) ejaculation (PE) is defined in *DSM-5* as a persistent or recurrent pattern of ejaculation occurring during partnered sexual activity within approximately 1 minute following vaginal penetration. The diagnosis only applies to individuals who ejaculate before they would like to. Although the diagnosis may be applied to those who engage in nonvaginal sexual intercourse, specific duration criteria for such activities have not been established.

In recent years, there has been considerable disagreement about the definition, nature, and even the name of the disorder. The *DSM-5* Sexual Dysfunctions sub-work group changed the name of the disorder from "premature ejaculation" to "premature (early) ejaculation," as some considered the existing name to be pejorative. Researchers have also argued that the time to ejaculation after penetration criterion is overly simplistic and may limit scientific understanding of the condition (Metz et al., 1997). Others have suggested that PE might not warrant the term "dysfunction," indicating that the disorder should probably not be of clinical concern unless it is extreme (Hong, 1984).

Owing in part to a lack of universally accepted diagnostic criteria, varying prevalence rates been reported. Importantly, there are currently no published epidemiological studies that assess the prevalence of PE as defined in DSM-5. However, many studies have assessed the prevalence of PE concerns. For instance, Masters and Johnson (1970) identified PE as one of the most common male sexual dysfunctions. According to Laumann and colleagues (1994), PE is the most common sexual disorder in men, with approximately 30% of men in the United States reporting the condition in the previous year. Unlike ED, this condition has been estimated to affect younger men more so than older men. As many as 40% of men under 40 years of age and only 10% of men over age 70 have been estimated to experience premature (early) ejaculation (Corona et al., 2004). When the intravaginal ejaculation latency time criterion is used (i.e., ejaculation occurring within 1 minute of penetration), however, prevalence rates are much lower, usually around 1-3% (Althof et al., 2010). High rates of comorbidity are reported for PE and ED, with about one-third of men who suffer from PE also experiencing ED (Corona et al., 2004).

### FACTORS ASSOCIATED WITH PREMATURE (EARLY) EJACULATION

Causal factors have been identified for both normal and premature ejaculation. Historically, PE has been considered to be a psychological problem; however, recent research has implicated different biological systems in the development and maintenance of the disorder.

Biological Factors. During sperm emission, the first stage of ejaculation, sperm moves from the epididymis into the vas deferens. This process is generated by the SNS, which controls the contraction of smooth muscles. Following sperm emission, the individual has the subjective experience that ejaculation is "inevitable," known as the "point of inevitable ejaculation." Rhythmic contractions occur in the striate muscles surrounding the spongious tissue, the cavernous tissue, and in the pelvic floor, causing ejaculation to occur. The subjective experience of orgasm is normally associated with the contractions of the striate muscles. In most men, emission, ejaculation, and orgasm are interconnected. For a small portion of men, however, these phenomena are independent. For example, some men train themselves to have the subjective experience of orgasm without ejaculation, while some men with PE experience emission without ejaculation.

The precise cause of PE is unknown, but the most promising biological etiologies include malfunction of the serotonin receptors, genetic predisposition, and disruptions of the endocrine system. Waldinger, Berendson, and colleagues (1998) noted that, in rodents, activation of one serotonin receptor speeds up ejaculation, while activation of another serotonin receptor delays ejaculation. It is plausible, then, that men with symptoms of the disorder may have disturbances in central serotonergic neurotransmission, which could result in a lower threshold for sexual stimulation (Waldinger, 2007). PE may also be influenced by genetic predispositions. In first-degree male relatives of Dutch men with lifelong PE, researchers found a high prevalence of PE (Waldinger, Rietschel et al., 1998). Similarly, a genetic study of Finnish male twins indicated that genetics account for 28% of the variance in PE (Jern et al., 2007). Recent research has confirmed the role of the endocrine system in the control of the ejaculatory reflex. Carani and colleagues (2005) found that

50% of men with hyperthyroidism also had PE. In addition to testosterone and prolactin, the hormone thyrotropin has been shown to play an independent role in the control of ejaculatory function (Corona, Jannini et al., 2011; Maggi et al., 2013).

Psychological Factors. One of the primary causes and maintaining factors of PE may be anxiety. Althof (2014) explained that the term "anxiety" is characterized by three different mental phenomena related to PE. First, anxiety may refer to a phobic response, such as fear of the vaginal canal. Similarly, one may have an affective response, such as negative feelings toward one's partner as a function of anxiety. Finally, anxiety may indicate performance concerns, such that a preoccupation with poor sexual performance leads to decrements in sexual function and increased avoidance of sexual situations. Therefore, anxiety may have a reciprocal relationship with PE; that is, performance anxiety may lead to problems with early ejaculation, which may then lead to performance anxiety (Althof et al., 2010). Despite the sound theoretical underpinnings, laboratory studies have generally not shown significant differences in levels of anxiety reported by men with and without PE.

Additionally, early learned experiences and a lack of sensory awareness may be important psychological factors contributing to PE. Masters and Johnson (1970) examined case histories of men with PE and found that many had early sexual experiences during which they felt nervous and rushed. According to Masters and Johnson, these men learned to associate sex and sexual performance with speed and discomfort. Kaplan (1989) considered lack of sensory awareness to be the immediate cause of PE. She believed that men with PE fail to develop sufficient awareness of their own level of arousal.

### **Sexual Pain Disorders**

The DSM-IV-TR included two sexual pain disorders, dyspareunia and vaginismus. The DSM-5 Sexual Dysfunctions sub-work group combined these two disorders into genito-pelvic pain/penetration disorder (GPPPD). In DSM-IV-TR, dyspareunia was defined as genital and/or pelvic pain, whereas vaginismus referred to an involuntary spasm or tightening of the pelvic muscles. The merging of dyspareunia and vaginismus emphasizes the multidimensional nature of genital pain, particularly in women. Mental health professionals, when confronted with a patient with any of these conditions, should make sure that the condition is fully assessed by a gynecologist or urologist.

# Genito-Pelvic Pain/Penetration Disorder DEFINITION, DIAGNOSIS, AND PREVALENCE

In *DSM-5*, GPPPD is defined as persistent or recurrent difficulties with one or more of the following: (1) vaginal penetration during intercourse; (2) vulvovaginal or pelvic pain during vaginal intercourse or attempts at penetration; (3) fear or anxiety about vulvovaginal or pelvic pain in anticipation of, during, or as a result of vaginal penetration; and (4) tightening or tensing of the pelvic floor muscles during attempted vaginal penetration.

GPPPD was established, in part, in response to arguments made by Binik (2010a), who questioned the logic of maintaining two separate sexual pain diagnoses for women, given the high rates of comorbidity between painful sex and difficulties with penetration. The overlap between these two concerns is notable, with one study finding that 72.4% of women with vaginismus reported symptoms of dyspareunia and 47.7% of women with dyspareunia reported symptoms of vaginismus (Peixoto & Nobre, 2013).

There has also been some larger debate regarding the conceptualization of GPPPD, with some considering whether GPPPD should be considered a pain disorder that interferes with sexual activity or a sexual dysfunction characterized by pain (Kingsberg & Knudson, 2011). Evidence for the pain conceptualization comes from studies that suggest nonpelvic chronic pain is associated with chronic genito-pelvic pain (Paterson et al., 2009). As more research is needed to answer these questions, the *DSM-5* Sexual Dysfunctions sub-work group decided to maintain the status of GPPPD as a sexual dysfunction.

In addition to the collapsing of dyspareunia and vaginismus, another important change with the release of DSM-5 was the exclusion of men from a sexual pain diagnosis. The DSM-IV-TR diagnosis of dyspareunia applied to both males and females. Due to a lack of empirical studies, male dyspareunia has been excluded from GPPPD diagnostic criteria (Bergeron et al., 2014). There is, however, evidence to suggest that men do occasionally suffer from localized or generalized pain during sexual activity, with prevalence estimates between 5% and 15% (Clemens, 2005). To address this type of pain, researchers have coined the term "urological chronic pelvic pain syndrome" (UCPPS), which applies only to men but is not included in DSM-5 (Shoskes et al., 2009). Davis and colleagues (2011) found that the patterns of sensitivity and pelvic floor muscle function observed in men with

UCPPS are notably similar to those of women with GPPPD.

GPPPD is frequently comorbid with sexual arousal problems in women. The genital changes that occur when women become physiologically aroused (i.e., swelling, lubrication of the genitals) facilitate penetrative intercourse. In the absence of these physiological sexual readiness cues, intercourse can result in friction, tearing, and overstimulation of genital tissue, leading to sexual pain. As a consequence, some have theorized that a lack of genital arousal may be a key antecedent to sexual pain symptoms.

GPPPD is new to DSM-5 and thus prevalence estimates are limited. One small Iranian sample yielded a prevalence rate of 10.5% among married women living in Tehran (Alizadeh et al, 2019). These rates may not, however, be generalizable at the population level. Prevalence estimates do exist for dyspareunia and vaginismus. Rates of dyspareunia range from 2% to 7% in general (Peixoto & Nobre, 2013), from 6.5% to 45% in older women (van Lankveld et al., 2010), and from 14% to 34% in younger women (van Lankveld et al., 2010). Prevalence rates for vaginismus are reported to be 5-6.6% (Fugl-Meyer et al., 2013; ter Kuile & Reissing, 2014). Notably, higher rates of painful sexual intercourse have been observed in clinical settings (Nobre & Pinto-Gouveia, 2008) and in countries where arranged marriages, polygamy, and/or widow inheritance are common (Amidu et al., 2010; Yasan et al., 2009). Some women are at increased risk of genito-pelvic pain after giving birth (Rosen & Pukall, 2016), with 10% of women reporting postpartum genito-pelvic pain (Paterson et al., 2009). Additional risk factors for GPPPD include poor health, lower education, low family income, high stress, more frequent emotional problems, and the presence of urinary tract symptoms.

# FACTORS ASSOCIATED WITH GENITO-PELVIC PAIN/ PENETRATION DISORDER

Correlates of sexual pain in women include a number of medical conditions, as well as anxiety about sexual activity. When sex is painful, research suggests that women may develop anxiety related to sexuality that subsequently maintains the pain associated with GPPPD.

*Biological Factors.* Genital pain is generally categorized as superficial or deep. Superficial pain may result from a dermatological disorder or another medical condition that impacts the genitalia (e.g., vaginal atrophy, anatomical variations, urinary tract infections, injury, and other diseases and infections of the vulva). Conversely, deep pain more commonly results from uterine fibroids, endometriosis, urinary disease, and/or ovarian disease (for review, see Schultz et al., 2005). Sexual pain has also been observed following pelvic radiation and chemotherapy (Fugl-Meyer et al., 2013; Kingsberg & Knudson, 2011).

At the superficial level, one of the major etiological factors for pain is a biological disorder known as provoked vestibulodynia (PVD; formerly vulvar vestibulitis syndrome). PVD is characterized by a sharp, burning pain experienced to any touch or pressure on the vulvar vestibule, a region that falls between the inner labia minora, the frenulum of the clitoris, and the lower portion of the vaginal opening (Pukall et al., 2005). This condition can be diagnosed by a gynecologist by probing the area with a cotton swab to assess evoked pain sensations. PVD may be related to a history of yeast infections and hormonal events in adolescence, including the early onset of menstruation and use of oral contraceptives (Farmer et al., 2011; Pukall et al., 2005). Another potential cause of superficial genital pain is vulvovaginal atrophy, or the deterioration/reduction of flexibility and lubrication in vaginal tissue, naturally co-occuring with menopause. The vaginal symptoms reported by premenopausal women with PVD and postmenopausal women with vulvovaginal atrophy are markedly similar (Kao et al., 2008).

One major hypothesized pathway to GPPPD involves the sensitization of neurons in the spinal cord and parts of the brain. It has been theorized that intense or abrasive stimulation of peripheral tissue during physical trauma may sensitize neurons that bring information about pain to receptive centers in the brain. As a result, the sensitized neurons will activate in response to less stimulation, or in some cases, in absence of simulation, resulting in pain from little to no touch. Indeed, women with this kind of genital pain also frequently report genital pain during nonsexual situations (Binik, 2010a).

Other etiological factors associated with deep genital pain include uterine fibroids, urinary diseases such as uterine retroversion and uterine myomas, ovarian diseases such as ovarian remnant syndrome, adenomyosis, endometriosis, pelvic congestion syndrome, levator and muscle myalgia, and IBS.

Little research has focused on the biological factors associated with vaginal spasms during sexual penetration, though some have suggested that these involuntary spasms of the pelvic floor muscles may be due to genital malformations and/or poor general pelvic muscle control (ter Kuile & Reissing, 2014). As with genital pain, high rates of provoked PVD have been reported among women diagnosed with vaginal spasms (Binik, 2010b). Experts in sexual pain have suggested that the vaginal spasms may be a physiological response to intense pain during penetration; that is, the vaginal spasm could be the body's automatic physical reaction to protect itself from anticipated pain.

Psychological Factors. Marked fear of pain and consequent anxiety with sexual activity have been proposed as both symptoms of and etiological mechanisms for sexual pain. Women with genital pain exhibit a selective attentional bias toward pain stimuli compared to controls, and genital pain is associated with state and trait anxiety as well as fear of pain (Payne et al., 2005). Women with genital pain also tend to fear sexual interactions, and they show more phobic anxiety of sexual activity than sexually healthy women. It may be that after sexual pain has been experienced initially, anxiety about sexual activity maintains the pain by increasing hypervigilance toward pain cues. Evidence supports this pathway: one study found that women with PVD displayed an attentional bias toward painrelated stimuli on an emotional stressor task compared to matched control women without PVD (Payne et al., 2005). Unsurprisingly, women with sexual pain are also more likely to have negative attitudes toward sexuality compared with women without pain.

GPPPD is far more common in women with histories of abuse. Indeed, one study found that women who experience sexual pain are 4.1 times more likely to have abuse histories (Harlow & Stewart, 2005), and vaginal spasms have been associated with a history of abuse (Reissing et al., 2004). Moreover, fear of physical abuse has been linked to genital pain (Landry & Bergeron, 2011).

Associations between depression and genital pain are frequently noted in the literature, although longitudinal studies have not observed a direct relationship (Schultz et al., 2005). It is feasible that women with depression are more likely to attend to pain in general and sexual pain in particular, but there is no evidence that depression causes pain or vice versa. It is more likely that this association is mediated by relationship satisfaction. Negative cognitions such as "My partner will leave me," "I am a failure as a woman," and "I must be tearing inside" are commonly reported by women with sexual pain. Women with genital pain report more pain when their relational distress increases, an indication that
sexual pain may be partially associated with negative feelings between or toward partners. Consequently, recent research has argued for a dyadic conceptualization of GPPPD, such that GPPPD should be viewed as a disorder that is frequently maintained in the context of relationships and therefore must be treated with relational factors in mind (Rosen & Bergeron, 2019).

With respect to vaginal spasms, women who experience vaginal spasms report greater anxiety symptom severity. It is unclear, however, whether anxiety is a cause or consequence of such spasms (Schultz et al., 2005). Lower rates of positive attitudes toward one's sexuality have been observed in women who experience spasms during sexual penetration (Reissing et al., 2004). It is possible that a lack of positive beliefs about one's sexuality may create a negative feedback loop, discouraging a woman from seeking out and experiencing positive sexual interactions and contributing to avoidance of sexual activity.

#### **Conclusion and Future Directions**

In summary, it is apparent that both biological and psychosocial factors play a prominent role in the etiology of sexual dysfunctions in men and women, and, as such, both sets of factors must be carefully considered in both assessment and treatment. The multidimensionality of sexuality calls for assessment and treatment strategies that account for all of the potential dimensions at play when an individual experiences a sexual problem.

All forms of sexual dysfunction occur in the context of a person's life. Consideration of that context, especially relational factors, can be used to guide treatment recommendations. Importantly, only a few of the sexual dysfunctions mentioned here have been formally conceptualized in a dyadic way, owing in part to a historical paucity of couplesbased research. Despite this empirical gap, it is likely that each sexual problem outlined in the DSM is highly influenced by one's interpersonal context. Relational factors that should be attended to in the context of treatment include overall relational satisfaction, comfort with one's partner, perceptions of a partner's expectations, patterns of sexual and nonsexual communication, and partner attentiveness in the context of a sexual encounter.

Similarly, effective treatment for sexual dysfunction may depend, in many cases, on effective psychoeducation. Misinformation related to sexual dysfunction abounds, particularly in an age with widespread exposure to Internet pornography. Individuals may, for example, self-diagnose a sexual dysfunction based on faulty information (i.e., believing one has ED when only engaging in sex in the context of alcohol use). While it remains extremely important to develop effective treatment strategies for sexual dysfunctions, ameliorating sexual problems may begin with more widespread access to scientifically sound information.

Taken together, it is evident that the future of the field will feature a large degree of multidisciplinary collaboration—among psychologists, psychiatrists, gynecologists, urologists, and primary care physicians—to continue to develop and refine research on the nature and treatment of sexual problems.

# CHAPTER 8

## Eating Disorders

Howard Steiger, Linda Booij, Annie St-Hilaire, and Lea Thaler

Eating disorders (EDs) are polysymptomatic syndromes defined by maladaptive attitudes and behaviors around eating, weight, and body image but typically accompanied by disturbances of self-image, mood, impulse regulation, and interpersonal functioning. The DSM-5 classifies EDs among "Feeding and Eating Disorders," and recognizes six subtypes: anorexia nervosa (AN), bulimia nervosa (BN), binge-eating disorder (BED), avoidant/restrictive food intake disorder (ARFID), rumination disorder (RD), and pica. Two residual diagnoses-other specified feeding or eating disorder (OSFED) and unspecified feeding or eating disorder (USFED)-capture ED variants that have clinical significance without fulfilling criteria for full-threshold syndromes. As pica occurs in unusual contexts associated with severe intellectual impairments or particular medical conditions, it will not ordinarily be treated alongside other EDs, and we therefore opt not to address this entity in this chapter. We will, however, review pathognomonic features of the remaining DSM-5 ED syndromes, as well as findings on concurrent traits and comorbid psychopathology. We also discuss the factors-biological, psychological, and socialthat are understood to explain varied convergences of eating and comorbid symptoms that shape clinical EDs.

## **Defining Characteristics**

#### Anorexia Nervosa

AN is defined by a relentless pursuit of thinness. Formerly attributed to a morbid fear of weight gain or obesity, *DSM-5* restates the concern of affected individuals without it being mandatory that there be intense fear of weight gain. Such fears are, however, a commonly present feature. What is required is that individuals restrict energy intake relative to requirements (leading to a markedly low body weight), experience a fear of weight gain or loss of control over weight gain, or display persistent behavior to avoid weight gain (even though already at a low weight), and experience either a disturbance in the way in which their body weight or shape is experienced, undue influence of body weight or shape on self-evaluation, or persistent lack of recognition of the seriousness of a currently low body weight. The modifications described respond to the reality that people with AN, especially when very young or from Asian or African cultures, do not always espouse fears of weight gain as a rationale for their food-refusal and self-induced emaciation. DSM-5 also drops the criterion sign of amenorrhea, it representing an imprecise reflection of nutritional status and being inappropriate in the case of males.

To provide an illustrative example, we describe "Joannie." Joannie, a 17-year-old high school student, eats a restricted range of "safe" foods—mainly vegetables and a few nuts or an occasional spoonful of yoghurt. She avoids eating with her family or friends, so that she will be able to fully control what, how much, and when she eats. She exercises at least 2 hours a day (on the treadmill) and never eats before 6 PM, to be sure not to have time to overeat during any given day. Joannie is 5'4" tall and weighs 88 pounds, giving her a body mass index (BMI: Kg/m<sup>2</sup> or lbs/ in<sup>2</sup> × 703) of 15.1—meaning that she is so thin as to

RD	Rumination disorder		

border on emaciation. Her weight has dropped over the past 6 months from an average of 128 pounds. Joannie compulsively insists that her fingertips have to touch when she circles her thighs with her hands, and when she feels that she has eaten something too rich in calories, even when it may have been what most people would call a snack, Joannie purges by vomiting or taking laxatives.

Although Joannie shows no binge eating (thus far), more than half of people with AN eventually develop binge-eating episodes—that is, periodic dyscontrol over eating, or incapacity to satiate. In consideration of this reality, *DSM-5* draws a distinction between AN, restricting subtype (AN-R), in which there is restriction of food intake but no binge eating or purging, and AN, binge-eating/ purging (AN-B/P) subtype, in which (as the label implies) regular binge or purge episodes occur. Joannie would be diagnosable as having AN-B/P subtype, because she regularly purges.

## Bulimia Nervosa

A defining feature of BN is binge eating (i.e., appetitive dyscontrol) followed by an effort to compensate for calories consumed through self-induced vomiting, laxative misuse, intensive exercise, fasting, or other means. BN occurs in people with normal or above-normal body weight who therefore (by definition) do not have AN. Binge-purge episodes occur at least once weekly in the DSM-5 definition. However, such episodes typically occur far more frequently and can, when the disorder is severe, occur many times daily. AN and BN share in common a core preoccupation with body shape and weight and the compulsion to restrict food intake. Excessive dietary restraint in people with BN eventually gives way to appetitive dysregulation and binge eating. Binges are characterized by consumption-often with a terrifying sense of dyscontrol-of excessive, sometimes massive, quantities of calories. Binge eating can provoke profound feelings of shame, anxiety, or depression and dramatic shifts in the sufferer's sense of self-worth and well-being. The preceding lends to BN a characteristic unpredictability or lability, as people with this syndrome tend to shift rapidly (depending on felt control over eating) from a sense of well-being, expansiveness, or excitability to profound despair, irritability, and depression.

Kiera serves as a "prototype." Kiera, aged 29, a recent graduate from law school, is serving as an apprentice in a law firm. People know her to be very hard-working but a bit of a "thrill seeker." She has had a number of short-lived relationships, drinks

alcohol fairly regularly, and dabbles with cocaine use when it is offered to her. Although she has a slim-normal frame, she is conscious of her weight and tries to keep her food intake down, often skipping breakfast and eating green salads for lunch. After supper, especially (but not always) if she has been drinking, Kiera finds she cannot stop eating, and she goes from two portions of her supper to eating cookies, cakes, food leftovers, and just about anything else she has to eat in her pantry and fridge. She then forces herself to vomit several times, sometimes using a toothbrush to provoke gagging. After a binge-purge episode, she feels very badly about herself. At such times, she can bruise her thighs with her fists; once she burned her upper arm with a lit cigarette.

## Binge-Eating Disorder

Like BN, BED is characterized by recurrent eating binges. However, in BED compensatory behaviors (such as vomiting, exercise, or fasting) are absent, so that BED is commonly associated with or leads to obesity. Defining characteristics include eating more rapidly than normal, eating until uncomfortably full, eating when not hungry, eating alone because of embarrassment around the quantity one eats, or feeling intense distress (guilt, disgust, or depression) after eating. Despite initial concerns that BED might not be a "mental" disorder, findings support the conclusion that obese individuals with and without BED differ in the sense that the former group displays higher overall caloric intake, additional pathological eating behaviors (such as chaotic or emotional eating), additional indices of comorbid psychopathology, and poorer response to treatment (Wonderlich et al., 2009). Notably, BED also emerges as a distinct disorder in familial-aggregation and genetic studies (Javaras et al., 2008).

## Avoidant/Restrictive Food Intake Disorder

ARFID, a new diagnosis in *DSM-5*, evolved from what was originally conceived to be a feeding problem of infancy or early childhood—effectively, the "picky eater" syndrome. The diagnostic concept has been retooled to make it applicable across the life span. ARFID comprises a range of conditions in which people become blocked in the ability to nourish themselves adequately, not because of concerns about weight gain, but because of such things as intense aversion to certain food tastes or textures, preoccupation with the nutritional value of certain foods, or inordinate fears that eating will cause indigestion or vomiting. ARFID syndromes differ from variants of AN in which people show persistent behavior to avoid weight gain anchored to body image concerns. Someone who eats a rigidly restricted range of foods because of a compulsive effort to consume only healthy, natural foods (colloquially described as "orthorexia"), if they fail to nourish themselves adequately, would often meet ARFID criteria. Some authors suggest that there may be distinct ARFID presentations (or even subtypes): one characterized by low interest in food or eating, another by avoidance based on the sensory characteristics of food (e.g., queasiness about certain food textures), and yet another based on concern about possible aversive consequences of eating (e.g., becoming unhealthy due to consumption of artificial food additives). Available research has suggested that, compared to patients with AN, ARFID patients tend to be younger, on average, to have higher rates of psychiatric comorbidity, and to be more often male (Bryant-Waugh, 2019).

John will serve as an ARFID prototype. Always prone to anxiety, John (who is 28 years old) ate normally until a year ago when his doctor suggested that he eat carefully, as his cholesterol levels were starting to approach the borderline range. Gradually, John eliminated more and more food items that he perceived to risk increasing cholesterol, dropping anything high in fat or oil, then eggs, then cheese, then meat. He now feels able to eat only vegetables, fruits, and grains, and even these in small quantities. His weight has dropped from a previously normal range to a BMI of under 16. John hates his thinness and wants to gain weight, but still avoids eating most foods for fear of developing high cholesterol.

#### Rumination Disorder

RD is characterized by the repeated regurgitation of food followed by rechewing, reswallowing, or spitting out of the regurgitated material. By definition, the behavior is not due to an associated gastrointestinal or medical condition, nor does it occur exclusively during an episode of AN, BN, BED, or ARFID. As etiology and comorbid characteristics are not well established, we will not treat RD in sections of this chapter addressing these aspects. We do note, however, that available studies suggest some connection with psychological disturbances. One study in 7- to 14-year-olds indicated that RD behaviors were positively associated with emotional and conduct problems and negatively associated with prosocial behavior (Hartmann et al., 2018). Another study identified a comorbid psychiatric disorder in 17% of children and adolescents diagnosed with rumination disorder (Chial et al., 2003).

## Other Specified Feeding or Eating Disorder; Unspecified Feeding or Eating Disorder

OSFED and USFED encompass eating syndromes that would in earlier DSM versions have been called eating disorder not otherwise specified. OSFED and USFED refer to eating problems that cause significant distress or impairment in functioning but that do not meet full criteria for a formal ED diagnosis. DSM-5 provides illustrative examples of OSFED to guide diagnostic decision-making, These include "atypical AN," in which all the criteria for AN are met except that the individual remains in the normal or abovenormal weight range after significant weight loss; "subthreshold bulimia nervosa" or "subthreshold binge eating disorder," in which frequency of problem behaviors occurs at lower than threshold frequency and/or for less than threshold duration; "purging disorder," characterized by recurrent purging in the absence of binge eating; and "night eating syndrome," characterized by recurrent eating episodes after awakening from sleep or excessive food consumption after an evening meal. For other instances, the USFED diagnosis is used. According to available evidence, "subthreshold" ED syndromes are often associated with comparable levels of distress, psychiatric comorbidity, and health-service usage to those in fully syndromic ED variants (Fairburn et al., 2007).

Are DSM diagnostic distinctions valid? Available efforts to develop valid ED classifications using taxometric methods, latent class analyses, or other statistical classification techniques have provided fairly good support for AN, BN, and BED as phenomenologically distinct entities (Wonderlich et al., 2007). Not only is each broad category at least partly discriminable using empirical methods, but there is also evidence to suggest that the categories may "breed true" within families. In addition, there is quite convincing support for the boundary between "restricter" and "binger/purger" variants of AN, and between BED and BN. However, there is mixed support for the distinction between anorexicand normal-weight variants of binge-purge syndromes (i.e., AN-binge/purge type vs. BN).

#### **Historical Perspectives**

The English physician Richard Morton is often credited with having introduced AN to the medical literature. In 1689, he documented two adolescent cases, one a boy, the other a girl, both suffering "nervous consumption," "want of appetite," and weight loss, in the absence of any apparent medical cause (Gordon, 1990, p. 12). Well-elaborated reports on AN emerged again in an 1860 account by the French physician Marcé and in independent reports (published in 1870) by Sir William Gull and Charles Lasègue. Gull is credited with coining the term "anorexia nervosa," but all three described a syndrome characterized by food refusal, onset in adolescence, amenorrhea, and lack of concern for consequences of not eating (Gordon, 1990). Intriguingly, reports on AN became relatively common through the nineteenth and twentieth centuries, but a pivotal diagnostic element-fear of weight gain-was first acknowledged only in accounts emerging well into the twentieth century. Late "entry" of this characteristic has been taken to suggest that fears of weight gain may not be essential to AN but, rather, may constitute only a contemporary rationale for instances of self-starvation, one shaped by contemporary cultural values.

The first formal reports on BN emerged much more recently, in roughly concurrent 1979 publications by Igoin in France, Boyadjieva and Achkova in Bulgaria, and Robert Palmer and Gerald Russell in England (Vandereycken, 1994). Having been formally recognized in the late 1970s, BN is widely thought to be a recently developing ED variant. Indeed, after an exhaustive review of available historical and crosscultural data, Keel and Klump (2003) concluded that AN and BN have distinct temporal and geographical distributions, with AN showing a relatively modest increase in incidence over the years and occurring frequently in geographical areas that are quite untouched by the "culture of slimness." In contrast, BN appears to have increased dramatically in prevalence during the latter part of the twentieth century and mainly in industrialized cultures. Updating this impression, recent reviews suggest that the incidence of AN has been surprisingly stable over past decades, whereas BN incidence seems to have increased markedly over the second half of the twentieth century and then to have declined slightly since that time (Currin et al., 2005; Keel et al., 2006; Smink et al., 2012).

The phenomenon of binge eating among individuals with obesity was described by Stunkard (1959) more than 60 years ago. However, BED has a rather short history in diagnostic nosology, having been introduced in 1994 in *DSM-IV* as a provisional ED diagnosis and as an official ED for the first time in *DSM-5*. Although newer still, the ARFID diagnosis has attracted considerable interest since its introduction as a formal *DSM-5* diagnosis in 2013.

## Epidemiology

The National Comorbidity Study Replication, which attempted to estimate nationwide ED prevalences in US adults in the early 2000s, reported lifetime rates of DSM-IVAN, BN, and BED in women to be .9%, 1.5%, and 3.5%, respectively (Hudson et al., 2007). Corresponding rates in men were .3%, .5%, and 2.0%. Swanson and colleagues (2011) extended the study to adolescents and reported lower prevalences (.3% and .9%, respectively) of AN and BN among 13- to 18-year-old boys and girls. A more recent and even larger epidemiological study applied DSM-5 criteria in a sample of 36,306 adults selected to represent the US population (Udo & Grilo, 2018). It documented lifetime prevalence for AN of 1.42%, for BN of .46%, and for BED of 1.25%, respectively, in women, and .12%, .08%, and .42% in men. Various current indications suggest that ED incidences (while stable in adults) may be rising in adolescents (Herpertz-Dahlmann, 2015).

Comprehensive epidemiologic data in representative populations is unavailable for ARFID and RD diagnoses. However, one population-based survey from Australia found a 3-month prevalence of ARFID of 0.3% among adults and older adolescents (Hay et al., 2017). ARFID prevalence in one pediatric treatment-seeking sample was found to be 1.5% (Eddy et al., 2015). As for RD, one study implicating 804 children aged 7–14 years indicated recurring RD behaviors in 1.49% (Hartmann et al., 2018).

The median age of ED onset is estimated to fall between 18 and 21 years; AN typically occurring by the mid-teens, BN around age 19, and BED around age 24 (Hudson et al., 2007; Udo & Grilo, 2018). Although AN and BN occur much more frequently in women than in men, BED displays a more even gender distribution, with a male-to-female ratio of roughly 2:3. Although it is widely believed that EDs are disorders of affluent, urban society, data show linkages with socioeconomic status and urbanicity to be much weaker than thought (Swanson et al., 2011).

## **Comorbid Psychopathology**

It seems that if one assertion can be made about EDs, it is that they are often not just about eating.

Rather, EDs frequently co-occur with mood, anxiety, substance abuse, personality, and other psychiatric disorders.

# Anxiety Disorders and Obsessive-Compulsive Disorder

Anxiety disorders are regarded as being among the most common of comorbid conditions found in people with an ED, and it is certainly true that EDs "ride" on anxious temperaments. A recent study estimates that 53.3% of people with an ED display an anxiety disorder, with generalized anxiety disorder observed in 30.5%, specific phobia in 16.6%, and social phobia in 14.7% (Ulfvebrand et al., 2015). Social anxiety appears to be distributed equally across different ED subtypes, with higher levels associated with more severe ED symptoms (Kerr-Gaffney et al., 2018). Findings indicate that anxiety symptoms tend to precede ED symptom onset. One study on the sequencing of symptom onset suggested that somatic anxiety symptoms at age 10 predicted binge-eating and fasting at age 14 and BN at age 16, whereas worry at age 10 predicted fear of weight gain, body dissatisfaction, excessive exercise, and dietary restraint at age 14, and a diagnosis of AN at age 16 (Schaumberg et al., 2019). In contrast, panic disorder has been reported to often emerge concurrently with, or following ED development (Godart et al., 2003; Pallister & Waller, 2008).

Although no longer classified as an anxiety disorder, given the prominence of anxiety in obsessivecompulsive disorder (OCD), we address OCD in this section. OCD reportedly occurs in 35% to 44% of people with AN (Kaye et al., 2004; Levinson et al., 2019). Some data have suggested that severity of compulsions predicts severity of core AN symptoms. Similarly, when individuals with AN report greater concern over mistakes, they display more severe AN and more OCD symptoms (Levinson et al., 2019).

To account for comorbidity between eating and anxiety disorders, Pallister and Waller (2008) proposed that cognitions and environmental experiences increase the likelihood of cognitive avoidance strategies that can take the form of disordered eating behaviors, anxiety-related behaviors, or both. Not unexpectedly, AN and OCD also display substantial shared genetic risk—but interestingly, genetic liabilities to various psychiatric phenotypes are common to AN and OCD, whereas liabilities to metabolic and anthropometric traits seem to be specific to AN (Yilmaz et al., 2020).

## Mood Disorders

Mood disorders also co-occur frequently in all ED subtypes. Ulfvebrand and colleagues (2015) found 43.1% of women and 40% of males with heterogeneous EDs display any mood disorder, with major depression occurring in 32.8% and 28.5%, respectively. Trends reported in studies examining the association between eating and mood disorders suggest that mood disorders have a greater affinity with bulimic ED variants (BN, BED, and AN-binge/ purge) than with AN-restrictive ones. Hudson et al (2007) reported that mood disorders occur in as many as 70% of adults with BN (Hudson et al., 2007), and Swanson et al. (2011) detected mood disorders in 49.9% of adolescents with BN (a 5.7-fold greater risk) and 45.3% of those with BED (a 4.6-fold risk), but in only 10.9% (a 0.7-fold risk) of adolescents with AN.

Findings suggest that mood disorder rates may be substantially lower in community-based samples than they are in treatment-seeking ones (Blinder et al., 2006). In other words, factors related to age, social standing, and recruitment may all influence the extent to which comorbid psychopathology becomes apparent in people with EDs. A community study by Zaider, Johnson, and Cockell (2000) points to a strong affinity between EDs and dysthymia. Other evidence has shown a strong association between BN and seasonal affective disorder (SAD), implying cyclical season-dependent recurrences in depressed mood that parallel seasonal variations in binge-purge behaviors (Ghadirian et al., 1999). Bipolar disorder, being rarer than depression, occurs at relatively low frequencies in people with EDs, with a recent study reporting the illness in .3% of women with AN, .7% of those with BN, and .4% of those with BED (Ulfvebrand et al., 2015)

Various areas of etiological overlap can be postulated to explain convergence between mood and eating disorders. An early twin study by Wade et al. (2000) attributed shared risk for AN and mood disorders to genetic factors. Common personality variables also seem to play a role, given that harm avoidance, rejection sensitivity, and lower selfdirectedness are associated with mood disorders and with EDs (Cardi et al., 2013). As for bipolar disorder, research suggests involvement of shared neurodevelopmental mechanisms in the pathophysiology of both disorders (Liu et al., 2016).

## Posttraumatic Stress Disorder

Findings have suggested a striking concurrence between certain ED variants and posttraumatic stress disorder (PTSD). The National Comorbidity Survey reported lifetime PTSD to occur in 45% of individuals with BN, compared to only 12% of those with AN (Hudson et al., 2007), and another study found PTSD to be present in 24% of women with BED (Grilo et al., 2012). In keeping with the preceding, a recent meta-analysis associated childhood sexual and emotional abuse with BN and BED, and childhood physical abuse with AN, BN, and BED (Caslini et al., 2016). Yet another study reports a dose-response relationship between childhood abuse and ED severity, linking more severe abuse with more pronounced eating symptoms, more binge-eating–purging behaviors, and earlier ED onset (Molendijk et al., 2017).

Various pathways, direct and indirect, might account for an etiological link between the EDs and traumatic events. Traumata directly affecting the body may have direct consequences for body image and, in turn, for eating and weight-control behaviors.

Alternatively, abusive experiences might affect self-, mood-, and impulse-regulation, which might indirectly heighten risk of maladaptive eating behavior. In keeping with the latter view, individuals with BN and comorbid PTSD show stronger reactivity of affect before and after purging compared to people with BN alone (Karr et al., 2013). In addition, our group has documented tendencies for people with BN who report past abuse to show greater abnormalities on indices of serotonin, dopamine, and cortisol functions (Groleau et al., 2014; Steiger et al., 2001, 2011). Such results imply that neurobiological sequelae of childhood abuse may adversely impact stress tolerance, impulse controls, and appetitive regulation.

#### Substance Use Disorders

Findings show that 10-55% of women with BN abuse substances, whereas 25-40% of females with alcohol dependence show some form of ED, often in the bulimia spectrum (Bulik et al., 2004; Holderness et al., 1994). Tobacco, caffeine, and alcohol are all commonly abused by individuals with EDs (Bahji et al., 2019). As with other areas of comorbidity, studies associate substance use more strongly with bulimic ED variants than they do with restrictive forms (Bahji et al., 2019; Bulik et al., 2004). Among individuals with EDs, those with substance use problems have been found to have more eating, weight, and shape concerns (Becker & Grilo, 2015); significantly more comorbid psychiatric diagnoses; more impulsivity and perfectionism (Bulik et al., 2004); and greater likelihood of genetic and developmental risks (Richardson et al., 2008).

## Attention-Deficit/Hyperactivity Disorder

Studies have indicated a distinct affinity between EDs, particularly those in the bulimia spectrum, and attention-deficit/hyperactivity disorder (ADHD). An 11-year case-control follow-up implicating 6- to 18-year-old girls with ADHD indicated girls with attentional problems to be 5.6 times more likely to meet criteria for BN (Biederman et al., 2010). Likewise, an 8-year follow-up of 337 boys and 95 girls with ADHD and 211 control boys and 53 control girls indicated greater likelihood of bulimia in the "case" group, especially so for girls (Mikami et al., 2008). Interestingly, impulsivity (and not hyperactivity or inattention) best predicted BN symptoms, particularly for girls. The relationship between EDs and attentional problems has been thought to be mediated by various factors common to both syndromes, including dopaminergic susceptibilities, deficits in executive function, impulsivity, internalizing problems, and secondary social difficulties (Levin & Rawana, 2016).

## Autism Spectrum Disorder

There has been considerable recent interest in the association between EDs and autism spectrum disorders (ASDs). Results of studies examining this association are highly variable, with reported rates of ASD in individuals with EDs ranging from 4% to 52.5% (Westwood & Tchanturia, 2017), with modal values seeming to occupy the 20% range (Huke et al., 2013). From the "other side of the coin," adolescent girls with ASD are reported to more often display ED symptoms than are teens without ASD-with 27% of girls with ASD reported to show clinically significant ED symptoms. Likewise males with ASD are reported to be at increased risk for low body weight and abnormal eating practices (Kalyva, 2009). Comorbidity between AN and ASD has been thought to result from shared cognitive, social, and emotion-regulation difficulties. For example, neurocognitive studies have suggested that people with AN and ASD show similar problems with emotion processing, set-shifting, and overattention to detail (Oldershaw et al., 2011). Comorbid ASD appears, according to available studies, to have a negative prognostic implication (Nielsen et al., 2015; Stewart et al., 2017).

## Personality Disorders

Another striking area of comorbidity seen in people with EDs is that with personality disorders (PDs; Cassin & von Ranson, 2005; Lilenfeld et al., 2006). The most recent and largest meta-analysis addressing comorbid PDs in people with EDs concluded that the mean proportion of people with an ED displaying any PD was 52%, compared to 9% in non-eating-disordered individuals (Martinussen et al., 2017). The mean proportion of any PD was 49% for AN and 54% for BN, with both disorders showing high proportions of borderline and avoidant PDs (between 19% and 25%), but with AN showing a significantly higher rate of obsessivecompulsive PD (in 23% of cases) versus 12% in BN (Martinussen et al., 2017). We note that the Martinussen study did not consider differences between restricter versus binger-purger variants of AN. When this distinction is examined elsewhere, rates of borderline PD are generally found to be rather low in restrictive AN but high in AN-binge/ purge subtype (see Cassin & von Ranson, 2005; Lilenfeld et al., 2006; Steiger & Bruce, 2004). Viewing available results together, the literature supports the following generalizations: (1) PDs are frequently present in individuals with EDs; (2) restrictive symptomatology seems to be associated with a high concentration of obsessive-compulsive PDs; (3) ED variants characterized by binge-purge symptoms coincide with more heterogeneous PD subtypes than do restrictive forms, including high rates of dramatic-erratic PDs (characterized by prominent attention- and sensation-seeking, extroversion, mood lability, and impulsivity); and (4) PD comorbidity in BED is comparable to that seen in BN, although the loading of dramatic-erratic PDs, like borderline PD, may be less pronounced (Friborg et al., 2014). Overall, it appears that the dietary overcontrol that characterizes restrictive AN is paralleled by generalized overcontrol, as a personality or adaptive style. Binge/purge symptomatology, in contrast, affects people who evince quite heterogeneous personality traits, although dysregulatory traits (e.g., affective instability, impulsivity) are overrepresented.

Malnutrition can have adverse effects on personality functioning (Keys et al., 1950), and this raises the concern that apparent personality problems seen in individuals with EDs may reflect state disturbances associated with an active ED and not trait tendencies. In other words, caution is warranted concerning the use of PD diagnoses in individuals with an active ED. Nonetheless, various findings suggest that personality problems seen in individuals with an ED often exist independently of the ED or may persist after recovery from the ED. For example, one investigation reported that 26% of women who recovered from AN or BN showed some form of ongoing PD (Matsunaga et al., 2000) and another found that women recovered from EDs reported higher levels of harm avoidance and lower self-directedness and cooperativeness scores than did normal control women (Klump et al., 2004).

## Etiology

EDs are thought to have a multidimensional etiology, including genetic liabilities (affecting mood, behavioral controls, sensitivity to reward, energy metabolism, and appetite), developmental processes (conducive to self-image or adjustment problems, or excessive concerns with achievement and social approval), environmental stresses (such as perinatal insults or childhood traumata), state-related effects (owing to the nutritional and mental status), and, ultimately, social inducements toward intensive dieting (e.g., Steiger & Booij, 2020; Striegel-Moore & Bulik, 2007; Treasure et al., 2010). The following sections review the various social, psychological, and biological factors that have been thought to contribute to risk for ED development.

## Sociocultural Context

Throughout much of the past century, North American and European cultural values have associated slimness with ideals of success, beauty, power, and self-control, and such associations are likely to underlie the long-standing tendency for people living in these continents—especially young females to be dissatisfied with their bodies and to too often display EDs. Many findings indicate that exposure to media images of thinness and internalization of the "thin ideal" contribute quite directly to body dissatisfaction and to development of body image preoccupation and clinical EDs—especially in women and girls (e.g., Culbert et al., 2015; Grabe et al., 2008).

Once regarded as a culturally and geographically bound phenomenon, since the late 1970s, reports have suggested substantial ED prevalences in diverse regions and cultures (including Africa, Asia, the Middle East, and South America)—an effect that is presumed (at least in part) to reflect the transmission across cultures of the "thin ideal" (Makino et al., 2004; Pike et al., 2014). In support, a multisite, cross-cultural survey associated extent of exposure to Western media with increased body dissatisfaction in populations living in various geographical areas (Swami et al., 2010).

Various theories have been proposed to account for the role of culture in ED development. One intuitively obvious idea is that pressure to be thin and internalization of the thin ideal foster body dissatisfaction, which in turn contributes to dieting and/or negative affect, and, ultimately, to clinical EDs (Stice & Agras, 1998). An alternative view, inspired by feminist theory, argues that social environments in which women are objectified and evaluated based on physical attributes contribute to heightened appearance consciousness and, in turn, heightened risk of ED development (Fredrickson & Roberts, 1997; Stice & Agras, 1998). Both views have received empirical support. A recent prospective study showed that in a significant proportion of people, signs of felt pressure to be thin preceded onset of body dissatisfaction, dieting, or negative affect (Stice & Van Ryzin, 2019). Likewise, a meta-analysis of 53 cross-sectional studies concluded that greater selfobjectification was related to disordered-eating attitudes and behaviors (Schaefer & Thompson, 2018).

#### **Psychological Factors**

The first psychometric studies on the EDs, published in the mid-1970s, led to an association of AN with such traits as obsessionality, social anxiety, introversion, neuroticism, and depression. These same reports introduced a distinction between EDs characterized solely by restriction of food intake (e.g., AN-R) and variants implicating binge eating and purging (AN-B/P subtype). Individuals with the AN-R subtype were described as conforming, obsessional, and emotionally and socially reserved, whereas those with AN-B/P were thought to be prone to impulsivity, antisocial attitudes, and externalization (Sohlberg & Strober, 1994). Later studies on BN broadened the boundaries of an association between binge eating and impulsive or erratic characteristics (Vitousek & Manke, 1994), and the stage was set for belief in a systematic distinction, on associated personality characteristics, between ED variants characterized by restriction and variants characterized by binge eating and/or purging. Although the fit proves to be imperfect, contemporary studies continue to find "restricter" and "binger/purger" groups to differ along the lines stated above (see Wagner & Vitousek, 2019). For instance, a meta-analytic study examining temperament in people with eating disorders concluded that individuals with BN, and to a lesser extent those with AN-B/P, are more novelty-seeking (i.e., prone to excitement or exhilaration in response to potential reward) than are individuals with AN-R, whereas individuals with AN-R are more persistent (i.e., prone to continuing an activity despite frustration or fatigue) than are individuals with BN (Ative et al., 2015). Findings such as these have supported the idea that there exists a systematic co-aggregation (at a group level) between AN-R and compulsive traits and between ED variants characterized by binge eating and/or purging (AN-BP and BN) and emotionality, risk taking, or oppositionality.

While it can be useful to examine the ways in which different temperaments and personality traits assort with different ED diagnoses, the practice can also obscure meaningful within-subtype heterogeneities. Studies have shown that AN, BN, and EDNOS variants all evince substantial withindiagnosis heterogeneity regarding comorbid personality traits (see Claes et al., 2012; Wildes et al., 2011). Indeed, despite differences in samples and measures across studies, findings point remarkably consistently to three broad, psychopathology-defined sub-phenotypes across EDs: (1) psychologically intact, (2) overregulated (compulsive and inhibited), and (3) dysregulated (impulsive and reactive) (Bohane et al., 2017; Haynos et al., 2017; Steiger et al., 2009). As a generality, the AN-R subtype coincides with the overregulated personality profile, whereas binge-eating/purging ED variants seem to occur about equally with any of the three profiles. Highlighting the clinical importance of the traitbased distinctions noted, investigators have associated the "dysregulated" characteristic with increased comorbidity (e.g., depression, self-mutilation, drug abuse), more developmental disturbances (e.g., child abuse, attachment problems), and poorer treatment outcome.

## Specific Traits

#### PERFECTIONISM

Individuals with AN, BN, and BED have all been found to have higher self-rated perfectionism scores than do healthy, normal eaters—and this is especially true for aspects of perfectionism associated with the setting of high personal standards and goals or being overly self-critical or concerned with others' judgments (Farstad et al., 2016; Steele et al., 2011). Arguing for its etiological importance, perfectionistic tendencies appear to predate ED onset, persist after recovery, be found in the non–eating-disordered relatives of those who develop an ED, and correspond to severity of such symptoms as dietary restraint and overvaluation of shape and weight (Bardone-Cone et al., 2007; Limburg et al., 2017).

#### IMPULSIVITY

People with binge/purge ED variants display more self-reported trait impulsivity and engage in more impulsive acts than do normal eaters or people with restrictive ED variants (Favaro et al., 2005; Rosval et al., 2006). Several studies emphasize sensation-seeking and negative urgency (the tendency to act hastily when distressed) as prominent traits in individuals with bulimic syndromes (Lavender et al., 2015). Others give precedence to motoric components of impulsivity (Rosval et al., 2006; Wonderlich et al., 2004). The presence of impulsive traits in people with EDs has been linked to more severe comorbidity (e.g., substance use disorders and borderline PD) and to poorer treatment outcomes (Lozano-Madrid et al., 2020; Reas et al., 2016). Some evidence favors the notion that impulsivity may be a temporal antecedent to BN onset. However, there is also reason to believe that the biological and psychological consequences of an active ED may "amplify" inherent impulsive tendencies (Lavender et al., 2015; Pearson et al., 2014).

#### BODY-IMAGE DISTURBANCE

Disturbance in the way one experiences one's body weight or shape is a defining characteristic of AN and BN and generally thought to have a fundamental etiological and maintaining role in the EDs. In support, many studies have reported that people with AN and BN tend to overestimate their body size, express greater body dissatisfaction, and engage in more body checking and body avoidance behaviors than do people without an ED (see (Lantz et al., 2018; Nikodijevic et al., 2018). Likewise, consistent with a causal role, an 8-year longitudinal study of risk factors for EDs in adolescents observed that body dissatisfaction preceded the onset of various ED forms (Stice & Van Ryzin, 2019). Although such findings are suggestive and appeal to intuitive causal assumptions, a recent systematic review of the literature on body image disturbance in AN notes that confirmation of a role of body disturbance in ED causality, maintenance, and relapse has been surprisingly elusive (Glashouwer et al., 2019).

#### DIETARY RESTRAINT

Cognitive components of dietary restraint—or restrictive eating attitudes (e.g., the belief that it is important or desirable to eat low-calorie foods or to compensate when one eats)—are thought to make a fundamental contribution to the development and maintenance of EDs (e.g., Fairburn et al., 2003). Overvaluing slim appearance and dietary control have a clear role in supporting the excessive dieting often seen in individuals with an ED—even though, paradoxically, chronic attempts to restrain eating often increase individuals' susceptibility to overeating (see the work of Polivy & Herman, 1993). Many findings also suggest that it is the combination of dietary restraint with other factors, such as negative mood or perfectionism, that may explain how dieting progresses to pathological eating in certain individuals (Goldschmidt et al., 2012; Stice & Shaw, 2018).

#### EMOTION DYSREGULATION

ED symptoms are often conceptualized as representing ill-chosen and maladaptive ways of regulating emotions, and there is ample evidence of a link between EDs and emotion regulation difficulties (Prefit et al., 2019). For instance, individuals with EDs display more global emotion dysregulation than do individuals with no ED (Lavender et al., 2015). Likewise, on specific indices, people with an ED show decreased emotional distress tolerance, decreased emotion understanding and acceptance, and heightened punishment sensitivity and harm avoidance. According to some sources, difficulties in identifying, responding to, and managing emotions predate ED onset (Racine et al., 2013; Shank et al., 2019). The possible precipitating and maintaining roles of negative affect in binge-eating symptoms has received particular attention (Martín et al., 2019). Affect-regulation models posit that negative emotions trigger binge episodes which serve (at least temporarily) to alleviate negative affect. Various functional analyses of binge-eating antecedents and consequences (often performed using "online" experience-sampling methods) offer support for this notion (Berg et al., 2013; Engelberg et al., 2007; Haedt-Matt & Keel, 2011).

#### NEUROCOGNITION

Neurocognitive performance in people with an ED has been compared to that in normal eaters on a wide range of tasks. Results generally associate the presence of an active ED with impairment of higherlevel cognitive functions, including inhibitory control, decision making, central coherence (i.e., the tendency to focus on details at the expense of global integration of information), set-shifting (the ability to switch perceptual or response sets), working memory (a core executive function), and attention bias (Smith et al., 2018). Many of the impairments listed are found to improve with nutritional rehabilitation, but some persistent impairments have been observed after rehabilitation (Cardi et al., 2013; King et al., 2019), and greater neurocognitive impairment has been associated with a more chronic course of AN (Saure et al., 2020).

Various studies have also suggested that, in individuals with an ED, social cognition is impaired (Cardi et al., 2018). The most widely applied socialcognitive construct in the ED literature is theory of mind (ToM). ToM refers to the ability to ascribe mental states to other people in order to understand and predict their behavior-something akin to empathy (Bora & Kose, 2016). Several studies have shown that, relative to healthy individuals, people with active AN have impaired ToM, manifested in the form of difficulties in understanding others' emotions, taking others' perspectives, and interpreting social behavior (Leppanen et al., 2018). Although associations are less robust than are those observed in people with active AN, impaired ToM has also been noted in individuals who have recovered from AN, in unaffected first-degree relatives of individuals with AN, and in individuals with BN (Tapajoz et al., 2019). Of note, a recent meta-analysis concluded that AN and autism are characterized by similar ToM profiles (Leppanen et al., 2018).

#### Developmental Factors

#### THEORIES ON FAMILY DYNAMICS

Traditional theories have promoted various stereotypes (some rather dubious) about families in which EDs develop-broadly associating AN with familial overprotectiveness and enmeshment and BN with familial disengagement, neglect, or hostility (see Smolak et al. 2013). Such concepts have received mixed support from self-report or, more rarely, observational studies of family functioning (Cerniglia et al., 2017; Lyke & Matsen, 2013; Steiger et al., 1991), which have suggested that AN, in its restricting form may, on average, be associated with family proneness toward enmeshment and overprotectiveness, whereas bulimic ED variants (including BN and BED) may be associated with proneness toward conflict and overt family dysfunction (Cerniglia et al., 2017; Steiger et al., 1991; Tetzlaff et al., 2016; Vidović et al., 2005). From a related perspective, developmental studies have associated EDs of both types with parent-child attachment problems (Tasca, 2019).

The trends described above require judicious interpretation for several reasons. First, because they are based on the averaging of tendencies across families, such descriptions are "caricatural" and risk concealing existent heterogeneities. Second, most of the findings that bear on questions related to family functioning have been generated through cross-sectional or retrospective designs, meaning that observations risk being contaminated by the effects of living with a member who is actively ill with an ED. Indeed, the few prospective family studies that exist provide very weak evidence of a priori involvement of family functioning variables in risk for ED development (see (Beato-Fernández et al., 2004; Nicholls & Viner, 2009). Third, effects observed, even if repeatable, need not represent causal factors but rather heritable "traits" (such as anxiousness or impulsivity) that might shape family interaction patterns without themselves having any direct etiological implication. Finally, most of the studies in question lack control groups representing other mental health entities, meaning that findings may not reveal ED-specific family tendencies at all.

Current thinking on the role of the family in the EDs rejects portrayals of the family as a core contributor to ED etiopathology. As a case in point, in 2010, the Academy for Eating Disorders (AED) stated that it "stands firmly against any etiologic model . . . in which family influences are seen as the primary cause of anorexia nervosa or bulimia nervosa, and condemns generalizing statements that imply families are to blame for their child's illness" (le Grange et al., 2010, p. 1). Correspondingly, there has been an important change in practices, one away from interventions that presumed the presence of family dysfunction and toward efforts to engage parents, family members, and friends as active contributors to treatment prepared with a good understanding of how to help and how to manage countertherapeutic reactions that are triggered by the child's illness (Anastasiadou et al., 2014; Lock, 2015). Many current treatment paradigms mobilize the family as a potential resource in therapy—and recent outcome research supports such initiatives (see Couturier et al., 2013).

#### MALTREATMENT

Such experiences as childhood physical, sexual, or emotional abuse are disturbingly common in individuals with EDs, especially in those with bulimia-spectrum disorders (BSDs; i.e., BN, BED, AN-binge-purge type, or subthreshold variants). According to available studies, roughly a third of adults with a BSD reports unwanted childhood sexual experiences, about half an experience of physical maltreatment (Fullerton et al., 1995), and more than three-quarters an experience of emotional abuse (Groleau et al., 2012). In population and clinical samples alike, childhood abuse has been found to predict severity of pathological eating attitudes and behaviors, body dissatisfaction, and overall eating symptom severity. Notably, a very large-scale study examined associations between EDs in adults and various forms of childhood maltreatment (e.g., harsh physical punishment, physical abuse, sexual abuse, emotional abuse, neglect, etc.). Results associated all forms of adversity with EDs, with sexual abuse and physical neglect being most strongly linked to EDs in men and sexual abuse and emotional abuse being most strongly linked to EDs in women (Afifi et al., 2017).

#### **Biological Factors**

#### BRAIN STRUCTURE AND FUNCTION

Neuroimaging studies associate the EDs with various anomalies in brain structure and function. AN is consistently associated with reduced gray and white matter volumes (see King et al., 2018, for a review). One meta-analysis on volumetric studies in AN concluded that, compared to findings in normal eaters, there is an average 4.6% reduction in gray matter and a 2.7% reduction in white matter volumes (Seitz et al., 2016). Interestingly, global brain volume reductions have not been observed in adolescents diagnosed with atypical AN (Olivo et al., 2018), suggesting that volumetric changes may be linked to severity of malnutrition. At the regional level, one meta-analysis showed smaller gray matter volume in the median cingulate cortex (involved in regulation of emotions) as well as in the posterior cingulate cortex and the precuneus (involved in self-reflection) (Zhang et al., 2018). Some structural brain changes noted are at least partly reversed by weight restoration, especially in younger individuals (Frank et al., 2019; Kaufmann et al., 2020; King et al., 2018).

Diffusion tensor imaging (DTI), which uses the diffusion of water molecules to generate magnetic resonance images, has shown white matter alterations in individuals with AN in the cingulum and the corpus collosum (Zhang et al., 2020) and in thalamocortical and occipital-parietal-temporal-frontal tracts (Gaudio et al., 2019). The preceding brain regions/ circuits have been associated with executive control, self-regulation, body image perception, and taste. Functional magnetic resonance imaging (fMRI) has been used to study neural connectivity when the brain is "at rest" (i.e., not activated by a particular task). Studies in individuals with AN point to reduced resting-state functional connectivity in default mode, frontoparietal, executive-control, and salience networks at various stages of illness, including recently ill, chronic, and recovered individuals (Cowdrey et al., 2014; Gaudio et al., 2016). Using task-based neuroimaging paradigms, neural alterations have been found in various brain circuits regulating reward, decision-making, and affect (see, e.g., Frank, 2012; Olivo et al., 2019).

Neuroimaging studies in individuals with bulimic symptoms indicate structural and functional alterations in the frontal cortex (involved in emotion regulation and executive function) (Mele et al., 2020). In addition, greater symptom severity in BN has been associated with reduced cortical thickness (Westwater et al., 2018). Studies in BN also point to functional and/or structural alterations in brain regions involved in the processing of food stimuli (visual cortex, precentral gyrus, and insula), reward (striatum), and self-referential processes such as body image (precuneus, anterior cingulate cortex, insula) (Mele et al., 2020). Whether functional and structural brain alterations in BN persist after recovery is unknown.

Although relevant studies are rare, neural changes implicated in BED appear comparable to those seen in BN. For example, BED and BN are both associated with an enlarged volume of the medial orbitofrontal cortex (Schafer et al., 2010), a brain region important for impulse control. Likewise, BED and BN are both associated with altered resting-state activity in the salience and default mode networks (Stopyra et al., 2019) and with altered neural activation of the cingulate and orbitofrontal cortex on a food reward processing task (Simon et al., 2016).

#### NEUROTRANSMITTERS

Serotonin (or 5-hydroxytryptamine: 5-HT) is widely distributed throughout the brain and has been implicated in the regulation of mood, cognition, social functioning, impulse control, and eating behavior (Booij et al., 2015). Anomalies have been reported in people with EDs on indices of 5-HT metabolites, plasma 5-HT precursor levels, 5-HT platelet uptake, and neuroendocrine responses to 5-HT agonists or antagonists, with several group differences also observed after weight restoration (Brewerton, 1995). In BN, findings show reduced platelet binding of serotonin uptake inhibitors and diminished neuroendocrine responses to serotonin precursors and agonists, with some changes again persisting after recovery (Brewerton, 1995; Steiger et al., 2011). One study by our group also showed unaffected first-degree relatives of patients with BN to have altered peripheral uptake of 5-HT compared to that in relatives of control women (Steiger et al., 2006). Such findings suggest that altered 5-HT may be a predisposing trait rather than a simple consequence of the disorder.

Positron emission tomography (PET) uses radioligands to allow for the *in vivo* characterization of neurotransmitter activity in different brain systems and regions. PET studies have shown that, relative to healthy individuals, people with AN have lower 5-HT transporter density in the medial parietal cortex (Yokokura et al., 2019) and greater 5-HT<sub>1A</sub> receptor activity in the frontal, parietal, and temporal cortices as well as in the raphe (Bailer et al., 2007; Galusca et al., 2008). Regional brain increases in 5-HT<sub>1A</sub> receptor levels have also been observed in individuals who have recovered from AN (Galusca et al., 2008). Such findings are indicative of generally diminished 5-HT function. Similarly, PET studies have documented widespread regional increases in 5-HT<sub>1A</sub> receptor levels in various brain regions in people with active BN (Bailer et al., 2011; Galusca et al., 2014). Conversely, inconsistent regional increases and decreases in 5-HT transporter density have been observed in individuals with BED (Majuri et al., 2017) and in individuals recovered from BN (Pichika et al., 2012)

Dopamine (DA) is a neurotransmitter associated with reward-driven behaviors, executive control, affect, and food intake (Broft et al., 2011; O'Hara et al., 2015). Reduced DA activity is thought, generally, to underlie excessive reward- or stimulusseeking behavior. Neuroendocrine challenge studies in individuals with AN provide evidence of increased DA neurotransmission (Kontis & Theochari, 2012), whereas studies in BN have documented decreased DA metabolites and reduced DA release in the putamen (Broft et al., 2012). Lower levels of DA<sub>2</sub> receptors have, furthermore, been associated with higher frequency of binge eating and vomiting (Broft et al., 2012). An implication may be that reduced DA activity in BN leads to disinhibition of eating behavior as a reward seeking behavior.

Other neurotransmitters, neuropeptides, and hormones have been studied. Neurotrophins act in cellular proliferation and survival, synaptic activity, and neural plasticity (Mitre et al., 2017). One widely studied neurotrophin, *brain-derived neurotrophic factor* (BDNF), is an important regulator of food intake and energy homeostasis and constitutes a plausible candidate in ED etiology and maintenance (Monteleone & Maj, 2013; Nakazato et al., 2012). A relatively consistent finding across studies is that serum BDNF is reduced in people with AN or BN (Brandys et al., 2011; Monteleone & Maj, 2013). In AN, serum BDNF levels have been shown to increase after partial weight restoration (Tyszkiewicz-Nwafor et al., 2019; Zwipp et al., 2014) and to compare with those in normal eaters after full recovery (Zwipp et al., 2014).

Glutamate is an excitatory neurotransmitter that has been implicated in reward processing, food intake, memory, and learning (Javitt, 2004; Karthik et al., 2020). Altered glutamate levels have also been associated with mood and obsessive-compulsive disorders (Javitt, 2004; Karthik et al., 2020). In AN, magnetic resonance spectroscopy studies have reported lower glutamate levels relative to those observed in healthy comparison individuals in various brain regions (Castro-Fornieles et al., 2007; Godlewska et al., 2017; Joos et al., 2011). One PET study investigated the association between BN and the metabotropic glutamate receptor subtype 5 (Mihov et al., 2020), a receptor important for the signaling of glutamate and highly expressed in the forebrain, striatum, and limbic regions. Relative to healthy women, individuals with BN were reported to have higher metabotropic glutamate receptor subtype 5 levels in brain regions involved in emotional and cognitive processing, reward-guided behavior, and food value representation (Mihov et al., 2020).

Abnormally low levels of *leptin*, a hormone secreted by fat cells that regulates appetite and energy expenditure, have been well-documented in women with active AN, whereas findings in BN are mixed (Monteleone & Maj, 2013). There is also some evidence for a role of *ghrelin*, which affects short-term regulation of appetite and long-term regulation of energy balance. Specifically, plasma levels of ghrelin have been reported to be high in AN, low in BED (Geliebter et al., 2005), and mixed in BN (Monteleone & Maj, 2013). Levels of oxytocin-a hormone associated with social functioning, attachment, and food intake-appear to be lower in individuals with AN relative to those in controls, while oxytocin levels in individuals with BN do not differ from those in normal eaters (Plessow et al., 2018).

Given the sex distribution of EDs, one enticing hypothesis has been that sex hormones (androgens and estrogens), may influence ED development. In support, findings derived from opposite-sex twin pairs (in which the female co-twin is exposed to more testosterone, *in utero*, than are females from a same-sex twin pair) point to a significant role of perinatal exposure to androgen in buffering against ED risk (Culbert et al., 2008, 2013). Corroborating this view, higher levels of circulating testosterone during puberty has been thought to protect against disordered eating in boys, whereas higher levels of estrogen may protect against genetic and phenotypic risk for disordered eating in girls (Ma et al., 2019; Mikhail et al., 2019).

The hypothalamic-pituitary-adrenal (HPA) axis is the body's main stress response system, driven by the hormone cortisol. Findings in AN and BN indicate various HPA axis alterations (Bou Khalil et al., 2017; Lo Sauro et al., 2008), some perhaps due to effects of malnutrition, some to comorbid mood and anxiety problems, some to exposure to trauma, and some due directly to having an ED. Several studies link pronounced psychopathology in individuals with an ED to more pronounced alterations in cortisol functioning (Bruce et al., 2012; Diaz-Marsa et al., 2008).

## Genetics

## FAMILY AND TWIN STUDIES

For disorders that have often been construed as "sociocultural creations," EDs are surprisingly heritable. Findings consistently indicate first-degree relatives of people with an ED to show increased liability for EDs compared to those of individuals with no ED (e.g., Strober et al., 2000). Providing even more convincing evidence of heredity, reported concordance rates for AN, BN, and BED in monozygotic twins range from 28% to 76% across studies (Wade & Bulik, 2018). Aside from indicating substantial genetic effects, the same twin studies tend to show the nonshared environment (e.g., a particular stressor experienced by one twin) to contribute more strongly to risk of an ED than does the shared environment (e.g., living in the same family environment).

While the preceding throws a challenge to models of ED etiology that emphasize family factors, an important nuance is necessary. Adult twin studies find most of the variance in under- or overeating to be explained by genetic and nonshared environmental effects. However, a twin study conducted in very young children has reported quite the opposite-effects of the shared (family) environment in the absence of genetic effects (Herle et al., 2017). Helping guide the understanding of this apparent inconsistency, a number of studies have indicated that genetic influences toward ED development may tend to be "switched on" at puberty (Ma et al., 2019). The preceding would imply that problematic under- or overeating may be a behavior that is learned in early childhood but is then transformed into a problem of clinical proportions by genetic effects that become activated around puberty.

#### CANDIDATE GENE STUDIES

There have been various efforts to identify singlegene variants (or sets of interacting genes) that may contribute to risk of an ED. Such approaches are generally driven by a theory-based "guess" about which gene (or set of genes) might make an important contribution to risk for a disorder. Findings from candidate gene studies often fail to replicate, and, consequently, the approach has fallen into disfavor. Nonetheless, some findings point to associations between EDs and polymorphisms of genes that, in theory, bear a logical association with ED risk-including those regulating key neurotransmitters like serotonin (Steiger et al., 2011), neuromodulators like BDNF (Ceccarini et al., 2019), hormones like estrogen (Nilsson et al., 2004), or those controlling appetitive behaviors like ghrelin (Muller et al., 2011).

Beyond the preceding, the candidate gene literature in EDs includes several observations suggesting gene-environment interactions. For instance, our group has shown that bulimic women carrying lowfunction alleles of the serotonin transporter polymorphism 5-HTTLPR when they report childhood abuse, display more novelty seeking, affective instability (Steiger et al., 2007), and dissocial (impulsiveaggressive) behavior (Steiger et al., 2008). A similar interaction implicating low-function 5HTTLPR alleles and familial/developmental stress has been linked to AN in a clinic study (Karwautz et al., 2011) and to binge eating in a large-scale community study (Akkermann et al., 2012). Similar interaction effects implicating other neural systems have also been documented. For instance, one of our findings indicated that, in BN, the DRD2 Taq1A polymorphism interacts with childhood abuse to moderate manifestations of novelty seeking (Groleau et al., 2012).

#### GENOME-WIDE ASSOCIATION STUDIES

Recent technologies support genome-wide association studies (GWASs) that use information gleaned from the entire genome to allow for isolation of novel genetic markers. The first study to document a finding of genome-wide significance for AN was published in 2017, by the Eating Disorders Work Group of the Psychiatric Genomics Consortium (PGC-ED; Duncan et al., 2017). Involving DNA from 3,495 people with AN and 10,982 normal-eater controls, the study associated a locus on chromosome 12 with AN, at a site previously linked to type-1 diabetes and autoimmune diseases (Duncan et al., 2017). Other findings from the same study indicated genetic correlations associating AN not only with mental illness phenotypes (like neuroticism and schizophrenia), but also with physical health phenotypes (like rapid glucose and lipid metabolism, highdensity lipoprotein cholesterol, and low BMI). In other words, aside from expected psychiatric components, findings characterized AN as having important metabolic and autoimmune components. We note that the autoimmune aspect of these findings corroborates a report based on more than 2.5 million Swedish healthcare registers that associated previous autoimmune disorders with later EDs and previous EDs with later autoimmune disorders (Hedman et al., 2019).

In 2019, the PGC-ED group published a larger follow-up GWAS involving data from 16,992 people with AN and 55,525 controls (Watson et al., 2019). The study identified eight genetic loci reaching genome-wide significance and again implicated psychiatric traits (e.g., obsessive-compulsive and major depressive disorders), metabolic traits (e.g., insulin resistance, lipid metabolism), and anthropometric traits (e.g., low BMI, low fat mass). Findings consolidate the idea that the genetic architecture of AN not only implicates psychiatric traits, but also metabolic factors and particular physical (anthropometric) characteristics.

## Epigenetics

A range of processes, referred to as "epigenetic" because they act "on top of" traditional genetic mechanisms, influence gene expression (and corresponding phenotypic variations) in the absence of actual DNA sequence changes. Many of these processes are believed to act in an environmentally responsive fashion (Cecil et al., 2020; Szyf, 2015) and hence to provide a plausible physical substrate for gene-environment interactions. Although various mechanisms may be involved, the most widely studied is DNA methylation. Various factors (childhood stress, nutritional status, maternal stress during gestation, perinatal complications, and current stressors) are believed to influence DNA methylation, which usually reduces gene expression (see Steiger & Booij, 2020). The likelihood that some or all of these factors act etiologically in the EDs has mobilized recent interest in the possible contribution of epigenetic processes to ED development and maintenance.

One of the first epigenetic studies in the EDs measured methylation levels in candidate genes in the DA system (implicated in mood, impulse control, reward sensitivity, and binge eating) and reported hypermethylation of the *DRD2* and *DAT* genes in people with AN and BN (Frieling et al., 2010). Other studies in AN have reported altered methylation of candidate genes regulating expression of alpha-synuclein (involved in neurotransmitter release) (Frieling et al., 2007), oxytocin (linked to social attachment) (Kim et al., 2014; Thaler et al., 2020), histone deacetylase (broadly influencing gene expression), and leptin (which inhibits hunger) (Neyazi et al., 2019).

Our group conducted some of the earliest studies on candidate gene methylation levels in people with BN. We focused on genes involved in the regulation of the HPA axis (e.g., *GR* gene; Steiger et al., 2013), neuroplasticity (*BDNF* gene; Thaler et al., 2014), and monoamines (e.g., *DRD2* gene; Groleau et al., 2014). The gist of results from these studies indicated that alterations in DNA methylation seen in individuals with BN tended to correspond to variations in comorbid tendencies (like suicidality, PD, or substance abuse) or to variations in exposure to childhood abuse.

Just as it has become possible to conduct genome-wide studies, techniques for sampling methylation levels throughout the genome have also become available. Our group has published two epigenome-wide studies comparing methylation levels in women with active AN to those in women in whom AN had remitted for at least 1 year or who had never had an ED (Booij et al., 2015; Steiger et al., 2019). In intriguing parallel to findings from the GWAS studies described above, our findings showed actively ill women to have altered methylation levels (and generally hypermethylation) on genes relevant to the mental status (e.g., serotonin, dopamine, glutamate), glucose and lipid metabolism, and immune function. Findings also showed chronicity of illness to be associated with more pronounced alterations in methylation levels and, importantly, that changes seen in actively ill individuals seemed to "reset" with symptom remission. The latter aspects suggest that changes in DNA methylation might be implicated in the exacerbation of certain psychiatric traits and physical sequelae that occur in a long-standing eating disorder. The findings also imply that methylation indices may have promise as markers of disease staging or therapeutic response.

#### **Toward an Integrated Etiological Concept**

The idea that EDs are multiply determined by biological, psychological, and social factors has been widely accepted for many years (see Garfinkel & Garner, 1983; Jacobi et al., 2004; Striegel-Moore & Bulik, 2007; Treasure et al., 2010). However, contemporary clinical science has recently led to advancements toward a more principled and better-articulated biopsychosocial perspective. The advent of epigenetic science has expanded our understanding of mechanisms by which environmental factors may influence genetic potentials, activating and shaping various mental illness phenotypes—including eating disorders—and points to real physical substrates for a putative crosstalk between "nature" and "nurture."

Genetic-epidemiological, molecular-genetic, brain imaging, neurobiological, and neuropsychological studies have resulted in an increased appreciation of the extent to which biology, and especially hereditary traits, act in risk for ED development. However, there has not been a simple pendulum swing away from attention to sociocultural or developmental processes and toward more psychobiological modeling. Rather, contemporary multidimensional models use emerging psychobiological data to elaborate a more properly integrated view. Eating disorders cease to be viewed as expressions of "superficial body consciousness," "capriciousness," or "stubborn oppositionality" in affected people, or as responses to "dysfunctional," "overinvolved," or "toxic" families. Instead, they are understood to represent the activation, by environmental stresses (and pressures promoting too much dieting) of real physical vulnerabilities to ED development borne by susceptible people. Such people do not "ask" to get an ED or "bring the ED on themselves." Rather, they develop EDs because they carry real vulnerabilities that get "switched on" by real environmental impacts. Likewise, when the disorder persists in affected people, it is not because they are "not trying hard enough to recover" or "choosing to keep their disorder." It is because a biopsychosocial "mix" of factors has caused the disorder to become entrenched and difficult to overcome.

Encouragingly, some findings from the epigenetic literature suggest that nutritional rehabilitation may help undo or "reset" problematic changes in DNA methylation at key genetic loci (e.g., Steiger et al., 2019). Available evidence also indicates that treatment models informed by an integrative biopsychosocial perspective help "humanize" the process of treatment, as they help clinicians and patients alike understand that EDs occur not because of failings in those affected (or in the families from which they arise) but because of the activation of real physical susceptibilities by lived environmental impacts. Arguably, informed models of ED development encourage an understanding of ED etiology and treatment that blames sufferers and their relatives less and that supports and validates more. For fuller treatments of such questions, see Steiger and Booij (2020).

To help clarify the type of "crosstalk" among putative risk factors that we assume to be involved in ED development, we introduce a concept that we believe provides a useful heuristic. The concept, supported by various available studies on the structure of ED pathology, is that, in the EDs, variables that bear directly on eating symptoms (restricting, bingeing, vomiting, body dissatisfaction, etc.) tend to map onto one factor or cluster, those that load onto generalized psychopathology (e.g., depression, anxiety, impulsivity, perfectionism) tend to cohere onto another. Furthermore, and more importantly, severity of symptoms in the ED-specific factor is often surprisingly independent of severity of symptoms in the comorbid factor. In other words, individuals displaying severe comorbid disturbances need not display correspondingly severe eating symptoms and vice versa.

To assist in discussing hypothetical causal interactions among putative eating-specific and generalized components of pathology in the EDs, we have listed in Table 18.1 various factors that might reasonably be thought to be relevant to each component. Putative eating-specific risk factors are listed in the left-hand column of Table 18.1. These are presumed to impinge directly on bodily components of self-representation and on eating-specific cognitions and behaviors. They include (1) biological factors related to bodily appearance, appetite regulation, or direct eating-disorder risk; (2) psychological and developmental processes linked to concern with body image or weight (e.g., identifications with weight-conscious parents and peers); and (3) social values that heighten concerns with weight and bodily appearance. Together, these factors are presumed to constitute the ingredientsbiological, psychological, and social-of marked concerns with eating, weight, and body image. We assume that such factors control the overall strength of eating-related concerns. However, we also assume that, alone, these factors may not be sufficient to explain development of a clinical ED.

A second group of factors, assumed to be nonspecific to eating (i.e., to underlie generalized susceptibilities or maladjustments) but to be important components of vulnerability to ED development nonetheless, are depicted in the right-hand

Table 18.1 Putative biological, psychological, developmental, and social risk factors for development of eating disorders			
	Eating-specific factors (direct risk factors)	Generalized factors (indirect risk factors)	
Biological factors	ED-specific genetic risk	Genetic risk for associated disturbance	
	Physiognomy and body weight	Temperament	
	Appetite regulation	Impulsivity	
	Energy metabolism	Neurobiology (e.g., 5-HT mechanisms)	
	Sex hormones	Sex hormones	
Psychological factors	Poor body image	Poor self-image	
	Maladaptive eating attitudes	Inadequate coping mechanisms	
	Maladaptive weight beliefs	Self-regulation problems	
	Specific values or meanings assigned to food, body	Unresolved conflicts, deficits, posttraumatic reactions	
	Overvaluation of appearance	Identity problems	
		Autonomy problems	
Developmental factors	Identifications with body-concerned relatives or peers Aversive mealtime experiences Trauma affecting bodily experience	Overprotection	
		Neglect	
		Felt rejection, criticism	
		Traumata	
		Relationship experience	
Social factors	Maladaptive family attitudes to eating, weight	Family dysfunction	
		Aversive peer experiences	
	Peer-group weight concerns	Social values detrimental to stable, positive self-image	
	Pressures to be thin		
	Body-relevant insults, teasing	Destabilizing social change	
	Specific pressures to control weight (e.g., through ballet, athletic pursuits)	Values assigned to gender	
		Social isolation	
		Poor support network	
	Maladaptive cultural values assigned to body	Impeded access to means of self-definition	

Factors are separated into those thought to contribute to eating-specific pathology and generalized psychopathology. Factors shown are meant to be illustrative, not exhaustive.

column of Table 18.1. These include (1) biological processes (e.g., neurotransmitter abnormalities, genetic susceptibilities influencing mental, metabolic and immune status), (2) psychological and developmental processes that shape general psychological development and self-concept (e.g., familial overprotection, developmental neglect, childhood traumata), and (3) sociocultural influences pertinent to overall self-image. We assume the latter set of factors to control presence and strength of generalized vulnerabilities and/or maladjustments. Although nonspecific, such factors might interact with eating-specific agents to contribute to risk of developing a clinical ED in various ways, as follows:

1. Given a social context that supports a "thin ideal" and that links body esteem to overall self-worth, the propensity to be perfectionistic or overly sensitive to social approval (shown on the left side of Table 18.1) might indirectly heighten susceptibility to intensive dieting and eventually to pathological eating practices. In this eventuality, one would expect, as tends to be the case, to find heavy loadings of perfectionism, self-criticism, reward dependence, and related characteristics in individuals who are prone to AN. Consider effects that might occur in a hypothetical example: An adolescent girl with a genetic predisposition toward anxious, perfectionistic traits might begin to diet to bolster her self-esteem. Weight loss produces various social rewards, as peers and parents pay her more positive attention. However, because dieting also leads to alteration of neurotransmitter function, a normal consequence of dieting, one effect might be an exacerbation of latent propensities toward anxiety and obsessionality and, gradually, increasing preoccupation with thinness. The adolescent's inherent tendency to demand too much of herself might become amplified, under new biological influences, into full-blown obsession-and intensive dieting gradually evolves into a full-blown ED. Based on currently available data, such effects are most likely to occur in people who, because of unique hereditary susceptibilities and/or hormonal influences, are particularly vulnerable to ED development.

2. Some individuals might carry a hereditary propensity toward altered neurotransmitter function. In other people, such sensitivities might result from epigenetically mediated interactions between genetic propensities and lived environmental exposures (e.g., trauma, intrauterine exposure to maternal stress, or dietary insufficiency). Once established, such tendencies might have predictable effects on mood and impulse regulation (acting on the right side of Table 18.1) while also conferring vulnerability to disorders of satiation, and hence bulimic eating patterns, in individuals disposed by social pressures emphasizing thinness (shown on the left side of Table 18.1) to restrict food intakeand to (in the process) reduce dietary intake of neurotransmitter precursors. Such tendencies might, in part, explain an affinity of bulimic eating syndromes for manifestations suggesting mood or impulse dyscontrol and, in part, account for the demonstrated importance, as a causal antecedent, of dietary restraint in bulimic syndromes. The stage becomes set for a cascade of maladaptive potentials expressed in the form

of symptoms like depression, anxiety, impulsivity, and dietary disinhibition (binge eating).

A main implication of the view we present here is that generalized susceptibilities, though not representing a specific (or perhaps even necessary) ingredient, are almost certain to enhance vulnerability to ED development. Furthermore, once an ED has developed, biopsychosocial consequences may promote increasingly more pronounced and entrenched disturbances in both eating-specific and generalized spheres. For instance, if the affected individual was not highly obsessional, affectively unstable, or impulsive to start with, he or she may soon become so under the influence on brain function and emotion regulation of increasing dietary dysregulation.

## Conclusion

Our thinking in this chapter has been structured around the concept that EDs, and the comorbid traits and syndromes that often coincide with them, have many common biological, psychological, and social determinants. This means that comorbid traits are often tightly woven into ED phenomenology and serve both as reflections of underlying causal elements and as manifestations of biopsychosocial consequences of the ED once it has developed. Following from this line of thinking, we propose that what may be of greatest interest about the EDs is, in fact, their tendency to implicate many nonspecific causal factors-and often to represent the activation, by excessive dietary restraint, of a diversity of generalized vulnerabilities. Such vulnerabilities might, in other contexts, find various alternative expressions. What is clear, however, is that an adequate model of ED etiology needs to accommodate ways in which diverse environmental impacts, occurring at diverse moments throughout the life cycle (and even prenatally), may be shaping the expression of latent biological factors that influence both mind and body.

## Life-Span and Multicultural Perspectives

Thomas M. Achenbach

## Introduction

This chapter employs two conceptual frameworks for understanding psychopathology across the life span in multiple cultural contexts. One framework is known as *developmental psychopathology*, which seeks to advance understanding, prevention, and treatment of psychopathology by conceptualizing maladaptive functioning in relation to developmental periods, sequences, and processes, as well as the tasks, challenges, and achievements characterizing particular developmental periods (Achenbach, 1974/1982, 2009).

The other framework embodies an empirically based, bottom-up paradigm for assessing psychopathology and for deriving taxonomic constructs of psychopathology via multivariate analyses of assessment data obtained on large samples of individuals. The chapter emphasizes practical applications of both frameworks to assessing, researching, and conceptualizing psychopathology across the life span in many contexts around the world.

#### **Developmental Psychopathology**

The discipline of developmental psychopathology originated primarily with efforts to understand maladaptive functioning from birth to maturity. Because there had been relatively little research on psychopathology between birth and maturity and because physical, social, cognitive, educational, and other developmental changes are so conspicuous during this period, developmental psychopathology initially focused on the nature, assessment, course, and consequences of maladaptive functioning among children. (I use "children" to include the entire period from birth to maturity.) However, it has since become clear that psychopathology of adulthood and later life is also best understood in terms of a life span approach that takes account of developmental variables from birth through old age.

## Deriving Empirically Based Constructs for Child Psychopathology

The developmental approach to the study of psychopathology was especially motivated by the need to obtain empirical data from which to derive constructs for psychopathology of childhood. Until 1968, the first edition of the Diagnostic and Statistical Manual (DSM-I, published in 1952)which embodied the official American psychiatric nosology-contained only the following two categories for child psychopathology: adjustment reaction of childhood and schizophrenic reaction, childhood type. Neither of these diagnostic categories was derived from empirical assessment of children's problems, and neither one provided explicit criteria for deciding which children qualified for which diagnosis. Although DSM-II added diagnostic categories for children's problems, the additional categories were not derived from empirical assessment data, nor did they provide explicit criteria for deciding which children qualified for which diagnoses.

The lack of empirically based differentiation among childhood disorders and the proliferation of powerful computers prompted multiple researchers to apply factor analysis and other

multivariate statistics to identify sets of problem items that tended to co-occur in large samples of children (e.g., Achenbach, 1966; Conners, 1969; Miller, 1967; Quay, 1964). Despite differences between instruments for rating problems, sources of data, samples of children, and analytic methods, reviews of these efforts revealed considerable convergence on two broad-spectrum groupings of children's problems designated as internalizing (or "overcontrolled") and externalizing (or "undercontrolled"), plus more numerous narrow-spectrum syndromes than were implied by the DSM diagnostic categories (Achenbach, 1966; Achenbach & Edelbrock, 1978; Quay & Werry, 1979). (The term syndrome is used here to designate a set of problems found to co-occur, consistent with the Greek meaning of "syndrome" as "the act of running together;" Gove, 1971, p. 2320. Syndromes are not necessarily equated with disorders, as problems may be found to co-occur for many reasons.) The internalizing grouping comprises problems of anxiety, depression, social withdrawal, and somatic complaints without apparent medical cause. The externalizing grouping, by contrast, comprises problems of aggressive and rule-breaking behavior. The broad-spectrum internalizing-externalizing distinction has since been employed in more than 75,000 published studies (Achenbach et al., 2016).

## Hierarchical Models

The study that originally coined the internalizingexternalizing distinction depicted hierarchical relations between narrow-spectrum syndromes and broad-spectrum groupings of problems to reflect findings that children whose problems matched certain narrow-spectrum syndromes were also classified as fitting either the broad-spectrum internalizing or externalizing grouping (Achenbach, 1966). These findings thus provided an empirical basis for bottom-up hierarchical models of psychopathology, which start with ratings of large pools of problem items at the bottom, move up to factor-analytically derived narrow-spectrum syndromes of co-occurring problems at the next level, thence to broad-spectrum internalizing and externalizing groupings, and ultimately to a general dimension of psychopathology (p) comprising scores for all the problem items (designated as Total Problems; Achenbach, 1966, 2009, 2020b, 2021). The reasons that particular problems are found to co-occur to form narrow- and broad-spectrum groupings may include biomedical, genetic, environmental, experiential, semantic, and other factors.

## Contrasts with the DSM

The findings of numerous childhood syndromesseveral of which were subsumed by broad-spectrum internalizing or externalizing groupings-argued against the DSM's implication that child psychopathology should be conceptualized in terms of minimally differentiated versions of adult psychopathology. Although the DSM qualifies diagnostic criteria for some disorders with references to children, the current DSM-5 conceptual model implies that the essential nature of most disorders remains similar from childhood throughout adulthood and into old age. As an example of a common kind of psychopathology having counterparts across the life span, major depressive disorder (MDD) is specified in terms of nine symptoms, five or more of which "have been present during the same 2-week period and represent a change from previous functioning" (DSM-5, p. 160). Among the symptoms are depressed mood, with the qualifier that it can be "irritable mood" in children and adolescents. Another symptom is significant weight loss or gain, with the qualifier that the diagnostician can consider "failure to make expected weight gain" in children (p. 161). Other than these minor qualifiers, the construct and criteria for MDD are the same across the life span.

As with previous editions of the *DSM*, the *DSM*-5 criteria for MDD were formulated by committees to represent what they viewed as the essence of MDD, with minor qualifiers to take account of what the committees thought might characterize MDD in children and no qualifiers for MDD in the elderly.

A life span developmental approach differs from the *DSM* approach in not assuming that most disorders are essentially the same across all developmental periods. Instead, research on different developmental periods is used to identify characteristics that discriminate between members of particular age groups who are judged to need mental health services versus peers who are judged not to need such services. The discriminating characteristics are then analyzed statistically to derive empirically based constructs for psychopathology within each developmental period. Scales for scoring the constructs are subsequently normed with data from population samples for each age group.

Specific methods for identifying discriminating characteristics will be outlined later, but the key

point is this: constructs for psychopathology should be based on empirical findings for individuals within particular developmental periods, rather than being negotiated by committees who then agree on criteria for each construct, with occasional qualifiers to take account of what the committees view as possible differences between adults and children.

Life span developmental research generates some constructs that differ between developmental periods but which longitudinal research may reveal to be linked between earlier and later developmental periods (heterotypic continuity). Life span developmental research also generates some constructs that are similar across developmental periods (homotypic continuity), as well as some constructs for which longitudinal research fails to detect links across developmental periods. In other words, developmental similarities and differences should be identified for successive developmental periods via empirical research using developmentally appropriate assessment instruments, sources of data, participant samples, and analyses. To map continuities and discontinuities across developmental periods, longitudinal research is required that applies developmentally appropriate assessment instruments, sources of data, and analyses to the same participants as they age. Much developmental research on psychopathology has focused on the period from birth to maturity, but developmental research is also needed to advance understanding of psychopathology in early, middle, and later adulthood.

## The Empirically Based Bottom-Up Paradigm

Although there were some earlier factor analytic studies of severe adult psychopathology (e.g., Wittenborn, 1951), the empirically based bottomup paradigm for advancing the developmental study of psychopathology employs factor analysis as one component of the Achenbach System of Empirically Based Assessment (ASEBA), which has evolved through programmatic efforts over more than a half century (Achenbach, 1966, 2020b). The following sections outline key components of the empirically based bottom-up paradigm for the developmental study of psychopathology across the life span.

#### Assessment Instruments

Empirically based bottom-up efforts have constructed assessment instruments tailored to each developmental period. The items comprising each instrument are designed to assess behavioral, emotional, social, and thought problems that would

potentially make individuals of a particular developmental level candidates for mental health services. Pools of candidate items were generated from research and from consultation with relevant professionals, including practitioners in medical, school, forensic, and child and family services, as well as mental health workers. Written at a fifth-grade reading level, the items are tailored to the kinds of informants who are familiar with the assessed individuals' functioning in particular contexts. Selfreport instruments are provided for individuals who are capable of completing them. Within a particular developmental period, some items may differ according to the intended kind of informant. For example, nightmares is an item on instruments completed by parents and youths but not on teachercompleted instruments.

In addition to the generation of large pools of candidate items, construction of developmentally appropriate instruments requires testing of various formats, instructions, rating scales, and periods on which informants are instructed to base their ratings. Pilot testing has included having large samples of informants complete successive drafts of the instruments, comment on the items and formats, and suggest additional items.

Extensive pilot testing and feedback from samples of the intended kinds of informants have been used to cull, augment, and refine the items, as well as to ensure that formats, instructions, rating scales, and rating periods function well. Because no single informant is apt to provide a complete picture of assessed individuals, parallel instruments have been constructed to obtain assessment data from different kinds of informants appropriate for each developmental period. For example, for the preschool period, one instrument is designed to be completed by parent figures, while a parallel instrument is designed to be completed by preschool teachers and daycare providers who see children in group settings (Achenbach & Rescorla, 2000).

For school-age children, there are parallel parent- and teacher-completed instruments, plus a self-report instrument completed by 11- to 18-yearolds (Achenbach & Rescorla, 2001). For adults and the elderly, there are self-report instruments plus collateral-report instruments for completion by people who know the assessed individuals, such as spouses, partners, family members, friends, and therapists (Achenbach et al., 2004; Achenbach & Rescorla, 2003). In the final versions of the instruments, problem items are rated on Likert scales as 0 = not true (as far as you know), 1 = somewhat or sometimes true, or 2 = very true or often true. Ratings are based on the preceding 2 months for ages  $1\frac{1}{2}-5$ and 60-90+ and for teachers' ratings of 6- to 18year-olds. For other instruments, ratings are based on the preceding 6 months.

#### Testing the Instruments' Psychometrics

As part of the development process, the instruments were completed for large samples of individuals who were referred for mental health and related services, such as special education for children and substance abuse services for adults. The instruments were also completed for population samples of individuals who had not been referred for such services during the previous 12 months. Distributions of ratings on each item were examined to identify items having too little variance to provide meaningful data.

Each item of each instrument was tested for its ability to discriminate between demographically similar referred and nonreferred samples, with effects of demographic variables such as age, gender, ethnicity, and socioeconomic status (SES) partialed out. Items that did not discriminate significantly between referred and nonreferred samples were then discarded, with the exception of a few items that did not discriminate significantly between heterogeneous referred versus nonreferred samples but were found to load significantly on factors from which syndromes were derived, as described later. The items' ability to discriminate significantly between demographically similar samples of referred versus nonreferred samples, plus-for some items-significant loadings on syndromes, thus supported the validity of the items as markers for psychopathology. After scales were constructed for scoring the items on syndromes, internalizing, externalizing, p, and other constructs, the scale scores were evaluated for discriminant, construct, and predictive validity (Achenbach et al., 2004; Achenbach & Rescorla, 2000, 2001, 2003).

The test-retest reliability of each scale scored from each instrument was supported by Pearson correlations (rs) between scores obtained from ratings by the same informants over intervals of one to two weeks. Changes in mean scale scores were tested over those periods with t tests to detect statistically significant differences between initial scores and scores obtained by the same individuals 1-2 weeks later. Longer-term stability of scale scores was supported by test-retest rs between scale scores obtained from ratings by the same informants over periods of months to years. The internal consistency of each scale was supported by Cronbach's alpha coefficient.

## Syndrome Scales

The lengthy efforts invested in constructing developmentally appropriate instruments designed for completion by different informants were intended both to obtain research data from which to derive constructs for psychopathology and to provide practical tools for clinically assessing individuals' needs for help. The derivation of constructs went through successive stages in which ratings of various samples were subjected to multiple factor analyses, separately for each gender and age range of assessed individuals and for different kinds of informants, as summarized by Achenbach (2009). To ensure that the assessed individuals had enough problems to enable detection of clinically meaningful syndromes, the samples that were factor analyzed in the initial stages of the research comprised individuals who were referred for mental health or related services. To minimize possible biases associated with clinical referral, later factor-analytic samples included nonreferred as well as clinically referred individuals whose *p* scores were at or above the median for a nationally representative US population sample of each gender-, age-, and informantspecific group. Multiple kinds of orthogonal and oblique exploratory factor analyses (EFAs) were used. (Orthogonal EFAs identify syndromes that are not correlated with each other, whereas oblique EFAs identify syndromes that are correlated with each other.)

Provisional syndromes were constructed to include items that loaded significantly on counterpart factors found in different EFAs of problem item ratings for each gender/age group within each developmental period, rated by different kinds of informants. The provisional syndromes were then subjected to confirmatory factor analyses (CFAs) to obtain the final versions of syndromes scored from instruments completed by a particular kind of informant (parent, teacher, self, adult collateral) for individuals at ages 11/2-5, 6-18, 18-59, and 60-90+ years (Achenbach et al., 2004; Achenbach & Rescorla, 2000, 2001, 2003). (CFAs test whether data fit syndromes that were previously identified by EFAs.) Items retained for syndromes had significant loadings in CFAs of ratings by a particular kind of informant. However, some items differed for versions of a particular syndrome scored from ratings by different kinds of informants. For example, Disturbs other pupils is on the Attention Problems syndrome scale scored from the Teacher's Report Form for Ages 6-18 (TRF) but not on the Attention Problems syndrome scale
scored from the Child Behavior Checklist for Ages 6–18 (CBCL/6-18) completed by parents nor on the Youth Self-Report for Ages 11–18 (YSR), neither of which requests ratings for *Disturbs other pupils*. Syndrome scale scores are operationalized by summing the 0-1-2 ratings of a syndrome scale's constituent items obtained by an individual on a particular assessment instrument completed by a particular informant.

## Internalizing and Externalizing Scales

To operationalize hierarchical structures of psychopathology, rs were computed between first-order syndrome scale scores obtained by individuals in each of the samples that had been used to derive the factors on which the syndromes were based, separately for each gender-, age-, and informant-specific group. The rs between syndrome scale scores were then factor analyzed. For ages 11/2-5, 6-18, and 18-59, two second-order factors were found that corresponded to the internalizing-externalizing distinction. (Secondorder factors consist of first-order syndromes that are mutually associated.) However, second-order factor analyses did not yield such factors for ages 60-90+ . The syndrome scales' loadings on the second-order factors varied somewhat between the multiple secondorder factor analyses of each instrument. The syndrome scales loading on the second-order factors also differed between the different age groups, reflecting age group differences in the syndromes.

Scores on the scale based on the internalizing factor for a particular instrument are operationalized by summing the scores obtained by an individual on the syndrome scales that loaded highly on the internalizing factor for that instrument. As an example, for the Adult Self-Report for Ages 18–59 (ASR) and the Adult Behavior Checklist for Ages 18–59 (ABCL), the Anxious/ Depressed, Withdrawn, and Somatic Complaints syndrome scales loaded highly on the internalizing factor. An individual's internalizing score is therefore operationalized by summing the individual's scores on those three syndrome scales. Analogous procedures apply to the externalizing scale scored from each instrument.

Another type of factor analysis, called bifactor analysis, can also be used to construct broadspectrum internalizing and externalizing scales. However, neither second-order nor bifactor analysis is necessarily the optimal approach to constructing broad-spectrum internalizing and externalizing scales for all purposes (Achenbach, 2021; Lahey et al., 2021; Markon, 2021). An advantage of secondorder factor analysis for constructing practical clinical assessment tools is that the syndrome, internalizing, and externalizing scales remain intact within the hierarchy that ranges from ratings of individual items at the lowest (most molecular) level, to syndrome scales at the narrow-spectrum level, internalizing and externalizing scales at the broad-spectrum level, and the p scale at the most general (molar) level. Figure 19.1 illustrates an empirically based hierarchy of scales scored on the ASR and ABCL (Achenbach & Rescorla, 2003).

Figure 19.1 Hierarchy of empirically derived problem scales for ages 18–59. Adapted from https://aseba.org/wp-content/uploads/2019/04/ catalog.pdf. Copyright 2019, T. M. Achenbach.

## DSM-Oriented Scales

Although the *DSM* diagnostic categories are products of a top-down paradigm, questions often arise about relations between *DSM* diagnoses and empirically based bottom-up assessment data. To provide cross-walks between *DSM* categories and data obtained with ASEBA instruments, *DSM*oriented scales were constructed by having international panels of experts identify ASEBA items for ages  $1\frac{1}{2}$ -5, 6–18, 18–59, and 60–90+ that the experts judged to be very consistent with particular *DSM* diagnostic categories (Achenbach, 2014).

Corresponding to DSM diagnostic categories, the constructs measured by the DSM-oriented scales are top-down scales that were constructed with ASEBA problem items (which had previously been tested for discriminant validity, as described earlier) by applying the collective judgment of international experts. Moreover, unlike the yes/no judgments required for DSM diagnostic criteria, the experts rated the ASEBA items on Likert scales as  $0 = not \ consistent, \ 1 = somewhat \ consistent, \ and \ 2 =$ very consistent with particular DSM diagnostic categories. An item was assigned to a scale for a DSM category if at least 60% of the experts rated it as very consistent with the category. At least five ASEBA problem items had to be rated as very consistent with a DSM category to form a DSM-oriented scale for that category.

In the first editions of the *DSM*-oriented scales, experts based their judgments on *DSM-IV* categories, separately for ages  $1\frac{1}{2}$ -5, 6–18, 18–59, and 60–90+ (Achenbach et al., 2004; Achenbach & Rescorla, 2000, 2001, 2003). The *DSM*-oriented scales were subsequently revised on the basis of new panels of international experts' identification of items that they judged to be very consistent with *DSM-5* criteria (Achenbach, 2014).

Like the empirically based ASEBA syndrome scales, each ASEBA DSM-oriented scale is operationalized by summing an informant's 0-1-2 ratings of the items comprising the scale. Standardized scores (normalized T scores) for the DSM-oriented scales are based on the same normative samples as the empirically based scales for a particular age and gender, rated by a particular kind of informant. Thus, although the DSM-oriented scales are based on experts' judgments, the DSM-oriented scales are operationalized and normed as quantitative dimensions like other ASEBA scales.

Reliability, validity, and internal consistency findings for the *DSM*-oriented scales are reported in the ASEBA manuals for ages  $1\frac{1}{2}$ -5, 6–18,

18–59, and 60–90+ (Achenbach et al., 2004; Achenbach & Rescorla, 2000, 2001, 2003). More than 300 publications report findings on associations between ASEBA scores and diagnostic data (Pascal & Achenbach, 2021). By classifying individuals according to whether their *DSM*-oriented scale scores are in the clinical range, users can apply a categorical *DSM* approach to using the scales. However, because there is abundant evidence that continuous measures of psychopathology are more reliable and valid than categorical measures, use of the continuous *DSM*-oriented scale scores is apt to be superior to categorical classification of individuals as clinically deviant versus nondeviant (Markon et al., 2011).

## Multi-Informant Assessment

Mental health professionals who work with children have long understood the value of obtaining data from adults such as children's parents and teachers, as well as from the children themselves. Over several decades, meta-analyses of rs between ratings of children's problems by people who play similar roles and see children in similar contexts (pairs of parents, teachers, mental health workers, observers) have yielded mean cross-informant rs around .60 (Achenbach, McConaughy, & Howell, 1987; De Los Reyes et al., 2015). Between people who play different roles and see children in different contexts (e.g., parents vs. teachers), cross-informant rs have averaged around .30. And between self-ratings by children versus ratings by others, the cross-informant rs have ranged from the .20s to the .40s, depending on the children's ages and on who rated the children. Even the rs around .60 for pairs of similar informants mean that each informant may provide different information about an assessed child, and even more so for pairs of informants whose roles differ in relation to an assessed child.

The modest cross-informant *r*s cannot be dismissed merely as resulting from measurement error because good reliability and validity have been demonstrated for the parent-, teacher-, and self-rating instruments (De Los Reyes, 2011). Instead, the modest *r*s are likely to reflect differences between children's behaviors in different contexts (e.g., home vs. school), as well as differences between the mindsets of informants such as parents versus teachers.

Although the need for multi-informant assessment of children is now widely recognized, adult mental health clients are usually the sole or main source of assessment data about themselves. There have been many fewer studies of cross-informant agreement regarding adult than child psychopathology, but meta-analyses of cross-informant rsbetween self- and collateral-ratings of adult psychopathology have found a mean r of only .45 (Achenbach et al., 2005). *DSM* diagnoses based only on adult self-reports have also been found to differ substantially from diagnoses based on data from other informants (Meyer, 2002; Meyer et al., 2001). Consequently assessment of adults as well as children should include data from informants who know the assessed person, as well as data from self-reports.

Within each age range, parallel ASEBA instruments are designed to obtain ratings of behavioral, social, emotional, and thought problems from different informants (parents, teachers, self, adult collaterals). The parallel instruments are scored on parallel syndrome, *DSM*-oriented, internalizing, externalizing, and Total Problems scales, although the items comprising the parallel scales are not necessarily identical for all informants. Hand-scored and computer-scored profiles display scale scores in relation to norms appropriate for the assessed individual's age, gender, the type of informant (parent, teacher, self, adult collateral), and multicultural norm group (explained later).

To operationalize the magnitude of agreement between different informants, the computer software generates Q correlations between the 0-1-2 ratings of problem items by each pair of informants. (Each Q correlation is computed by applying the formula for r to the 0-1-2 ratings by a pair of informants.) To enable users to evaluate the magnitude of a Q correlation between a particular pair of informants, the software displays the 25th percentile, mean, and 75th percentile Q found in large reference samples of similar pairs of informants. The software describes Qs below the 25th percentile as below average; Qs from the 25th through the 75th percentile as average; and Qs above the 75th percentile as *above average*. To enable users to identify cross-informant agreements and disagreements on specific items, the software displays the problem items comprising each scale in side-by-side lists with the 0-1-2 ratings of each item by up to 10 informants.

The software additionally displays the standardized problem scale scores (normalized T scores) on side-by-side bar graphs for ratings by up to 10 informants. This enables users to identify scales on which informants agree versus disagree in reporting low, intermediate, or high levels of the problems that comprise a scale standardized on the basis of norms for the assessed person's age, gender, the type of informant, and the multicultural norm group. If they deem it appropriate, clinicians can elect to show the bar graphs to clients to help them see similarities and differences between reports by different informants.

# Competence, Adaptive Functioning, and Strengths Scales

Evaluation of needs for mental health services should include assessment of competencies, adaptive functioning, and strengths as well as assessment of problems. Individuals whose problems are in the clinical range and who have low levels of favorable characteristics are apt to need different kinds of help than individuals who have higher levels of favorable characteristics. Like ASEBA items for assessing problems at particular developmental periods, ASEBA items for assessing favorable characteristics are tailored to particular developmental periods and to the kinds of informants who are able to provide information about those characteristics. Also like the ASEBA problem items, ASEBA items for assessing favorable characteristics were culled and refined from large pools of candidate items on the basis of data from large samples of informants who completed successive pilot editions. The items were then tested for their ability to discriminate between demographically similar samples of clinically referred and nonreferred individuals in a particular age range. However, unlike the problem items, the items for assessing favorable characteristics were not factor analyzed to derive constructs. Instead, these items were aggregated into scales for assessing certain favorable aspects of functioning that discriminate well between clinically referred and nonreferred samples and that can serve as targets for interventions.

As an example, the CBCL/6-18 includes items that request parents to list up to three sports and three non-sports hobbies, activities, and games that their child likes to take part in. Parents are asked to indicate the amount of time their child spends in each one, compared to others of the same age (*less than average, average, more than average, don't know*). Parents are also asked to indicate how well their child does in each one, compared to others of the same age (*below average, average, above average, don't know*). Parents are additionally asked to list up to three jobs or chores their child does and how well their child does each one. These items are scored on the *Activities* scale.

Other CBCL/6-18 items assess involvement in organizations; friendships; how well the child gets

along with siblings, parents, and other kids; and how well the child plays and works alone. These items are scored on the *Social* scale. Additional items assess various aspects of school functioning, scored on the *School* scale. The scores for the Activities, Social, and School scales are summed to yield a *Total Competence* scale score. Raw scores on each competence scale are converted to normalized *T* scores and percentiles based on normative samples, separately for each gender at ages 6–11 and 12–18. Unlike ASEBA scales for assessing problems, low scores on the competence scales are clinically important.

The YSR has self-report versions of the competence items that are scored on scales like those for the CBCL/6-18, plus items interspersed among the problem items that describe positive qualities and are rated on 0-1-2 Likert scales like the problem items. Examples include "I am pretty honest" and "I like to help others." The 0-1-2 ratings on these items are summed to yield a scale score for *Positive Qualities*.

The ASR has adaptive functioning items that are scored on scales for *Friends, Spouse/Partner, Family, Job, Education,* and *Mean Adaptive*, which is computed by averaging standard scores on the scales that are relevant to the adult who completed the ASR. (An adult who—during the preceding 6 months had no spouse/partner, job, or enrollment in an educational program would not be scored on these scales.) The ABCL has collateral report versions of the Friends and Spouse/Partner items and scales.

The four instruments spanning ages 18–90+ are also scored on a *Personal Strengths* scale, which is the sum of 0-1-2 ratings on favorable items scattered among the problem items. Examples include "Can do certain things better than other people" and "Likes to help others." Competence, adaptive functioning, and strengths scales are displayed on profiles in relation to norms appropriate for the assessed individual's gender, age, group, and the type of informant. Table 19.1 summarizes ASEBA self-report and informant-report instruments for ages 1½ through 90+ years, as well as the scales scored from them.

## **Multicultural Applications**

Research, assessment methodology, and theory pertaining to psychopathology have originated mainly in a few rather similar societies. ("Societies" refer here to geopolitically demarcated populations that include countries but also populations that are not countries, such as Puerto Rico, Hong Kong, and Flanders, the Flemish speaking region of Belgium.) However, it should not be assumed that the models and methodologies originating in a few societies automatically apply to people in all other societies. Instead, models and methodology developed in a particular society should be empirically tested for generalizability to other societies.

The application of the same standardized research methods to people in different societies is known as *etic* research. The term "etic" was derived by the linguist Kenneth Pike (1967) from *phonetic* (i.e., linguists' systems for standardized representations of speech sounds that are meaningful in any of the world's languages). Etic research differs from *emic* research (Pike, 1967), derived from *phonemic* (i.e., linguists' systems for representing sounds that are meaningful in a particular language). Whereas etic research uses the same standardized methods to assess people in many societies (with translations, if needed), emic research uses methods tailored to a particular society.

There is a long history of cross-cultural research that compares two or three societies and draws inferences about all members of each society from differences on measures applied to samples from each society (Hermans & Kempen, 1998). By contrast, the multicultural research on psychopathology addressed here assesses population samples in many societies using the same standardized assessment methods to obtain distributions of quantitative scores, both within and between societies. To facilitate such research, ASEBA instruments are available in the 113 languages listed in Table 19.2. Published reports of use of ASEBA instruments in more than 100 societies and cultural groups are also available (Pascal & Achenbach, 2021).

## Generalizability of Syndrome Structures Across Many Societies

To test the degree to which the syndrome structures derived from factor analyses of primarily US ASEBA data would be found in other societies, CFAs have been performed on data from population samples in more than 50 societies. Separate CFAs have been performed on the ratings of problem items on each ASEBA instrument in population samples for ages 1½–5, 6–18, 18–59, and 60–90+ (Ivanova et al., 2007a, 2007b, 2007c, 2010, 2011, 2015a, 2015b, 2020, 2021, 2022; Rescorla et al., 2012). The ASEBA syndrome structures were supported by the root mean square error of approximation (RMSEA) obtained for CFAs of data obtained with the ASEBA instruments in non-US societies around the world. Thus, despite vast differences in

languages, cultures, gene pools, political and economic systems, geographical locations, etc., people's ratings of ASEBA problem items yielded similar syndrome structures within age ranges 1½–5, 6–18, 18–59, and 60–90+.

## Generalizability of Problem Item Structures Across Many Societies

To provide another test of the generalizability of the measurement structure of ASEBA instruments, the mean of the 0-1-2 ratings was computed for each problem item on each ASEBA instrument in each sample. Q correlations were then computed between the mean of the ratings on each item of a particular instrument for Society A versus Society B, Society A versus Society C, and so on for all pairs of societies. (Each Q correlation was computed by applying the formula for r to the set of mean 0-1-2 ratings obtained on problem items for one society versus the set of mean 0-1-2 ratings obtained on the same problem items for a second society.) The Q correlation between the mean item ratings measured the similarity in rank ordering of item ratings between the two societies.

The Q correlations computed between every pair of societies in which ratings for a particular instrument (e.g., the ASR) were obtained were then averaged to compute the omnicultural mean Q correlation between rankings of item ratings for that instrument. Surprisingly, the omnicultural mean Q correlation for every instrument across samples from many different societies for ages 11/2-5, 6-18, 18-59, and 60-90+ was in the .70s (Rescorla et al., 2011, 2012, 2016a, 2016b, 2020). These large omnicultural mean Q correlations indicate considerable similarity in the problem items that tended to receive relatively low, medium, or high ratings from different kinds of informants rating individuals of different ages across many different societies on every inhabited continent. Moreover, the finding that the omnicultural mean Q correlation for every instrument was in the .70s, despite differences between the instruments, societies, samples, age ranges, and raters, indicates a striking degree of uniformity in the quantitative measurement of item structures across populations around the world.

## Multicultural Comparisons of Problem Scale Scores

The omnicultural mean Q correlations and CFA findings support the generalizability of measurement structures for ASEBA problem items and syndrome scales across many societies around the world. However, these findings do not necessarily mean that scale scores were the same in every society, nor for different genders, nor for different ages within the age ranges for which each instrument was designed. In order to test possible societal, gender, and age differences in the magnitudes of problem scale scores, analyses of variance (ANOVAs) were used to compare scores on all scales of each instrument for the societies from which population samples were assessed with each instrument (Rescorla et al., 2011, 2012, 2016a, 2016b, 2020). For each instrument, the effects of gender, age, and interactions on problem scales ranged from nonsignificant to very small, according to Cohen's (1988) criteria for effect sizes (ESs) in ANOVAs. Furthermore, the negligible interactions of society with gender and age indicated that the gender and age effects were similar across societies.

The effects of differences among societies were significant for all problem scales scored from all ASEBA instruments for ages  $1\frac{1}{2}$ -90+ years, with ESs ranging from very small to large, according to Cohen's criteria. Interestingly, when the largest societal ESs were identified for each instrument, 27 of the 33 largest ESs were for internalizing scales.

This suggests that societal differences affect the actual prevalence of internalizing problems more than other problems and/or that societal differences affect self- and informant-perceptions of internalizing problems more than other problems. The "other" problems that show smaller societal differences than internalizing problems include not only problems scored on externalizing scales but also problems assessed by scales for attention problems and scales designated as Functional Impairment, Memory/Cognition Problems, Dementia Problems, and Psychotic Problems scored from both the OASR and OABCL. The small societal differences found for these four scales (Rescorla et al., 2020) suggest that the prevalence as well as the self- and informant-perceptions of the problems assessed by these scales vary much less across societies than problems assessed by the OASR and OABCL Worries, DSM-Oriented Anxiety Problems, and DSM-Oriented Somatic Problems scales, for which large societal ESs were found.

## Multicultural Norms for Problem Scales

On most ASEBA instruments, the means of the problem scale scores were distributed approximately normally around the average of the mean problem scale scores for all the societies (i.e., around the omnicultural mean). Figure 19.2 displays the mean CBCL/6-18 Total Problems scores for 42 societies. As can be seen in Figure 19.2, the omnicultural mean (overall mean) was 24.04.

To enable users to view problem scale scores in relation to norms appropriate for the informants completing ASEBA instruments (including selfassessment instruments), multicultural norms were constructed as follows (with some variations for particular instruments, as documented by Achenbach and Rescorla, 2007a, 2010, 2015, 2019):

- 1. For a particular instrument such as the CBCL/ 6-18, we computed the mean Total Problems scores for the normative sample from each available society.
- 2. For most instruments, the distribution of Total Problems scores from multiple societies was close to normal, with approximately two-thirds of the societies' mean Total Problems scores being within  $\pm 1$  SD of the omnicultural mean and one-sixth of the societies' mean Total Problems scores being either greater than 1 SD below the omnicultural mean or greater than 1 SD above the omnicultural mean.

Figure 19.2 Mean CBCL-6-18 Total Problems scores in 42 societies. Copyright 2012, L. A. Rescorla.

- 3. For a particular instrument, we designated societies having mean Total Problems scores of greater than 1 SD below the omnicultural mean as Group 1 (i.e., societies having relatively low problem scores on that instrument). Societies having mean Total Problems scores  $\pm 1$  SD from the omnicultural mean were designated as Group 2 (i.e., societies having intermediate problem scores on that instrument). And societies having mean Total Problems scores greater than 1 SD above the omnicultural mean were designated as Group 3 (i.e., societies having relatively high problem scores).
- 4. To construct Group 1 norms for each problem scale on an instrument, we first computed a cumulative frequency distribution of scores on that problem scale in a Group 1 society's sample, separately for each gender within each age range for which the instrument was normed (e.g., the CBCL/6-18 has separate norms for each gender at ages 6–11 and 12–18). The cumulative frequency distribution generated a percentile for each raw scale score. Separately for each gender within each age group, the percentiles obtained for scores in all the Group 1 samples for a particular problem scale were then averaged to form a Multicultural Group 1 cumulative frequency distribution for that scale.
- 5. Normalized T scores were then assigned on the basis of the averaged percentiles. The normalized T scores and averaged percentiles

were subsequently programmed into a scoring module.

# Multicultural Norms for Personal Strengths and Positive Qualities

ASEBA instruments for ages 18-59 and 60-90+ include items for personal strengths that are interspersed among the problem items. The Personal Strengths scale for each instrument is operationalized by summing the 0-1-2 ratings of the items comprising the scale for that instrument. Multicultural norms for the Personal Strengths scales have been constructed according to procedures like those described earlier for problem scales. Interestingly, the self- and collateral-ratings of personal strengths items are considerably more homogeneous within societies than are ratings of items on each of the problem scales (Rescorla et al., 2016a, 2016b, 2020). As a result of the greater homogeneity within societies, the ESs for differences between societies in Personal Strengths scale scores are considerably larger than the ESs for differences between societies in problem scale scores. Scores on the Positive Qualities scale of the YSR are also much more homogeneous within each society than are scores on problem scales.

The greater within-society homogeneity of selfand collateral-ratings of favorable items than of problem items suggests that the ratings of favorable items reflect societal values and attitudes more than do ratings of problem items. Despite the possible effects of societal values and attitudes on the withinsociety homogeneity of ratings of favorable items, Personal Strengths scores on the instruments for ages 18–90+ and the YSR Positive Qualities scale all discriminated significantly between demographically similar samples of clinically referred and nonreferred individuals (Achenbach et al., 2004; Achenbach & Rescorla, 2001, 2003). In other words, the larger effects of society on ratings of favorable items do not prevent the Personal Strengths and Positive Qualities scales from discriminating significantly between referred and nonreferred individuals within societies.

## Effects of Society, Culture, and Individual Differences on Ratings of Problems and Positive Qualities

The evidence summarized in the foregoing section that ratings are considerably more homogeneous within societies for favorable items than for problem items raises questions about the relative magnitude of effects of society, culture, and individual differences on ratings of problem versus favorable items. As used in this chapter, "societies" refer to geopolitically demarcated populations having a dominant language, including countries but also populations that are not countries, such as Puerto Rico. "Cultures" are harder to define but generally refer to people who share particular sets of characteristics, such as behaviors, attitudes, beliefs, traditions, values, and ideals.

In research to identify major cultural groups around the world, the Global Leadership and Organizational Effectiveness (GLOBE) study (House et al., 2004) obtained measures of attitudes and other characteristics of people in 62 societies. Using these international data, plus previous research and theory, more than 200 scholars from 69 societies classified societies into 10 culture clusters designated as Anglo, Confucian Asia, Eastern Europe, Germanic Europe, Latin America, Latin Europe, Middle East, Nordic Europe, and Southern Asia.

To test the effects of culture cluster, society, and individual differences on CBCL/6-18 ratings of problems for 72,493 children from 45 societies, Rescorla et al. (2019) grouped societies according to the 10 GLOBE culture clusters. They then used hierarchical linear modeling (HLM) to estimate the percentage of variance in 17 CBCL problem scale scores accounted for by culture cluster, society, and individual differences. Averaged across all 17 problem scale scores, Rescorla et al. found that a mean of 4.2% of variance was accounted for by culture cluster, 6.1% of variance was accounted for by society, and 89.8% of variance was accounted for by individual differences and variables not measured in the HLM model. Although the effects of society and culture cluster were each significant at p< .001, together they accounted for a mean of only 10.3% of the variance in scale scores. The effects of individual differences within societies thus greatly outweighed the combined effects of societal and cultural differences. Like the ANOVA findings for societal effects cited earlier, internalizing problems showed larger effects of society and culture cluster (sum = 14.4% of variance) than did externalizing problems (sum = 8.2% of variance).

In a subsequent study, Ivanova et al. (2022) applied similar HLM analyses to scores obtained on 17 YSR problem scales paralleling the 17 CBCL scales, plus the YSR Positive Qualities scale. The scores were obtained by 39,849 youths who completed YSRs in 38 societies from the 10 GLOBE culture clusters. Averaged across all 17 problem scales, Ivanova et al. found that a mean of 1.5% of variance was accounted for by culture cluster, 6.0% of variance was accounted for by society, and 92.5% of variance was accounted for by individual differences. Compared to the 89.8% for the CBCL/6-18, slightly more variance in the YSR (92.5%) was thus accounted for by individual differences. Compared to the 4.2% for the CBCL/6-18, less variance in the YSR was accounted for by culture cluster (1.5%). And about the same amount of variance (6.1% vs. 6.0%) was accounted for by society. However, considerably less variance in YSR Positive Qualities was accounted for by individual differences (83.4%) than was found for the mean of YSR problem scales (92.5%) or CBCL/6-18 problem scales (89.8%). These findings are consistent with Rescorla's findings of greater within-society homogeneity for ratings of favorable items than problem items (Rescorla et al., 2016a, 2020), further indicating that ratings of favorable items are affected by societal/cultural influences more than are ratings of problem items.

## **Applications to Clinical Services**

The instruments described in the foregoing sections are products of the conceptual frameworks of developmental psychopathology and of the empirically based paradigm for assessing and deriving constructs of psychopathology. The instruments are designed for assessing and conceptualizing psychopathology for many purposes that link practical clinical applications to assessment of individuals' needs for help; research to advance understanding, prevention, and treatment of psychopathology; and training of practitioners, as addressed in the following sections.

ASEBA instruments can be used in many settings with many service models and requiring little clinician time or cost. The full-length instruments described so far can be completed in about 10-20 minutes on paper or online. (Briefer instruments will be presented later.) Instruments completed on paper can be scored by clerical workers on handscored profiles or can be entered into computers for scoring and storing data. Instruments can be completed online using desktops, laptops, tablets, and smartphones. When entered online, the data are scored automatically for access by clinicians. For informants who cannot complete the instruments independently, interviewers with no specialized training-such as receptionists-can read the items aloud and enter the responses.

When used in clinical settings, all ASEBA instruments can be routinely completed by clients and informants. Profiles of scale scores, comparisons of item ratings by different informants, *Q* correlations between 0-1-2 ratings of problem items by different informants, graphs of scale scores, and other information can be generated by PC and Web versions of ASEBA software, with scale scores displayed in relation to multicultural norms appropriate for each informant.

## Multicultural Family Assessment Module

For family therapy, the Multicultural Family Assessment Module (MFAM; Achenbach, Rescorla, & Ivanova, 2015) can be used to display bar graphs of problem scale scores obtained from ratings of a child by multiple informants (child, mother, father, other family members, teachers) on side-by-side bar graphs that show how the child appears to different informants. Moreover, the MFAM displays bar graphs of problem scales scored from ASRs completed by each parent or other family member to describe themselves and ABCLs completed to describe their partner or other adult family members. As Figure 19.3 shows, the MFAM generates bar graphs that compare child and adult scale scores on syndromes that have counterparts for ages 6-18 and 18-59. The MFAM also generates bar graphs that compare child and adult scale scores on DSMoriented scales.

If clinicians deem it appropriate, they can show MFAM bar graphs to family members and encourage them to point out similarities and differences between magnitudes of scores obtained from different informants' ratings. For example, ratings by

three of a boy's teachers may be elevated on the DSM-oriented ADH Problems scale, whereas ratings by the boy's parents are in the normal range on this scale. Although the teachers view the boy as having attention deficit hyperactivity disorder (ADHD), the parents say he that he cannot have ADHD because he spends hours engrossed in video games. The elevated scores on the ADH Problems scale scored from TRFs completed by the boy's teachers provide detailed documentation of the teachers' perceptions of the boy's problems in three different classrooms, but the normal-range scores on the ADH Problems scale scored from the CBCLs completed by the boy's parents and their reports of his engrossment in video games indicate that interventions for ADHD problems should focus on the boy's functioning in school rather than being based on the assumption that he has an inherent attention deficit that affects his functioning at home as well as school.

Another clinically useful function of the MFAM is to reveal similarities and differences between child and parent scores on counterpart scales. For example, if a mother and daughter both have elevated scores on the Anxious/Depressed syndrome scale, this suggests that they may both need help in this area. Even when a child is the identified client, elevated problem scale scores for parents and marked discrepancies between parents' ratings of themselves and their partner may provide a basis for interventions to help the parents.

## Progress and Outcomes App

It is increasingly recognized that evidence-based assessments of progress and outcomes are essential for optimizing and evaluating mental health and related services. By comparing data from standardized assessments administered at intake into a service and again on subsequent occasions during and at the end of the service, clinicians can obtain evidence for improvements and other changes in client functioning. If improvement is insufficient, clinicians can use data obtained from repeated assessments to guide changes in services. When possible, it is also valuable to repeat assessments after services end in order to evaluate outcomes over periods such as 6–12 months.

To help clinicians compare repeated assessments of their clients, the Progress and Outcomes (P&O) App (Achenbach, 2020a, 2020b) generates bar graphs of ASEBA problems and strengths scale scores obtained for individual clients on two or more occasions. To determine whether changes in scale scores exceed chance expectations, the P&O

Multi-Informant Comparison - Syndrome Scale T Scores

\* nc = The scores are not computed due to missing data.

Figure 19.3 Bar graphs produced by the Muticultural Family Assessment Module (MFAM) displaying syndrome scores for Lana, Martin, and their son Robert.

Copyright 2015, Achenbech & Rescorla.

App does statistical computations based on the standard error of measurement. Without the clinician doing any statistics, the P&O App's output displays asterisks with bars for scale scores that show changes exceeding chance expectations from one assessment to another. Data from multiple informants can be included in the output, which clinicians can show clients for discussion of the evidence for improvement and/or possible needs for changes in services.

For users who wish to compare outcomes for groups of clients receiving different service conditions, the P&O App can apply chi square and ANOVA/ANCOVA statistical analyses. The ASEBA Manual for Assessing Progress & Outcomes of Problems & Strengths (Achenbach, 2020a), provides details of various ways to evaluate progress and outcomes for groups as well as for individual clients.

#### Brief Problem Monitor

The full-length ASEBA forms presented so far provide the input for the P&O App, which tests changes over periods of months to years. For briefer assessments of changes over periods of days, weeks, or months, versions of the Brief Problem Monitor

(BPM) can be filled out online or on paper in 1-2minutes to assess internalizing, externalizing, attention problems, and Total Problems over a period specified by the clinician (e.g., 7 days). Whereas the P&O App measures changes over longer periods, the BPM measures changes that occur in relation to interventions rendered over limited time intervals, such as contingency management to reduce a child's disruptive behavior in a classroom. Separate versions of the BPM are designed for completion by parents and teachers of 6- to 18-year-olds (BPM-P, BPM-T), for completion by 11- to 18-year-old youths to describe themselves (BPM-Y), and for completion by 18- to 59-year-olds and their collaterals (BPM/18-59; Achenbach & Ivanova, 2018; Achenbach et al., 2017). Software for scoring the various versions of the BPM generates bar graphs comparing scale scores obtained from multiple informants on multiple occasions, plus line graphs comparing trajectories of scores over 2-10 occasions. Like the other instruments described in this chapter, the scale scores are standardized for the gender and age of the person being assessed, the type of informant (parent, teacher, youth, adult,

adult collateral), and the appropriate multicultural norm group.

## **Applications to Research**

In addition to providing practical clinical assessment of psychopathology for ages 1½–90+ years in societies around the world, the empirically based instruments have yielded syndromal constructs and broad-spectrum aggregations of syndromes on which research is targeted. Scale scores for individuals assessed with the instruments in turn provide operational definitions of the constructs in many kinds of research, as reported in more than 11,000 publications from more than 100 societies and cultural groups (Pascal & Achenbach, 2021). The following sections provide illustrations of research applications of the empirically based assessment instruments and constructs derived from them.

# Genetic and Environmental Effects on Informant Discrepancies

Dutch researchers have tested the degree to which discrepancies between informants' ratings reflect "informant biases" versus differences in genetically and environmentally influenced aspects of functioning that may be captured by different informants' ratings. In one study, CBCL/11/2-5 internalizing and externalizing scores were compared for mothers' versus fathers' ratings of 3,501 pairs of 3-year-old twins (van der Valk et al., 2001). Based on correlations between mothers' and fathers' ratings of monozygotic (MZ) and dizygotic (DZ) twins, genetic modeling showed that mother-versus-father discrepancies validly captured different genetically influenced aspects of the children's functioning rather than being artifacts of informant biases. Longitudinal studies of parents' ratings of Dutch twins have also shown that mother-versus-father discrepancies validly capture different genetically influenced aspects of the children's functioning over multiple developmental periods (Bartels et al., 2004, 2007).

Even though mothers and fathers see their children under generally similar conditions, the foregoing studies show that each parent may nevertheless capture different genetically influenced aspects of their children's functioning. The differences between the aspects of their children's functioning captured by mother-versus-father ratings may reflect differences in children's interactions with their mothers versus fathers, or differences between what mothers and fathers perceive and remember, or both. Additional Dutch research has tested genetic and environmentally influenced aspects of 7-year-old twins' functioning in the markedly different environments of home versus school, as rated by mothers versus teachers, who play markedly different roles vis-à-vis the children (Derks et al., 2006). For more than 2,000 pairs of twins, Attention Problems syndrome scores from the CBCL/6-18 and TRF yielded an estimate of 32% of variance for genetically influenced aspects of scores that were common to mother and teacher ratings. An additional 9% of variance that was common to mother and teacher ratings reflected environmentally influenced aspects of Attention Problems scores.

Of the variance that was specific to mothers' ratings, 45% was accounted for by genetic influences, whereas 14% was accounted for by environmental influences. Of the variance that was specific to teachers' ratings, 23% was accounted for by genetic influences, whereas 36% was accounted for by environmental influences. Like the findings for motherversus-father ratings of 3-year-olds, these findings show that discrepancies between mother-versusteacher ratings validly reflect differences in genetic and environmental effects, rather than just informant biases.

## Longitudinal Studies

Repeated assessments of the same individuals as they grow older are essential components of the developmental study of psychopathology across the life span. The value of repeated assessments can be maximized by including procedures that can be directly linked across developmental periods while taking account of developmental changes in the aspects of functioning to be assessed, the sources of assessment data, and the normative distributions of scores with which to compare individuals' scores. To avoid ethnocentric assumptions that longitudinal findings in one society are automatically generalizable to other societies, it is also important to compare results from different societies where similar assessment procedures and longitudinal methods are used.

US National Longitudinal Study. The US National Longitudinal Study initially assessed a nationally representative sample of 2,734 4- to 16-year-olds on the basis of home interviews in which parents rated their children's problems and competencies and reported on many child and family variables. Subsequent assessments 3, 6, and 9 years later included parent, teacher, and self-ratings on instruments that assessed ASEBA models for psychopathology, plus reports of signs of disturbance, such as suicidal behavior, receipt of mental health services, trouble with the law, substance abuse, and being fired from a job.

Scores on scales for empirically based syndromes significantly predicted scores on the corresponding syndrome scales and various signs of disturbance at 3-, 6-, and 9-year intervals, after controlling for numerous demographic and other variables (Achenbach et al., 1995a, 1995b, 1995c, 1998; Wadsworth & Achenbach, 2005). The empirically based syndrome models for psychopathology and the assessment procedures for operationalizing them thus revealed considerable continuity in patterns of problems from early childhood to adolescence and from adolescence to young adulthood. The findings also showed that the empirically based syndrome scores could predict signs of disturbance that were not included in the syndrome models. Parent, teacher, and selfratings on competence and adaptive strengths scales added significantly to the prediction of signs of disturbance, especially to the prediction of total disturbance scores, which aggregated the different signs of disturbance.

Developmental Course of Relations Between Psychopathology and SES. In addition to testing the developmental continuity and predictive power of the empirically based models, the US National Longitudinal Study tested hypotheses that required data spanning multiple developmental periods in a representative population sample. As an example, Wadsworth and Achenbach (2005) tested the hypothesis that factors associated with SES contribute to differences in levels of psychopathology. Early cross-sectional studies had found that psychopathology is more prevalent among lower SES than upper SES adults (e.g., Hollingshead & Redlich, 1958). However, cross-sectional studies of adults cannot test the extent to which the higher prevalence results from "downward drift" in SES among adults whose psychopathology impairs their ability to maintain higher SES or instead results from a higher initial incidence of psychopathology among lower SES people.

To prevent the possible contribution of downward drift from confounding research on relations between SES and psychopathology, it is necessary to compare the developmental courses of psychopathology for children whose families differ in SES. This excludes downward drift as an explanation because children's psychopathology is not apt to cause their families' SES to drift downward.

Over the 9 years of the US National Longitudinal Study, it was found that the scores of significantly more children from low SES than high SES families increased from the normal to the clinical range on the ASEBA Anxious/Depressed, Somatic Complaints, Thought Problems, Rule-Breaking Behavior, and Aggressive Behavior syndromes. These findings supported the hypothesis that low SES predicts developmental increases in the problems modeled by these syndromes. However, it was also found that, among children who initially obtained clinically elevated scores on the Withdrawn/Depressed and Somatic Complaints syndromes, fewer from low SES than higher SES families subsequently obtained scores in the normal range. For these particular kinds of problems, the evidence thus indicated a greater "cumulative prevalence" of elevated problem scores among lower than higher SES children. In other words, there was a greater developmental accumulation of (i.e., less remission of) elevated scores among children from lower than higher SES families. Both the greater incidence and greater cumulative prevalence of particular kinds of problems thus contributed to the higher prevalence of psychopathology among those born into lower than higher SES families.

Zuid Holland Longitudinal Study. A Dutch longitudinal study started with parents' ratings of their 4- to 16-year-old children on Dutch translations of the ASEBA instruments that were used in the US National Longitudinal Study (Verhulst, Akkerhuis, & Althaus, 1985). The Dutch parents also reported on child and family variables like those assessed in the US study. The sample was selected to be representative of 4- to 16-year-olds living in the Province of Zuid (South) Holland. The participants were then reassessed at four 2-year intervals, followed by 6- and 10-year intervals, over a total of 24 years, when the oldest participants were 40 years old. At every assessment, Dutch translations of developmentally appropriate versions of the US instruments were completed by participants and by informants who knew the participants. Standardized diagnostic interviews (SDIs) were also administered to adult participants, and the participants and other informants provided data on signs of disturbance and other aspects of functioning. The participants' own children were eventually assessed with the ASEBA instruments that had been used to assess the participants when they were children. The participants' childhood ASEBA scores were found to significantly predict their children's ASEBA scores (van Meurs et al., 2009).

For 1,365 participants rated by their parents at the initial assessment and rated by themselves 24 years later, high scores on all the ASEBA syndromes rated by their parents significantly predicted high scores 24 years later on the self-rated counterparts of the syndromes, with the exception of the Thought Problems and Attention Problems syndromes (Reef et al., 2009). These findings thus indicated homotypic continuity (i.e., consistency of low, medium, or high scores on the same syndromes) over 24 years for the Anxious/Depressed, Withdrawn, Somatic Complaints, Rule-Breaking Behavior, and Aggressive Behavior syndromes, despite the difference in raters (parents initially, self 24 years later).

Although not significantly predicted by their parents' initial ratings on the Thought Problems syndrome, the adults' self-ratings on this syndrome were significantly predicted by parents' initial ratings on the Anxious/Depressed, Attention Problems, Rule-Breaking Behavior, and Aggressive Behavior syndromes. Moreover, the adults' selfratings on the Attention Problems syndrome were significantly predicted by their parents' initial ratings on the Anxious/Depressed and Thought Problems syndromes. The significant prediction of adult Thought Problems and Attention Problems ratings from scores on other syndromes thus indicated heterotypic continuity for these kinds of problems. The parents' initial ratings also significantly predicted DSM diagnoses made from SDIs administered to their adult offspring 24 years later (Reef et al., 2010).

Multi-Informant Ratings from Age 4 to 40 Years. Ratings of the Dutch participants by multiple informants at all seven assessment points enabled the research team to compute agreement between ratings by 12,059 informant pairs when the participants were assessed at various ages from 4 to 40 years (Van der Ende et al., 2012). Cross-informant correlations between ratings of internalizing and externalizing problems were computed from parent, teacher, adult partner, and self-ratings. The magnitudes of the cross-informant correlations were similar to those found previously in meta-analyses of cross-informant correlations (Achenbach et al., 1987, 2005) and depended more on the kinds of informant pairs than on the age of the participants or on whether the ratings were for internalizing or externalizing problems. Participants were found to rate themselves higher on the problem scales than their parents, teachers, or partners rated them. Multicultural comparisons of parents' CBCL ratings versus youths' YSR ratings have also shown that youths rated themselves higher than parents rated them on counterpart problem scales in 25 very diverse societies (Rescorla et al., 2013). The differences found between self-versus-informant ratings of people of different ages and in diverse societies further underscore the need for multi-informant assessment of psychopathology.

Dutch versus US Developmental Trajectories. The parallel assessment instruments used in the Zuid Holland and US longitudinal studies have enabled researchers to rigorously compare developmental trajectories for psychopathology in the Netherlands versus the United States. As an example, the data used in the previously described Wadsworth and Achenbach (2005) test of associations between SES and the development of psychopathology were compared with data from the Zuid Holland study to determine whether conclusions would differ for the US versus Dutch populations (Van Oort et al., 2011). Comparisons of this sort are especially important, because smaller economic differences and more equal access to healthcare for lower versus upper SES families in countries such as the Netherlands than in the US could affect associations between SES and the development of psychopathology.

Parents' ratings of 833 US children and 708 Dutch children were compared for assessments spanning 9 years in both societies. After correcting for chance differences, only minor Dutch-US differences were found between tendencies for the incidence and cumulative prevalence of clinically elevated scores on certain syndromes to be higher for children from lower than higher SES families. Although more detailed data on SES, plus data from more societies, might support other conclusions, the similarity of findings in Dutch and US population samples are consistent with findings from a review of studies in 15 societies where empirically based problem scale scores were consistently found to be higher for children of lower than higher SES families (Achenbach & Rescorla, 2007b).

Generation R Longitudinal Study. Another Dutch longitudinal study started with 8,880 women living in Rotterdam who were assessed during pregnancy. ("R" in "Generation R" stands for Rotterdam.) The pregnant women were assessed via ultrasound, blood and urine samples, and questionnaires, while fathers of the children were assessed via blood samples and questionnaires. Over the first 5 postnatal years, the children were assessed via biological, observational, questionnaire, and other measures, and they are continuing to be assessed at later ages. Numerous

467

Generation R findings of associations between prenatal and postnatal variables have been published (reviewed by Tiemeier et al., 2012). The Generation R study's use of standardized rating instruments from the ASEBA family of instruments used in the US and Zuid Holland longitudinal studies enables researchers to analyze the developmental course of psychopathology in terms of the empirically based models used in those studies, as well as in many other studies.

As an example, mothers and fathers rated Generation R children on the CBCL/11/2-5 at ages 3 and 5. Children who were identified as having small subcortical volumes via brain imaging at postnatal age 6 weeks were found to have significantly higher internalizing problem scores than other children on the CBCL at age 3 (Herba et al., 2010). Furthermore, at age 5, elevated internalizing scores were found for children who carried the short allele of the 5-HTTLPR polymorphism in the promoter region of the serotonin transporter gene (5-HTT, SLC6A4) and whose mothers reported high levels of anxiety at prenatal assessments and/or postnatal assessments (Tiemeier et al., 2012). This finding is important because previous studies have yielded inconsistent results regarding interactions between the short allele of the 5-HTTLPR polymorphism and individuals' own stressful experiences during childhood. Caspi et al. (2003) initially reported that carriers of the short allele were at elevated risk for developing depression after maltreatment and other stressful childhood experiences. However, several subsequent studies failed to support this geneenvironment (G×E) interaction (e.g., Risch et al., 2009), while other studies concluded that inclusion of chronic illnesses as stressors and use of observational data on stress provided support for the G×E interaction (e.g., Caspi et al., 2010).

Because serotonin appears at about 5 weeks after conception, differences in serotonin transporter availability related to the 5-HTTLPR polymorphism could affect vulnerability to effects of prenatal stressors such as maternal anxiety. Generation R findings that mothers' anxiety during either the prenatal or postnatal period (with prenatal anxiety controlled) predicted subsequent elevations in age 5 CBCL internalizing scores for children with the short allele suggest that maternal anxiety can affect children with the short allele by both prenatal intrauterine processes and postnatal environmental processes. Furthermore, when mothers had high anxiety either prenatally or postnatally, children with two short alleles obtained higher CBCL internalizing scores than did children with a single short allele who, in turn, obtained higher internalizing scores than children with no short alleles. However, children whose mothers did not report much anxiety either prenatally or postnatally obtained low internalizing scores, regardless of whether they had 0, 1, or 2 short alleles. In other words, high prenatal and postnatal maternal anxiety levels were associated with high age 5 internalizing scores, but short alleles appeared to exacerbate internalizing problems only among children whose mothers reported high anxiety either pre- or postnatally.

Although the Generation R findings indicate that the short and long 5-HTTLPR alleles differentially affect children's reactions to pre- and postnatal stress, the effects were very small. Technological advances in many facets of research, such as genetic and neuroimaging methods, are greatly increasing the power of research to detect very small effects of this sort. Each small effect may be important, but the many small effects are further complicated by myriad interactions among them. Consequently, developmentally appropriate multivariate phenotypic models and standardized procedures for assessing them are needed to provide common foci across studies of the many potentially relevant variables and the interactions among them.

## **Applications to Training**

With advances in evidence-based practice, it is essential for mental health trainees to learn the use of evidence-based assessment to provide foundations for applying and evaluating the progress and outcomes of evidence-based treatment. Empirically based instruments serve as tools for obtaining multi-informant evidence regarding the problems and strengths of clients across the life span. By routinely using developmentally appropriate ASEBA instruments, trainees can obtain well-differentiated pictures of clients' specific problems and strengths, as seen from multiple perspectives. Trainees can also compare aggregations of problems and strengths to norms based on population samples of peers in terms of standardized scale scores for empirically based and DSM-oriented constructs. If trainees examine clients' completed forms and scored profiles before interviewing the clients, they can use the data as a take-off point for interviewing. Trainees can begin by asking clients whether they have questions about the forms and can then ask them about items they endorsed and comments they entered. For example, if a youth endorsed the YSR item "I can't get my mind off certain thoughts" and entered

"death" in the space for a description, the trainee can say "I see that you can't get your mind off death. Please tell me more about that."

After trainees become acquainted with clients, they can fill out the appropriate ASEBA self-report form (YSR, ASR, or OASR) for comparison with the clients' own responses to the form filled out at a progress or outcome assessment. To sharpen trainees' clinical skills, they can discuss discrepancies between their responses and the self-reports with supervisors.

## Conclusion

This chapter was organized around the frameworks of developmental psychopathology and empirically based assessment and taxonomy. Although developmental psychopathology originated with efforts to understand maladaptive functioning from birth to maturity, it has become clear that understanding psychopathology of adulthood and later life can also benefit from a developmental approach. In the 1960s, the lack of empirically based differentiation among childhood disorders prompted multivariate research that identified several narrow-spectrum syndromes of co-occurring problems, plus broad-spectrum groupings of problems designated as internalizing and externalizing. Findings for large samples of children revealed hierarchies of problems that spanned from numerous specific problems at the bottom most molecular level, to syndromes of co-occurring problems at the next higher level, to aggregations of mutually associated syndromes into internalizing and externalizing groupings at the next higher level, and culminating in a general psychopathology dimension (p) at the top most molar level.

Assessment instruments tailored to ages 11/2-5, 6-18, 18-59, and 60-90+ years filled out by appropriate informants (parents, daycare providers, teachers, self, adult collaterals) were used to assess clinical and general population samples from which empirically based problem scales were derived via EFAs and CFAs. Large general population samples of "healthy" individuals (i.e., not referred for mental health services) were used to construct norms based on distributions of scores obtained for each gender within particular age ranges and rated by particular kinds of informants. A life span approach was used whereby assessment instruments and their items were tailored to successive developmental periods, and the informants were chosen to be appropriate for the respective developmental periods. It was not assumed that disorders would be the same across developmental periods. Instead, longitudinal

studies were used to test for possible homotypic and heterotypic continuities between empirically derived taxonomic constructs from earlier to later developmental periods. The studies also tested the effects of diverse variables on the developmental course of psychopathology and competencies.

The assessment instruments produced by this research are designed for practical applications in diverse clinical and research contexts. In addition to being designed for initial assessment, the instruments are designed for repeated administration to assess progress and outcomes and to measure changes from earlier to later assessments across the life span. Brief versions of the instruments are available that can be completed in 1-2 minutes at userselected intervals of days, weeks, or months.

To test the generalizability of the syndromes derived from mainly US samples, CFAs have been performed on problem item ratings obtained in population samples from more than 50 non-US societies on all inhabited continents. Despite the many differences among the societies, the empirically derived syndrome structures have been supported for ages 11/2-5 through 90+ years in ratings by different informants. Moreover, Q correlations between the 0-1-2 ratings of problem items across different societies have averaged in the .70s for all age groups rated by different informants. These findings indicate considerable consistency in the quantitative measurement of problem item structures around the world.

Comparisons of mean problem scale scores (sum of 0-1-2 ratings on items comprising a scale) across many societies have yielded approximately normal distributions for most problem scales in each age group. On each instrument, mean Total Problems scores for approximately two-thirds of societies were within ±1 SD of the omnicultural mean (mean of the mean Total Problems scores obtained in all the societies for that instrument), while approximately one-sixth were greater than 1 SD below the omnicultural mean (designated as "low-scoring" or Group 1 societies) and one-sixth were greater than 1 SD above the omnicultural mean ("high-scoring" or Group 3 societies). Scores for Group 1 societies were averaged to construct Group 1 norms and likewise for Group 2 and Group 3. (Because scores for US normative samples were at the middle of the Group 2 distributions for some instruments, those Group 2 norms were based on the already widely used US norms.) Multicultural norms were also constructed for the ages 18-59 and 60-90+ Personal Strengths scales and for the ages 11–18 Positive Qualities scale.

Tests of the effects of culture cluster (e.g., Confucian), society, and individual differences on CBCL/6-18 ratings in 45 societies revealed that culture cluster differences accounted for a mean of 4.2% of variance in problem scale scores, societal differences accounted for a mean of 6.1% of variance, and variables associated with individual differences accounted for 89.8% of variance. For YSR ratings in 38 societies, culture cluster differences accounted for a mean of 1.5% of variance in problem scale scores, societal differences accounted for a mean of 6.0% of variance, and individual differences accounted for 92.5% of variance. For the YSR Positive Qualities scale, culture cluster differences accounted for 6.5% of variance, societal differences accounted for 10.1% of variance, and individual differences accounted for 83.4% of variance. Although the effects of cultural and societal differences were statistically significant (except on YSR problem scores), individual differences within culture clusters and societies greatly outweighed societal and cultural differences in ratings of problems on the CBCL/6-18 and both problems and Positive Qualities on the YSR.

The empirically based instruments were designed for use in many clinical settings employing many service models. Empirically based forms completed online or on paper are scored on profiles that compare individuals' scores with norms and with scores from other informants. The MFAM compares scores obtained by child clients with scores obtained by adult family members on syndromes and *DSM*oriented scales that have counterparts for ages 6–18 and 18–59. The P&O App provides statistical tests of differences between scores obtained at different points in time.

Research applications of the empirically based instruments have included tests of genetic and environmental effects on informant discrepancies, longitudinal studies, and many other kinds of studies.

The empirically based instruments facilitate training in evidence-based practice by providing trainees with well-differentiated pictures of clients' problems and strengths, tools for assessing progress and outcomes, and methods for comparing trainees' perceptions of clients with the clients' self-perceptions and perceptions by multiple informants.

## Attention Deficit Hyperactivity Disorder

Siri Noordermeer and Jaap Oosterlaan

Individuals with attention deficit hyperactivity disorder (ADHD) suffer from persistent and age-inappropriate levels of inattention and/or hyperactivity-impulsivity, occurring in multiple situations, to such a degree that symptoms have a severely detrimental impact on their daily life functioning or development. Throughout the past decades, scientific interest in ADHD and knowledge about the disorder have grown exponentially. While a large body of research is available on ADHD, the number of unanswered questions remains substantial. ADHD has proved to be a heterogeneous disorder, causing a difficult challenge for research to create a consistent image of the disorder. Partly due to this heterogeneity, the past three decades have been characterized by an increase in questions and concerns about the validity of ADHD and stigmatization of patients diagnosed with the disorder (Mueller et al., 2012). This chapter covers the prevalence, course, comorbidities, and functional impact of ADHD, as well as diagnosis, treatment, and etiology and risk factors of the disorder. We hope to convey the heterogeneity and complexity of ADHD and provide an extensive and critical overview of our current understanding of the disorder.

## **A Short History**

It is frequently thought that ADHD is a "twentyfirst-century disorder," caused by the abundant stimuli which are part of the current information technology society (e.g., TV, smartphones, social media), resulting in an information overload too intense for many children to cope with. Although a range of societal factors might potentially contribute to the number of children diagnosed with ADHD, ADHD-like symptoms were reported as early as 1902 (Spencer et al., 2007). Early reports of ADHD-like behavior were primarily focused

474

on children's malfunctioning and mainly targeted symptoms of hyperactivity and impulsivity. For decades, these children were described as having minimal brain damage (MBD), which was later nuanced to minimal brain dysfunctioning as at that time no evidence was found for brain abnormalities. In 1968, DSM-II introduced a childhood mental disorder characterized by hyperactivity, labeled "hyperkinetic reaction of childhood." With the release of DSM-III in 1980, symptoms of inattention were also recognized as part of the disorder and even became the major focus. The condition was renamed as "attention deficit disorder," and it could either be diagnosed with or without hyperactivity. DSM-IV again redefined the diagnosis in 1994, distinguishing the predominantly inattentive (ADHD-I) and predominantly hyperactiveimpulsive (ADHD-H) subtypes, as well as the combined subtype (ADHD-C), which describes children showing both inattentive and hyperactiveimpulsive symptoms. Although debate is ongoing regarding the validity of this distinction (Coghill & Seth, 2011), the current version of DSM (DSM-5) retains these subtypes, which are now called

Abbreviations						
	ADHD-C	ADHD-combined				
	ADHD-H	ADHD-hyperactive/impulsive				
	ADHD-I	ADHD-inattentive

		tomography				

presentations. The eleventh edition of the alternative classification system, the *ICD-11*, includes a comparable diagnosis of attention-deficit hyperactivity, with previous editions including the diagnosis of hyperkinetic disorder, and describes a set of symptoms similar to the *DSM* combined presentation. Similar to the *DSM-5*, the *ICD-11* now also differentiates between three types: inattentive, hyperactive-impulsive, and combined.

## Prevalence, Course, Comorbidities and Functional Impact

## Prevalence

The most recent estimate, based on a large number of studies, is that 7.2% of children worldwide suffer from (any presentation of) ADHD (Thomas et al., 2015). However, prevalence rates of ADHD vary dramatically between studies. Through the years, reported rates in different countries have ranged from as low as 1% to as high as 20% among school-aged children. Some of this variability is likely attributable to a rise in clinical referrals and diagnoses throughout the years, as shown by US national surveys (Robison et al., 1999; Visser et al., 2010). However, other factors may also play a role, such as the classification system used to determine the diagnosis of ADHD. The two most commonly used diagnostic classification systems, DSM and ICD, focus on slightly different aspects of the disorder, and, even within these systems, different versions have employed different diagnostic criteria over the years. In addition, a diagnosis of ADHD requires symptoms to be present in different contexts (pervasiveness of symptoms) and to cause impairment in daily life functioning, but studies differ in terms of the adoption of these two criteria, resulting in different prevalence rates. Moreover, the use of different informants, such as clinicians or teachers, is associated with different prevalence estimates (Faraone et al., 2015). Region of study has been suggested to be associated with variability of prevalence estimates as well, but a review reported that after accounting for the aforementioned factors the prevalence of ADHD does not differ between countries in Europe, Asia, Africa, the Americas, and Australia (Faraone et al., 2015; Thomas et al., 2015). Interestingly, despite popular opinion, there is no evidence for an increase in the actual prevalence of ADHD over the past three decades (Faraone et al., 2015).

In general, boys are two to three times more likely to be diagnosed with ADHD than are girls (Ramtekkar et al., 2010; Willcutt, 2012). Among all individuals with ADHD (children and adults alike), females are more likely to meet criteria for the inattentive presentation, while males are more likely to be diagnosed with the combined presentation (Willcutt, 2012). The fact that inattentive behavior is less disturbing and burdensome for the family and school than hyperactive-impulsive behavior, combined with the fact that girls with ADHD are less likely to suffer from accompanying disruptive disorders (Spencer et al., 2007), may result in girls being underdiagnosed with ADHD. Hence, it is possible that the prevalence of ADHD may not even differ between boys and girls as much as previously thought, but rather reflects lower rates of clinical referrals in girls. This possibility is substantiated by findings of (more) equal prevalence estimates of ADHD in adult males and females (Cortese, Faraone, et al., 2016; Murray et al., 2019; Simon et al., 2009).

## **Developmental Course**

ADHD was initially recognized as only a childhood disorder, and it was thought to largely remit in adolescence. However, recent literature shows that in a large number of cases at least some symptoms persist into adulthood. Persistence rates are highly dependent on the definition of persistence used, with pooled estimates from follow-up studies showing that at age 25, approximately 15% of ADHD patients still meet full criteria for ADHD. Using a more lenient approach, focusing on "ADHD in partial remission," provides a much larger persistence percentage of approximately 65% (Faraone et al., 2006). A more recent follow-up study even reported persistent ADHD (meeting full criteria) in 79% of adolescents and young adults (Cheung et al., 2015).

In addition to children with ADHD persisting into adulthood, there also seems to be an adult- or a late-onset variant of the disorder, although the exact prevalence of this variant of the disorder is unclear. However, it appears to be considerable, since the available studies into (young) adults with ADHD report the percentage of late-onset cases to range between 68% and 88% (Caye et al., 2016). Interestingly, during retrospective assessment, the majority of individuals with the late-onset variant did not meet diagnostic criteria for ADHD as children, although they seem to exhibit (at least some) symptoms in adolescence (i.e., between the ages of 12 and 16; Asherson & Agnew-Blais, 2019). Since the discrepancy between boys and girls (almost) vanishes during adulthood, it may be that women are more represented in the late-onset group, given that

females were more likely to show large symptom increases in adolescence rather than in childhood (Murray et al., 2019). Another possible explanation for the adult- or late-onset variant of the disorder may be that this variant in fact represents cases that remained undetected in childhood due to a lack of proper assessment or care (Taylor et al., 2021).

ADHD prevalence is estimated at 5% in young adulthood (Willcutt, 2012) and at 3–4% in adults (Fayyad et al., 2017; Polanczyk & Rohde, 2007) and in old age (> 60 years) (Michielsen et al., 2012), percentages very similar to prevalence rates in childhood and adolescence. Altogether, these numbers show a fairly consistent image of the prevalence of ADHD. Although ADHD is still best described as a disorder that originates in childhood, and often at least partly—persists into adulthood, late-onset ADHD may account for a substantial number of cases.

## Comorbidities and Functional Impact

More often than not, ADHD patients experience comorbid disorders and problems (Gillberg et al., 2004; Spencer et al., 2007). Externalizing disorders most frequently reported in children with ADHD include oppositional defiant disorder (ODD) and conduct disorder (CD), with estimates around 60% for ODD and about 40% for CD (Connor et al., 2010). Although often less expected, children with ADHD frequently also experience serious internalizing problems, such as mood or anxiety disorders (with estimates varying between 15% and 45%; Elia et al., 2008; Spencer et al., 2007). Other comorbidities frequently associated with pediatric or adolescent ADHD include autism spectrum disorders (65-80% show several symptoms of autistic disorder; Gillberg et al., 2004), learning disabilities including reading disorder (15-45%; Sexton et al., 2012; Spencer et al., 2007), sleep disorders (25-50%; Corkum et al., 1998), tic disorders (8-33%; Kadesjö & Gillberg, 2003; Palumbo et al., 2004; Steinhausen et al., 2006; The MTA Cooperative Group, 1999), substance use disorders (1.35-2.36 times increased chance of developing nicotine dependence or alcohol or drug abuse; Charach et al., 2011), and developmental coordination disorder (~50%; Gillberg et al., 2004). Adults with ADHD are reported to have a 1.5 to 7 times increased likelihood of developing mood, anxiety, and substance use disorders (Kessler et al., 2006).

Even in the absence of comorbid disorders, ADHD has a major impact on the patient's life, as well as on society as a whole. Children and adolescents with ADHD often suffer from poor social skills leading to conflicted peer relationships and social rejection by peers, low self-esteem, adverse academic outcomes, and increased school failure (Faraone et al., 2015). Moreover, these children and adolescents show more delinquent behavior, suffer more often from injuries and accidents, and are frequently seen as a burden on their families, where there is an increased risk for parental and family conflict. In adolescence, ADHD patients have been shown to start smoking at an earlier age and smoke more on a daily basis (Lee et al., 2011; McClernon & Kollins, 2008) and to engage in risky sexual behavior more often (Flory et al., 2006).

When looking at adult or lifetime ADHD, it is clear that the disorder has a strong negative impact on an individual's overall functioning, expressed in terms of academic and vocational underachievement, a lower socioeconomic status, marital difficulties, and general health problems such as obesity (Biederman et al., 1993, 2006; Faraone et al., 2015; Sawyer et al., 2002). Occurrence of antisocial behaviors, including theft, assault, vandalism, traffic violations, or disorderly conduct, is highly increased in adults with lifetime ADHD, and a higher number of individuals are arrested, convicted, and incarcerated (Barkley et al., 2004; Biederman et al., 2006; Küpper et al., 2012). Mental health problems are reported in the majority of adults with ADHD, including depression, anxiety disorder, antisocial personality disorder, and substance use disorder (Biederman et al., 2006; Küpper et al., 2012). In the workplace, individuals with ADHD may suffer from poor productivity, absenteeism, and general occupational underachievement or unemployment, partly as a result of other comorbid mental health problems as mentioned before (Küpper et al., 2012). In the United States, it has been shown that ADHD has a "substantial economic impact," most specifically due to extra costs in healthcare and education in children with ADHD and loss of productivity and income loss in adults (Doshi et al., 2012).

## **Current Diagnostic Issues**

The validity of ADHD and its three presentations is a prominent topic of discussion. Several issues can be pointed out in the current diagnostic criteria and procedures that may limit their use in clinical practice and seem to play a large role in the current controversy regarding the existence and validity of the disorder.

A first important issue is the subjective weighing of behavioral criteria to diagnose ADHD. Both symptom dimensions of ADHD-inattention and hyperactive/impulsive behavior-should be seen as parts of continua, which range from typical to severely abnormal behavior. While ADHD patients characteristically have more severe symptoms of inattention and hyperactivity/impulsivity than individuals in the "normal population," the cutoff between "normal variation" and "abnormal behavior" is rather arbitrary. In this context, functional impairment is a key criterion that should be fulfilled to establish the diagnosis of ADHD. However, here a second issue arises due to the subjectivity in assessing if the symptoms interfere with or cause an actual reduction in the quality of an individual's social, academic, or occupational functioning. Although impairment in itself remains a subjective criterion, it plays a pivotal role in the diagnostic process and should be reviewed critically. Another important criterion for the diagnosis of ADHD, as previously mentioned, is pervasiveness. This criterion posits that several symptoms should be present in at least two different situations (e.g., at home and at school or at home and at work). This is important, since pervasiveness of symptoms rules out the possibility that symptoms merely result from the situational context of the patient. With this criterion, a third issue arises, namely the time-consuming aspect of having to evaluate behavior in different settings, which generally also requires different informants. Therefore, this criterion is not always correctly assessed due to practical choices in the diagnostic process. In addition, the requirement of "several" symptoms is rather arbitrary. This is also true for the age-of-onset criterion, requiring "several" symptoms to have been present prior to the age of 12. Another issue with the latter criterion is that with a diagnostic assessment at a later age, it may be hard to adequately remember if this was the case.

Finally, another issue arises with the criterion that for a diagnosis of ADHD the symptoms should not be better explained by another mental disorder. This means that full attention should be given to *differential diagnosis*, which is, again, time-consuming and therefore not always adequately done. Symptoms of ADHD, especially inattention, are not specific to ADHD and can easily be caused by other mental disorders or result from problems in the environment. For example, children may have trouble concentrating due to in-home conflicts between their parents, or hyperactive and impulsive symptoms in an adult may better be accounted for by borderline personality disorder or mania. Somatic conditions can also be a direct cause of ADHD-like symptoms. In such cases, it is important to acknowledge the actual cause of the behavioral symptoms and target the intervention accordingly.

Several consensus guidelines emphasize the importance of strictly following standard diagnostic criteria for the diagnosis of ADHD as detailed in the DSM or ICD (Kendall et al., 2008; Pliszka, 2007; Seixas, 2013; Wolraich et al., 2011). However, important criteria including impairment, pervasiveness, and differential diagnostics are easily and often overlooked in the diagnostic process. A recent review showed that the estimated prevalence based on symptoms alone (without accounting for additional criteria such as impairment) was far higher than prevalence estimates based on full DSM criteria (Faraone et al., 2015). These data underline the importance of strictly adhering to diagnostic criteria to guarantee the validity of the diagnosis. Since many ADHD rating scales omit diagnostic criteria like functional impairment, all guidelines agree that assessment should always include a full clinical interview, preferably a family interview (Seixas, 2013).

Evaluating adult ADHD creates some extra challenges because diagnostic criteria were originally defined to evaluate children's behavior. For a long time, most symptom definitions were unmistakably targeted at children, such as "runs about or climbs excessively in situations in which it is inappropriate." It is clear that such symptoms should be adapted to match similar adult behaviors, for example focusing on subjective feelings of restlessness instead of inappropriate hyperactive behavior. While the current DSM-5 and ICD-11 include a few examples targeted at adolescents or adults, the previous versions of both the DSM and the ICD do not provide adapted formulations for adults. Therefore, until recently (2013 for the DSM; 2018 for the ICD), it was up to the researcher or clinician to translate the diagnostic criteria into adult behaviors, making assessment highly subjective and weakening the validity of the diagnosis in adulthood. Although specific diagnostic assessment tools for ADHD adults are being developed and translated (Kooij et al., 2019), validation studies of those instruments to assess adult ADHD are largely lacking. Another issue in the diagnostic process of adult ADHD assessment arises from the criterion that symptoms must be present before the age of 12. With increasing age it becomes more difficult to correctly remember the exact age of onset of symptoms, and opportunities to use informants from different settings (e.g., teachers, parents) are reduced.

Moreover, validity of this age-of-onset criterion is under debate, given the discovery of late-onset variant of ADHD. Overall, it is important for practitioners to keep these issues in mind while diagnosing adults with ADHD. Unfortunately, due to a lack of research on the validity of diagnostic criteria for adults, assessment of adult ADHD will remain (at least partly) subjective until diagnostic instruments for adults with proved reliability and validity are mode widely available.

Another issue that currently receives prominent attention is the validity of the two-symptom dimensions of ADHD as they are currently defined (Milich et al., 2001; Willcutt et al., 2012). While this two-dimensional approach can be useful in creating behavioral profiles of the disorder, it is unclear to what extent the current dimensions cover all variance in the disorder. The heterogeneity in research findings suggests that important factors in the classification of the disorder are still overlooked and that the current division into three presentations might not be optimal (Milich et al., 2001). It is possible that a different or complementary classification system might provide a more useful approach to guide further research into the disorder. For example, defining ADHD presentations based on not only the presence of inattentive and hyperactive-impulsive symptoms-thus conventional diagnostic criteria-but taking into account risk and protective factors, neurocognitive profiles, and comorbidities may prove useful. While yielding a more holistic view, including all these factors will likely provide more information about different etiologies that may underlie presentations, leading to a better understanding of the heterogeneity in findings and therefore being a more viable option (Pievsky & McGrath, 2018), although such an approach needs further study.

## Treatment

## Standard Treatment of ADHD

It is widely accepted that either *behavioral therapy, medication*, or a *combination of both* is most beneficial for the majority of patients. Most treatment guidelines recommend starting with either behavioral therapy (in preschool children or children with moderate symptom severity) or medication (in cases with severe symptoms, comorbidities, or if high levels of family stress are present) or a combination of both. If only one type of treatment is given, it is recommended to add the second type of intervention if the first does not provide sufficient improvement (Graham et al., 2011; Kendall et al., 2008; Pliszka, 2007; Wolraich et al., 2011). In all cases, psychoeducation about ADHD and the various treatment options is indicated at the start and throughout the course of treatment for children, including the child with ADHD as well as the parent. Psychoeducation seems effective in adults as well, including the adult with ADHD as well as their significant other, but lack proper investigation and warrant further research (Hirvikoski et al., 2020).

Different types of behavioral therapy have been recognized as well-established stand-alone treatment options in pediatric ADHD (Evans et al., 2013; Fabiano et al., 2009; Lee et al., 2012; Pelham & Fabiano, 2008), mostly by increasing desired behavior and decreasing undesired behavior using principles of positive and negative reinforcement and social learning (Faraone et al., 2015). Three types of evidence-based behavioral treatments have been identified to be successful for children with ADHD: behavioral parent training, classroom management, and peer interventions, with each targeting the child with ADHD in a different setting (Evans et al., 2013). Behavioral treatment in adults with ADHD is less intensively studied, but particularly cognitive-behavioral therapy, where behavior is improved via alleviation of cognitive distortions associated with ADHD's core symptoms, appears to be effective in adults with ADHD, showing comparable effects to behavioral treatments for children with ADHD (López-Pinar et al., 2018).

Medication treatment for pediatric as well as adult ADHD typically involves either stimulants (such as methylphenidate sold under different brand names such as Ritalin) or nonstimulants (such as atomoxetine, sold under brand name Strattera, and is believed to enhance neurotransmission of dopamine (DA) and norepinephrine (NE) in the brain (De Crescenzo et al., 2017). With regard to stimulants, the first pharmacological choice for children and adolescents is methylphenidate, while for adults amphetamines are first choice (Cortese et al., 2018). A few other pharmacological options are available, including mixed amphetamine salts and lisdexamfetamine dimesylate (LDX), but currently these are all clearly framed as second-line options (Seixas, 2013). Immediate-release stimulants exert their effects within 1 hour after ingestion and are effective for approximately 3-5 hours, while extendedrelease stimulants and atomoxetine are effective for 8-10 hours and only require once-daily dosing.

The beneficial effect of both stimulants and atomoxetine on ADHD symptoms has been well documented for children and adults (Cortese et al., 2018; Faraone et al., 2015). Pharmacological treatment often not only ameliorates core symptoms, but can also have a beneficial effect on other aspects of the individual's health and functioning. For children and adolescents, effects on comorbid oppositional defiant behavior, social behavior, quality of life, academic productivity, classroom behavior, and cognitive functions have been consistently reported (Chamberlain et al., 2011; Coghill, 2010; Langberg & Becker, 2012; Molina et al., 2009; Pietrzak et al., 2006; Prasad et al., 2013; Van der Oord et al., 2008). For adults, reductions in criminal convictions, violent reoffending, traffic accidents and mortality rates, suicidal behavior, depression, and substance misuse are reported to be associated with pharmacological treatment (Kooij et al., 2019). However, for all age groups there is little and inconsistent evidence for the long-term beneficial effects of medication beyond 2 years of use (De Crescenzo et al., 2017; Krinzinger et al., 2019).

In general, stimulants and atomoxetine are well-tolerated drugs. Most frequently reported side effects include headache, abdominal pain, decreased appetite, and insomnia, but side effects are uncommon and generally mild (Findling, 2008). Atomoxetine is more often associated with nausea and sedation than are stimulants and may be slightly less effective, but it holds the advantage that it less likely leads to medication misuse or diversion (Findling, 2008; Pliszka, 2007) and may improve comorbid tics (Cortese et al., 2013). Stimulants and atomoxetine may sometimes lead to reductions in weight and height gain in children, possibly due to a loss of appetite (Cortese et al., 2013), although some authors have suggested that the growth reduction is related to ADHD itself (Faraone et al., 2008). So-called drug holidays (taking children off medication during weekends or holidays) are often advised as they may be helpful to normalize reductions in height and weight gain (Pliszka, 2007). For adults with ADHD specifically, a higher likelihood of discontinuation was reported, compared with children and adolescents, possibly due to the side effects of decreased appetite and insomnia (De Crescenzo et al., 2017).

While serious concerns have been raised regarding health risks for children using medication for the treatment of ADHD, most of these concerns lack scientific support. Small cardiovascular effects of stimulant and nonstimulant medication have been reported, including slightly elevated blood pressure and heart rate, but there is currently no evidence that ADHD drugs increase the risk for serious cardiovascular events in children or adults (Cortese et al., 2018; Hennissen et al., 2017; Pliszka, 2007). In addition to an increased resting heart rate and blood pressure, adults seem to also face an increased risk for transient ischemic attack, which needs further investigation (De Crescenzo et al., 2017). The validity of other concerns for pharmacological treatment in children and adolescents, including an elevated risk for suicidal thoughts, psychosis, and substance use disorders, is still largely unclear. Currently, it is known that ADHD in itself holds an elevated risk for these events, but there is no clear evidence that ADHD medication adds to this risk (Graham et al., 2011; Pliszka, 2007; van de Loo-Neus et al., 2011). In adults, there seems to be no evidence of increased suicide events or ideation, while atomoxetine may reduce comorbid anxiety but not comorbid depression (De Crescenzo et al., 2017; Kooij et al., 2019). In all cases, risk management of possible adverse effects and preexisting conditions, such as cardiac defects, is of highest concern, at the start as well as throughout treatment of children, adolescents and adults (Cortese et al., 2013; De Crescenzo et al., 2017; Graham et al., 2011; Kooij et al., 2019; Pliszka, 2007; Warren et al., 2009).

When directly comparing the efficacy of medication treatment with behavioral therapy in children, a large hallmark study (the Multimodal Treatment Study of Children with ADHD; MTA) reported that behavioral treatment is effective in reducing core symptoms of ADHD, but not as effective as a strict medication management program (The MTA Cooperative Group, 1999), which is supported by more recent studies (Van der Oord et al., 2008). Combining pharmacological treatment and behavioral therapy does not seem to have an additional effect on ADHD symptom reduction (Pliszka, 2007; Van der Oord et al., 2008), but it may have an additional effect on internalizing symptoms, social skills, parent-child relations, and reading achievement (Molina et al., 2009). Comparable findings seem to be applicable to adults, but, given the scarcity of studies into this, more research is warranted to be able to draw firm conclusions.

## Alternative Treatment Methods

Currently, behavior therapy and pharmacological treatment are the only two evidence-based treatments for ADHD. However, these treatment options offer incomplete symptom relief in more than 30% of patients (Swanson et al., 2001), behavioral therapy is relatively cost-intensive (Jensen et al., 2005), and nonpharmacological treatments are often favored by parents, leading to an increasing interest in alternative treatment options. Although none of these alternative treatment methods is sufficiently investigated to draw robust conclusions, we discuss here the most promising ones.

The role of *nutrition* in ADHD has provoked controversy in both research and media. While preliminary results suggested that ADHD might be caused by nutrition in a number of cases, more recent reports have provided new clarification and nuanced some previous conclusions. Two specific dietary elements are seen as promising targets. First, lower plasma and blood concentrations of polyunsaturated fatty acids have been found in children with ADHD (Gillies et al., 2012). A recent review suggest that supplementation of these acids, in particular omega-3, can alleviate ADHD symptoms in some children (Bloch & Qawasmi, 2011; Sonuga-Barke et al., 2013). Unfortunately, the reported effects are merely small, suggesting supplementation of these acids is insufficient as stand-alone treatment (Chang et al., 2018; Stevenson et al., 2014).

Second, a meta-analysis of 10 studies showed that there is evidence that some children with ADHD (~30%) may respond to a restriction diet, leaving out synthetic food colors or other additives (Nigg et al., 2012). However, although evidence shows that ADHD symptoms may be reduced by leaving out artificial food colors from the diets of subgroups of children with ADHD, large-scale studies using blind assessment are needed to draw strong conclusions (Stevenson et al., 2014). Moreover, results of these studies are difficult to interpret since children on a restriction diet are not only limited in their food intake, but also receive much more attention and structure at home, which can also have a beneficial effect on their behavior. Moreover, placebo effects cannot be ruled out in studies using a restriction diet.

Another popular alternative treatment option for ADHD is *neurofeedback (NF) training*. During NF training, children learn to control specific brainwave patterns as measured by electroencephalography (EEG), using real-time audio/video feedback. Several studies showed improvement in ADHD-related behavior after extensive NF training (Van Doren et al., 2019), leading many (commercial) healthcare suppliers to offer NF as stand-alone ADHD treatment. Unfortunately, the limited quality of current NF research prevents valid conclusions to be drawn, and NF can currently only be described as a "promising" treatment for ADHD (Cortese, Ferrin et al., 2016; Van Doren et al., 2019). The same holds for *cognitive training* (e.g., working memory training) in children with ADHD. The limited evidence available shows promising results regarding symptom improvement as rated by parents, but without generalization to classroom behavior (Rutledge et al., 2012). Finally, physical exercise may have an effect on functional outcomes in ADHD, in both motor skills and executive functioning, but more methodologically sound studies are warranted to justify any clinical recommendations (Vysniauske et al., 2020).

Taken together, behavior therapy and medication are the only evidence-based treatment options for ADHD. While many promising alternative treatment options are emerging, better-quality research is needed before valid conclusions can be drawn regarding the efficacy of such treatments (Faraone et al., 2015; Sonuga-Barke et al., 2013; Stevenson et al., 2014). Effective treatment of ADHD involves many considerations, and treatment protocols should always be tailored and evaluated on an individual basis. Personal characteristics of the patient (such as symptom severity, comorbid problems, and the patient's social environment) should be weighed together with advantages and disadvantages of the available treatment options in order to set up an individual treatment plan.

## **Etiology and Risk Factors**

During the past three decades, a large number of investigators have attempted to clarify the etiology of ADHD by focusing on a range of isolated etiological factors (e.g., Barkley, 1997; Sergeant, 2005; Sergeant et al., 2003). While several factors, for example heritability, have been found to play a substantial role, the "single cause" approach has proved unsuccessful in explaining even a minority of the occurrences of the disorder. Currently, ADHD is best described as a multifactorial disorder, in which a variety of factors, and combinations of these factors, contribute to the overall risk of developing the disorder. A large number of risk factors have been identified, and an increasing number of studies are investigating complex interactions between these risk factors. The current notion is that, in most cases, ADHD is caused by an interaction between risk genes and environmental factors and that there is no single risk factor that is either necessary or sufficient to explain ADHD. Currently, even with a multifactorial approach only a proportion of the variance in ADHD symptoms can be explained.

## Genetic Influences

In the etiology of ADHD, genes seem to play a vital role, with family, twin, and adoption studies consistently reporting high heritability rates. A recent review of twin studies showed a mean heritability of 74% for both children and adults, males and females, and even inattentive and hyperactiveimpulsive symptoms (Faraone & Larsson, 2018). While this suggests that the disorder is for the largest part caused by risk genes, an unsatisfactorily low percentage of them have been identified so far. Over the past decades, a considerable number of studies have tried to identify specific genes associated with ADHD. Initially, genetic linkage was applied to assess which chromosomal regions are linked to ADHD, and this resulted in abundant but conflicting literature. Because that method only detects genetic variants that have large effects, the paucity of significant findings suggests that common DNA variants having a large effect on ADHD are unlikely to exist. A meta-analysis on candidate genes, selected due to a plausible link to ADHD, showed that only six of the many proposed candidate genes could consistently be linked to a risk for ADHD in children, with small effect sizes (odds ratios 1.11 to 1.33; Gizer et al., 2009). The candidate genes include DA transporter and receptor genes (DAT1/ SLC6A3, DRD4, DRD5), serotonin transporter and receptor genes (5-HTT/SLC6A4, HTR1B), and the SNAP25 gene involved in neurotransmission. For adults with ADHD, a meta-analysis reported a significant association between ADHD and a gene involved in neuronal and dendritic development (BAIAP2), but the effects of this gene were small (Faraone & Larsson, 2018). Several attempts have been made to obtain a complete picture of the genes involved in ADHD using genome-wide association studies (GWAS), a method in which the whole genome can be investigated rather than a small number of specifically selected genes, which allows this method to detect very small etiological effects. While GWAS studies in ADHD research have identified 85 candidate genes in total, up until now, GWAS studies have unfortunately not significantly increased our understanding of ADHD risk genes. This is because even the genes that showed genomewide significance only showed this association with ADHD as a set with other genes, but could not be singularly linked to ADHD. A meta-analysis that assessed the more recent epigenome-wide association study (EWAS) approach in adults with ADHD, in which the entire genome is searched for epigenetic marks, reported no overall significant sites

to be associated with ADHD (van Dongen et al., 2019). Rather, only cohort-specific findings were reported, and the necessity of (even larger) datasets was emphasized.

Recent studies attempted to integrate the current body of genetic findings to investigate specific mechanisms implicated in the risk for ADHD development. These studies emphasized the involvement of genes responsible for neurite development and outgrowth and DNA methylation (Faraone & Larsson, 2018; van Dongen et al., 2019). These findings suggest that, in ADHD patients, small alterations in the outgrowth of axons and dendrites in the brain caused by risk genes and epigenomic effects influencing DNA methylation at specific loci may play a substantial role in the development of the disorder (Poelmans et al., 2011).

## Environmental Risk Factors

Several environmental risk factors have been implicated in ADHD. These environmental risk factors-factors other than the genotype that can influence a child's development-generally are divided into two domains: neurobiological and psychosocial factors. Neurobiological risk factors often associated with ADHD can for a large part be characterized as complications during pregnancy or delivery. They include maternal smoking or alcohol use during pregnancy, eclampsia, fetal distress, premature birth, poor maternal health, and higher maternal age (Bhutta et al., 2002; Biederman & Faraone, 2005; Linnet et al., 2003). Many of these risk factors can lead to hypoxia in the fetal brain. Notably, the basal ganglia, a brain structure often implicated in ADHD, is particularly sensitive to the effects of hypoxia (Froehlich et al., 2011). Psychosocial risk factors often associated with ADHD include poor socioeconomic status, family dysfunction (including maltreatment, maternal mental disorders, paternal criminality, marital problems, and in-home conflict), and large family size (Banerjee et al., 2007; Biederman & Faraone, 2005). Moreover, parenting styles, specifically harsh and negative parenting, have been associated with ADHD. Previous concerns that watching too much TV at a young age may lead to ADHD-like attention problems (Christakis et al., 2004) are not supported by scientific studies (Banerjee et al., 2007).

Importantly, while many of these factors are strongly associated with the presence of ADHD in a family, they should currently still be considered correlates rather than *causes* of ADHD. For example, while maternal smoking may directly cause ADHD through neurobiological alterations in the fetal brain, it is also possible that the mother's predisposition to smoke during pregnancy is a result of her having ADHD or a vulnerability to it, which is transferred to the child genetically. Moreover, it is important to state that while the above-mentioned risk factors are linked to an increased risk for the development of ADHD, many children who have experienced one or more of these risk factors do not develop ADHD, and, conversely, not all children with ADHD show one or more of these risk factors. Thus, even though these risk factors may be important, their presence of is only true for a limited proportion of individuals with ADHD, and it may be that other confounding factors are involved, such as parental ADHD and interactions with environmental factors, thus warranting more research (Thapar et al., 2013).

## Gene by Environment Interactions

While a variety of risk genes and environmental factors have been linked to ADHD, none of them fully explains the risk for developing the disorder. For example, it is possible that in a monozygotic twin pair, sharing 100% of their genotype at birth, one child develops ADHD while the other does not. Such a situation would result from a "gene by environment interaction" (G×E), meaning that the effect of specific genes may vary due to differences in the environment and that the very interaction between specific genes and environmental factors may be the main mechanism by which environmental factors increase the risk for ADHD. For example, one twin might have experienced hypoxia during birth while the other did not, resulting in one twin with and one without ADHD. Another example of G×E is that a specific environment (such as maternal smoking or alcohol use during pregnancy) may be damaging to many infants, but more specifically so to those infants who carry specific risk genes making them more vulnerable to the adverse effects of this environment.

To date, due to a large variation in implicated risk genes and environmental factors, most hypotheses on G×E have only received attention in a single study, resulting in literature with limited overlap and low levels of reproduced findings (Faraone et al., 2015; Thapar & Cooper, 2016). A literature review showed that, overall, psychosocial factors seem to interact with ADHD risk genes, primarily with *DAT1* and *5-HTT*, in the development of the disorder (Nigg et al., 2010). Unfortunately, due to limited overlap between studies it is unclear whether this interaction exists for all psychosocial factors or only specific ones. For neurobiological factors, even less overlap was found, although the interaction between *5-HTT* and stress has been associated with specific behaviors of hyperactivity and impulsivity (Faraone et al., 2015). Findings for maternal smoking or alcohol use during pregnancy are highly inconsistent and suggest that if an interaction with risk genes occurs, this may cause hyperactive behavior, but not necessarily the full range of ADHD symptoms.

## Heterogeneity in Etiology

Taken together, while some risk genes and environmental factors for ADHD have been identified and replicated, possibly a far higher number remains unknown, and we have only just begun to unravel the complex interactions between these different risk factors. One of the causes for the large inconsistency between findings so far may be the heterogeneity of behavioral symptoms of the disorder. In linking specific risk genes to a behavioral outcome (i.e., phenotype), heterogeneity in phenotype considerably reduces the power to find risk genes. In this context, researchers have suggested the field move toward identification of endophenotypes or intermediate phenotypes (Castellanos & Tannock, 2002). Endophenotypes refer to heritable traits that are supposed to be more strongly associated with the genotype than the phenotypical manifestation and less influenced by environmental factors than the phenotype. Examples of endophenotypes are neurocognitive deficits or specific neurobiological abnormalities characteristic for ADHD. Identifying endophenotypes may provide useful directions in the search for candidate risk genes for the disorder but may also be useful in itself to understand underlying mechanisms of dysfunction. Although identifying risk genes may not uncover the full complex multifactorial etiology of the disorder, it may be a first step toward clarifying the neurobiological underpinnings of ADHD.

## Neurocognitive and Neurobiological Abnormalities

Given the high heritability rates of ADHD, the disorder is suspected to have an important neurobiological basis. With advancing techniques, considerable progress has been made in unraveling the neurobiological underpinnings of the disorder, although a lot of uncertainty still exists. This field of research can roughly be divided into two domains: abnormalities in neurocognitive functioning and neurobiological abnormalities as measured by neuroimaging techniques.

## Neurocognitive Abnormalities

The search for neurocognitive deficits in ADHD has been on the fast track in recent years, resulting in a large number of studies and a variety of neurocognitive functions suggested to be deficient in ADHD. Early neurocognitive studies into ADHD have primarily attempted to objectify the symptoms of inattention, motor restlessness, and impulsivity (e.g., Corkum & Siegel, 1993; Kuehne et al., 1987; Porrino et al., 1983). This has proved to be a fruitful approach as patients with ADHD are often found to be impaired on objective measures of sustained attention, motor restlessness, and impulsivity (Alderson et al., 2007; Huang-Pollock et al., 2012; Huizenga et al., 2009; Losier et al., 1996; Rapport et al., 2009). However, findings remain inconsistent. More recent neurocognitive studies adopted a broader perspective and investigated a large variety of neurocognitive functions in children and adults with ADHD. The most consistently found deficits involve executive functions and include impairments in behavioral inhibition, planning, vigilance, and working memory (Faraone et al., 2015). With regard to nonexecutive deficits, impairments in timing, reaction time variability, and decision-making have been consistently related to ADHD (Thapar & Cooper, 2016). Furthermore, problems with delay aversion, such as making suboptimal choices and overestimating the magnitude of immediate rewards over delayed rewards, are often seen in ADHD patients. Given the large variety of neurocognitive deficits implicated in ADHD, it is possible that a more general deficit may underlie poor performance across tasks. Some evidence exists that a general processing deficit (Alderson et al., 2007), attentional lapses during task performance (Tamm et al., 2012), or motivational deficits (Konrad et al., 2000) may underlie poor performance on many neurocognitive tasks. However, more research is needed to clarify this issue.

It is interesting to note that while a number of ADHD patients are impaired on one or two neurocognitive functions, another substantial group of patients does not show any neurocognitive deficit at all, and very few show deficits in all functions (Faraone et al., 2015; Thapar & Cooper, 2016). Moreover, neurocognitive problems seem to be independent of the developmental course of ADHD (i.e., persistence vs. remission of symptoms later in life; van Lieshout et al., 2013), suggesting that these deficits may not share the same etiology as the behavioral symptoms of the disorder or are more sensitive to developmental changes over time. Altogether, this is an interesting issue that deserves more attention in future research.

## Neurobiological Abnormalities

Neuroimaging techniques can be useful tools to elucidate the neurobiological mechanisms that underlie the behavioral and neurocognitive deficits observed in ADHD. One of the most used imaging techniques is magnetic resonance imaging (MRI), allowing in vivo 3D imaging of brain structure and function.

Brain volumes, as measured by structural MRI, have been studied for decades, and many brain regions have been suggested to be reduced in ADHD. In general, ADHD patients often show a reduced overall brain volume (Hoogman et al., 2017) and reduced thickness of the cortex (Hoogman et al., 2019) compared to healthy controls. Reductions in more specific regions are also observed; according to a mega-analysis, most consistently in structures within the basal ganglia (including the striatum), amygdala, and hippocampus (Hoogman et al., 2017). Other structures that have been reported in previous meta-analyses include the ventromedial orbitofrontal and medial prefrontal cortex, corpus callosum, anterior cingulate cortex, and cerebellum (Frodl & Skokauskas, 2012; Valera et al., 2007). Although older studies reported volume reductions to be often more pronounced in the right hemisphere (Frodl & Skokauskas, 2012; Valera et al., 2007), the more recent mega-analysis showed that reductions in (at least) the caudate and putamen are bilateral rather than unilateral (Hoogman et al., 2017).

Diffusion tensor imaging (DTI) is a relatively new MRI technique allowing in vivo measurement of the microstructural integrity of brain white matter. Despite the significant number of DTI studies being performed, results are still somewhat limited by methodological issues, such as head motion (Aoki et al., 2018). Meta-analyses in DTI mainly focus on the predominantly used characteristic fractional anisotropy (FA), which reflects white matter microarchitecture by assessing the spherical or isotropic diffusion (Aoki et al., 2018; van Ewijk et al., 2012). Alterations appear to be widespread, including frontal, striatal, and cerebellar regions, consistent with other structural imaging findings, and may be present in terms of significantly lower and higher FA values in individuals with ADHD.

483

The latter seems to be driven by the methodological approach, since especially whole-brain approaches show mixed findings, while tract-based approaches consistently show decreased FA.

In general, structural brain abnormalities in ADHD are viewed as reflecting a developmental delay rather than a static deficit. Converging evidence shows that volume reductions and abnormal white matter integrity may normalize around mid to late adolescence, most particularly so in (structures within) the basal ganglia (Hoogman et al., 2017, 2019). Notably, the explorative life span modeling approach as used by Hoogman and colleagues (2017, 2019) to study longitudinal development in large, cross-sectional samples suggested a delay of maturation and a delay of degeneration, which is in line with a large longitudinal study that showed a developmental delay in cortical thickness in children with ADHD (Shaw et al., 2007). In the latter, the authors showed that, in typically developing children, the development of cortical thickness follows a growth curve described by an increase in thickness during childhood, reaching peak thickness around 7-8 years of age, and a subsequent decrease in thickness during adolescence. ADHD patients showed a similarly shaped growth curve that was delayed by approximately 3 years, reaching peak thickness around 10-11 years of age. However, even though the absence of differences in brain characteristics in adults is quite clear and suggests a normalization process, this must be interpreted with some caution since the majority of studies have been cross-sectional rather than longitudinal. Taken together, these results suggest that ADHD mightat least partly-be due to a delay in brain maturation and that some or even all of the brain abnormalities in ADHD might resolve in adolescence or adulthood. Independent of this catch-up in brain maturation, long-term pharmacological treatment seems to have an additional positive effect on brain development in children with ADHD in that volume reductions are less pronounced and have sometimes even normalized in medicated children compared to treatment-naïve children (Frodl & Skokauskas, 2012; Schweren et al., 2012). It may be noteworthy that direct associations between pharmacological treatment and brain volumes have not been found in the mega-analysis (Hoogman et al., 2017), possibly due to normalizing effects being too local.

Using functional MRI, brain activation can be investigated during performance of cognitive tasks. Interestingly, regions with abnormal activation in ADHD patients largely overlap with brain regions that are found to be reduced in volume, and studies combining structural and functional approaches show intercorrelations between abnormalities. During tasks that tap into cognitive processes such as attention, response inhibition, and reward anticipation, reductions in activity are most frequently found in frontal, parietal, and temporal brain regions as well as the basal ganglia (Cortese et al., 2012; Dickstein et al., 2006; Hart et al., 2013).

In line with findings of altered brain activity in ADHD patients, electroencephalography (EEG) studies show abnormal electrical brain activity in children, adolescents, and adults with ADHD. The P300, an event-related potential (ERP) component thought to represent attentional and executive functioning, has a decreased amplitude in patients with ADHD (Szuromi et al., 2011). Also during rest, patients with ADHD show abnormal electrical brain activity compared to healthy controls. More specifically, increased theta activity (associated with drowsiness or cortical underactivation) and reduced beta activity (associated with a less attentive state) are often found, indicative of brain immaturity. It is possible that this theta-to-beta ratio reflects a developmental delay in childhood ADHD since replication of EEG abnormalities in adults with ADHD is largely lacking (Arns et al., 2013; Saad et al., 2018).

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) have been used to study the neurochemistry of the ADHD brain. Components of catecholamine signaling systems are encoded by risk genes implicated in ADHD and play a large role in the neurochemistry of the disorder (Caylak, 2012; Durston & Konrad, 2007; Madras et al., 2005). One of these components, DA, is highly active in the striatum, and striatal DA levels play a pivotal role in the regulation of psychomotor activity and rewardseeking behavior (Spencer et al., 2005). However, even though a meta-analysis of PET and SPECT studies focusing on striatal DA transporter alterations showed a 14% higher DA transporter density in ADHD in the striatum, this does not mean it is specific for ADHD. Interestingly, striatal DA transporter density in ADHD was associated with previous psychostimulant exposure, thus the high DA transporter density may be a consequence of previous stimulant treatment rather than a characteristic of ADHD (Fusar-Poli et al., 2012).

Another component implicated in ADHD is NE, which plays an important role in the regulation of attention and behavior and is mainly effective in the (pre)frontal cortex (Arnsten & Li, 2005; Madras et al., 2005). PET studies have shown dysregulation of both DA and NE in ADHD and suggest underactivity of these neurotransmitters in cortical regions but overactivity in subcortical regions (Ernst et al., 1998; Fusar-Poli et al., 2012; Madras et al., 2005; Spencer et al., 2005; Swanson et al., 1998). Most effective pharmacological treatments for ADHD are thought to ameliorate behavioral symptoms of the disorder by optimizing neurotransmission in catecholamine signaling systems, consequently normalizing DA and NE levels in the striatum and frontal cortex (Arnsten & Li, 2005; Madras et al., 2005).

### Disturbed Connectivity

Abnormalities in brain structure and function are predominantly found in (pre)frontal cortical regions and the basal ganglia. These findings have led to a prominent theory that neurobiological deficits in ADHD are mainly located in the so-called frontostriatal circuit (Bush et al., 2005; Durston & Konrad, 2007), which includes brain regions in and between the frontal cortex and the striatum, a component within the basal ganglia. Concurrent with this theory, the perspective on neuropathology in ADHD has shifted from identifying local deficiencies to studying connectivity between brain regions. Brain regions are interconnected through a large number of white matter tracts and can constitute a functional network of activation during a cognitive task. Consequently, one local deficiency (either cortical or subcortical) could disturb the whole functional network, indirectly causing a reduction in brain activation in another, more distant brain region and its functioning.

Structural as well as functional brain connectivity can be measured using various MRI techniques. Findings of DTI studies show structural alterations in several white matter tracts in children and adults with ADHD, including decreased microstructural organization in frontostriatal tracts (Aoki et al., 2018). Findings from functional connectivity studies suggest that, during rest as well as during cognitive tasks, ADHD patients display altered connectivity between brain regions, but findings seem to be affected by study approach. A theory-driven meta-analysis focusing on four established brain networks, including the default mode network (DMN), the cognitive control network (CCN), the salience network (SN), and the affective/motivational network (AMN), showed altered connectivity in the DMN (Sutcubasi et al., 2020). Specifically, in children and adolescents, ADHD was associated with both altered within-DMN connectivity and altered connectivity between DMN and the CCN, SN, and AMN. In adults, ADHD was similarly associated with altered within-DMN connectivity, but altered connectivity between DMN and other brain networks was only present for the CCN. However, a theory-free approach, including all resting-state connectivity studies, showed no spatial convergence of ADHD-related hyper- or hypoconnectivity in the brain (Cortese et al., 2021), although post hoc meta-analysis showed that the left superior temporal gyrus had a consistently altered connectivity, with evidence of both hypo- and hyperconnectivity. While connectivity research in ADHD is still relatively new, it is an important topic in research and shows potential in unraveling the neurobiological underpinnings of the disorder.

## Conclusion

ADHD is one of the most frequently diagnosed childhood psychiatric disorders and is known to often persist into or even emerge during adulthood, causing severe impairment in the patient, in the patient's family and social environment, and in school or work functioning. This chapter has summarized the current knowledge on different aspects of ADHD. Advancement has been made in the clinical conceptualization of ADHD throughout the past century, and a standard treatment protocol is now well established, encompassing behavioral treatment and/or medication. Alternative treatment options are sought, but well-setup and replicated studies proving its efficacy are still lacking. Many factors have been identified that may play a role in the etiology and development of the disorder, including several risk genes, environmental factors, neurocognitive deficits, and brain abnormalities. However, a coherent model integrating all these factors is still missing, although it is clear that this model should include a multitude of diverse factors.

In this chapter, we have emphasized the important role of etiological and phenotypical heterogeneity, which has created a challenge in the diagnosis of ADHD as well as in research into the different mechanisms underlying the disorder. This heterogeneity in research findings might indicate that the current classification of ADHD and its three presentations may—in spite of being clinically valuable—not provide optimal guidance for identifying the underlying mechanisms. However, in research as well as clinical practice, diagnostic criteria for ADHD are often misinterpreted or applied very loosely. This issue should be worked out first, before new advancements can be made in resolving current heterogeneity and lack

485

of clarity in the etiology and clinical manifestation of the disorder. The present shift in research into ADHD from a categorical approach toward a spectrum of symptoms approach may prove valuable and informative, both for clinical practice and scientific research.

# Autism Spectrum Disorders

Fred R. Volkmar and Kevin Pelphrey

Autism and related conditions (previously termed the pervasive developmental disorders and more recently the autism spectrum disorders [ASDs]) share their major similarity in the significant difficulties in social development and interaction associated with problems in communication and behavior. These conditions have been the source of great interest for decades but only with the official recognition of autism in 1980, in DSM-III, did research begin to increase (Rosen et al., 2021); over time this increase has been quite dramatic, with several thousand scientific papers appearing each year. Despite this increase, research in some areas (e.g., aging in autism; Piven et al., 2011) is quite limited but, overall, very significant progress has been made in both understanding and treating these conditions.

# **Diagnostic Concepts**

Autistic disorder (sometimes referred to as *childhood autism* or *infantile autism*) is the prototypic disorder of the group and the one that has been the focus of most of the available research. Research is much less extensive on the broader spectrum of disorders (ASDs) and caution should be used in overgeneralization of results from more "classic" autism to this larger population.

Initially described by Leo Kanner (1943), all subsequent definitions have kept some degree of continuity with Kanner, who emphasized two key features: autism (lack of social interest/engagement from the time of birth) and what he termed resistance to change or insistence on sameness (difficulties with change, stereotyped movements). Kanner's work prefigures much current research which is aimed at understanding genetic and brain mechanisms of social vulnerability coupled with an overengagement in the nonsocial world. Other diagnostic concepts were proposed before and after 1943, and *ICD-10* and *DSM-IV* explicitly recognized a number of these, although DSM-5 returned to a more unitary model potentially at some price in terms of restricted coverage (Volkmar et al., 2021). Conditions included in ICD-10 and DSM-IV were Asperger's disorder (serious social vulnerability associated with perseverative interests, good vocabulary, and motor clumsiness), two "disintegrative" conditions where skills were dramatically lost (Rett's disorder, now known to be a single-gene disorder), and childhood disintegrative disorder (CDD), where autism has its apparent onset after years of clearly normal development and a "subthreshold" category: pervasive developmental disorder not otherwise specified for cases not meeting specific criteria for one of these conditions but with problems that seem best viewed as related to autism (see Jackson & Volkmar, 2019, for a review).

The *DSM-IV/ICD-10* definitions were very similar and require characteristic problems in social interaction as well as problems in communication and play and in unusual environmental responses and restricted-repetitive interests. The onset of the condition must be before age 3 years. Social

Abbreviations			
ASD	Autism spectrum disorder		
BAP	Broader autism prototype		
CDD	Childhood disintegrative disorder		
FFA	Fusiform face area		
FFG	Fusiform gyrus		
OFC	Orbital frontal cortex		
PC	Posterior cingulate		
PFC	Prefrontal cortex		
PRT	Pivotal response treatment		
STS	Superior temporal sulcus		
TD	Typically developing		
TPJ	Temporoparietal junction		
US	Unaffected sibling		

problems are weighted more heavily than other factors. The polythetic *ICD-10/DSM-IV* approach allowed for more than 2,000 combinations of the 12 diagnostic criteria.

DSM-5 differs from its predecessor in a number of important ways (Volkmar et al., 2021). For autism, two overarching decisions for DSM-5 have had significant impact: the decision to derive the definitions from reanalyses of research diagnostic instruments and the decision to remove all subthreshold categories throughout the manual. For autism, the decision was to move to a more unitary construct of ASD and a somewhat narrower one more consistent with Kanner's original (1943) view of autism (see McPartland et al., 2012; Smith et al., 2015; Volkmar & McPartland, 2014; Volkmar et al., 2021). This reflected concern about the reliability and validity of more fine-grained distinctions and an awareness of the growing body of research on the complex genetic bases of autism (Lord et al., 2012; Rosen et al., 2021). The move toward a more rational name for the overall category is praiseworthy as is the attempt to provide ratings for dimensions of dysfunction. Other aspects of the new system may prove problematic in relation to several factors including the narrowing of the concept, gender, cultural, and developmental issues (Volkmar et al., 2021). Social-communication features are now grouped in one category while the restricted interest category has changed to include unusual sensitivities but provides many fewer ways for a diagnosis to be achieved and appears to differentially exclude more able and less "classic" cases. Consistent with the overall DSM-5 in general no subthreshold categories are provided but a new condition, socialcommunication disorder, is. The rationale for this category and its actual use in practice remain to be determined (Topal et al., 2018). Although a large data reanalysis of items collected as part of research diagnostic assessments was performed, a true field trial was not actually conducted although some work was done on reliability; using the data available diagnostic accuracy was good if both historical information and direct assessment instruments were available (but decreased when they were not). A major unanswered question is how well items derived from research-based instruments which require considerable training in administration/ interpretation can readily be extrapolated to more typical clinical settings (Volkmar et al., 2021). One unprecedented issue has emerged in the context of the COVID-19 pandemic. For nearly a year, we have not been able to complete the Autism Diagnostic Observation Schedule (ADOS) because the measure is not possible to complete with validity while wearing a face shield and/or mask. This reveals an important vulnerability in an approach to diagnosis that reifies such a complex neurodevelopmental disorder via any one measure or instrument. The exclusion of new diagnoses of Asperger's disorder cases (while grandfathering in older "well established" cases) remains problematic. The decision to exclude Asperger's even as a subcategory of ASD was unfortunate given the emergent data on validity of the concept (e.g., Chiang et al., 2014) and the wide public acceptance of the concept (Greenberg, 2013).

#### Prevalence, Gender, and Cultural Perspectives

Several complications arise in the interpretation of epidemiological studies. Prevalence estimates can vary dramatically if different diagnostic approaches are used. DSM-IV and ICD-10 criteria were designed to be more neutral to IQ (i.e., a goal in the development was that criteria worked reasonably well in both lower and higher cognitive functioning individuals). The tendency to equate ASDs (i.e., autism and related conditions) with more classical autism is yet another problem, as is the tendency to rely on school diagnoses rather than on results of actual independent assessment. The school setting may use the autism label to justify services when another category might be more appropriate (this is problem of diagnostic substitution). Other issues include greater public awareness and recognition. As well, in general, in epidemiological studies higher rates have been obtained when smaller samples are studied (presumably reflecting better case finding). On balance the median rate of strictly defined autistic disorder is about 1 per 800 but if a broader autism spectrum definition is used this rate significantly rises to the order of 1 in 150 (Fombonne, 2005). The apparent increase in prevalence of the condition likely reflects the many factors noted above, although there is the potential for some slight increase relative to specific genetic mechanisms (e.g., higher risk for older fathers of having a child with autism; Puleo et al., 2012).

There is a strong gender predominance in autism, with males being 3 to 5 times more likely to have the condition. When females have autism they tend, on balance, to be more cognitively impaired suggesting some complex interaction of severity with genetic risk and gender. Kanner's original paper (1943) noted a preponderance of well-educated and successful parents; this has not been confirmed in subsequent studies that controlled for referral bias. Autism appears, particularly in younger children, remarkably the same in individuals from various countries but cultural practices regarding special education and treatment may have a significant impact on outcome (Brown & Rogers 2003). There is remarkably little research on cultural or ethnic differences although some early suggestion of increased risk in immigrant families has not generally been supported in the literature (Fombonne, 2005).

Some recent work has emerged that questions the usually accepted male predominance in autism (Volkmar et al., in press). This awareness comes with emerging data on gender differences even in screening instruments if one examines large datasets (e.g., Oien et al., 2017) and the growing awareness of differences of syndrome expression in girls with a potentially milder form of social difficulty and/or a great ability to "camouflage" and fit in (Rynkiewicz et al., 2016). There is some suggestion of potential bias on diagnostic instruments as well (see (Volkmar et al., 2021). Concerns have also been raised relative to underdiagnosis in minority groups as a result of bias in screening and diagnostic instruments, lack of efforts to ensure identification, and so forth (Grinker et al., 2015; Mandell et al., 2009). The issues assume greater importance given the growing interest in autism in developing countries and the need to adapt approaches to other cultures (Freeth et al., 2014; Grinker et al., 2015; Volkmar et al., 2021). Indeed, even within the United States, there has been concern about the applicability of current diagnostic approaches to minority groups (Volkmar et al., 2021).

### Historical Perspectives

It is likely that some of the first reports of autism may have been those of so-called "feral" children (Wolff, 2004) and case report of children seen in the 1800s in resididential instutitions in the United States (Donvan & Zuker, 2016). It is a tribute to the genius of Leo Kanner that he was able to identify a central distinguishing feature (autism or lack of social engagement) that differentiated the condition from other developmental problems. His report also, unfortunately, served to mislead early investigators, given his mention of high levels of professional attainment in parents, his mistaken impression of normal intellectual levels (reflecting his observation of better nonverbal abilities or splinter skills), and his use of the word "autism," suggesting to many a point of continuity with schizophrenia. Diagnostic ambiguity complicated much available research until work in the 1970s clarified the strong genetic and brain basis of autism. Its first inclusion in *DSM*-*III* marked a critical moment in research which has steadily increased since that time.

Diagnostic practice has varied over the years. Early attempts were made to more truly operationalize Kanner's definition, for example, Rutter's (1978) approach proved highly influential for DSM-III. Subsequent to DSM-III, a revision (the DSM-III-R) was made given concerns that the DSM-III approach lacked a developmental orientation (given its focus on the "infantile" form of the conditions); unfortunately, this also came at a price in the DSM-III-R terms of overly inclusive diagnosis. DSM-IV was in place since 1994, and it and the ICD-10 definitions have proven highly influential: research has very dramatically increased with thousands of peer-reviewed papers appearing each year now. As noted above, the implications of the new DSM-5 approach remain to be seen.

In addition to changes in diagnostic practice, significant shifts in clinical work and research have occurred. It has become apparent that structured, intensive intervention programs (of various types) are associated, on balance, with improved outcomes (e.g., relative to the number of adults who are self-sufficient and independent; Howlin, 2013). However, some children do not make this much progress and remain in need of considerable support throughout adulthood. Basic research advances have occurred in a number of areas, but those in genetics and neurobiology have been the most important and are discussed subsequently.

#### Onset and Course

In his original (1943) description Kanner suggested that autism was inborn (i.e., congenital) in nature. With one important qualification, those who have developmental regression into autism, subsequent research has, largely, been consistent with this view. Many parents are worried about the child's development in the first year of life and the vast majority (90%) by age 2. Common reasons for concern include worries that the child might be deaf, social deviance or lack of engagement, odd interests in the nonsocial world, and language delay (Chawarska & Volkmar, 2020). Despite the apparent early onset, issues of diagnosis in infants remains complex. Complexities arise given the relative dearth of robust screening instruments or approaches until the infant reaches about 18 months, and, even when concerns arise, diagnostic stability seems to be reached with reasonable certainty only around age 3. The most common situation is one where a child moves from seeming to have more strictly defined autism to a "broader spectrum" of ASD and vice versa. It is not uncommon for a child to have the social-communicative features of autism at 18-24 months but not to yet apparently express the unusual, restricted interests or repetitive behaviors which then go on to make their appearance by age 36 months. Often such children have some unusual interests (e.g., in fans, lights, etc.) that may presage the development of the more characteristic repetitive interests or behaviors. Rarely, a child who seems classically autistic makes considerable progress and loses the diagnosis. A further complexity is introduced by the phenomenon of regression, typically reported in about 20% of cases. This issue is also complex since parental experiences of regression sometimes are clouded by failure to note early delays: sometimes development slows, and the pattern of apparent regression is actually more one of relative stagnation (e.g., a child seems to say a few words and then doesn't progress at expected rates), and, less commonly, a significant and major regression occurs. This phenomenon remains poorly understood but appears, on balance, to be a relatively bad prognostic sign. In some rare cases the child develops normally until 4 or 5 years of age and then has, over a relatively short period of time, a catastrophic loss of skills often associated with anxiety and development of autistic presentation; the specific term for this phenomenon ("childhood disintegrative disorder") was included in DSM-IV but was excluded in DSM-5.

The ability to diagnosis autism early in life has important implications for treatment since it seems likely that early intervention is associated with better outcome (Jackson & Volkmar, 2019). The issue assumes added urgency with the awareness that recurrence risk in younger siblings may approach 20%. Although delays in diagnoses remain frequent, the increased awareness of professionals and the lay public, along with important changes in social policy (e.g., in the United States the mandate for schools to provide intervention starting at age 3 years), appear to have fostered better early identification. There is some suggestion that the new DSM-5 approach may underidentify young children (Matson et al., 2012) and that screeners work much less well than had been expected (Oien et al., 2018). Both social interest and behavior problems may increase as the child approaches the primary school years. In adolescence, some individuals become highly motivated and make gains while others seem to lose skills. Some children do so well that they technically "lose" their diagnosis: these "optimal outcome" cases are seen with increasing regularity but typically retain some residential problems (Kelley et al., 2006; Orinstein et al., 2014; Tyson et al., 2014). Epilepsy is relatively common in individuals with more "classic" autism, with peaks of onset in early childhood and again in adolescence, and treatment of the seizures may further complicate service provision.

The first outcome studies of autism in young adulthood suggested that perhaps 5-8% of cases achieved adult self-sufficiency and independence with about two-thirds of cases in need of residential care; these numbers have changed dramatically, with probably 25-30% of cases now able to achieve independence (Howlin, 2013). Increasing numbers of adolescents with ASD now move on to college (Accardo et al., 2019; van Schalkwyk et al., 2016), and programs are beginning to be developed specifically for them (White et al., 2016). Similarly, interest has increased in providing vocational supports (Gerhardt et al., 2014). But there are major gaps in transitional planning and in supports for students post college or in employment (Hatfield et al., 2018; Solomon, 2020). It is sadly the case that, despite the vast increase in research on autism, there is vanishingly little on adults (especially seniors) in general and their treatment needs in particular (Piven et al., 2011; Shea & Mesibov, 2014).

# **Psychological Perspectives**

The social disturbance in autism is highly distinctive and consistently emerges as a, if not the, defining feature of the condition (Carter et al., 2014). The social problems seen in autism are in marked contrast to normative social development where, from the moment of birth, the typically developing infant is interested in the human face and voice. From the perspectives of both psychology and neurobiology, the challenge is in understanding how these deficits arise and what their implications are for learning and development. There have been significant shifts in theoretical views over the decades since autism's first description.

The earliest interest in the neuropsychology and potential neuropsychological theories and models of autism can be traced to the case report of Kurt Godstein (Scheerer et al., 1945) and his description of a person with autism and savant skills. Subsequently many different theoretical models have been developed (Vivanti & Messinger, 2021). The earliest theoretical approaches conceptualized autism as a disorder that arose within the context of deviant caretaking experience. A few early investigators did note the unusual pattern of variability in intellectual skills, often with some peak skills in nonverbal areas and occasional unusual or "savant" abilities (e.g., in memory, drawing, calendar calculation; Hermelin, 2001). Over time, a body of research began to suggest that autism was a brainbased disorder with a strong genetic component. In addition, work within developmental psychology made it clear that, from the moment of birth, the typically developing infant was remarkably social (raising questions about theoretical notions like a normative "autistic phase" of development that has been postulated in some early psychoanalytic models). By the 1970s and into the 1980s, theoretical approaches shifted to more specific processes like perception, language, cognition, and attention.

Theoretical models are important for several reasons: they help organize and systematize knowledge, suggest potential mechanisms of pathogenesis, provide hypotheses for research, and may have implications for treatment. Chown (2017) has provided a very helpful overview of theoretical models and also has noted some of the important challenges that theories of autism face in their development. These include the need for universal applicability (i.e., over the entire range of syndrome expression), to enhance knowledge through a focus on some specific aspects of autism, to encompass the role of individual differences, and to reflect the uniqueness of the individual with autism. Consistent with all good scientific theories (Higgins, 2004), theories of autism must be coherent, testable, economical, generalizable, explanatory, and enhance research and hypothesis testing.

The first example of a theoretical model of autism was the early psychoanalytic one of clinicians like Bettelheim and colleagues (Bettelheim, 1959, 1967; Despert, 1971) that explained autism on the basis of inadequate parenting and "refrigerator" mothers. During the 1970s, a significant body of evidence emerged to make it clear that autism was brain-based and strongly genetic and responded best to structured teaching rather than unstructured psychotherapy (Jackson & Volkmar, 2019). During the 1980s and subsequently, several different and more sophisticated theoretical models emerged and will be briefly reviewed here. Each has its strengths and limitations, and all have, to some variable degrees, enhanced both research and clinical work.

# Theory of Mind Hypothesis

Probably the most influential theory of autism was proposed by Simon Baron Cohen (Baron-Cohen et al., 1985) and postulated that individuals with ASD lacked a "theory of mind" (ToM) or the inability to (simply termed) to put themselves in the place of the others. In the ToM hypothesis approach (Baron-Cohen, 1995), social difficulties are viewed as a function of a basic difficulty in intersubjectivity (i.e., understanding the mental life of self and others). This view emphasizes the difficulties that individuals with autism have in understanding the intention, desires, and beliefs of others, with resulting difficulties for predicting behavior and understanding others. Individuals with ASD who are capable of understanding false beliefs when explicitly prompted to do so are less capable of spontaneously anticipating an actor's behavior on the basis of the actor's false belief (Sonja et al., 2009) or taking the protagonist's innocent intentions into account to exculpate for accidental harms (Moran et al., 2011). In the classic "Sally Ann" task, children with ASD are significantly impaired when interpreting pretense (Bigham, 2010), less able to make inferences based on event scripts in comprehending narratives (Nuske & Bavin, 2011), and worse at taking on another person's visual perspective, especially when it involves understanding that different people may experience seeing the same object differently at the same time (Hamilton et al., 2009). This model's accounts have focused on many of the significant communication problems in autism (e.g., with pragmatic language, figurative language, and implied meaning). Some treatment approaches have been developed using it. However, some problems arise given the very strong relationship of ToM skills to overall language ability. Another problem arises in that more cognitively able individuals can readily solve usual ToM problems but remain significantly socially impaired (Dahlgren & Trillingsgaard, 1996). A final, major problem arises in that many of the earliest social manifestation of autism arise in development well before ToM skills are typically manifest. Despite these limitations, this theoretical approach has generated a truly impressive body of research.

Although helpful in stimulating research, this approach did not yield strong conceptual models for understanding the social dysfunction which appears to be the hallmark of the disorder. Indeed, in some ways it is only in recent years that the emphasis of psychological models began to shift to approaches emphasizing social information processing (paralleling, in some respects, the growing appreciation of the role of the social brain in the condition; Brothers, 1990). The potential for examining possible genetic and brain mechanisms has given added urgency to these endeavors. Several different theoretical approaches have been used in the past two decades.

# Executive Dysfunction Hypothesis

"Executive functioning" is an umbrella term for a set of higher-order cognitive processes that encompass working memory, cognitive flexibility, impulse control and inhibition, attention shifting, planning and organizing, and initiating behavior (Pennington et al., 1997). It is of interest that deficits in these skills frequently are noted in individuals with autism as well as in those with frontal lobe area difficulties of various types (see McPartland et al., 2014). Some of the problems suggestive of executive functions difficulties in ASD include the behavioral rigidity, difficulties in multitasking, and problems with attention and forward planning (Ozonoff & Schetter, 2007).

The executive dysfunction hypothesis suggests that these difficulties in forward planning and executive functions are the core underlying problem in ASD and result in both the behavioral and social problems that define the condition (e.g., see Ozonoff & Schetter, 2007). As is also true of the ToM hypothesis, there is a sustainable body of empirical support for executive function difficulties in autism (Lai et al., 2017). This theoretical model has some advantages over the ToM hypothesis in that it more readily accounts for some of the nonsocial aspects of clinical presentation. On the other hand, and as with the ToM hypothesis, one difficulty for this approach is that it lacks specificity to autism (i.e., major problems in areas of executive dysfunction also are noted in conditions as diverse as schizophrenia, obsessive-compulsive disorder, Tourette syndrome, and, particularly, attention deficit hyperactivity disorder). Another challenge arises given the diverse profiles of deficit in this area presented across the broad spectrum of ASD (see (Hill, 2004, for a review). In addition, these difficulties are not unique to autism and levels of severity do not straightforwardly relate to degree of social impairment (Dawson et al. 1998).

# Weak Central Coherence Theory

In this theoretical model the core feature is the perceptual-cognitive style in ASD that relates to how a person processes diverse sources of

information and then processes it to form a coherent and meaningful whole. This model posits that in typical development there is a tendency toward information processing that will pull together the diverse pieces of information constantly available to the developing child and construct them into a coherent whole, thus allowing the child to grasp "the big picture." This model posits that in autism this processing style is disturbed or absent, resulting in an information processing style in which the focus is on smaller parts rather than on the whole and thus is more detail-focused (Firth, 1989, 2003; Firth & Happé, 1994). More recently, the model has been refined to suggest that persons with ASD have superior local processing and poor (but not always absent) global processing (Happé & Booth, 2008). One of the great advantages of this model is that it can be used to account more fully for both the social and nonsocial features of ASD (Happe, 1996), such as the interpretation of social cues in context, the problems with circumscribed interests, the tendency to focus on parts of objects, insistence on sameness, sensitivity to change, and the occasional person with ASD who has very detail-oriented knowledge in fields like mathematics and engineering. Kanner (1943) observed important aspects of this style in his first description of autism, writing that individuals with autism have an "inability to experience wholes without full attention to the constituent parts. . . . A situation, a performance, a sentence is not regarded as complete if it is not made up of exactly the same elements that were present at the time the child was first confronted with it" (p. 246).

There are important limitations to this theory as well. These include the inconsistent findings across studies (e.g., Hatton, & Hare, 2004; Ropar & Mitchell, 2001), and, in addition, these problems are not specific to autism (e.g., similar findings are seen in disorders like Williams syndrome; Bernardino et al., 2012).

Extreme Male Brain Theory

Another proposed cognitive theory is provided by the extreme male brain theory (Baron-Cohen, 2002). This theory centers around two rather different cognitive styles, "empathizing" and "systemizing," as related to how an individual tries to understand and process information, particularly social-affective information. As proposed by Baron-Cohen, the "empathizing" style is one where the drive is to understand and predict the thoughts and emotions of others, as well as to produce an emotionally appropriate response. In contrast, the "systemizing" style is one in which the drive is to systematically study and analyze the details that make up a system in order to understand its operation. Baron-Cohen argues that, on balance, females tend to be more naturally empathetic while males tend to naturally systemize. In this model it is suggested that persons with autism present an exaggerated (or extreme) version of this dichotomy, presenting with typical systemizing and reduced empathizing. It is noteworthy that in his original report Asperger (1944) noted that all his cases were males and that fathers had rather similar social difficulties (i.e., this is a long-standing observation in autism. In his original (1944) report Asperger stated that "[t]he autistic personality is an extreme variant of male intelligence. Even within the normal variation, we find typical sex differences in intelligence. . . . In the autistic individual, the male pattern is exaggerated to the extreme" (p. 129).

Empathizing can be likened to aspects of ToM, and systemizing can be likened to components of local processing (i.e., weak central coherence), so this model has the advantages of incorporating aspects of both of these other theorical approaches.

Critics of this theory argue that the fundamental basis of the theory (sex-based differences in cognitive styles) are based on old stereotypes much more than proven science (Krahn & Fenton, 2012). Indeed, the theory is based on studies conducted by the theory author (Baron-Cohen) and/or his students and are largely based on instruments developed by this group (e.g., the Systemizing Quotient, the Empathizing Quotient; Baron-Cohen, 2010; Baron-Cohen, 2011, 2012; Baron-Cohen et al., 2014).

### Limitations of Current Theoretical Approaches

There have been several attempts to provide overall critiques of requirements for satisfactory theoretical models of autism (e.g., Chown, 2017; Gernsbacher & Yergeau, 2019; Pellicano, 2011). Although all the proposed models noted above (and several others) have had important implications for research and treatment, there has not yet been a single unified theory that accounts for all the features of ASD (Chown, 2017).

Difficulties include the broad range of autism, marked changes over the course of development, and the multiple areas of difficulty encountered in this population. This is consistent with the view that while ASD is currently viewed as a single "disorder" for the purpose of classification, it may actually be comprised of a broader phenotype potentially related to multiple etiologies but with a final common pathway (Whitehouse & Stanley, 2013). This view would help us understand the various and conflicting findings related to different subgroups of ASD. One of the important challenges for psychological models is the need to firmly center them within the developmental context (e.g., within an awareness of the importance of early development of cognition within the context of social experience; Klin et al., 2003).

However, even with their limitations, theoretical models have clearly advanced the field because they have suggested specific hypothesis and approaches to both research and clinical intervention. The unification of these models with more basic neuroscience findings remains an important research goal (McPartland et al., 2014).

# **Biological Perspectives**

Advances in understanding the biological basis of autism have increased dramatically in the past decade. Progress has occurred in several areas, including both genetics (State & Levitt, 2011) and our understanding of the social brain. And, as noted subsequently, attempts have been made to link specific brain regions and processes to some of the observed psychological phenomena and theory. Genetic studies have revealed a large number of leads for genes potentially involved in the condition, many of which relate to cell-to-cell connections in the brain. At present, the translational significance of these findings remains unclear, but there is long-term potential for clarifying specific mechanisms that impact general or more delineated brain regions. Critically, it is now clear that genetic contributions to autism include a wide array of rare de novo gene mutations as well as numerous common genetic variants, acting in concert to shape neurodevelopment. Further, there is no clear "autism gene," in that no specific genetic difference has been identified that is entirely specific to autism. Rather, the genes that contribute to autism risk also contribute to the risk for other neurodevelopmental conditions including intellectual disability and schizophrenia. This, together with an emerging understanding of the role of epigenetic factors (e.g., gene methylation), highlight the importance of biologically oriented studies that address multiple levels of analysis including genes (gene structure and expression), brain (development of structure, function, and connectivity), and behavior/cognition (e.g., Parikshak, Gandal, & Geschwind, 2015).

The nature of the social brain in autism has been a major focus of research interest over the past two decades. "Social perception" refers to "the initial stages in the processing of information that culminates in the accurate analysis of the dispositions and intentions of other individuals" (Allison et al., 2000, p. 1). Additionally, social perceptions are an ontogenetic and phylogenetic prequel to more sophisticated aspects of social cognition, including ToM skills. Successful social perception involves a set of three distinct but interrelated social cognition abilities: (1) individuating and recognizing other people, (2) perceiving their emotional states, and (3) analyzing their intentions and motivations. Social perception, in turn, facilitates a fourth and more sophisticated aspect of social cognition: (4) representing another person's perceptions and beliefs, or "theory of mind."

While neuroscientists have only recently focused on identifying the neural substrates of social perception, the construct has been of interest to psychologists for decades. For example, a major focus of Fritz Heider's work was the description of cognitive mechanisms for the perception of social objects. In collaboration with Mary-Ann Simmel, he provided elegant experimental demonstrations of the ways in which the perception of people differs from the perception of objects, particularly with regard to the attributions we make for each category of visual stimulus (Heider & Simmel, 1944). Psychological scientists commonly divvy up human cognitive abilities into memory, attention, reasoning, perception, etc. Our textbooks help to consecrate these categories, but nature does not respect the boundaries. Humans are, at their core, social and affective beings, but these essential characteristics have often been treated as sources of noise to be excluded from controlled experiments in the laboratories of cognitive psychologists. This point of view has recently been overcome, owing in large part to remarkable new discoveries that have provided strong evidence for the need for an "apocryphal" chapter regarding the unique ways in which the brain processes social information.

Neuroscientists became deeply interested in social perception when it was discovered that neurons within the temporal cortex and amygdaloidal complex of monkeys were sensitive to and selective for social objects (e.g., faces and hands) and complex social stimuli (actions in a social context and direction of gaze). On the basis of these seminal findings, the field began to think seriously about the possibility of a network of brain regions dedicated to processing social information. The label "social brain" was coined by Leslie Brothers (1990)

and served to capture elegantly the core, emerging idea. The social brain is now defined as the complex network of areas that enables us to recognize other individuals and evaluate their mental states (e.g., intentions, dispositions, desires, and beliefs). The key idea is that human beings, in response to the unique computational demands of their highly social environments, have evolved cognitive mechanisms and associated, dedicated neural systems supporting such abilities as recognizing other agents and their actions, individuating others, perceiving the emotional states of others, analyzing the intentions and dispositions of others, sharing attention with one another, and representing another person's perceptions and beliefs. Brothers (1990) emphasized the contributions of the superior temporal sulcus (STS), amygdala, orbital frontal cortex (OFC), and fusiform gyrus (FFG) to social perception. In humans, the STS region, particularly the posterior STS in the right hemisphere, analyzes biological motion cues, including eye, hand, and other body movements, to interpret and predict the actions and intentions of others (e.g., Pelphrey et al., 2005). The FFG, located in the ventral occipitotemporal cortex, contains a region termed the fusiform face area (FFA), which has been implicated in face detection (identifying a face as a face) and face recognition (identifying one's friend vs. a stranger) (e.g., Kanwisher et al., 1997). The OFC has been strongly implicated in social reinforcement and reward processes more broadly (e.g., Rolls, 2000, 2009). Finally, the amygdala, a complex structure that is highly interconnected with cortical (including the STS and FFG) and other subcortical brain structures, has been implicated in helping to recognize the emotional states of others through analysis of facial expressions as well as in multiple aspects of the experience and regulation of emotion.

To understand social brain function, we must be as attentive to the interconnections of neuroanatomical structures as we are to their individual contributions. Currently, in humans, much is known about the roles played by the individual brain regions, but very little is known about the ways in which they are interconnected and thus even less is known about how they interact functionally. However, we can take some initial guidance from the monkey brain. Here, it is known that the STS region has reciprocal connections to the amygdala, which is connected to the OFC (Amaral et al., 1992); the STS is also connected with the OFC, which itself is connected to the prefrontal cortex, which is itself connected to the motor cortex and the basal ganglia, thus completing what Allison and colleagues (2000) described as a pathway from social perception to social action.

A flood of neuroimaging work in adult humans (and increasingly in children and adolescents) has revealed a small but remarkably consistent set of cortical regions in and around the posterior parietal cortex associated with thinking about other people's thoughts, or ToM: bilateral temporoparietal junction (TPJ), medial PFC (mPFC), and posterior cingulate cortex (PC). The mPFC, is recruited when processing many kinds of information about people (Amodio & Frith, 2006), whereas the right TPJ is recruited selectively for thinking about thoughts (Saxe & Kanwisher, 2003).

Just over a decade ago, neuroscientists began to argue for the existence of two different kinds of abilities or neural systems that enable mind-reading. Sabbagh (2004) reviewed evidence for an orbitofrontal/medial temporal circuit and argued that the ability to decode others' mental states from observable cues is different from the ability to reason about others' mental states. Using animations of rigid geometric shapes that depict social interactions versus false-belief stories, Gobbini and colleagues (2007) showed that the two tasks activated distinctly different neural systems: the social animations activated a "social perception" system comprised of the STS, the frontal operculum, and inferior parietal lobule, whereas the false-belief stories activated a "mental state reasoning system" consisting of the TPJ, the anterior paracingulate cortex, and the posterior cingulate cortex or precuneus.

There is now clear behavioral and neuroimaging evidence for deficits in both the social perception and mental state reasoning systems in ASD. Next, we review selected behavioral and neuroimaging evidence from the empirical record.

# The Social Perception System

Eye-tracking studies demonstrate that toddlers with ASD fail to orient to the social significance of biological motion; instead, they focus on nonsocial, physical contingencies, contingencies that are disregarded by neurotypical peers (Klin, et al, 2009). Strikingly, later eye tracking work has revealed that individual differences in the ways in which infants view social scenes is highly heritable, with much greater similarity among monozygotic versus dizygotic twins. Furthermore, this work revealed that the atypical early patterns of social viewing that precede an autism diagnosis are under strong genetic regulation, thereby suggesting that scan paths might be a strong endophenotype and predictive biomarker of autistic social dysfunction. With the continued maturation of eye tracking research in autism, several meta-analyses have emerged to provide clarity and greater order to the field. For instance, in reviewing and quantitatively aggregating numerous eye-tracking studies of social and nonsocial stimuli in people with and without autism, Frazier and colleagues (2017) concluded that autistic individuals exhibit reliable gaze abnormalities suggesting a basic problem with selecting socially relevant versus irrelevant information for attention. This difference is persistent across age and worsens during perception of human interactions.

In the auditory domain, Rutherford and colleagues (2002) developed a test called "Reading the Mind in the Voice" and showed that adults with ASD have difficulty decoding/extracting mental state information from vocalizations. With respect to visual signals, Kaiser and colleagues (2010) found that when young children were shown point-light displays of coherent versus scrambled biological motion, children with ASD, compared to unaffected siblings and typically developing peers, exhibited hypoactivation in the FFG, amygdala, ventromedial PFC (vmPFC), ventrolateral prefrontal cortex, and posterior STS. These findings indicate widespread disruption of the social perception system in young children with ASD. Eye-gaze shifts that are difficult (vs. easy) to decode (e.g., when a target shows up, the actor looks toward empty space, rather than the target) were found to differentially activate the STS region in typical adults but not in adults with ASD (Pelphrey et al., 2005). In addition, activation of the FFG, but not the amygdala, can be altered to a normal level in individuals with ASD by compelling people with ASD to perform visual scan paths that involve fixating on the eyes of a fearful face (Perlman et al., 2011). With respect to auditory signals, individuals with ASD (vs. controls) fail to activate the voice-selective regions of the STS in response to vocal sounds (Gervais et al., 2004).

The behavioral deficit in mental state reasoning in ASD has been linked to less activation in the TPJ region (Lombardo et al., 2011). Participants were asked to judge, "How likely is the British Queen to think that keeping a diary is important?" (mental state reasoning) or "How likely is the British Queen to have bony elbows?" (physical reasoning). In typical individuals, the TPJ region activated more strongly to mental state reasoning than physical reasoning; however, in individuals with ASD, there was no such selective activation in this region. Interestingly, there was no interaction between group and judgment conditions in the dmPFC, perhaps because both judgment conditions require people to represent the British Queen as separate and different from them which are correlates of direct and reflected self-knowledge.

Historically, a lack of predictive, biologically informed profiles has contributed to the status quo of imprecise treatments, wasted time and resources, and failures to optimize progress for children and families living with ASD. Fortunately, this situation is rapidly improving. Research within the field of developmental social neuroscience has now advanced sufficiently to provide the first sensitive, quantitative, and biologically meaningful markers of ASD symptoms (e.g., Kaiser et al., 2010). These tentative biomarkers are now being evaluated for their utility in measuring and predicting individual responses to evidenced-based interventions (e.g., Yang et al., 2016). As such, the work has advanced our understanding of ASD and may ultimately inform and guide personalized therapies. (McPartland et al., 2014).

Because autism is a developmental disorder, it is particularly important to diagnose and treat ASD early in life. As noted previously, early deficits in attention to other's actions, for instance (what we call biological motion), derail subsequent experiences in attending to higher-level social information, thereby driving development toward more severe dysfunction and stimulating deficits in additional domains of functioning, such as language development. The lack of reliable predictors of the ASD during the first year of life has been a major impediment to its effective treatment. Without early predictors, and in the absence of a firm diagnosis until behavioral symptoms emerge, treatment is often delayed for 2 or more years, eclipsing a crucial period in which intervention may be particularly successful in ameliorating some of the social and communicative impairments seen in ASD.

In response to the great need for sensitive (able to identify subtle cases) and specific (able to distinguish autism from other disorders) early indicators of ASD, such as biomarkers, many research teams from around the world have been studying patterns of infant development using prospective longitudinal studies of infant siblings of children with ASD compared to infant siblings without familial risks. Such designs gather longitudinal information about developmental trajectories across the first 3 years of life, followed by clinical diagnosis at approximately 36 months. Biobehavioral markers—especially eye-tracking studies—of multidimensional social processes are beginning to prove useful in early identification of atypical developmental processes among children at increased genetic risk for developing difficulties in social information processing (e.g., Jones & Klin, 2013; see also Anderson, 2014).

Studies pursuing early biobehavioral markers are potentially problematic in that many of the social features of autism do not emerge in typical development until after 12 months of age. It is not certain that these symptom features will manifest during the limited periods of observation involved in clinical evaluations or in pediatricians' offices. Moreover, across development, but especially during infancy, behavior is widely variable and often unreliable. At present, longitudinal behavioral observation is the only means to detect the emergence of ASD and predict a diagnosis (Jones & Klin, 2013). However, measuring the brain activity associated with social perception can detect differences not appearing behaviorally until much later. The identification of biomarkers utilizing the imaging methods we have described offers promise for earlier detection of atypical social development. Event-related potentials (ERP) measures of brain response predict subsequent development of autism in infants as young as 6 months old who showed normal patterns of visual fixation (as measured by eye tracking) (Elsabbagh et al., 2012). These types of studies illustrate the great promise of brain imaging for earlier recognition of ASD. With earlier detection, treatments could move from addressing existing symptoms to preventing their emergence by altering the course of abnormal brain development and steering it toward compensation or normality.

To the extent that research can further elucidate developmental trajectories of the neural circuitry supporting pivotal, early developing social abilities, it might inform the design of more effective programs for identifying and remediating risk for difficulties in these areas. It is generally accepted that earlier educational interventions are more effective for treating a variety of behavioral and academic childhood problems and neurodevelopmental disorders. Therefore, early identification of children with difficulties in social cognition is pivotal to optimizing individual intervention outcomes. A neurobiological marker for individual differences in multidimensional social representation abilities would then not solely be important for improving early identification, but also could offer advantages for earlier interventions. Moreover, it could be that the neurobiological marker would relate to the severity of specific deficits, helping us to better

understand the heterogeneity characteristic of neuropsychiatric disorders. With this information, more targeted treatments could be developed, on a child-by-child basis, and implemented early in ontogeny. Early targeted intervention then might guarantee the most effective course of intervention possible, also improving efficiency and standardization. Furthermore, functional neuroimaging techniques, might actually provide a means to better quantify treatment effectiveness and reveal whether behavioral improvements correspond to compensatory changes in brain function or normalization of developmental pathways.

Early and longitudinal study will be critical in defining brain phenotypes. This is because the shape of developmental trajectories of brain functioning in specific circuits will provide more detail on the nature of the abnormalities than will analysis of brain phenotypes in adulthood. Despite much progress, there is still much to learn about the early longitudinal changes in brain connectivity, function, and temporal dynamics that support the development of the ability to integrate a broad array of emotional and social cues from multiple sensory modalities (e.g., vision, touch, audition) in the service of social cognition. Likewise, the neurobiological basis of individual differences in multimodal, multidimensional social cognitive abilities remains poorly understood. There are straightforward and compelling methodological reasons to adopt a longitudinal design. Neuroimaging data are inherently noisy because individual brains are different from one another. A longitudinal design is the only way to study developmental processes coupled with the power of within-subject statistics. It also makes it more likely that we will be able to detect relationships between different developmental changes. For example, just knowing that both Task A and Task B change between 4 and 6 months of age tells us almost nothing about those tasks, but individual differences in the response to Task A at time 1, or the change in Task A performance, are good predictors of individual differences in the magnitude of change in Task B and will yield much stronger inferential leverage upon which to build lasting theoretical contributions.

There is currently no single biological test for ASD. The diagnostic process involves a combination of parental report and clinical observation. Children with significant impairments across the social/ communication domain who also exhibit repetitive behaviors can qualify for the ASD diagnosis. As discussed earlier, there is wide variability in the

precise symptom profile an individual may exhibit. Since Kanner first described ASD in 1943, important commonalities in symptom presentation have been used to compile criteria for an ASD diagnosis. These diagnostic criteria have evolved during the past 76 years and continue to evolve, yet impaired social functioning remains a required symptom for an ASD diagnosis. Deficits in social functioning are present in varying degrees for simple behaviors, such as eye contact, and for complex behaviors, like navigating the give-and-take of a group conversation, for individuals of all functioning levels (i.e., high or low IQ). Moreover, difficulties with social information processing occur in both visual (e.g., Pelphrey et al., 2002) and auditory (e.g., Dawson et al., 1998) sensory modalities. While repetitive behaviors or language deficits are seen in other disorders (e.g., obsessive-compulsive disorder and specific language impairment, respectively), basic social deficits of this nature are unique to ASD. Onset of the social deficits appears to precede difficulties in other domains (Osterling, Dawson, & Munson, 2002) and may emerge as early as 6 months of age (Maestro et al., 2002).

This focus on social cognition and the importance of the social brain led us to hypothesize that factors contributing to the expression of ASD exert their effects through a circumscribed set of neuroanatomical structures, so that the simplest and potentially most powerful signatures of ASD will be found at the level of brain systems. Such "neural signatures" of ASD may serve as critical endophenotypes to facilitate the study of the pathophysiological mechanisms. Endophenotypes, or characteristics that are not immediately available to observation but that reflect an underlying genetic liability for disease, expose the most basic components of a complex psychiatric disorder and are more stable across the life span than are observable behavior (Gottesman & Shields, 1973). In a study pursuing neural signatures of ASD, we assessed three groups of children using functional magnetic resonance imaging (fMRI). These were children diagnosed with ASD, unaffected siblings (US) of children with ASD who were typically developing, and typically developing (TD) children without a relative with ASD. The three groups of participants were matched on chronological age and were of similar cognitive ability, all within the average range. Notably, the US and TD groups were matched on measures of social responsiveness and adaptive behavior. This rigorous matching ensured that both groups were unaffected by ASD and demonstrated equivalent levels

of social responsiveness. In addition, strict exclusion criteria were used for the TD and US groups to rule out other developmental disorders and the "broader autism phenotype" (BAP) in each participant, as well as in first- and second-degree relatives of the US participants.

We measured brain responses in these groups of children using fMRI while they viewed socially meaningful biological motion (movements of other people) to reveal three types of neural signatures: (1) state activity related to having ASD that characterizes the nature of disruption in brain circuitry; (2) trait activity reflecting shared areas of dysfunction in US and children with ASD, thereby providing a promising neuroendophenotype to facilitate efforts to bridge genomic complexity and disorder heterogeneity; and (3) compensatory activity, unique to US, suggesting a neural systems level mechanism by which US might compensate for an increased genetic risk for developing ASD. The identification of state activity extends previous research implicating the right amygdala, right pSTS, bilateral FG, left vlPFC, and vmPFC in adults with ASD by showing that dysfunction in these regions is already present in school-age children with ASD (Castelli et al., 2002; Gilbert et al., 2009; Schultz et al., 2000). This was an important advance in the field, given that previous reports of atypical neural response to biological motion included only adult subjects. In addition, activity in the state-defined right pSTS was associated with the severity of social deficits in individuals with ASD. Individuals with higher social responsiveness scale scores (SRS; Constantino & Frazier, 2013) exhibited less activation to biological motion within the right pSTS. This finding suggests that activity in the pSTS might serve as a biological marker to subdivide the autism spectrum on the basis of severity. Furthermore, activity in the state-defined region of the left vIPFC was found to reflect the level of social responsiveness of the TD children, indicating a coupling of social behavior and brain mechanisms for social perception. The evidence of dysfunction in brain mechanisms for social perception in young children with ASD explains previous behavioral findings of disrupted biological motion perception (Klin et al., 2009). Given that social interaction relies on the accurate perception of other people's actions, state activity indicating regions of dysfunction associated with the manifestation of ASD provides a significant step toward more fully characterizing the biological underpinnings of this neurodevelopmental disorder.

In accordance with Gottesman and Gould's (2003) characterization of endophenotypes, trait activations, including those in the left dlPFC, right ITG, and bilateral FG, were shared between affected individuals (ASD group) and first-degree relatives (US group). These findings are particularly noteworthy because we explicitly ruled out BAP in the US group. This implies that our neuroimaging paradigm offers a remarkable level of sensitivity that transcends clinical evaluation. Although the US group was indistinguishable from the TD group at the behavioral level, the trait activity findings reveal similar neural signatures in the US and ASD groups. Consistent with this interpretation, social responsiveness was associated with overall trait activity in the US group and with trait-defined left dlPFC in the TD group. Furthermore, whereas the state regions could arise as an effect of having ASD, the trait activity cannot be explained in this way; rather, this trait activity likely reflects the genetic vulnerability to develop ASD. The key implication of our trait activity findings is that we provide a functional neuroendophenotype that should help bridge the gene-behavior gap, thereby accelerating the search for pathophysiological mechanisms.

The US group exhibited unique areas of activation in the vmPFC and the right pSTS, regions previously implicated in aspects of social perception and social cognition (Adolphs, 1999). These regions might reflect the absence of additional genetic or environmental factors that confer risk for ASD. Alternatively, they could represent a process through which brain function was altered over development to compensate for an increased genetic risk to develop ASD. We found that the activity in these regions did not vary with chronological age. Thus, it is possible that the compensatory regions reflect the outcome of a process occurring earlier in development, during a sensitive period for the development of brain mechanisms for social perception. This might be likely, given that autism is a developmental disorder that emerges during the first years of life, well before age 4 years (the youngest age studied in this sample). Nonetheless, we cannot yet draw firm conclusions regarding the compensatory activity. Indeed, longitudinal research in younger children is critically needed to better understand the origins of this compensatory activity, which likely has both genetic and environmental influences. Future studies are needed to compare the activity in these regions in US participants with and without BAP, to determine the function and etiology of this brain response to biological motion. The implication of these findings is that these regions could represent important targets for treatments and provide a measure of the effectiveness of intervention, as well as a better understanding of the mechanisms through which successful treatments function. The US exhibited unique areas of activation in regions previously implicated in aspects of social perception and social cognition. This might reflect the absence of additional genetic or environmental factors that confer risk for ASD. Alternatively, it could represent a process through which brain function is altered over development to compensate for an increased genetic risk to develop ASD.

Our study and many other group-based comparative studies reveal important clues about the neurobiological mechanisms that give rise to ASD symptomatology. Yet, treating ASD as a unitary condition, whereby individuals with ASD are grouped together and compared to "neurotypical" (typically developing) people, undermines the potential of translational research to contribute to "precision medicine" (Insel, 2014) in ASD. Because of the limited quality of the behavioral methods used to diagnose ASD and current clinical diagnostic practice, which permits similar diagnoses despite distinct symptom profiles (McPartland et al., 2011), it is possible that the group of children currently referred to as having ASD may actually represent different syndromes with distinct causes. The ability to integrate a broad array of social cues from multiple sensory domains is impaired in many neuropsychiatric disorders. The spectrum from mental health to mental illness is continuous and not categorical-Mother Nature has not yet read the DSM-5. Thus, a dimensional, individual differences approach is crucial to understanding multimodal social cognitive abilities and their development. Autistic individuals are currently defined solely on the basis of behavioral indicators. Undoubtedly, this approach lumps together individuals with common behavioral phenotypes but possibly quite different underlying etiologies. By defining functional brain phenotypes based on neurofunctional/behavioral developmental pathways and activation patterns, fMRI studies of children have the potential to dissect the heterogeneity present in these disorders. Functional neuroimaging studies could reveal different brain phenotypes in the circuitry involved in social cognition. This approach may allow us to partition individuals with autism, a complex, etiologically heterogeneous disorder, into more homogenous subgroups (e.g., Yang et al., 2017). These profiles, in turn, may

inform treatment of ASD by helping us to match specific treatments to specific profiles.

The challenge of quantifying brain profiles in ASD is now being addressed via the application to brain imaging data of artificial intelligence (AI) theories and analytic techniques in order to derive sensitive, reliable brain measures that are informative at the level of the individual (e.g., Björnsdotter et al., 2016; Yang et al., 2016, 2017; Zhuang et al., 2018). Consider, for instance, our use of fMRI and machine-learning multivariate pattern analysis (MVPA) techniques to identify profiles of activation in young children with ASD that predict responses to 16 weeks of an evidence-based behavioral treatment (Yang et al., 2016)-pivotal response treatment (PRT). Neural predictors were identified in the pretreatment levels of activity in response to biological versus scrambled motion in the neural circuits that support social information processing (STS, fusiform gyrus, amygdala, inferior parietal cortex, and superior parietal lobule) and social motivation/ reward (orbitofrontal cortex, insula, putamen, pallidum, and ventral striatum). The predictive value of our findings for individual children with ASD was supported by a MVPA with cross-validation. By predicting who will respond to a particular treatment for ASD, these findings marked the very first evidence of prediction/stratification biomarkers in young children with ASD. In MVPA, the samples were divided into training and testing datasets, which constitute a cross-validation framework in which the predictive model is first trained with the training set and then used to predict the regression labels of the sample in the testing set. This type of cross-validation provides approximately unbiased estimates of effects, generalizable to new samples, thus helping to minimize the likelihood that the results overfit the data (Chawarska, Macari, et al., 2016; Chawarska, Ye, et al., 2016).

Our findings move the field toward the goal of targeted, personalized treatment for individuals with ASD. The knowledge gained can be utilized in future work to tailor individualized treatment, refine PRT, and develop novel interventions. This study adds to the understanding of the pretreatment neural underpinnings of successful behavioral response to PRT. In the future, our results may drive the construction of algorithms to predict which, among several treatments, is most likely to benefit a given person. In addition, PRT is a multicomponent treatment; hence, future studies might use dismantling designs to isolate treatment components and their association with the neuropredictive targets identified here. This line of work could inform the development of treatment strategies that would target specific patterns of neural strengths and vulnerabilities within a given patient—consistent with the priority of creating individually tailored interventions, customized to the characteristics of a given person.

The predictive biomarkers identified in this study can be interpreted as the pretreatment neurobiological readiness to respond to a specific treatment, PRT. It should be noted that the brain regions where activity before treatment correlated with SRS scores before treatment did not overlap with the neuropredictive network described here, which indicates that the neuropredictive network is specific to change in severity in young children with ASD. As such, our findings offer the hope that pre- or concurrent treatments (whether pharmacological, direct stimulation, neurofeedback, or behaviorally based) that improve the functioning of the neuropredictive markers identified here may increase the effectiveness of evidenced-based behavioral treatments for core deficits in children with ASD. On the other hand, our findings are also particularly important for those children who would otherwise be the least likely to benefit from these expensive and time-consuming forms of treatment. For example, in a randomized, double-blind, cross-over functional fMRI study (Gordon et al., 2013), we reported that intranasal oxytocin administered to children with ASD increases activity during social versus nonsocial judgments in several of the same brain regions identified as predictive in the present study (e.g., amygdala, orbitofrontal cortex, STS region, and ventral striatum). These findings, coupled with those in the current report, raise the provocative hypothesis that the administration of intranasal oxytocin, by priming key neural circuits for social motivation and social perception, may serve to enhance the effectiveness of interventions like PRT in the very children who might be less biologically ready to respond.

This and similar research developments mark the start of a new era in which advanced neuroimage analysis will evolve into an integral part of a translational research chain. Novel behavioral treatment and pharmacotherapies for ASD may be further developed in young children, with the tremendous benefit of directly and more precisely assessing impairment and change in targeted neural circuits. Neuroimaging-derived biological markers could be used, at the outset, to make treatment decisions related to dose, duration, intensity, and specific behavioral treatment approach as well as related to the use of concurrent pharmacological intervention.

# **Functional Somatic Symptoms**

Peter Henningsen, Theo K. Bouman, and Constanze Hausteiner-Wiehle

### Introduction

In this introduction, we describe the clinical phenomenon of functional somatic symptoms (FSS) which, in DSM-5, is mostly categorized under the heading of "somatic symptom disorder." The symptoms referred to as FSS are comprised of varying combinations of pain in different parts of the body, functional disturbances attributed to organs like cardiovascular or gastrointestinal dysfunctions or dizziness, and symptoms surrounding fatigue. Somatic symptoms in general are part and parcel of everyday life, with at least 75% of the general population experiencing some form of mild to severe physical symptoms in any given month (Kroenke, 2003). Somatic symptoms are by definition subjectively experienced phenomena, whereas somatic signs are objective evidence of disease. Sometimes it is possible to correlate these symptoms with presumed etiological factors, be they physical or psychological (e.g., muscle pain after exertion, headache while angry) but often there is no obvious cause for them. In most instances, symptoms neither go along with suffering nor with impairment of function. They disappear spontaneously or with self-help measures like rest or an aspirin. These transitory symptoms are not signs of an illness; they are part of health. A state of health is not the absence of all (bodily) symptoms, but rather the ability of the human organism to self-regulate in a way that these symptoms are transitory and do not impair daily functioning for long.

However, in about 25% of the sufferers, the symptoms persist for a longer period, prompting them to contact their doctors for medical care (Kroenke, 2003). In medical investigations, for a large proportion of persistent somatic symptoms no obvious and clear-cut organic pathology (like a tumor, inflammation, or nerve damage, etc.) can be identified that explains the occurrence, the extent, and the persistence of the symptoms. These somatic symptoms are here called "functional," referring to the fact that organ or organismic dysfunctions rather than structural pathology is underlying them and also indicating the possibility that these symptoms have a function for the person in their life context (e.g., indicating homeostatic dysbalance). We avoid the wastebasket term "medically unexplained symptoms" because such a negative definition is difficult to accept for patients and because it falsely implies that medicine has no role in dealing with these symptoms (Creed et al., 2010). Moreover, it also assumes a dichotomy between medically explained and unexplained symptoms, thereby ignoring the fact that most symptoms can only be partially explained by organic disease at best and at any given time.

The prevalence of FSS in the population is around 10% (Roenneberg et al., 2019). Around 25%—and in some contexts up to 60%—of all patients in primary as well as in outpatient secondary care suffer from FSS (Nimnuan et al., 2001; Roenneberg et al., 2019). Typically, there are three types of symptom clusters to be considered: pain in

Abbreviations				
CD	Conversion disorder

one or more locations (most often concerning back, head, abdomen, extremities, and joints), disturbed functions (dizziness, cardiovascular or gastrointestinal functions, weakness, numbness, etc.), and fatigue.

FSS occur worldwide and there is no indication that socioeconomic gradients between countries are correlated with higher or lower somatic symptom counts, whereas within countries there is an association between higher levels of social adversity and higher FSS rates (Gureje et al., 1997; Gustafsson et al., 2015). For most cultures, somatic symptoms appear to be a well-accepted way to experience and present personal and/or social distress (Chaturvedi, 2013; Nichter, 2010). However, there are variations among cultures, as exemplified by culture-bound syndromes. For example, the *dhat syndrome*, being the fear of loss of semen accompanied by fatigue and other somatic symptoms, is somewhat common among Indian young men (Kirmayer & Sartorius, 2007). In times of increasing migration, knowledge of these culturally shaped variations in somatic presentations becomes more important. However, sociocultural differences are relevant also among Westernized societies (e.g., the rate of distressing chronic low back pain in Germany is twice what it is in Great Britain; Raspe et al., 2004).

Across cultures, women report more functional and other somatic symptoms than men, at a rate of approximately 2:1. They also show more healthcare utilization and a lower all-cause mortality. There are various possible reasons for these differences that illustrate the close interplay between biological, psychological, and sociocultural/environmental factors, ranging from differences in sensory perception and rates of traumatization to gender role expectations including communication and health behavior, and, last but not least, gendered healthcare (Hausteiner-Wiehle et al., 2011). Distinguishing between sex and gender, Ballering et al. (2020) found that feminine gender characteristics like type of hobbies, dietary preferences, or time spent on household tasks are associated with increased common somatic symptoms and chronic diseases, especially in men. Female sex is associated with more and more distressing common somatic symptoms, but not with a higher prevalence of chronic diseases.

FSS occur across the life span. In children and adolescents, persistent symptoms like abdominal pain, headache, or fatigue are a frequently overlooked cause for school absenteeism (Vassilopoulos et al., 2020). In people over the age of 65 years, the rate of FSS is similar to younger people, whereas

the rate of somatic symptoms due to organic disease rises with age (Hausteiner-Wiehle et al., 2011). As a consequence, it is more challenging to clearly differentiate organic pathology from functional backgrounds of somatic symptoms in older people. Doctors are quite reluctant to label symptoms as "functional," especially in men and the elderly, resulting in "organic" overdiagnosis and over treatment and symptom persistence. However, any exaggerated concern of doctors that they might overlook significant organic disease when defining somatic symptom(s) in a patient as functional does not seem to be warranted. A systematic review has shown that once an adequate workup of the symptoms has been made, the rate of revised diagnoses in followup studies of FSS was only 0.5% (Eikelboom et al., 2016). Hence, although mistakes are made both in the direction of overlooked organic pathology and in the direction of missed functional background, the latter is much more frequent in high-tech Western healthcare systems (Henningsen, 2016).

It is a misconception to assume that somatic symptoms that are functional in nature are less "severe" than those caused by clearly defined organic disease. In fact, they can cause significant impairment of function (i.e., quality of life is reduced, sick leave and early retirement are increased), and the extent of this impairment is no less than in organically defined disease (Joustra et al., 2015). Interestingly, it is the total number of somatic symptoms, independent of their nature, that correlates best with impairment (Tomenson et al., 2013).

Patients with FSS clearly have higher rates of anxiety and depressive symptoms than healthy people and also than patients with organic disease with comparable somatic symptoms (Henningsen et al., 2003). Nevertheless, many patients with severe FSS do not have high rates of anxiety or depressive symptoms, and therefore it is misleading to assume that FSS generally are a form of "masked depression" or "masked anxiety" (Löwe et al., 2008). Heuristically, it may be best to view depressive, anxiety, and somatic symptoms as three dimensions of distress that are interrelated but not identical.

# Historical Labels and Classifications in This Field

When looking at the historical development of labels and concepts for FSS in psychiatry and somatic medicine since the nineteenth century, it becomes apparent that multiple perspectives often complicate a clear understanding of the phenomenon. For one, the concept of hysteria as an important root has influenced the field in two different ways. The first is through the development of psychoanalysis and Sigmund Freud's (1856-1939) concept of hysteria as a neurotic condition characterized predominantly by variable, mainly sensorimotor symptoms and "hysterical conversion" of unacceptable affect into somatic symptoms. Whereas Freud considered this process to be a "mysterious leap from the mind to the body," a later physician and psychoanalyst, Franz Alexander (1891-1964) tried to be more specific (Alexander, 1950). He postulated that unconscious conflictrelated blockage of normal aggressive as well as nurturing impulses led to overactivation of the sympathetic and parasympathetic branches of the autonomous nervous system, respectively. This in turn would lead to FSS like syncope, "cardiac neurosis," or diarrhea and constipation.

The term "conversion disorder," if not the concept underlying it, is retained in official classifications up until *DSM-5*. Freud's contemporary and colleague Wilhelm Stekel (*1868–1940*) later coined the term "somatization" as a synonym for this "psychogenic" process. Lipowski (1988) defined somatization more descriptively as a tendency to experience and express psychological distress in the form of somatic symptoms that individuals misinterpret as serious physical illness and for which they seek medical help.

A second influence of the concept of hysteria centered on the hysteric or histrionic (i.e., attentionseeking), emotionally labile, and dramatic personality type frequently exhibiting multiple somatic symptoms. Pierre Briquet (*1796–1881*) formulated a polysymptomatic variant of hysteria which was later taken up by Guze and Perley (1963) in their description of Briquet's syndrome, characterized by a combination of "pseudoneurological" (i.e., sensorimotor with functional somatic symptoms attributed to a multitude of organ systems: cardiovascular, gastrointestinal, etc.) lasting for most of the patient's life. This in turn became the model on which the *DSM* category of somatization disorder was formed in *DSM-III*.

In a more general historical perspective FSS can be considered as a symptom pool that is more or less constant over time and for which different diagnostic labels were and are "en vogue," but also critically discussed, at varying points in time (Shorter, 1993). Spinal irritation and neurasthenia were such labels in the nineteenth century, vegetative neurosis and psychogenic pain were labels in the twentieth century, and chronic fatigue syndrome or idiopathic environmental illness are examples in the twenty-first century.

An important aspect of the official diagnostic tradition in this field is the fact that there have long been two perspectives on FSS that are connected poorly if at all. On the one hand, there is the professional perspective on the experience and behavior of the person who complains of (often multiple) somatic symptoms. This is a perspective typical for psychiatrists and psychotherapists, with the idea of classifying FSS of sufficient severity as a mental disorder. On the other hand, there is the perspective of somatic specialists who in their field encounter patients with typical somatic symptoms in whom the suspected organic disease cannot be confirmed (e.g., the gastroenterologist sees patients with diarrhea and constipation but without evidence of gastrointestinal pathology; similarly, the gynecologist with patients with chronic pelvic pain, or the cardiologist with patients with chest pain). These somatic specialists will usually classify these patients within their somatic specialist field with a label of functional somatic syndrome like irritable bowel syndrome (IBS) or noncardiac chest pain. This approach leads to well-described organ-specific patterns of functional symptoms, but it not only neglects the patient's experience and behavior, it also very often also overlooks many functional symptoms of the patient related to other organ systems (Wessely et al., 1999).

# Pathopsychophysiology

In this section we describe the current understanding of the psychophysiological mechanisms underlying the subjective experience of enduring somatic symptoms for which, by definition, there is no clearly defined organic pathology to be found that explains the symptoms. The aim is to provide an account that does justice to two rather different ways of explaining these "organically unexplained" symptoms: as a bodily expression of unresolved psychological stress and conflicts (from central processes to body periphery or "top down") and as a psychological amplification or exaggeration of normal bodily sensations (from the body periphery to central processes or "bottom up").

The first traditional way of explaining these symptoms via a psychogenic or "top-down" mechanism was mentioned before; it implied that psychological stress and conflicts cannot be resolved by psychological or behavioral means and are "converted" into somatic symptoms. This conceptualization justified the application of psychotherapy, namely psychoanalysis, in these patients (a former edition of Alexander's [1936] book was called *The Medical Value of Psychoanalysis*). However, neither a specific conflict nor a consistent overactivation of the autonomous nervous system in these patients could ever be verified empirically, and the fact that culturally shaped variations in symptom experience would require, in this model, culturally shaped differences in basic psychophysiology also spoke against its validity.

Another traditional explanation of the psychopathophysiology of patients with FSS can be called more "bottom up": normal introspectively transmitted signals from the body periphery (e.g., resulting from stress-related arousal and focused attention) are amplified in central processing and hence in perception. "Somatosensory amplification," described by Barsky et al. (1988) as the tendency to amplify a broad range of uncomfortable bodily sensations (most of which are not the pathological symptoms of serious diseases) has become one popular concept in this tradition. Its focus on perceptual amplification of normal bodily arousal signals and cognitivebehavioral consequences, such as catastrophization and body scanning, puts the experience of somatic symptoms close to (illness) anxiety. It is therefore not surprising that the role of somatosensory amplification has also been confirmed in hypochondriasis (i.e., in a condition characterized not primarily by somatic symptoms but by the fear of having a serious somatic disease; Barsky & Wyshak, 1990). As a consequence, psychotherapy, in this case typically cognitive-behavioral therapy, is clearly indicated as a treatment of choice for patients with FSS.

This "anxiety-style approach" to the explanation of somatic symptoms has also influenced the definition of somatic symptom disorder in DSM-5 (see below). However, for the intuitively appealing model of somatic amplification of peripheral stress-related arousal, which rather has evolved into a family of models with slight variations (see Van den Bergh et al., 2017), empirical evidence is limited at best. For the first component of the concept, there is no convincing evidence of a causal role of peripheral stress-related arousal even for more severe FSS patterns. For instance, in a well-designed study, Houtveen et al. (2010) did not find significant differences in 24-hour monitoring of cardiac autonomic and respiratory parameters between persons high on FSS compared to those low on FSS. Also, in clinical populations with more severe FSS, meta-analytic evidence did not show, after correction for publication bias, significant differences in physiological parameters compared to healthy controls (Tak et al., 2009). Studies measuring attentional deployment toward body- or illness-related stimuli also fail to provide convincing evidence for an attentional bias toward these stimuli (Van den Bergh et al., 2017). And finally, there is clear evidence for a positive correlation of (catastrophic) misattribution of benign bodily sensations with FSS, but it is unclear to what extent this correlation is a consequence rather than a causal factor for FSS. Thus, newer accounts view somatic amplification as the intensification of perceived external and internal threats to the integrity of the body ("somatic threat amplification") rather than amplification of perceived or actual bodily events only (Köteles & Witthöft, 2017).

In recent years, a new understanding of the brain not as a mere passive information processing device but as an active and constant comparator between prior predictions and actual sensory input (from the environment and from the body) has provided a more integrative understanding of the processes underlying somatic symptom experience (Edwards et al., 2012; Henningsen, Gundel et al., 2018; Van den Bergh et al., 2017). This predictive processing (PP) approach, popular in computational psychosomatics and psychiatry (Petzschner et al., 2017), is based on Bayes' statistical principles. It postulates an overarching, non-dualistic, and dynamic mechanism that integrates the two following aspects when explaining why individuals, for example, are chronically fatigued, chemically sensitive, aching allover, suddenly dizzy, or paralyzed: first, topdown central aspects act as priors (i.e., a Bayesian term for preformed facilitations generated from prior experiences across hierarchical levels of the central nervous system). On a psychological level of description, they are analogous to (unconscious) expectancies or (conscious) expectations. These priors are constantly compared to the second, bottomup peripheral aspect constituted by sensory signals. In this truly integrative biopsychosocial account of perception, sensory input, be it exteroceptive (visual, auditory, etc.) or interoceptive, is not seen as the primary determinant, with central/psychological processes "only" as secondary modifying factors. The actual percept is influenced by the strength or precision of the sensory input as much as by the strength or precision of the prior (i.e., the steepness of the respective statistical distribution curves).

If a prediction error occurs (i.e., when walking on a floor with black tiles, the prior will predict further black tiles, and a red tile will constitute a prediction error), the "inner working" or "generative" model, on which the prior is based, may be adapted to integrate the new information (i.e., the prediction is changed to "black tiles with occasional red ones"). Another possibility is that the sensory input is actively influenced so that it better conforms to the prior (i.e., "I walk back where no red tiles occurred"). This active influence means that autonomic and/or other neural activations may actually be a way of adapting sensory input to prior perceptual expectations (e.g., back pain as an active inference to conform to the prior of "back-breaking" work strain or a red blush as an active inference to conform to the prior of shame). Failure of inference can occur on several levels: With potent prior beliefs ("Environmental toxins are invisible, ubiquitous, and dangerous"), low-precision sensory input close to random fluctuations (1 second of blurred vision) can amount to conscious expectations (brain fog, risk of falling) and generate high-precision perceptions to comply with them (dizziness, disturbances of equilibrium or cognition)-a situation comparable to phantom sensations (Henningsen, Gundel et al., 2018). The unconscious, automatic character of the inferential process and the compelling quality of reality/trueness makes the experience of somatic symptoms relatively impermeable for deliberate conscious reasoning. It leads to a secondary failure of inference; namely, to the conscious belief that the interocept indeed is a symptom (i.e., an expression of abnormal bodily function).

This Bayesian PP perspective blurs any categorical distinction between so-called medically unexplained symptoms and symptoms emerging from physiological dysfunction (see Van den Bergh et al., 2017). The same inferential processes are involved in both types, with the difference being a matter of degree: namely, to what extent priors versus sensory input dominate somatic symptom perception. Whereas the somatic amplification model refers to typical threat-related priors only, the PP-based model allows for a much broader variety of priors (e.g., related to damage, strain or weakness in pain, or fatigue conditions).

The PP perspective renders plausible also the direct influence of (interpersonal) context factors on symptom perception: prior interpersonal experiences especially in dealing with bodily sensations and symptoms will influence the prediction of future symptom experiences (Fotopoulou & Tsakiris, 2017). As a clinically very stimulating recent model, the PP account is not yet well-validated empirically. However, neurobiological evidence is now accumulating that supports the assumption suggested by the mathematically well-tested PP models (Allen, 2020).

# Etiology

What are the etiological factors that bring about the experience of FSS? Here we describe the most relevant vulnerability, triggering, and maintaining factors, using the biopsychosocial model of pathopsychophysiology just described. We see that they differentially influence both routes to symptom perception, priors, and sensory input (see Figure 22.1, in which the prior is—slightly inexactly because only referring to the cognitively conscious part called "expectation" here).

To start with vulnerability, genetic factors contribute to the predisposition to FSS, but only to a

Figure 22.1 Etiological factors in functional somatic symptoms (FSS)/bodily distress. Adapted from Henningsen et al. (2018b).

limited extent, explaining up to 33% of the variance (Gasperi et al., 2020; Kato et al., 2010). Genomewide and other searches attempting to identify single genes responsible for the disposition of chronic (multisite) pain, an important component of FSS, so far have yielded inconsistent results; epigenetic mechanisms are increasingly seen as also highly relevant (Denk et al., 2014; Johnston et al., 2019). These epigenetic mechanisms offer a potential mechanistic link to the well-established role that childhood adversities have as a possible predisposing factor for FSS: they increase the odds for the development of bodily distress up to fourfold (Afari et al., 2014). There is also evidence that genetic vulnerabilities may moderate the relation between posttraumatic stress disorder (PTSD) and functional somatic pain conditions (Gasperi et al., 2020).

Attachment patterns form another link between childhood adversity and somatization, with maternal insensitivity at 18 months predicting parentascertained somatization in 5-year-old children, and attachment insecurity in adults correlating with somatization, with strongest links existing between attachment anxiety and health anxiety (Maunder et al., 2017). The PP model sketched above renders plausible a direct influence of dysfunctional (e.g., overly anxious) attachment patterns on symptom experience via the caregiver-child interaction around seemingly threatening bodily sensations, which leads to the formation of according priors in the child; that is (non-conscious) expectancies and (conscious) expectations that bodily sensations must be threatening.

Deficiencies in emotion recognition and regulation have also been linked to increased vulnerability for FSS and bodily distress. One example is *alexithymia*, referring to the inability to "read" (i.e., to perceive and name) one's own emotional states. A systematic review confirmed an association between difficulties in emotion regulation and FSS across different diagnoses (Okur Güney et al., 2019). However, the specificity of this finding and potential causality remain to be determined.

Similar questions apply to the positive correlations found between personality characteristics like neuroticism, harm avoidance, or lower agreeableness and somatization or somatoform disorders (Noyes et al., 2001; Rezaei et al., 2020). The chronic experience of FSS shares many features with personality disorders (Bass & Murphy, 1995) in terms of their developmental origin, persistent nature, disruptive impact on social functioning, and chronic course. Viewed from the angle of categoric diagnoses, a meta-analysis (Bornstein & Gold, 2008) complements this notion, showing that somatization disorder, a severe form of somatoform disorder (according to the *DSM-IV*) with multiple chronic FSS, is comorbid with the majority of personality disorders—but there is no special association with only one or two of them (e.g., with histrionic personality disorder).

Prior organic illnesses create a vulnerability and a triggering factor potentially via both routes sketched in Figure 22.1: sensory input and expectation created through prior experience. For instance, symptoms compatible with IBS were more frequently reported after gastrointestinal infections or active inflammatory bowel disease (Halpin & Ford, 2012). As another example, functional dizziness has recently been divided into a variety that is secondary to vestibular disease (most often benign paroxysmal positional vertigo and vestibular migraine) and a variety that occurs primarily (i.e., without prior vestibular disease; Habs et al., 2020). As a third very recent example, post-COVID fatigue is, with post-COVID muscular pain and shortness of breath, a very frequent symptom weeks after the acute Coronavirus infection has subsided (Jacobs et al., 2020). It remains to be determined to which extent this is due to ongoing autoimmunological and other pathological organic processes that influence somatosensory input and to which extent expectancy effects and priors are involved, influenced by symptom experience during acute infection, but also by other effects of the illness like isolation, threatening treatments, etc.

In terms of further triggering factors, stressful work conditions are particularly important. Patients with more severe FSS are at much higher risk for sick leave and early health-related retirement (Rask et al., 2017), but it is also the psychosocial workplace characteristics that increase the risk for somatic symptoms in the work force. For instance, prospective studies with thousands of civil servants in Great Britain and other working populations have shown that an imbalance between effort and (material and nonmaterial) reward, or the chronic experience of individual and organizational injustice at baseline, are related to higher rates of FSS, but also of depression and cardiovascular diseases at follow-up (Herr et al., 2017, 2018). Recent adverse life events also are relevant as triggering factors (Bonvanie et al., 2017), with accidents in general having a special role as they may induce chronic symptoms via both routes; that is, through nociceptive and other somatosensory input, and through

expectancy formation regarding symptom experience but potentially also regarding compensation (Wynne-Jones et al., 2006).

If persisting, these triggering factors and predisposing personality aspects obviously also contribute to the maintenance of FSS. Further maintaining factors arise from the often difficult interactions of these patients with the healthcare system, leading to missed or delayed diagnosis, inappropriate treatments, and frustrations on all sides. Somatizing communication behavior and persistent beliefs about biomedical causations of patients and doctors alike are relevant here. As an example, in an experimental study, Van Wilgen et al. (2012) found that the more patients manifested somatic symptoms and psychosocial distress, the more negative beliefs and emotions were elicited in healthcare providers. Systemic factors of the healthcare system, such as its subdivision in different somatic specialities on the one side and mental healthcare on the other, contribute to these significant barriers for earlier recognition and better diagnosis and treatment (Henningsen et al., 2011; Murray et al., 2016).

# Classification

In this section, we focus on the current classification of FSS according to the *DSM-5*. Additionally, we discuss diagnostic alternatives, for example in the upcoming *ICD-11*. Both systems choose a much broader approach than former classifications. Nevertheless, they are still not satisfactory; they continue to propagate parallel classification of the same clinical phenomenon as mental disorders in psychosocial medicine versus as functional somatic syndromes in somatic medicine, thereby supporting the parallel use of widely differing, sometimes even contradictory therapeutic approaches. Especially for clinical purposes, including doctor–patient communication, a more consistent, more practical, more integrative classification is needed.

# DSM-5 Somatic Symptom Disorder

In 2013, DSM-5 introduced a new chapter entitled "Somatic Symptom and Related Disorders." It replaced the chapter of "Somatoform Disorders" (SfD) which was included in DSM-III and DSM-IV from 1980 to 2013. The main diagnostic category in the chapter is somatic symptom disorder (SSD), in which the central issue is the presence of one or more somatic symptoms that are distressing and result in a significant disruption of daily life (criterion A). They may be pain, either localized or widespread, or functional symptoms related to organs (cardiovascular, gastrointestinal, etc.), fatigue, or any other cluster of somatic symptoms, even belonging to a well-known medical condition. In order to qualify for the diagnosis of SSD the patient should in addition exhibit misattributions, excessive concern, anxiety, or preoccupation related to the symptoms (criterion B). When this condition lasts for at least 6 months it is specified as persistent. Two other specifiers refer to SSD with predominant pain and to severity (mild, moderate, severe), respectively.

There are major differences between the diagnosis of SSD and its precursor SfD. First, while SfD (pre-DSM-5) excluded medically explained symptoms from consideration, SSD has no such exclusion; whether there is a relevant medical account for a symptom is no longer pivotal. Second, there is a new psychobehavioral requirement that at least one of these features be present: disproportionate conviction of serious disease, high health anxiety, and/ or preoccupation with the symptoms. Third, SSD is just one single diagnosis; it largely contains the former SfD subcategories of somatization disorder (the most severe polysymptomatic form of SfD), undifferentiated somatization disorder (a low-threshold form of SfD with one symptom over 6 months), pain disorder (SfD with predominant pain symptoms), and hypochondriasis.

It may be fair to say that SSD justifies its inclusion as a mental disorder by the psychobehavioral features as defined in criterion B. In contrast, the classification of SfD as a mental disorder was not justified by any mental symptoms or features in its definition. It can only be understood historically through its derivation from older psychogenic concepts of somatization.

Since 2013, relatively few empirical studies have been published that evaluate the diagnostic criteria for SSD. In the general population, SSD prevalence has been estimated at 4.5% (Häuser et al., 2020). For the assessment of one core criterion of SSD, somatic symptoms, well-established self-report scales have existed for quite some time, most notably the Patient Health Questionnaire (PHQ-15; Kroenke et al., 2002) and more recently a shorter 8-item form with similar characteristics, the Somatic Symptom Scale-8 (SSS-8; Gierk et al., 2014). For the assessment of the other core aspect, the psychobehavioral features of SSD, a new selfreport scale was developed, the Somatic Symptom Disorder-B Criteria Scale (SSD-12; Toussaint et al., 2016). Four items each for the cognitive, affective, and behavioral component comprise this 12-item scale, thereby combining aspects that were assessed separately in other scales. A first diagnostic gold standard study based on (a German adaptation of) the structured clinical interview for *DSM-5* (SCID-5) module on SSD showed that in 372 patients from a psychosomatic outpatient clinic, the diagnostic accuracy of the self-report scales SSS-8 and PHQ-15 combined with the SSD-12 was moderate, with areas under the curve (AUC) of up to .79 (Toussaint et al., 2020). This indicates that these self-report scales can be used as a time-efficient way to identify patients at risk of SSD.

In a study comparing patients fulfilling DSM-5 SSD criteria with those fulfilling prior SfD criteria, 239 patients of a sample of 438 from a psychosomatic outpatient clinic (54.6%) who took part in a diagnostic interview fulfilled criteria for DSM-5 SSD and 139 patients (31.7%) fulfilled criteria for any kind of clinician-rated ICD-10 SfD (ICD-10 SfD is very similar to DSM-IVSfD) (Hüsing et al., 2018). There was an overlap of 102 (23.3%) patients who received both diagnoses, with 37 patients receiving an ICD-10 SfD diagnosis only (i.e., mostly did not fulfill criterion-level severity of psychobehavioral features) and 102 patients receiving a DSM-5 SSD diagnosis only (i.e., mostly somatic symptoms were not seen as "medically unexplained"). Not surprisingly, patients diagnosed with only DSM-5 SSD appeared to be more severely impaired in terms of general and health-related anxiety and psychological distress associated with their somatic symptoms, whereas patients with only ICD-10 SfD had a lower physical health-related quality of life.

Like the comparison of SSD and SfD in the different versions of *DSM*, the comparison of diagnostic criteria for a functional somatic syndrome from somatic medicine will yield only partial overlap with *DSM-5* SSD. For example, in patients with a fibromyalgia syndrome, only between 28% and 35% also met criteria for SSD (Axelsson et al., 2020; Häuser et al., 2020); the majority of fibromyalgia syndrome patients did not reach criterion cutoff severity for the psychobehavioral features of criterion B. The patients with both diagnoses appear to have higher symptom burden and impairment than those only fulfilling the criteria for fibromyalgia syndrome.

The new *DSM-5* category SSD has been criticized for several reasons (Rief & Martin, 2014). First, the failure to take account of the presence or absence of organic disease is seen as problematic (Scamvougeras & Howard, 2020). In the definition of SSD, it is justified by the unreliability of the distinction between "organically explained" and "unexplained" somatic symptoms—but this distinction has been shown not to be particularly unreliable, with revised diagnoses in follow-up studies as low as 0.5% (Eikelboom et al., 2016). As a consequence of the lack of distinction in referring to somatic symptoms in general, criterion A of SSD might be overly inclusive: if one is suffering from somatic symptoms in the course of a medical illness and (quite understandably) is worrying about it a lot (e.g., a young woman with fatigue in the course of her multiple sclerosis), one would already qualify for the diagnosis, thereby adding an often unwanted mental disorder diagnosis to the medical one (Frances & Chapman, 2013).

Second, the criterion B features have been criticized for their overreliance on illness anxiety and hypochondriasis and for their inadequate consideration of cognitive characteristics such as a selfconcept of bodily weakness and behavioral and interpersonal characteristics like dissatisfaction with medical care (Hausteiner et al., 2009; Klaus et al., 2015). As an additional difficulty, there is no clear threshold for when to define symptom-related thoughts, feelings, and behaviors to be excessive or disproportionate (Rief & Martin, 2014). In view of this last criticism, a study has tried to determine some of these thresholds: in a population-based study, it appeared that a range of 3-4 hours a day spent on dealing with physical symptoms seems indicative of excessiveness (Toussaint et al., 2021).

In terms of practical acceptance of the new SSD diagnosis, focus groups with general practitioners also showed that they see the excessiveness definition of psychobehavioral features as problematic, but nevertheless the newly included psychological criteria were seen as an important advancement in comparison to the previous need of merely excluding a physical disease (Lehmann et al., 2019).

# DSM-5 Conversion Disorder/Functional Neurological Symptom Disorder

In *DSM-5*, conversion disorder (CD) or, given synonymously but in parentheses, *functional neurological symptom disorder* (FNSD) is also part of the chapter "Somatic Symptoms and Related Disorders." However, the diagnosis of CD is based on a rather different concept than SSD. It also relies on the symptoms being distressing and having impairing consequences, but it also clearly defines their functional character ("altered voluntary motor or sensory function").

Diagnosing CD (FNSD) requires that clinical findings provide evidence of incompatibility between the symptom and recognized neurological or medical conditions and cannot be better explained by another medical or mental disorder. Examples are anesthesia of the hand in a glove-like distribution incompatible with functional neuroanatomy, or the so-called Hoover sign, where a weakness in hip extension is present when directly tested, but not when reflexively activated through contralateral hip flexion. This positive or "rule-in" evidence for incompatibility is conceptually different from mere "rule-out" or exclusion of organic disease; clearly establishing the functional nature of a neurological symptom very often is possible through clinical examination and a good description of the weakness, gait disorder, seizure, etc., and it is clinically important to demonstrate the incompatibility also to the patient (Stone et al., 2020).

Unlike with earlier conceptions of conversion disorder, in *DSM-5*, the diagnosis does not require the presence of psychological stressors or suggestive historical (e.g., biographical and situational) assumed causes (the *DSM-IV* had required preceding "conflicts or other stressors"). This seems justified because systematic reviews have shown that although patients with CD (FNSD) clearly have higher rates of traumatizations and severe life events preceding symptom onset than do healthy controls, many patients with this disorder do not (Ludwig et al., 2018).

Applying the PP model of FSS to CD (FNSD) highlights a wider range of past sensitizing events than "only" psychological stressors and psychological trauma, such as physical trauma, medical illness in oneself or significant others, or physiological/psychophysiological events. According to this model, strong ideas and expectations about these events correlate with abnormal predictions of sensory data and body-focused attention (Espay et al., 2018). For instance, patients with functional tremor perceived themselves, according to self-report diaries, as trembling for 84% of their waking day, whereas objective actigraphy showed tremor only on 4% of the waking day (Pareés et al., 2012).

Patients with functional neurological symptoms very often also have other somatic symptoms which are often pain-related and functional in nature; that is, they often fulfill criteria for CD (FNSD) and SSD at the same time. This fact calls into question the separation of these diagnoses in *DSM-5* in the first place (Maggio et al., 2020).

# Other diagnoses in the DSM-5 chapter on "SSD and Related Disorders"

The following three diagnoses also belong to the DSM-5 chapter on "SSD and Related Disorders." This much more inclusive approach compared to the *DSM-IV* emphasizes the overlap of these conditions, especially regarding their comorbid occurrence and the shared relevance of symptom interpretation, body scheme, sick role, and illness behavior. However, somatic symptoms are not a central feature in their definition. For that reason, they are only briefly mentioned here.

*Illness anxiety disorder* (IAD) is derived from two *DSM-IV* sources: the illness subtype within simple phobia (which was and is an anxiety disorder) and the subgroup of hypochondriacal patients who have no somatic symptoms (see above). *DSM-5* IAD's core features are the excessive preoccupation with having or acquiring a serious illness, a high level of anxiety, being easily alarmed about personal health status, and performing excessive health-related behaviors or exhibiting maladaptive avoidance, respectively. Somatic symptoms are not present or only mild in intensity.

*Factitious disorder* is new to this *DSM-5* chapter, having had its own chapter in *DSM-IV*. It refers to deliberate simulation of illness for the purpose of acquiring the sick role, in the absence of obvious external rewards.

Psychological factors affecting medical condition were part of the DSM-IV Appendix entitled "Other Conditions That May Be the Focus of Clinical Attention." This diagnosis is considered when a patient is suffering from a medical condition, and when psychological or behavioral factors adversely affect its onset, maintenance, or course (e.g., through stressors influencing pain syndromes or skin disease, other lifestyle factors, or noncompliance with a medical regimen). If the psychobehavioral factors relate to criterion B of SSD and if the emphasis primarily is on somatic symptoms, the latter diagnosis should be preferred.

Finally, in *DSM-5*, *body dysmorphic disorder* has been relocated to a new chapter, "Obsessive-Compulsive and Related Disorders." Somatic symptoms per se appear as part of several other diagnoses in *DSM-5* (e.g., as a somatic subtype of delusional disorder).

# Other Diagnostic Classifications

In the mental health section of the upcoming *ICD-11*, the category of "bodily distress disorder" appears to be very close to the *DSM-5* SSD as it incorporates the three main changes made in the transition from SfD to SSD: no reference to the somatic symptoms being not fully explained by organic disease, requirement of anxiety-type psychobehavioral features, and one diagnosis replacing several distinct SfD diagnoses. In view of the close similarity in the definitions, the difference in naming the disorder between *DSM-5* SSD and *ICD-11 bodily distress disorder* is unfortunate.

In another approach to classify FSS as *functional* somatic disorders (FSD; Burton et al., 2020), it is proposed that FSD should occupy a neutral space within disease classifications, favoring neither somatic disease etiology, nor mental disorder-a step that is possible in the ICD system, but obviously not in a classification for mental disorders only, like the DSM system. FSD should be subclassified as (a) multisystem (i.e., symptoms relating to multiple organ systems like cardiovascular, neurological, gastrointestinal, etc.), (b) single system (e.g., only cardiovascular or only neurological), or (c) single symptom (e.g., fatigue). Whereas additional specifiers may be added to take account of psychobehavioral features or co-occurring organic diseases, neither of these is sufficient or necessary to make the diagnosis.

## Conclusion

FSSs are very common; they can induce profound suffering, markedly decreased functioning, and high healthcare costs. At the same time, they are often neglected as a problem in a clinical and research tradition that concentrates on a dichotomy of somatic and mental disorders-with FSS not fitting well into either category. There have been significant advances in our understanding of the pathopsychophysiology and etiology of these symptoms, with progress in a more integrative "embodied" biopsychosocial approach. Current classification still lacks both clarity and the integrational ability to bridge the "either-or" of our dualistic system. Management of FSS must be interdisciplinary, with a broad diagnostic approach and with body-mind interventions that improve the patient's capacity to understand and regulate their psychological and biological functioning. If psychotherapy appears advisable, it must be explained and carried out as a cautious and confidential space where one's biological and psychosocial individuality can be experienced and shaped, to overcome adverse experiences and dysfunctional beliefs, and to reach a better acceptance, agency, and participation of the bodily self. All of this starts with the healthcare provider's sound knowledge of and attitude, and commitment toward FSS, bridging divorced fields of medicine and psychology that belong together.

# Sleep and Circadian Rhythm Disorders

Lampros Bisdounis, Simon D. Kyle, Kate E. A. Saunders, Elizabeth A. Hill, *and* Colin A. Espie

# Circadian Rhythms and the Sleep–Wake Cycle

Chronobiology is a branch of science concerned with periodic phenomena that occur in humans and other living organisms. These periodic phenomena oscillate in temporal cycles which are referred to as biological rhythms. There are three biological rhythms: ultradian (less than 24 hours), circadian (around 24 hours), and infradian (more than 24 hours). The term "circadian" describes molecular, physiological, and behavioral processes which operate periodically on a 24-hour cycle. These processes have a genetic origin and are endogenous in nature. As such, they are selfsustained and do not require rhythmic input from the environment to oscillate. Exogenous cues, called zeitgebers, synchronize these endogenous processes with the environment in a process called entrainment. The light-dark cycle induced by the earth's axial rotation is the most important zeitgeber. Light entering the eye through the retina is captured by circadian light receptors in the optic nerve, called photosensitive retinal ganglion cells. These cells project via the retinohypothalamic tract to the central circadian pacemaker in the hypothalamus, the superchiasmatic nucleus, allowing clock neurons to entrain to environmental light. This process enables the internal circadian rhythm to align with the external light-dark cycle (Foster & Kreitzman, 2014). Examples of internal circadian rhythms being out-of-sync with the external environment are jet lag and working night shifts.

The most conspicuous process following circadian principles in humans is the sleep-wake cycle. The alteration between sleep and wakefulness is a highly regulated phenomenon dependent on two processes: *sleep homeostasis* and circadian rhythms (Borbély, 1982; Borbély et al., 2016). Sleep homeostasis is defined as the pressure for sleep which accumulates during wakefulness and dissipates during the night of sleep. When the waking period is extended beyond typical levels (i.e., staying awake during the night), sleep pressure builds up and leads to a sleep debt. In this instance, both duration and intensity of the subsequent sleep are increased, demonstrating the homeostatic drive for sleep. In return, the gradual increase of sleep pressure is counterbalanced by the endogenous circadian signal for alertness and sleep propensity. Overall, these two processes naturally maintain consolidated periods of sleep and wakefulness while regulating their timing and duration.

# **Characteristics of Sleep in Good Sleepers**

On the behavioral level, sleep is defined as a reversible state of altered consciousness, perceptual disengagement, physical quiescence, recumbent posture, and eye closure. On a neurophysiological

level, sleep can be divided into two distinct stages of vigilance: non-rapid eye movement (NREM) and rapid eye movement (REM) sleep (Berry et al., 2020).

NREM typically precedes REM sleep and is marked by normal respiration, decreased muscular tonus, synchronous cortical activity, and gradual increase of sleep depth (i.e., the exogenous arousal threshold required to achieve awakening). Based on sleep depth, NREM is further subdivided into three stages: N1-3. These stages constitute an arousal continuum, with lighter sleep in N1 and N2, and deep sleep (or slow-wave sleep; SWS) in N3. By contrast, REM sleep is characterized by cardiorespiratory variability; muscle atonia; episodic bursts of rapid eye movements; and desynchronous, lowamplitude, mixed-frequency electroencephalogram (EEG) activity. REM sleep can also be subdivided into two microstates: tonic and phasic. Tonic REM is parasympathetically driven and involves muscle atonia and low-amplitude EEG. Superimposed on tonic REM sleep, phasic REM is sympathetically driven and involves rapid eye movements, distal muscle twitches, and cardiorespiratory irregularity.

In healthy adults, sleep is initiated through NREM, marked by a brief period of N1. This process is a cornerstone of healthy sleep. Sleep initiation through REM is a reliable marker of pathology in adults, most often of narcolepsy. During the first sleep cycle, N1 lasts 1-7 minutes, followed by N2 lasting 10-25 minutes. It takes good sleepers 10-15 minutes to reach N1 after lights are turned off, yet the same sleepers often report taking an average of 15-30 minutes to fall asleep. Consequently, it has been suggested that subjective onset of sleep is linked to N2, although the precise definition of sleep onset itself has been the source of scientific debate. The subsequent N3 stage lasts 20-40 minutes. Prior to entering REM, a brief 5-10-minute ascent to N2 is typically observed. Finally, the first REM episode occurs on average 70-100 minutes after the first N1. This REM episode is short-lived, typically lasting less than 5 minutes. The alteration between NREM and REM sleep follows a neurophysiological ultradian pattern and is referred to as the NREM-REM cycle. In good sleepers, the NREM-REM cycle is repeated four to five times during nocturnal sleep. Although the duration of the NREM-REM cycle does not change throughout the night, the length of each sleep stage does. As the night progresses, REM sleep becomes longer and NREM becomes shorter. N3/SWS occupies less time in the second NREM-REM cycle and

might disappear altogether in following cycles. N2 is subsequently expanded to occupy the remaining NREM portion of the cycle.

## **Measures of Sleep and Circadian Phase**

The assessment of sleep and circadian rhythms (SCR) includes several tools, conventionally classified into two broad types of measurement: subjective and objective. Subjective assessments include self- or clinician-reported measures such as clinical interviews, questionnaires, and sleep diaries. Objective assessments include polysomnography, accelerometer devices called actigraphs, and circadian phase assessments (i.e., the use of molecular, physiological, or psychological processes to characterize a person's circadian phase). The diagnosis of most SCR disorders covered in this chapter relies chiefly on symptom self-report. Objective measures can be used to complement the subjective assessment and rule out the presence of comorbidities, such as sleep-related breathing or movement disorders. In this chapter, we avoid using the terms "subjective" and "objective" given that such language overemphasizes the accuracy of laboratory measures and undermines the reliability of self-report observations (Fuoco, 2017).

Clinical interviews are essential for the diagnosis of all sleep and circadian disorders. To aid the conduct of the interview, several structured (Merikangas et al., 2014; Taylor et al., 2018) and semi-structured interview protocols (Edinger et al., 2004) have been developed (Espie, 2022). The clinical interview should include a thorough examination of the chief sleep complaint, covering elements like sleep hygiene, sleep environment, pre-bed behavior, work schedule, sleeping arrangements, circadian preference, and daytime functioning (Riemann et al., 2017). At a minimum, clinical interviews should also include a detailed medical history with current and past medication and substance use (including alcohol, caffeine, and nicotine). The presence of comorbid psychiatric disorders such as depression, anxiety, bipolar disorder (BD), and psychosis should be actively examined, too. Information about elements important for the clinical interviews of specific sleep and circadian disorders are covered in the respective sections of this chapter.

Sleep diaries constitute a form of experience sampling that captures daytime and nighttime behaviors and the experience of the previous night. The assessment covers an extended period of time, usually 2 weeks. They are the mainstay assessment of sleep due to being an ecologically valid, easy to administer, and inexpensive tool. However, sleep diaries rely on participants' recollection of their sleep and wake times. A commonly used, standardized diary is the Consensus Sleep Diary (Carney et al., 2012). Typical parameters derived from sleep diaries include sleep onset latency (i.e., time needed to transition from wakefulness to sleep), wake-time after sleep onset (i.e., time spent awake after initial sleep onset and prior to final awakening), total sleep time, time in bed, sleep efficiency (i.e., ratio of total sleep time to time in bed), and number of awakenings.

Notwithstanding the importance of self- and clinician-reported measures, polysomnography is generally considered the reference standard sleep assessment. Polysomnography is a simultaneous overnight recording of several physiological measures, with internationally recognized consensus guidelines for conduct and scoring (Berry, 2020). However, it is an expensive tool that requires trained personnel, appropriate facilities, and can be time-consuming and burdensome for the patient. A standard polysomnography includes EEG, electrooculographic, and electromyographic indices measured by electrodes on the scalp, around the eyes, and on the chin, respectively. This combination of channels allows staging of sleep and wake. Additional channels measure breathing, respiratory effort, cardiac rhythm and electrical activity, blood oxygen saturation, body position, and limb movements. A digital video can also be recorded. Polysomnography provides data on *sleep continuity*, sleep architecture, and cortical activation. Sleep continuity includes parameters similar to sleep diaries, such as sleep onset latency, wake after sleep onset, total sleep time, time in bed, sleep efficiency, and number of awakenings. Sleep architecture refers to the duration and proportion of sleep stages, as well as the latency to REM sleep and number of NREM-REM cycles. Cortical activation is quantified using finer measures of EEG analysis that allow for the extraction of sleep microstructure elements. Following a fast Fourier transformation, the frequency and amplitude of the sine wave constituents are extracted from the EEG data and stratified in given frequency bands (i.e., slow waves, <0.5 Hz; delta, 0.5-4 Hz; theta, 4-8 Hz; alpha, 8-12 Hz; sigma, 12-16 Hz; beta, 12-35 Hz; and gamma, 32-100 Hz). Data are then presented as the absolute or relative power of each frequency band. The most used quantitative EEG in polysomnography is power spectral analysis. At present, such analyses are used almost exclusively in research setting rather than in clinical practice.

An actigraph is a motion-sensor device typically worn on the wrist. It is low cost, with small patient burden, and can be used for longitudinal assessment over multiple weeks. Although it is a frequent tool in SCR research, its applications extend to any research question around activity. Actigraphs record gross motor activity, and mathematical algorithms are applied to estimate rest and activity patterns from the motor data. Therefore, given these devices principally assess rest-activity, they are only considered proxy measures of sleep and wakefulness. Unlike polysomnography, there are no universal guidelines for the conduct and scoring of actigraphy. Analysis of actigraphy data can provide a graphical summary of sleep and wakefulness over time, as well as parametric and nonparametric variables about general rest and activity. Parametric variables include sleep onset latency, wake after sleep onset, total sleep time, time in bed, sleep efficiency, and awakenings. Nonparametric variables include (1) L5, the average activity during the least active 5-hour period; (2) M10, the average activity during the most active 10-hour period; (3) the intradaily variability, a fragmentation index of daily rhythms; and (4) interdaily stability, an estimate of the synchronization to the 24-hour light-dark cycle (Gonçalves et al., 2014). Compared to polysomnography, actigraphy generally overestimates sleep and underestimates wakefulness. This discrepancy is small, and actigraphy is generally good in detecting sleep periods in healthy individuals (Conley et al., 2019). However, actigraphy is not as robust in measuring sleep in people with sleep or other chronic disorders (Conley et al., 2019; Smith et al., 2018). This discrepancy is probably due to the difficulty of actigraphy in detecting wake periods before and after sleep, exacerbated by the proneness of these populations to remain inactive in bed when trying to fall asleep (Conley et al., 2019; Williams et al., 2018). In terms of their availability, there are commercial "wearables" (e.g., Fitbit, by Fitbit Inc.) and research-grade actigraphs (e.g., MotionWare, by CamNtech; Axivity, by Axivity Ltd.; and GENEActiv, by Activinsights), with the validity and reliability of these devicesespecially commercial ones-being a source of continuous scientific debate (Chinoy et al., 2021; Scott et al., 2019).

# Classification Systems for Sleep and Circadian Rhythm Disorders

SCR disorders constitute a heterogeneous group of disruptions, with distinct clinical presentations, etiologies, prognoses, and treatment needs.
Although their debilitating nature has long been recognized, sleep disorder nosologies have only become available in the past four decades. Presently, there are three classification systems for sleep disorders. Two systems are incorporated within larger taxonomies: the *ICD-11*, and the *DSM-5*. The final system was developed by a scientific society in sleep medicine: the *International Classification of Sleep Disorders, 3rd Edition* (ICSD-3) (American Academy of Sleep Medicine, 2014).

Despite some discrepancies, the three classification systems are more concordant than their previous iterations. The ICD-11 and ICSD-3 have maintained the same seven classifications (six for ICD-11, which does not include the subgroup of "other sleep disorders") as in their previous versions: insomnia, sleep-related breathing disorders, central disorders of hypersomnolence, circadian rhythm sleep-wake disorders, sleep-related movement disorders, parasomnias, and other sleep disorders. The DSM-5 includes eight disorder categories: insomnia disorder, hypersomnia disorder, narcolepsy, breathing-related sleep disorders, circadian rhythm sleep-wake disorders, parasomnias, restless leg syndrome, and substance/ medication-induced sleep disorder. An important point of convergence is that all three nosologies do not distinguish between "primary" and "secondary," or "organic" and "inorganic" disorders. This substantial modification from previous editions was motivated by two factors. First, there is considerable uncertainty about the causal directionality between "primary" and comorbid sleep disorders. In light of this phenomenon, a sleep medicine consensus group argued, in 2005, that the term "secondary" introduces the erroneous assumption that treatment of the "primary" disorders suffices to treat the comorbid sleep problem (National Institutes of Health, 2005). Second, evidence shows that several sleep disorders share a substantial number of features, regardless of their status as primary or comorbid diagnoses. Consequently, they require the same therapeutic approach, again regardless of the clinical attention focused on the "primary" diagnosis.

In the remainder of this chapter, we focus on the following sleep disorders: insomnia disorder, delayed and advanced circadian phase disorders, irregular sleep–wake rhythm disorder (ISWD), non–24-hour sleep–wake rhythm disorder (N24SWD), narco-lepsy, hypersomnolence disorder, and parasomnias.

## Insomnia Disorder

Insomnia is a condition characterized by a persistent difficulty in initiating or maintaining sleep despite adequate opportunity to do so, leading to day-time impairment. In terms of its prevalence, insomnia is the second most common psychiatric disorder (Wittchen et al., 2011) and the most common sleep disorder (Ohayon, 2002). Around one-third of the general population reports acute insomnia symptoms over a 12-month period (Perlis et al., 2020), while 1 in 10 people experiences chronic sleep problems (National Institutes of Health, 2005). These prevalence estimates are found across different countries. The main factors related to the prevalence of insomnia are gender, age, and other illness. Insomnia is more prevalent in women than in men. Moreover, although insomnia symptoms and sleep fragmentation increase with age, insomnia diagnoses remain stable across different age groups (Morin et al., 2015). This phenomenon could be due to the fact that, when compared to younger adults, older adults do not often attribute their daytime problems to poor sleep (Morin et al., 2015). Research on the prevalence and treatment of insomnia in children and adolescents is lacking, yet insomnia symptoms are commonly reported by these age groups. In terms of comorbid disorders, insomnia is more common in people with psychiatric or other medical disorders compared to the general population.

#### Etiological Models of Insomnia

Several theoretical models have been proposed regarding the etiology and psychopathology of insomnia, and, for the most part, these models are complementary and not mutually exclusive. Research on these models has fundamentally guided treatment development for insomnia.

In the earliest model, Kleitman (1939) coined the term *sleep hygiene* and appraised the available evidence regarding the effect of pre-bed behaviors and bedroom environment on sleep (Kleitman, 1987). Currently, sleep hygiene refers to a set of habits and practices intended to promote healthy sleep. Sleep hygiene does not yield a strong improvement in insomnia symptoms as a monotherapy, and it is a common control condition in sleep intervention trials. More information on sleep hygiene as an intervention component is provided below.

Later, Bootzin described the model of *stimulus control*, grounded in the principles of behaviorism and classical conditioning (Bootzin, 1972). Within this model, sleep is interpreted as a conditioned response to certain behaviors and environments. As such, insomnia arises when patients associate sleep-related stimuli with activities other than sleep. For

example, sleep is typically associated with items such as the bedroom and the bed, and bedtime rituals such as brushing your teeth. In the case of insomnia, it is typical for a patient to spend hours lying in bed awake with the hope of increasing their total sleep time. Although this seems intuitively reasonable, it can be counterproductive, given that now the bed is associated with wakefulness. Another example is spending countless of hours in bed scrolling on the phone or watching TV. Here the bed is again associated with practices that are not conducive of sleep. Stimulus control therapy is a seminal module of multicomponent interventions for insomnia, which are covered below.

The first comprehensive model of insomnia, and still one of the most influential, is the 3P (or three-factor) model by Spielman, developed in 1987 (Spielman et al., 1987). The 3P model was adapted from stress-diathesis models, and it characterizes the emergence and maintenance of insomnia based on predisposing, precipitating, and perpetuating factors. In the 3P model, premorbid traits such as genetic vulnerability, psychological factors, and social situations create a diathesis for the development of insomnia. Then these elements interact with factors such as life stress and psychiatric or other medical conditions to stimulate acute episodes of insomnia. As we have already covered, the typical response to insomnia includes compensatory behaviors that exacerbate and maintain the disorder rather than relieve it. These behaviors constitute the perpetuating factors of insomnia and are motivated by sleep preoccupation and dysfunctional beliefs about sleep.

Building on the 3P model, Perlis's neurocognitive model was the first to integrate biological and psychological elements in its formulation (Perlis et al., 1997). According to this model, chronic insomnia is a neurological condition caused partly by behavioral factors and partly by classical conditioning. Diverging from previous theories, worrying and rumination are not the cause of sleeplessness here. That is, patients are not awake because they are worrying; they worry because they are awake. Central to the neurocognitive model is the concept of hyperarousal and its three dimensions: somatic, cognitive, and cortical arousal. Cortical arousal in particular (defined as high-frequency brain activity; 14-45 HZ) is linked to the manifestation of insomnia. Heightened cortical arousal around sleep onset and during NREM sleep reflects increased sensory and information processing as well as enhanced long-term memory formation. These phenomena arise from classical conditioning and are responsible for impairments in the initiation, maintenance, and perception of sleep.

Still viewing sleep and arousal as opposing phenomena, but emphasizing the role of cognitive arousal, Harvey's cognitive model of insomnia focuses on worrying, rumination, and maladaptive coping behaviors (Harvey, 2002). Sleep preoccupation is at the core of this model. Excessive worrying over lack of sleep and its consequences exacerbate dysfunctional beliefs about sleep and lead to counterproductive safety behaviors. This pattern encourages selective attention to sleep cues and monitoring of perceived sleep threats. As a result, somatic and cortical arousal are increased, and they subsequently interfere with sleep initiation and maintenance.

The psychobiological inhibition model outlines the automaticity and near-involuntary nature of healthy sleep and argues that insomnia is developed and perpetuated by repeated unhelpful attempts to regulate sleep (Espie, 2002). As such, disruptions arise from selective attention to sleep cues, sleep preoccupation, and increased sleep effort, a phenomenon defined as the *attention-intention-effort pathway* (Espie et al., 2006). These processes lead to a failure in inhibiting wakefulness and falling asleep by preventing the otherwise automatic "de-arousal" that precipitates healthy sleep.

Most recently, the neurobiological model defines insomnia as a dysfunction of sleep–wake regulation and focuses on neurophysiological substrates of the disorder (Buysse et al., 2011). Here, sleep problems results from persistent wake-like neuronal activity during NREM sleep in the limbic and parietal cortices, thalamus, and hypothalamic-brainstem system. This localized wake-like activity coincides with typical sleep-like activity in the frontal and central cortices. Co-activation of these regions can potentially explain not only the impairments in sleep initiation and maintenance but also the irregular processing of sensory and emotional information in insomnia.

#### Assessment of Insomnia

Insomnia is a heterogeneous disorder, and often multiple tools are needed to capture all symptoms adequately (Buysse et al., 2006). Diagnostically, it relies on the subjective symptom experience. Across all nosologies, it is diagnosed on the basis of patientreported dissatisfaction with the quantity or quality of sleep, manifested as a difficulty getting to sleep and/or remaining asleep. This dissatisfaction also needs to be accompanied by some form of daytime dysfunction. Clinical interviews and sleep diaries constitute the essential items for the identification and characterization of insomnia. Global scales of insomnia and sleep quality are also frequently used, especially in research settings. Polysomnography or actigraphy assessments of sleep are not necessary for the routine evaluation of insomnia in clinical practice, although they can complement the diagnostic accuracy (Buysse et al., 2006; Schutte-Rodin et al., 2008).

Clinical interview is the cornerstone of insomnia diagnosis. The previously discussed models can provide a framework for the clinical assessment of insomnia by guiding practitioners to collect information on predisposing, precipitating, and perpetuating factors. Integral to the diagnosis of insomnia are the accompanying daytime impairments since almost half of insomnia patients report daytime fatigue as the primary determinant that prompts them to seek help from a healthcare provider (Morin et al., 2006). Typical examples of daytime dysfunction include fatigue, sleepiness, problems in attention and concentration, and mood disturbance. Along with a clinical interview, the most helpful tool for the assessment of insomnia is the sleep diary. Sleep diaries can help delineate the nature and severity of the sleep complaint and uncover sleep-related thoughts and behaviors. Additionally, sleep diaries can capture night-tonight variability in sleep, an element particularly salient for individuals with chronic insomnia. Their use in sleep intervention research is also widespread as sleep diaries can provide detailed information about the adherence to and efficacy of the treatment. In terms of the duration of the sleep diaries, a minimum of 2 weeks is typically recommended. Insomnia is not defined by standardized quantitative criteria about sleep, so outcomes need to be carefully evaluated (Buysse, 2013). However, insomnia patients may be distinguished from good sleepers when sleep onset latency, wake after sleep onset, or early morning awakening exceed 30 minutes. These scores also typically reflect a sleep efficiency that is lower than 85% (Lichstein et al., 2003; Morin et al., 2015).

Although clinical interviews and sleep diaries are invaluable instruments for the diagnosis of insomnia, they can be time-consuming and often not practical for busy clinical settings (Bastien et al., 2001). As such, several brief scales have been proposed for the screening and assessment of insomnia. Among the most widely administered ones are the Insomnia Severity Index (Bastien et al., 2001), the Sleep Condition Indicator (Espie et al., 2014),

the Athens Insomnia Scale (Soldatos et al., 2000), and the Pittsburgh Sleep Quality Index (Buysse et al., 1989). The Insomnia Severity Scale, the Sleep Condition Indicator, and the Athens Insomnia Scale are all brief screening scales for insomnia with comparable validity and reliability (Chiu et al., 2016; Wong et al., 2017). The Insomnia Severity Index is based on DSM-4 and ICD-2 diagnostic criteria for insomnia, the Sleep Condition Indicator is based on DSM-5 criteria, and the Athens Insomnia Scale is based on ICD-10 criteria. The Pittsburgh Sleep Quality Index is a measure of general sleep disturbances and their associated daytime interference. Although this scale was not initially designed to screen for insomnia, it shows good validity and reliability, and expert panels have recommended it for the routine evaluation of insomnia (Buysse et al., 2006; Morin et al., 2015).

Sleep is clearly and objectively impaired in insomnia. Therefore, although objective assessments are not necessary for the diagnosis of insomnia, they can still be useful. Actigraphy, in particular, is increasingly being used. Following the commission of a task force and the publication of a subsequent systematic review, the American Academy of Sleep Medicine (AASM) endorsed actigraphy as an optional assessment tool for insomnia (Smith et al., 2018). In this review, the authors summarized the limitations of actigraphy in producing accurate sleep variables for insomnia patients, but highlighted that discrepancies are within a "clinically acceptable range" (Smith et al., 2018). A recent meta-analysis quantified these discrepancies. The authors showed that, compared to polysomnography, actigraphy overestimates total sleep time and sleep efficiency and underestimates sleep onset latency in patients with sleep and other chronic disorders (Conley et al., 2019).

Polysomnography is more rarely used for the assessment of insomnia compared to actigraphy. In clinical practice, polysomnography is most often used to rule out other potential sleep problems that might contribute to the insomnia complaint. In research, polysomnography is an invaluable tool for assessing putative mechanisms and evaluating the efficacy of SCR interventions. According to polysomnography, insomnia patients exhibit heightened sleep fragmentation and a decreased percentage duration of N3/SWS and REM (Baglioni et al., 2014). A review of power spectral analyses on EEG data of insomnia patients revealed increased beta activity across wakefulness, sleep onset period, NREM and REM sleep (Bastien et al., 2011). The

interpretation of these findings is that heightened beta power reflects increased cortical activation.

Different assessments of sleep are not always congruent. Up to 50% of insomnia patients report a shortened sleep duration which is not reflected by polysomnography or actigraphy (Edinger & Krystal, 2003). This misalignment between selfreport and actigraphic/polysomnographic estimates of sleep duration is called *sleep misperception*. Recent advances have proposed electrophysiological explanations for this phenomenon. Namely, instead of misperceiving sleep, some insomnia patients might be sensitive to transitions from low- to high-frequency spectral power in centralposterior brain regions (Lecci et al., 2020). These subtle shifts from sleep to wakefulness are only observable through high-density EEG and are not reflected in conventional polysomnographic measurement. Thus, although insomnia is a disorder of objectively measured sleep, it is also a condition not fully appreciated by the existing reference standard of sleep-wake measurement.

#### Management of Insomnia

There are two primary treatment modalities for the management of insomnia: cognitive behavior therapy for insomnia (CBT-I) and medication. CBT-I is recognized as a safe and highly effective intervention with more long-lasting treatment effects compared to medication alone. On the other hand, medication for insomnia is only recommended for short-term use, given risks of side effects, tolerance, and withdrawal effects. Consequently, CBT-I is endorsed as the first line of treatment by numerous organizations worldwide, such as the National Institute for Health and Care Excellence (National Institute for Health and Care Excellence, 2021), the British Association for Psychopharmacology (Wilson et al., 2019), the European Sleep Research Society (Riemann et al., 2017), and the American College of Physicians (Qaseem et al., 2016). Nevertheless, at present, the most common clinical response to insomnia is the prescription of hypnotic medication (Siriwardena et al., 2010).

#### COGNITIVE BEHAVIOR THERAPY FOR INSOMNIA

CBT-I is a multicomponent psychological treatment, usually ranging from four to eight treatment sessions delivered weekly or biweekly. It is effective when delivered digitally or in-person, either individually, in a group, or in a self-help format. CBT-I can be administered by licensed clinicians, physicians, and trained personnel, including psychology

graduates and primary-care nurses. Treatment effects are also not moderated by gender, age, education, occupational status, hypnotic medication use, or comorbid conditions (Espie et al., 2001; Wu et al., 2015). There is some evidence that higher insomnia severity might predict greater improvements following CBT-I, but this phenomenon might be at least partially due to more room for improvement (Espie et al., 2001). According to the most comprehensive review to date, CBT-I is associated with a large reduction in insomnia severity and a moderate to large increase in sleep quality at posttreatment (van Straten et al., 2018). Modest reductions in insomnia severity after CBT-I remain at 3-, 6-, and 12-month follow-up (van der Zweerde et al., 2019). Diary measures of sleep continuity have also consistently shown an improvement following CBT-I (Mitchell et al., 2019; van Straten et al., 2018). However, there is no meta-analytic evidence that CBT-I improves polysomnographically defined sleep parameters, while the evidence for actigraphy is mixed (Mitchell et al., 2019).

CBT-I aims to restructure cognitive and behavioral processes linked to problems with sleep, with several of its components directly arising from theoretical models of insomnia. Therefore, a typical intervention protocol includes behavioral (i.e., sleep restriction, stimulus control, and relaxation), cognitive (i.e., paradoxical intention, cognitive restructuring, mindfulness, positive imagery, and putting the day to rest), and educational (i.e., psychoeducation and sleep hygiene) components (Espie, 2022). Here, we cover principal components of CBT-I that stem from relevant theoretical work: sleep restriction, stimulus control, cognitive restructuring, and sleep hygiene.

Sleep restriction therapy (SRT) is arguably one of the most potent elements of CBT-I. It can be administered as part of multicomponent CBT-I and as a stand-alone treatment. SRT involves limiting and later standardizing time in bed to parallel the total sleep time reported by the patient (Spielman et al., 2011). Rooted in the principles of Spielman's 3P model, current models of SRT highlight that the intervention exerts its therapeutic effects via restricting awake time in bed, regularizing sleepwake schedule, and reconditioning the association between bedroom factors and sleep (Maurer et al., 2018). This is referred to as the Triple-R model (Maurer et al., 2018). According to this theory, SRT reduces insomnia symptoms and improves sleep quality by targeting physiological and cognitivebehavioral factors simultaneously and reciprocally

529

(Kyle et al., 2014; Maurer, Espie et al., 2020). In effect, the intervention leads to a regularization of time in bed and a restructuring of associations between sleep and sleep-related factors. Preliminary evidence by the team behind the Triple-R model shows that the intervention can also improve quality of life and alleviate circadian misalignment (Maurer, Espie et al., 2020; Maurer, Ftouni et al., 2020). It should be noted, however, that in some populations (e.g., BD) sleep loss has been associated with a range of adverse outcomes (Plante & Winkelman, 2008), and in these instances SRT should either be avoided or adapted.

Stimulus control therapy originates from Bootzin's stimulus control theory (Bootzin, 1972), described earlier. Building on this model, the aim of stimulus control therapy is to challenge the association between sleep-related stimuli and wakefulness and restore the qualities of the bed and bedroom as predictors of sleep and sleepiness. Consequently, all non-sleep-related activities, with the exception of sex, are eliminated from the bedroom. The instructions are to only go to bed if sleepy/tired, exit the bedroom if sleep has not occurred within 15 minutes, and only use the bedroom for sleep-related activities. This set of instructions applies to both the initial sleep onset period and any subsequent attempts to resume sleep. Stimulus control therapy is an integral part of CBT-I, and, according to a recent review by AASM, it is an effective standalone treatment for insomnia (Edinger et al., 2021).

As discussed in Harvey's cognitive model of insomnia (Harvey, 2002), dysfunctional beliefs about sleep are prominent features of the disorder. Worry before bedtime and sleep preoccupation during daytime are intrusive and maladaptive cognitions and are among the most challenging elements of insomnia to treat (Harvey, 2002). Unrealistic expectations of sleep (e.g., "I need 8 hours of sleep every night") and catastrophizing when such expectations are not met (e.g., "One night of bad sleep affects the whole week") are among the most prevalent dysfunctional beliefs about sleep identified. As a therapy, cognitive restructuring involves the identification, challenge, and eventually modification of such thought patterns. This involves alerting the patient about the influence of certain cognitions on their mental state and substituting inaccurate beliefs about sleep with accurate facts and a healthier mentality. Accompanying elements of cognitive restructuring are paradoxical intention techniques, monitoring attentional biases, and reducing safety behaviors. Although a protocol for a purely

cognitive therapy of insomnia exists (Harvey et al., 2007), it has not been thoroughly studied and no randomized controlled trial (RCT) has been published in this area (van Straten et al., 2018).

Sleep hygiene stems from Kleitman's eponymous theory (Kleitman, 1987). It refers to a set of practice recommendations aimed at fostering behaviors conducive of healthy sleep. Most of these recommendations are prohibitions, such as reducing nicotine and alcohol consumption before bedtime, but some include increasing exercise early in the morning and developing a healthy diet. Additionally, patients are asked to create a comfortable bedroom environment, one that is quiet, dark, and cool in temperature. In primary care, "sleep hygiene advice" is the most common first response to individuals presenting with complaints of insomnia (Everitt et al., 2014). Nevertheless, this advice is most often inadequate, and primary care physicians subsequently choose to prescribe medication due to a lack of knowledge in the provision and administration of CBT-I (Everitt et al., 2014). Indeed, there is no strong evidence supporting the use of sleep hygiene as a stand-alone treatment (Edinger et al., 2021). In fact, sleep hygiene is a common minimal treatment control in intervention trials of insomnia treatment.

#### PHARMACOLOGICAL TREATMENT OF INSOMNIA

Several medications are used for the management of insomnia owing to their therapeutic effect. Their prescription, however, requires careful consideration given the risk-benefit profile of each drug and the contraindications of each patient. Moreover, prescription recommendations might change depending on the country (e.g., doxepin, ramelteon, suvorexant, and lemborexant are authorized for the treatment of insomnia only in the United States; melatonin is not approved by the US Food and Drug Administration [FDA] and it is sold over the counter in the United States, while in the United Kingdom melatonin is a prescriptiononly medication). A comprehensive list of medications used in insomnia includes benzodiazepines, z-drugs (or non-benzodiazepines), melatonin and melatonin receptor agonists, selective histamine H<sub>1</sub>antagonists, antidepressants, orexin (or hypocretin) receptor antagonists, antipsychotics, antihypertensives, nonselective antihistamines, and anticonvulsants (Krystal, Prather, & Ashbrook, 2019; Morin et al., 2015). Here we focus on evidence-based and not off-label prescriptions. This includes benzodiazepines, z-drugs, melatonin and melatonin receptor agonists, selective histamine H<sub>1</sub>-antagonists, and orexin antagonists.

Benzodiazepines (estazolam, flunitrazepam, flurazepam, lorazepam, lormetazepam, nitrazepam, temazepam, and triazolam) act on sleep and arousal via allosteric modulation of the gammaaminobutyric acid (GABA) type A receptor (Guina & Merrill, 2018). The binding of these agents enhances the inhibitory effect of GABA<sub>A</sub>, resulting in sedative, hypnotic, anxiolytic, anticonvulsant, and myorelaxant effects. They are generally effective in reducing sleep onset latency, while reductions in night-time awakenings are also common. Their recommended use is restricted to 2-4 weeks (Riemann et al., 2017), given the risk of tolerance, dependence, cognitive decline, and impaired daytime functioning (Holbrook et al., 2000). Benzodiazepines have been associated with a general suppression of REM sleep and a decrease in low-frequency EEG brainwaves in the delta range (Brunner et al., 1991; Feige et al., 1999).

Z-drugs (eszopiclone, zaleplon, zolpidem, and zopiclone) share the common mechanism of action with benzodiazepines: potentiating the inhibitory effects of GABA through allosteric modulation of the GABA<sub>A</sub> receptor (Morin et al., 2015). Their structural difference with benzodiazepines lies in their relative selectivity for the alpha 1 subunit of the GABA<sub>A</sub> receptor. They are generally preferred to benzodiazepines by medical practitioners because of perceived superiority in effectiveness and safety (Siriwardena et al., 2006). Indeed, early studies reported that z-drugs are safe and effective in reducing insomnia symptoms compared to placebo. However, later reviews have shown that this effect might be smaller than initially thought, especially when both published and unpublished data are considered (Huedo-Medina et al., 2012). Z-drugs are associated with a similar side-effect profile to benzodiazepines (Agravat, 2018; Huedo-Medina et al., 2012), yet they yield a reduced risk of tolerance and withdrawal (Agravat, 2018). Still, z-drugs are currently the most frequently prescribed hypnotic medication worldwide (Sateia et al., 2017).

Melatonin receptor agonists include agents binding to type 1 and 2 melatonin receptors. The theoretical premise underlying the use of exogenous melatonin and melatonin agonists (ramelteon) is that pineal melatonin is involved in the regulation of the human circadian rhythms and consequently the sleep–wake cycle. Reviews about their efficacy in insomnia show small and small to moderate reductions in sleep latency with little evidence for improvements in sleep duration and night-time awakenings (Low et al., 2020). The only common side effect is daytime sleepiness (Wilson et al., 2019).

Doxepin is the only histamine antagonist medication indicated for use in insomnia. Technically a tricyclic antidepressant, doxepin acts on the arousal system via selectively blocking the histamine  $H_1$ receptor in the hypothalamus. Low doses of doxepin have been found to improve sleep continuity and, as such, are recommended (only in the US) for insomnia patients with sleep maintenance and early morning awakening problems (Sateia et al., 2017). Doxepin has minimal abuse potential.

Suvorexant and lemborexant are the only dual orexin receptor antagonists recommended for use in insomnia. They exert their therapeutic effects through inhibiting the binding of the neuropeptides orexin A and B in the hypothalamus, thus suppressing arousal and delaying wakefulness. Suvorexant is effective at preserving sleep continuity and increasing sleep duration (Patel et al., 2015), with sustained improvements even after prolonged discontinuation (Vermeeren et al., 2015). Lemborexant improves sleep initiation and continuity measures both at post-treatment (Rosenberg et al., 2019) and at a 1-year follow-up (Yardley et al., 2021), with daytime sleepiness and headaches being the only reported side effects. Both medications have a favorable risk-benefit profile compared to benzodiazepines and z-drugs.

# Circadian Rhythm Sleep–Wake Disorders

Circadian sleep-wake rhythm disorders (CRSWDs) are conditions of either an alternation of the endogenous circadian system (intrinsic CRSWDs) or a misalignment between the endogenous circadian system and the desired sleep-wake schedule (extrinsic CRSWDs). The DSM-5 recognizes six CRSWDs: (1) delayed sleep phase disorder (DSPD), (2) advanced sleep phase disorder (ASPD), (3) ISWD, (4) N24SWD, (5) shift work disorder, and (6) unspecified type. Excluding the unspecified type, out of these five disorders only shift work is an extrinsic CRSWD. The ICSD-3 and ICD-11 recognize an additional condition, jet-lag disorder, which is also an extrinsic CRSWSD (Sateia, 2014). In this chapter we focus on intrinsic CRSWDs.

# Delayed Sleep Phase Disorder

First described by Weitzman, DSPD occurs when there is a delay in the sleep-wake cycle

(Weitzman et al., 1981). DSPD patients report typically falling asleep between 1-4 A.M. and waking up in the late morning or afternoon. They are also faced with persisting difficulties when trying to adhere to a conventional or desired sleep-wake schedule that necessitates earlier sleep and wake times. When allowed to follow their preferred time schedule, sleep quantity and quality are normal. The prevalence of DSPD is around 2% in the general population (Schrader et al., 1993), but it can be as high as 16% in adolescents and young adults (Gradisar et al., 2011). The higher prevalence in this age group might be related to neurodevelopmental changes in SCR timing during puberty, exacerbated by an inflexible social and occupational timetable. There are no known gender differences in DSPD, however this might be due to limited epidemiological studies.

# ETIOLOGICAL MODELS OF DSPD

In clinical practice, DSPD is the most common circadian rhythms disorder, with 83% of patients with a CRSWD having a diagnosis of DSPD (Dagan & Eisenstein, 1999). This might be partially due to the fact that DSPD affects an economically active population and is associated with severe disruptions in occupational life and productivity. Nevertheless, the etiological basis of DSPD remains unclear. Suggestive evidence highlights a circadian period that is longer than average (Micic et al., 2013), hypersensitivity to evening light (Aoki et al., 2001; Watson et al., 2020), and sleeping through the advanced period of the light phase response curve (Ozaki et al., 1996). A promising area of inquiry in the etiology of DSPD is its relationship with mood disorders. The high comorbidity between DSPD, depression, and BD might at least be partially indicative of a shared etiological background. However, there is currently not enough research on the reciprocity or the causal mechanisms underlying this association. It is plausible that the link between DSPD and mood disorders results from the constant struggle of DSPD patients to conform to societal demands.

#### ASSESSMENT OF DSPD

The assessment of DSPD relies on self-reported sleep–wake behaviors and circadian preference. At a minimum, the clinical interview for DSPD should include an examination of sleep propensity and arousal throughout the day. In order to determine the patient's preferred timing of activities (often referred to as "morning lark" or "night owl"), global measures of circadian preference can be used, such as the Morningness and Eveningness Questionnaire (Horne & Östberg, 1976) and the Munich Chronotype Questionnaire (Roenneberg et al., 2003). Sleep diaries and actigraphy are additional tools that can complement the clinical evaluation of DSPD. However, an important caveat in the administration of these assessments is duration. A data collection period of at least 2 weeks is typically recommended to obtain sufficient information about work- and free-days. As such, there has been an increased focus on the use of actigraphy in DSPD as a more practical and less cumbersome alternative to sleep dairies. Guidelines over the past decade have highlighted that actigraphy data correlate well with biological markers of circadian phase and can reliably evaluate morning or evening preference in CRSWDs (Morgenthaler et al., 2007; Smith et al., 2018).

Laboratory measures of endogenous timing are not necessary, but they can be used to corroborate the diagnosis and guide the administration of treatment. Polysomnography is not recommended for the evaluation of DSPD, and its use in research is rare. Assessments of circadian phase markers such as melatonin are more common. Studies have consistently found a delayed onset of dim light melatonin in DSPD compared to healthy controls, but not a significant difference in phase angle of entrainment (i.e., the interval from circadian phase and to the timing of an external time cue, here bedtime onset) (Saxvig et al., 2013; Wyatt et al., 2006).

# MANAGEMENT OF DSPD

Several treatment modalities have been proposed for the management of DSPD, with the earliest one being *chronotherapy*. In this case, chronotherapy was defined as a behavioral intervention where sleep–wake times are progressively delayed by 3 hours every day until a desired bedtime is reached. Despite its theoretical intuitiveness, implementation in experimental studies is usually problematic owing to patient noncompliance. There are currently no RCTs exploring the efficacy of this intervention, while the evidence from case studies is mixed. Treatment options with bright light therapy and melatonin agonists as monotherapies or in combination are more common.

Bright light therapy (BLT) capitalizes on the phase-shifting properties of light. Exposure to bright light in the morning has the potential to shift circadian rhythms earlier, leading to a phase advance in people with a delayed phase. BLT can be conducted at home, using light boxes that emit a bright light of 2,500-10,000 lux. There is no consensus over the treatment duration, but 30-60 minutes daily for 2-4 weeks is common. Preliminary evidence about the effectiveness of BLT for DSPD is encouraging, but it is only based on case series data from a small number of participants (Auger et al., 2015). As a result of the limited evidence base, the AASM does not formally endorse BLT for the treatment of DSPD (Auger et al., 2015). Additionally, one RCT tested the efficacy of a novel behavioral intervention for people with a late chronotype. The treatment relies on increasing exposure to natural light in the morning, minimizing exposure to light in the evening, and regularizing the sleep-wake, meal, and exercise schedules (Facer-Childs et al., 2019). The intervention advanced the sleep-wake schedule by an average of 2 hours as measured by actigraphy and circadian phase markers, reduced symptoms of depression and stress, and improved performance on cognitive and physical tasks (Facer-Childs et al., 2019). Although encouraging, these findings rely on a small sample (n = 22) from a single RCT.

Similar to BLT, exogenous melatonin is used in DSPD due to its chronobiotic properties. As represented in a melatonin phase response curve, exogenous melatonin leads to differential entrainment based on the time of its administration. Melatonin advances the circadian phase when administered in the late afternoon or evening, with the strongest effect observed when administered 5-7 hours prior to habitual time in bed. Although timing of the melatonin administration influences the magnitude of the phase advancing effect, there is no evidence of a dose-response effect. Exogenous melatonin produces comparable phase advancing results when administered in doses ranging from 0.3 to 5 mg (Burgess et al., 2010; Mundey et al., 2005). In terms of its effectiveness, exogenous melatonin taken in the evening is associated with a significant advance in the endogenous pineal melatonin onset, earlier sleep onset time, and decrease in sleep onset latency (van Geijlswijk et al., 2010). More recent work has combined morning BLT with evening melatonin and found that a combination treatment protocol leads to greater phase advancements of the dim light melatonin onset compared to either treatment administered as a monotherapy (Burke et al., 2013).

#### Advanced Sleep Phase Disorder

In contrast to DSPD, ASPD manifests as an advance in the sleep-wake cycle. Patients with ASPD report falling asleep between 6–9 P.M. and waking up between 2–5 A.M. When trying to delay their sleep–wake schedule to conform to the social environment, these patients report persisting difficulties, especially sleepiness in the evening. ASPD is more common with increasing age, but its prevalence in the general population is unknown. In middle-aged adults its prevalence is around 1%, and in outpatient sleep centers the prevalence is around 0.04% (Curtis et al., 2019). However, since an earlier sleep–wake pattern is conventionally acceptable in social and occupational settings, it is assumed that advanced sleep phase is underreported.

At present, possible putative mechanisms of an advanced sleep phase include (1) a missense mutation (i.e., the wrong amino acid incorporated into a protein) in the human CKI $\delta$  gene (Xu et al., 2005), (2) a mutation in a phosphorylation site within the CKI-binding domain of the PER2 protein (Toh et al., 2001), (3) an endogenous circadian period that is shorter than average (Zalai et al., 2018), and (4) increased sensitivity to morning light (Zalai et al., 2018).

The assessment of ASPD is identical to DSPD, including a clinical interview with complementary use of global measures of circadian preference, sleep diaries, and actigraphy. During the clinical interview, particular focus needs to be given to the family history of ASPD, given its inheritance pattern (Jones et al., 1999). Actigraphy here might also be preferred over sleep diaries especially for older patients with mild cognitive impairment or dementia. Polysomnography assessments are extremely rare in ASPD. An early study using polysomnography showed a significantly earlier sleep onset and offset clock time in patients compared to healthy controls (Jones et al., 1999). Laboratory assessments of dim light melatonin onset have also shown significant phase advances in ASPD patients compared to both unaffected siblings (Satoh et al., 2003) and healthy controls (Jones et al., 1999).

The mainstay treatment for ASPD is BLT. Here the entrainment properties of light are utilized to delay circadian timing through the administration of bright light in the evening. Notwithstanding, results on the efficacy of BLT in ASPD are mixed. Some studies have shown that evening BLT can effectively delay sleep onset and offset, improve sleep quality, reduced night-time awakenings, and phase delay both melatonin and core body temperature rhythms (Campbell et al., 1993; Lack & Wright, 1993, 2007). However, other sources of evidence have failed to find any improvements in sleep or circadian rhythms following BLT (Pallesen et al., 2005; Palmer et al., 2003; Suhner et al., 2002). In a review it was suggested that the absence of an effect in some studies might be due to low intensity of the BLT (Palmer et al., 2003) or heterogeneous samples, since a formal diagnosis of ASPD was not required in all studies (Suhner et al., 2002).

#### Irregular Sleep–Wake Rhythm Disorder

ISWD is characterized by an unstable sleep-wake pattern. Although total sleep time might be within the normal range, it is fragmented in multiple bouts of sleep. As such, there is not a primary night-time sleep episode, with the most consolidated period of sleep typically not exceeding 4 hours. In extreme cases of ISWD, sleep is distributed randomly throughout the 24-hour day. The primary symptoms of the disorder include complaints of insomnia and excessive daytime sleepiness (EDS).

The disorder primarily affects older adults diagnosed with dementia, other neurological conditions, or brain injury. In all these instances, loss of neurons and functional changes in the superchiasmatic nucleus are the most likely contributing factors to the circadian disorganization observed in ISWD. In otherwise healthy individuals, the disorder typically occurs in care homes or as a result of very poor sleep hygiene. In these cases, as opposed to neurodegeneration, a reduced exposure to external zeitgebers, decreased activity, and a lack of a structured schedule are the possible causal factors for ISWD. The prevalence of ISWD is unknown, with medical conditions being the only potent risk factor. Interestingly, age is not an independent risk factor for ISWD. Although instances of the disorder increase with age, this phenomenon is primarily due to the higher prevalence of particular medical conditions in the elderly, such as dementia (Sack et al., 2007).

The treatment of ISWD aims to consolidate sleep and reduce daytime sleepiness. Several studies in patients with dementia have found supporting evidence for the use of BLT. Here, the goal of BLT is to increase the rest–activity amplitude and stabilize the endogenous circadian phase. Three to five thousand lux of morning BLT administered for 2 hours over 2 weeks was found to decrease napping, increase sleep efficiency, and reduce nighttime awakenings (Fetveit & Bjorvatn, 2004). In other studies, similar effects were more modest or even absent (Skjerve et al., 2004). As such, reviews do not support the use of BLT in ISWD, potentially due to heterogeneity in inclusion/exclusion criteria and treatment protocols of the included trials (Forbes et al., 2014). A promising research avenue for light therapy in patients with dementia is whole-day bright light in care-home facilities owing to preliminary positive results on sleep, mood, and cognition (Riemersma-Van Der Lek et al., 2008). Trials on the administration of exogenous melatonin and melatonin agonists in patients with dementia and ISWD showed that there is no improvement on sleep outcomes following treatment (McCleery & Sharpley, 2020). Similarly, the use of prescription medication for sleep is not recommended in patients with dementia due to low efficacy and potentially serious side effects such as confusion, falls, and dependency. Two trials reported on the use of two orexin antagonists, suvorexant (Herring et al., 2019) and lemborexant (Moline et al., 2021). Using polysomnography and actigraphy, these trials showed that orexin antagonists can increase sleep duration and reduce nighttime awakenings in patents with dementia and sleep problems. An overarching limitation in the treatment literature of ISWD is the poor identification of the disorder at study entry, with participants typically identified as patients with dementia and a broadly defined sleep problem, very rarely specifically diagnosed with ISWD.

# Non-24-Hour Sleep-Wake Rhythm Disorder

N24SWD manifests as periodic bouts of insomnia and/or daytime sleepiness owing to a misalignment between the 24-hour light–dark cycle and the non-entrained endogenous circadian rhythm. The disorder often presents as a delayed sleep onset, with sleep and wake occurring progressively later in the day.

N24SWD is rare in sighted individuals and in visually impaired people who retain some level of light perception, but it affects around two-thirds of those who are totally blind and unable to perceive photic stimuli. The remaining one-third of totally blind patients manage to entrain their circadian rhythms through a strict daily schedule of activities, such as exercising, eating, and social interaction. Onset of N24SWD typically occurs shortly after loss of light perception, and demographic differences in its prevalence remain unknown.

The treatment of N24SWD aims to synchronize the patient's endogenous clock with the 24hour light–dark cycle. If entrainment is achieved, the symptoms of insomnia and/or daytime sleepiness dissipate. In sighted individuals, there is preliminary evidence supporting the effectiveness of timed phototherapy after the minimum body temperature (Hayakawa et al., 1998; Watanabe et al., 2000). The use of exogenous melatonin in the early evening has also been found to be effective for sighted individuals with N24SWD (Hayakawa et al., 1998; McArthur et al., 1996). However, given the fact that the evidence base does not include any RCTs, neither timed phototherapy nor exogenous melatonin is currently recommended. In blind N24SWD patients, exogenous melatonin at night can effectively entrain circadian rhythms (Lockley et al., 2000). Additionally, an RCT including blind patients with N24SWD found a melatonin receptor agonist, tasimelteon, was also effective at entraining the circadian clock and improving clinical measures of sleep (Lockley et al., 2015). Improvements were sustained at follow-up but dissipated rapidly following discontinuation (Lockley et al., 2015). The medication was well-tolerated and led to minimal side effects. As a result, tasimelteon is approved for use N24SWD in blind individuals only (Auger et al., 2015).

## Narcolepsy

Narcolepsy is a rare neurological condition marked by EDS and *cataplexy*, an involuntary loss of muscle tone during wake triggered by strong, mainly positive emotions. Narcolepsy patients may also experience sleep paralysis and hypnagogic hallucinations (i.e., vivid imagery during sleep initiation or before wakefulness). The disorder affects 1 in 2,000-4,000 people, with epidemiological studies relying heavily on self-reported questionnaires, thus probably providing an incomplete picture of its prevalence (Kornum et al., 2017). The typical age of onset of narcolepsy is between 10 and 20 years of age, with potential diagnostic delays of up to 15 years (Scammell, 2015). The associated symptoms are severe, with profound difficulties focusing and staying awake during daytime and especially during periods of minimal activity, such as when watching a movie.

Narcolepsy is divided into two diagnostic types according to the ICSD-3: narcolepsy type 1 (NT1) is marked by EDS, cataplexy, and low levels of hypocretin 1 peptides (also called orexin-A), while narcolepsy type 2 (NT2) is marked by EDS, no cataplexy, and typical levels of hypocretin. The *DSM-5* refers to NT2 as *hypersomnolence disorder*, and it is covered in a subsequent section. Most importantly, the demarcation criterion for NT1 and NT2 is the level of hypocretin peptides in the cerebrospinal fluid of the patients. As such, hypocretin-deficient patients (cerebrospinal fluid hypocretin ≤110 pg/ mL) without cataplexy would be classified as NT1 owing to longitudinal data showing that patients with low levels of hypocretin do develop cataplexy at some point (Andlauer et al., 2012). The presence of a rare group of patients with cataplexy and typical hypocretin levels has caused an ongoing debate. At present, these patients are classified as NT1.

Although the exact cause of narcolepsy is not confirmed, genetic factors are undoubtedly important. Certain genes in an area of chromosome 6 known as the human leucocyte antigen complex are responsible for encoding antigen-presenting molecules of the major histocompatibility complex. Genetic mutations in these regions have been implicated in the causality of narcolepsy. More specifically, up to 98% of NT1 patients carry the allele HLA-DQB1\*06:02 of the human gene HLA-DQB1 (Han et al., 2014; Nishino et al., 2000). This allele is also prevalent in 5-40% of the general population, yet only 1 in 1,000 of these carriers present with NT1 (Kornum et al., 2017), Preliminary data suggest that the allele might be more common in NT2 patients compared to the general population, too (Kornum et al., 2017).

The diagnosis of narcolepsy is made on the basis of a clinical interview and a multiple sleep latency test (MSLT). Cataplexy and EDS are assessed through an interview with several questionnaires available that evaluate sleepiness. The most prominent of these questionnaires are the Epworth Sleepiness Scale (Johns, 1991), the Stanford Sleepiness Scale (Hoddes et al., 1972), and the Karolinska Sleepiness Scale (Shahid et al., 2011). MSLT is a test that consists of five nap opportunities separated by 2-hour breaks. The assessment takes place in a quiet, cool, and comfortable environment, 1.5-3 hours after a night of habitual sleep. The assessment is terminated after 15 minutes following sleep onset, or after 20 minutes if the patient does not fall asleep. Sleep onset is defined here as the transition from wakefulness to any sleep stage. A mean sleep latency of 8 minutes or less, and occurrence of REM sleep on at least two naps are indicative signs of narcolepsy. A polysomnographic assessment the night before MSLT is also recommended to rule out any comorbid sleep disorders.

The management of narcolepsy includes a combination of pharmacological and behavioral interventions. Modafinil, methylphenidate, pitolisant, solriamfetol, and dextroamphetamine sulfate are approved medications for narcolepsy in the United States and Europe. These medications exert their wake-promoting effects by increasing the release or reducing the reuptake of dopamine or norepinephrine. Methylphenidate has a high abuse potential and is associated with a range of side effects, while pitolisant was only approved as a treatment in 2019 (Thorpy, 2020). Modafinil is currently the most widely prescribed medication in narcolepsy, owing to its favorable treatment effects and contained sideeffect profile. Sodium oxybate is the only approved medication for the treatment of cataplexy, but the off-label use of venlafaxine is also common. Studies have shown that, as opposed to medication alone, a combined intervention that includes stimulants and a regularized sleep-wake schedule with two 15minute naps during the day is most effective protocol at reducing sleepiness and involuntary sleep in the daytime (Rogers et al., 2001)

## Hypersomnolence Disorder

Hypersomnolence disorder or hypersomnia refers to a condition characterized by EDS despite adequate amount of sleep the night before. For the diagnosis of hypersomnia, EDS-related symptoms need to persist for at least 3 days a week for more than 3 months; they need to result in considerable adverse consequences in functioning and not be better explained by another sleep, medical, or psychiatric disorder. The prevalence of hypersomnia is challenging to estimate, but around 28% of adults report a complaint of EDS and 1.5% meet the criteria for the disorder (Ohayon et al., 2012). Hypersomnia typically manifests in late adolescence or early childhood, and there are no genderbased differences regarding its prevalence. A major obstacle in the study of hypersomnia is that terms such as "hypersomnolence (disorder)," "(excessive) somnolence," "hypersomnia (disorder)," and "(excessive) daytime sleepiness," are often used interchangeably. Operational definitions vary, and as such, scientific inaccuracies and biases in the results might be present (Barateau et al., 2017). Here, "hypersomnia" refers to the DSM-5 diagnosis of hypersomnolence disorder and the ICSD-3 diagnosis of idiopathic hypersomnia. The clinical assessment of hypersomnia typically includes an interview, sleep diaries, and EDS questionnaires. The polysomnographic assessment of hypersomnia should be normal, except for potential increased sleep duration.

The most common treatment for hypersomnia is methylphenidate or modafinil. Nevertheless, the evidence base for the effectiveness of either agent is limited. In a recent review, the authors noted that no RCT has examined the effectiveness of methylphenidate in hypersomnia (Sowa, 2016). This might be partially due to the popularity of modafinil as a treatment option following its introduction in the US markets in 1998. However, surveys show that almost half of hypersomnia patients are still using methylphenidate (Ali et al., 2009). The role of cognitive and psychological mechanisms in the maintenance of hypersomnia have also been highlighted (Billiard et al., 1994). As a result, researchers have developed a multicomponent psychological intervention (Kaplan & Harvey, 2009) that has yet to be examined empirically.

# Parasomnias

Parasomnias refer to aberrant and disruptive behaviors or experiences that occur during sleep or in the transition between sleep and wakefulness. Parasomnias are broadly classified into three groups depending on the sleep stage they typically occur in. In the first group, *NREM parasomnias*, the disorders included are confusional arousals, sleepwalking, sleep terrors, and sleep-related eating disorder. In the second group, *REM parasomnias*, the disorders included are REM sleep behavior disorder, sleep paralysis, and nightmare disorder. In the final group, *other parasomnias*, the disorders included are exploding head syndrome, sleep-related hallucinations, and sleep enuresis.

NREM parasomnias are recurrent events characterized by incomplete awakening from NREM sleep and usually occur in the first third of the night, during the transition from N3. These disorders are marked by sudden motor actions, reduced responsiveness to the external environment, and absent cognition or visual imagery. Typically, patients do not recollect NREM parasomnias, and the reporting of such events is done by the patient's parents or bedpartner. NREM parasomnias are more prevalent in children than adults, their diagnosis relies solely on clinical interview, and their management is variable. In pediatric cases, the disorders are considered benign as children tend to outgrow them. Psychoeducation protocols are preferred over other interventions, but in some cases, anticipatory awakenings 15-20 minutes prior to the typical onset of a parasomnia episode has been found to be effective (Tobin Jr, 1993). For adult NREM parasomnias, interventions typically include sleep hygiene, regularization of sleep-wake cycles, and alleviation of stress triggers.

REM parasomnias are abrupt and repetitive motions that range from small movements to

violent acts, sometimes accompanied by vocalizations. Although REM is associated with muscle atonia, these disorders are associated with an excess of muscle tone and/or an excess of phasic twitching activity. In these cases, patients reenact their dreams, and, upon awakening, they are fully alert and able to recollect their dream or nightmare. The diagnosis of these disorders is based on clinical interviewing and polysomnography to confirm the events occur during REM sleep in the absence of muscle atonia. Similar to NREM parasomnias, the management of REM parasomnias is variable. In sleep paralysis and nightmare disorder, psychoeducational interventions such as reassurance and stress management are common, while medication is only prescribed in very severe and persisting cases. In REM sleep behavior disorder, the clinical response is typically preventative and includes a reevaluation of the patient's current medication regime. Most notably, the presentation of REM sleep behavior disorder has been found to be a potent marker of later development of a particular class of neurodegenerative disorders, called *a*-synucleinopathies. Such disorders include Parkinson's disease, Lewy body dementia, and multiple system atrophy and are caused by the aggregation of alpha-synuclein proteins. Studies have shown that 80% of patients presenting with REM sleep behavior disorder will later develop  $\alpha$ -synucleinopathies, suggesting that the neurodegenerative processes responsible for these disorders initially target neuronal circuits regulating REM sleep (Peever et al., 2014).

## Sleep and Circadian Rhythms in Psychiatric Disorders

SCR disruptions are transdiagnostic symptoms characterizing the course of several psychiatric disorders. Historically, the psychiatric disorder has been viewed as primary and as the cause of the SCR condition, with the assumption being that the latter resolves with the successful treatment of the former. SCR disruptions typically precipitate the formal presentation of other disorders, prevail in remission, and their treatment leads to reductions in other mental health problems. Consequently, recent reviews have conceptualized such disruptions as contributory elements in the multifactorial causation of psychiatric disorders (Freeman et al., 2020). Here we address this conceptualization and consider the role of SCR in four such disorders: major depression disorder (MDD), generalized anxiety disorder (GAD), BD, and schizophrenia.

# Sleep and Circadian Rhythms in Major Depression Disorder

Sleep disturbances are prominent features of MDD and are particularly salient to patients, caregivers, and clinicians (Chevance et al., 2020). In terms of the nosology, ICD-11 includes "changes in sleep" as a diagnostic criterion for depression, while DSM-5 mentions the presence of "insomnia or hypersomnia nearly every day." Around 70-90% of MDD patients report persistent sleep disturbances (Soehner & Harvey, 2012; Tsuno et al., 2005), with insomnia being the most common. More specifically, daytime fatigue, reduced total sleep time, and difficulties initiating and maintaining sleep are the most prevalent problems reported by patients. MDD is also associated with changes in sleep architecture, a finding first observed in the 1970s. When compared to healthy controls, people with depression typically exhibit a decrease in N3/SWS and a disinhibition of REM sleep, indexed by reductions in REM latency and duration and an increase in the frequency of rapid eye movements during REM sleep (Baglioni et al., 2016; Riemann et al., 2020).

Early polysomnographic results encouraged investigations into the specificity of these biomarkers, with the intention of identifying depression subtypes and optimizing treatment to reflect differential disorder strata. Subsequent investigations challenged the diagnostic specificity and clinical utility of these biomarkers. In multiple reviews, it was revealed that the N3/SWS and REM sleep alterations seen in MDD are also prevalent in several other psychiatric disorders (Baglioni et al., 2016). Instead of a disorder-specific model, these reviews endorsed a transdiagnostic, dimensional approach to SCR in psychopathology. According to this approach, SCR disruptions transcend discrete diagnostic classifications and are ubiquitous in psychiatric disorders, possibly due to a shared causal mechanistic origin. As such, the same SCR endophenotype can be a risk factor for the development of multiple such psychiatric disorders, with no SCR endophenotype being unique to any such condition.

The causal effect of SCR disruptions in the development of MDD is evident by four elements. First, genetic and epigenetic research has supported the notion of a shared etiological background between insomnia and MDD. Two genome-wide association studies have identified genome-wide significant loci implicated in insomnia and potentially depression, with the single nucleotide polymorphism rs113851554 in the MEIS1 gene producing the strongest effect (Hammerschlag et al., 2017; Lane et al., 2017, 2019). Twin studies have also shown a significant genetic overlap between insomnia and depression symptoms when considering longitudinal associations of the two phenotypes (Gregory et al., 2016). Second, sleep problems precipitate the presentation of depression and are a risk factor for later development of MDD. A meta-analysis of prospective cohort studies involving 150,000 participants showed that individuals with insomnia have up to double the risk of later developing depression (Li et al., 2016). More recent reviews are in line with these findings, highlighting that the risk might be higher when applying stricter criteria for the diagnosis of insomnia (Hertenstein et al., 2019). Third, fatigue and insomnia are the most common residual symptoms of depression in otherwise treated individuals. More than half of MDD inpatients report a sleep problem at discharge (Schennach et al., 2019), and those with a sleep complaint in remission have a shorter time to relapse compared to those without (Inada et al., 2021; Sakurai et al., 2017). Finally, the strongest causal inference about the role of sleep disruptions in MDD can be made from evaluating the effects of sleep interventions on depression symptoms. The treatment of insomnia symptoms through CBT-I is accompanied by moderate to large reductions in depression at post-treatment and even at a 12-month follow-up (Ashworth et al., 2015; Henry et al., 2021; Kyle et al., 2020). Other principal SCR interventions, such as BLT and total sleep deprivation, have been found to lead to a reduction in depression symptoms as well (Boland et al., 2017; Geoffroy et al., 2019). However, many of these studies have considerable methodological limitations (Mårtensson et al., 2015; Stewart, 2018) and often lack adequate characterization of sleep and/or circadian rhythms, thus restricting the causal inferences that we can extrapolate from them.

# Sleep and Circadian Rhythms in Generalized Anxiety Disorder

Both *DSM-5* and *ICD-11* include sleep disturbances as a core symptom of GAD, with *DSM-5* specifically referring to problems initiating or maintaining sleep, or nonrestorative, restless sleep. Nevertheless, a surprisingly limited number of studies have examined the role of SCR in GAD, even despite the clear association between sleep and anxiety (Freeman et al., 2020). At the core of GAD is hyperarousal, expressed as enhanced cognitive, somatic, and physiological activation. Hyperarousal is an antagonistic process in the initiation and

maintenance of healthy sleep and, as such, an element particularly prevalent in insomnia disorder (Riemann et al., 2010).

The comorbidity between GAD and insomnia is high (Monti & Monti, 2000), with 74% of primary care patients with GAD reporting symptoms of insomnia (Marcks et al., 2010). Difficulties falling and staying asleep in GAD patients are also found in polysomnographic studies (Cox & Olatunji, 2016). However, the evidence on the effects of anxiety in sleep architecture is sparse. Preliminary data show a decrease in N3/SWS and an increase in N1 sleep, while findings on alterations of REM sleep are inconclusive (Baglioni et al., 2016; Monti & Monti, 2000).

The temporal relationship between GAD and insomnia remains a matter of scientific debate. Some longitudinal studies have suggested that anxiety precedes insomnia (Johnson et al., 2006; Ohayon & Roth, 2003), while others have indicated that insomnia precedes the occurrence of anxiety disorders (Breslau et al., 1996; Soldatos, 1994). Similar to research in MDD, stronger evidence on the causal directionality of sleep and anxiety problems should arise from intervention trials. However, although anxiety and insomnia are encountered more frequently together than in isolation, studies rarely examine the comorbidity of the two. A meta-analysis of CBT-I trials showed a moderate improvement of anxiety symptoms posttreatment (Belleville et al., 2011) that was sustained at a 6-month follow-up (Hagatun et al., 2018). A notable limitation is that no trial in the aforementioned meta-analysis delivered CBT-I to people with GAD. In fact, in 2014, two reviews found that there is no RCT examining the effects of insomnia treatment on people recruited with a specific diagnosis of GAD (Dolsen et al., 2014; Taylor & Pruiksma, 2014), and, to our knowledge, no such trial has been published since. One trial compared three insomnia interventions in participants with insomnia on its own and insomnia comorbid with another psychiatric disorder (Bélanger et al., 2016). However, participants with GAD only constituted 9.6% of the sample, and no data were presented for them specifically. Another trial compared the sequential administration of CBT-I and CBT for GAD in 10 patients with comorbid insomnia and GAD (Belleville et al., 2016). CBT for GAD led to a significant decrease in worrying and increase in sleep quality, but no significant improvements were detected for insomnia or anxiety symptoms. CBT-I led to significant improvements in sleep quality and

insomnia but not in worrying or anxiety. Sequential implementation of both treatments yielded a superiority in improvements for the group that received CBT for GAD first. However, these findings should be interpreted with particular caution due to the small sample size.. All in all, the evidence base is presently too small to make any claims on directionality between sleep and anxiety. More recent theoretical notions posit that the causal relationship between anxiety and sleep is bidirectional owing to shared substrates in the brainstem and cerebral cortex regulating arousal and sleep–wake (Freeman et al., 2020). Such perspectives are yet to be evaluated empirically.

## Sleep and Circadian Rhythms in Bipolar Disorder

SCR disruptions are cardinal features of BD, and particularly salient to patients (Gordon-Smith et al., 2021). DSM-5 and ICD-11 recognize decreased need for sleep as a symptom of mania, and insomnia or hypersomnia as symptoms of depression. Individuals with BD also exhibit a delayed circadian phase, favoring a late rise and bedtime (Melo et al., 2017). These impairments are ubiquitous in acute illness episodes (Harvey, 2008) and have been associated with increased suicidality (Palagini et al., 2019), lower quality of life (Bradley et al., 2017), decreased occupational functioning (Boland et al., 2015), and poorer performance on neurocognitive assessments of inhibitory control, sustained attention, and processing speed (Bradley et al., 2020; Kanady et al., 2017). Even in euthymia, 70% of patients report persisting sleep problems, such as inability to fall asleep, daytime dysfunction, and increased use of hypnotics (Geoffroy et al., 2015; Harvey et al., 2005). Moreover, sleep problems in euthymia account for a considerable proportion of symptom change over longitudinal assessments (Soehner et al., 2019) and predict acute episode relapse even when accounting for residual mood symptoms (Cretu et al., 2016).

Much like in all other psychiatric disorders, the assessment of SCR problems in BD relies on phenomenology and self-report measures. However, objective measures such as actigraphy, polysomnography, and circadian phase assessments have consistently corroborated the SCR problems described by individuals with BD. According to reviews of actigraphy findings, BD patients exhibit longer total sleep time, sleep onset latency, and night awakenings during euthymia compared to healthy controls (Ng et al., 2015). BD patients also sleep longer compared to insomnia patients, but this is the only significant difference between the two patient groups (Ng et al., 2015). In terms of sleep architecture, BD patients show increased sleep latency and REM sleep duration across all stages (Zangani et al., 2020). During (hypo)mania, BD patients exhibit shorter total sleep time (Zangani et al., 2020). In euthymia, total sleep time is no different from that of healthy controls (Soehner et al., 2018); however, there is a reduction in the duration of non-REM Stage 2 sleep accompanied by a longer duration of the first REM episode and increased total percentage of REM sleep (Estrada-Prat et al., 2019; Sitaram et al., 1982). Alterations in melatonin and cortisol secretion have also been described in BD regardless of the illness stage (Geoffroy, 2018; Melo et al., 2017). Serum melatonin levels are overall decreased in BD, and dim light melatonin onset is significantly later (Nurnberger et al., 2000). Additionally, cortisol levels upon awakening and in response to stress-invoking situations are higher in people with BD (Girshkin et al., 2016).

Transcending initial beliefs about SCR disruptions as only symptoms of BD, accumulated evidence suggests that they might also be involved in the pathogenesis and illness progression of the disorder (Plante & Winkelman, 2008). Circadian gene polymorphisms have been implicated in the genetic diathesis and drug response in BD. Such genes include CLOCK, NPAS2, ARNTL1, NR1D1, PER3, RORA, RORB, CSNKepsilon, and GSK3beta (Geoffroy, 2018). In a seminal study by Roybal, deletion of exon 19 in the CLOCK gene in mice resulted in manic-like behavior such as hyperactivity, risk-taking behavior, heightened reward sensitivity, and abnormal sleep-wake patterns characterized by reduced sleep (Roybal et al., 2007). Administration of lithium or restoration of a functional CLOCK gene in the ventral tegmentum ameliorated the manic-like behavior (Roybal et al., 2007). Additionally, sleep deprivation has been directly linked with the cause of mania (Plante & Winkelman, 2008). Initial reports by Wehr described sleep loss as "the final common pathway to mania," owing to findings that total sleep deprivation was associated with the emergence of manic mood (Wehr et al., 1987). In later years, the manic-inducing effects of sleep loss in BD were replicated, but it was also found that sleep loss has the potential to produce strong antidepressant effects. Consequently, total sleep deprivation interventions for bipolar depression began to emerge (Benedetti et al., 1997). At present, such interventions are typically combined with the administration of bright light, and several reviews have supported their efficacy (D'Agostino et al., 2020; Gottlieb et al., 2019; Ramirez-Mahaluf et al., 2020). However, conclusion from these reviews should be interpreted with caution. The majority of the included trials are uncontrolled and nonrandomized or include mixed samples of unipolar and bipolar patients (Bisdounis et al., 2021). Most of these trials also do not include any assessment of sleep or circadian rhythms despite it being the presumed mechanism of action of these interventions (Bisdounis et al., 2021).

Sleep problems also constitute the most wellreplicated risk factors of later development of BD in children who have a parent with BD and are thus at a familial risk of the disorder (Duffy et al., 2019; Levenson et al., 2015). Cumulative research over the past two decades using bipolar offspring has identified several markers of vulnerability to future development of BD. Among the proposed loci of interest, SCR disruptions are the most wellreplicated and widely generalized markers (Melo et al., 2016). In these studies, increased energy levels and a decreased need for sleep were among the earliest identified symptoms (Sebela et al., 2019), followed by irregularity in sleep patterns (Singh et al., 2008) and delayed sleep-wake rhythms (Melo et al., 2016). Combined with self-reported outcomes, measures of rest-activity, such as actigraphy, indicated a decreased need for sleep as a risk marker, together with decreased social jet lag (i.e., the discrepancy in social and biological timing between work and nonwork days) and a larger discrepancy on sleep duration and sleep onset latency between weekends and weeknights (Sebela et al., 2019). In a sample of high-risk offspring, individuals classified as poor sleepers were twice as likely to develop BD compared to peers classified as good sleepers (Levenson et al., 2017).

#### Sleep and Circadian Rhythms in Schizophrenia

The prevalence of SCR disruptions in schizophrenia is approximately 80% (Cosgrave et al., 2018). Self-report and polysomnographic evidence indicate that patients with schizophrenia exhibit longer sleep onset latency and wake after sleep onset, as well as decreased total sleep time and sleep efficiency. In terms of the sleep architecture, patients with schizophrenia show a decrease in the duration of N3/SWS and REM sleep compared to healthy controls (Chan et al., 2017).

Insomnia symptoms are the most frequent SCR complaints in schizophrenia, but ASDP and DSPD are also common. Interestingly, the presence of

insomnia in patients with schizophrenia might indicate a particular disorder subtype (Freeman et al., 2020). Behavioral genetic studies have highlighted that insomnia correlates with paranoia, hallucinations, and cognitive disorganization, but not with negative affect and grandiosity (Taylor et al., 2015). Accumulated evidence also suggests that these problems appear prior to the formal presentation of schizophrenia. Studies in populations at ultra-high risk of psychosis show that insomnia is a strong predictor for the development of persistent psychosis (Reeve et al., 2018). Additionally, in longitudinal studies using experience sampling monitoring, among people with a diagnosis within the schizophrenia spectrum, poor sleep quality predicted increases in paranoia (Kasanova et al., 2020) and auditory hallucinations (Mulligan et al., 2016) the following morning. The majority of patients with schizophrenia experiencing persecutory delusions also report sleep problems prior to the onset of these delusions (Freeman et al., 2019). Experimental studies in nonclinical populations show a marked increase in psychotic experiences following sleep loss (Barton et al., 2018). So far, this relationship appears to be unidirectional, with psychosis not being a potent predictor of insomnia (Reeve et al., 2018; Waite et al., 2020). However, it has been suggested that the relationship between psychosis and insomnia might be fully mediated by negative affect (Freeman et al., 2020).

More robust evidence regarding the relationship between sleep and psychosis comes from intervention studies. In a large RCT of students with insomnia, CBT-I led to a small yet significant reductions in paranoia and hallucination scores (Freeman et al., 2017). These post-treatment changes in psychotic experiences were mediated by improvements in insomnia symptoms. There was limited evidence for reverse causation. Smaller open-label and pilot RCTs of CBT-I have shown significant sleep improvements both for individuals with schizophrenia and those at ultra-high risk of psychosis (Bradley et al., 2018; Chiu et al., 2018; Freeman et al., 2015; Hwang et al., 2019). Although no significant changes in psychosis was detected in any of these studies, these trials were not powered to be definitive.

Despite their prevalence and importance in treatment and symptom development, SCR disruptions are not part of the diagnostic criteria for schizophrenia in either *DSM-5* or *ICD-11*. This might reflect a phenomenon where sleep problems in schizophrenia are not formally assessed and prioritized by clinicians (Rehman et al., 2017) despite patient reports that sleep and daily rhythms are particularly salient domains for them (Freeman et al., 2019). Recent advancements in this area might see the integration of SCR rhythms in the diagnosis, assessment, and management of schizophrenia in both research and clinical practice.

#### Sleep and Circadian Rhythms in Medicine

The 2017 Nobel Prize in Medicine was jointly awarded to Jeffrey C. Hall, Michael Rosbash, and Michael W. Young for their work on the molecular underpinnings of the circadian clock. Although the scope of this chapter was to highlight the role of SCR in mental health, understanding the circadian principles of our physiology can provide insight into human health at large. SCR disruptions have been implicated as central or peripheral elements of disorders ranging from cardiovascular and neurodegenerative diseases to cancer and pathogen infection. Emerging evidence also indicates that without changing the dosage, synchronizing drug administration with endogenous circadian rhythms can improve treatment potency. Thus, beyond their role in pathogenesis, pathophysiology, and psychopathology, new developments in circadian medicine highlight the potential of circadian principles even in potentiating drug action and optimizing treatment efficacy.

# Paraphilia, Gender Dysphoria, and Hypersexuality

James M. Cantor

Research findings in human sexuality are increasingly scrutinized, not only for their scientific merits, but also for perceived political implications. Indeed, even the very inclusion of this chapter in a book with "psychopathology" in its title could be interpreted by some as a political statement. Correspondingly, the inclusion/exclusion of any given sexual phenomenon within this chapter could be so interpreted. For present purposes, atypical sexuality is intended broadly. Rather than represent any political view, this reflects the ultimately pragmatic purpose of facilitating clinical intervention and research. Such work spans not only people with conditions listed in the DSM or ICD, but also people presenting to clinicians experiencing distress about other behaviors or interests at the edges of or entirely outside cultural norms.

The scientific understanding of atypical sexualities begins with an unanswerable question: What objective line divides healthy sexual diversity from psychopathological sexual interest? The lack of any universal response reflects its dependence on context and, often, a compromise among competing legitimate principles, including the freedom of individual sexual expression, the societal interest in preventing sexual victimization, and the professional ethic of protecting patient-clients from self-harm. Each of these issues can pertain differently across the types of sexual atypicality. Consensual paraphilias, such as the erotic interest in pain, have given rise to entire subcultures, analogous to the gay communities of previous decades. Nonconsensual paraphilias, such as the erotic interest in children or in rape, motivate persons to engage in sexual offenses, leading legislatures to enact increasingly putative and lengthy sentences and to establish publicly accessible registries of offenders. Cases of transsexualism, of "sex addiction" (often termed *hypersexuality* in the research literature), and of highly unusual paraphilias (such as erotic interest in nonhuman animals or in being an amputee) have been featured in contemporary entertainment media and documentaries (e.g., Lawrence, 2006; Reay et al., 2013; Williams & Weinberg, 2003).

Historically, the diagnostic issue receiving most attention in sexuality was the removal of homosexuality from the DSM, reflecting official opinion that the stigma associated with a diagnosis outweighed any potential benefits. In being the most familiar example, ethical and political discussions of many of the other sexual phenomena (especially transsexuality and transgenderism) often reason by way of analogy to that precedent. The extent to which the depathologization of homosexuality applies to other phenomena varies widely across them. Complete consideration of each issue concerning every atypical sexual interest or behavior is beyond the scope of this chapter (unfortunately!). Nonetheless, it can be illustrative to explicate some of the issues potentially affected by official diagnostic status.

- Will insurance cover its treatment?
- Will adding/removing a category remove the ability of a client to use psychotherapy to develop a

#### Abbreviations AB/DL Adult Babies/Diaper Lovers AID Amputee identity disorder Body integrity identity disorder BIID **BSTc** Ventral subdivision of the bed nucleus of the stria terminalis ETII Erotic-target identity inversion FtM Female-to-male MtF Male-to-female ROGD Rapid-onset gender dysphoria

healthy adjustment to their sexual interest pattern, analogous to a person using psychotherapy for support during their "coming out" process?

- Will inclusion subject people to sexually violent predator regulations, and do these implications differ across nations and jurisdictions?
- Will diagnostic status affect determinations of legal culpability when the motivation to engage in a behavior is diagnosable as a mental illness?
- Does inclusion of a category produce social requirements for accommodation, as civil rights issues for sexual minorities or for people with mental illnesses?
- Does official status change access to resources, such as access to funding for sex reassignment surgery?
- Does that principle apply to sex reassignment only or to all body modification?
- Does there exist a public interest in regulating the public expression of a behavior, and how can one distinguish genuine public interest from sociopolitical tolerance for diversity?

Neuroanatomic and genetic research on these conditions has lagged behind that of other behavioral phenomena. Thus, this chapter necessarily emphasizes description over etiology. Great care must be taken when generalizing findings regarding individuals with atypical sexual interests or behaviors. (1) On the one hand, much of what we know about the nonconsensual paraphilias derives from research on sex offenders and may not represent the population of people with paraphilias. On the other hand, mutual support groups, such as for selfidentified pedophiles working to remain offense-free as well as professionally led groups for pedophiles unknown to law enforcement, have emerged (e.g., Beier et al., 2009; Cantor & McPhail, 2016). Such groups may provide a new window on nonoffending pedophiles but may also represent a nontypical cross-section. (2) Reports of hypersexuality (also termed "sex addiction," "sexual compulsivity," etc.) frequently rely on self-referral and self-diagnosis from individuals who already presume the validity of analogies between sexual behavior and drug or alcohol use. The ICD-11 includes code 6C72 for compulsive sexual behaviour disorder, replacing ICD-10's excessive sexual drive and excessive masturbation. The DSM-5 contains no specific equivalent, but nevertheless permits diagnosis with code F52.8 for other specified sexual dysfunction (Krueger, 2016). (3) The still-increasing politicization of physical and mental healthcare for transgender and potentially transsexual children, adolescents, and adults adds self-selection, self-report, and self-censoring biases to research and clinical reports.

## **Paraphilias**

"Paraphilia" refers broadly to any powerful and persistent sexual interest other than sexual interest in copulatory or precopulatory behavior with morphologically typical, consenting, adult human partners. Although some paraphilic interests have been reported in women, the paraphilias occur nearly exclusively in men. DSM-5 introduced the distinction between paraphilias and paraphilic disorders: paraphilias are not diagnosable disorders unto themselves. The more restrictive term, "paraphilic disorder" now refers to the subset of individuals either who experience distress or impairment or who harm or risk harm to others due to their paraphilic interest. Thus, the existing literature includes samples that, after 2013, would be said to have a paraphilia but not a paraphilic disorder (such as surveys of cross-dressing social groups as well as other samples that would now be said both to have a paraphilia and to be diagnosable with a paraphilic disorder [such as phallometric studies of convicted, pedophilic child molesters]). Thus, among the paraphilic individuals in the studies reviewed here, some would and some would not have received a DSM-5 diagnosis. Paraphilias may be classified under two broad headings: (1) those in which the sexually interesting *object* is something other than phenotypically normal humans between the ages of physical maturity and physical decline, and (2) those in which the sexually interesting *activity* is something other than copulatory or precopulatory behavior with a consenting partner.

# **Object Paraphilias**

#### Erotic Age Preferences

The erotic age preferences are termed according to the level of physical development of an individual's most preferred sexual object (Blanchard et al., 2009). In sexual interest research, *oedophilia* refers to the strong or preferential sexual interest in specifically prepubescent children (i.e., children showing Tanner stage 1 features, typically age 10 and younger). *Hebephilia* refers to the equivalent interest in pubescent children (Tanner stages 2–3, typically ages 11–14). Because pedophilia and hebephilia can co-occur or be difficult to distinguish, authors have used *pedohebephilia* as a superordinate category to refer to both. *Ephebophilia* refers to persons in adolescence or late puberty (Tanner stage 4, typically ages 15 to physical maturity), and *teleiophilia* refers to the erotic age preference toward adults after reaching physical maturity and before physical decline (Tanner stage 5, typically ages, 17–45). Finally, there also exist individuals whose primary sexual interests are for elderly persons, termed *gerontophilia*.

Hebephilia is consistently described as a paraphilia along with pedophilia, whereas ephebophilia and teleiophilia represent nonparaphilic states. This is consistent with the evidence demonstrating convergent validity among indicators of hebephilia, yet poor divergent validity between hebephilia and pedophilia (Stephens, Seto et al., 2017). The range of erotic age interests has led to the overarching term *chronophilia*, and taxometric analyses suggest age interests follow a dimensional rather than categorical pattern (Stephens, Leroux et al., 2017; however, see also McPhail, Olver et al., 2018).

The typical behaviors of pedophilic and hebephilic sex offenders consist of touching the breasts, buttocks, or genitals of the child or inducing the child (such as with bribes or threats) to touch or fellate the offender. Abduction and violent sexual abuse of children are comparatively rare. Some pedophilic men report experiencing an interest in children that is romantic as well as erotic (Wilson & Cox, 1983). Pedophilia and hebephilia supply the motivation behind a substantial proportion of cases of child molestation, but these erotic age preferences are not synonymous with sexual offenses against children (Seto, 2008): some cases of child molestation, especially those involving incest, are committed in the absence of any identifiable deviant erotic age preference (e.g., Freund et al., 1991). In such cases, the child is a sexual target of convenience to the offender. Conversely, there are men with no known records of sexual contact with a child who present to clinicians seeking assistance in dealing with their erotic interest in children.

The number of people apprehended for the possession or distribution of child pornography on the Internet continues to grow (Seto, 2013). Whereas only a minority hand-on sexual offenders against children appear to have a genuine sexual preference for children, the majority of child pornography offenders do (Seto et al., 2006). Meta-analytic comparison of online-only (child pornography) offenders, hands-on sexual offenders against children, and mixed offenders revealed the online-only offenders to show less antisociality and greater victim empathy (Babchishin et al., 2015).

Individuals seeking clinical intervention to help manage their sexual attractions to children remain underserved but have garnered increased attention (e.g., McPhail, Stephens, & Heasman, 2018). Online and other surveys of self-identified pedophiles and hebephiles are now adding to observations from forensic samples (Cantor & McPhail, 2016). Examination of online discussions among people coping with their sexual attractions to children demonstrated they employed self-management strategies across four themes: management of sexual preferences (distraction, psychotherapy, and sex drive-reducing medications such as chemical castration, and legal means of sexual expression such as fantasy), management of risk to offend (avoidance, abstinence, behavioral self-monitoring), and management of mood (healthy lifestyle, psychotherapy and antidepressants, and personal acceptance of their attractions), as well as social contacts (peer support, family support, and religion; Stevens & Wood, 2019).

Catering to sexual interests at the other end of the chronophilias, the Internet includes sites dedicated to sexual depictions of elderly women. An unknown proportion of sexual offenders are gerontophilic; reviews suggests that 2–7% of rape victims are elderly women (Ball, 2005), and homosexual gerontophilic sexual offending also exists (Kaul & Duffy, 1991). Sexual homicides of the elderly show evidence of greater brutality, even though the victims are less likely or able to resist or protect themselves (Safarik et al., 2002).

#### Fetishism

Fetishism denotes a heterogeneous group of paraphilias in which the individuals' strongest sexual interest is focused on classes of objects or features of objects other than the external reproductive organs of phenotypically normal human beings. The term does not apply to erotic interests that include the mere use of objects, such as dildos, costumes, or ropes; it applies to instances where those objects represent the central feature rather than a supportive role in sexual activity. Although fetishism is sometimes discussed as an erotic interest in an arbitrary object, many fetishes involve objects that are highly gender-specific (e.g., shoes, underwear) or are closely related to people (e.g., urine, feces, body parts). Chalkley and Powell (1983) reviewed the files of all individuals over a 20-year period who met criteria for nontransvestic fetishes in a teaching hospital. Forty-eight cases were so identified, and the objects included clothing (58.3%), rubber

and rubber items (22.9%), footwear (14.6%), body parts (14.6%), leather and leather items (10.4%), and soft materials and fabrics (6.3%).

#### STUFF-FETISHISM

*Stuff-fetishism* refers to the erotic interest in specific materials, such as rubber, leather, or fur. Individuals with this fetish will seek out items composed of those materials for use during masturbation, as in a case described by Gosselin and Wilson (1980, pp. 50–51):

After fifteen years of marriage, Mr. W.'s wife died. He made no serious attempt to acquire another partner, because he was "pretty much able to look after himself" and the appearance of his house bore this out. . . . [H]e kept in his house a complete "rubber room" lined throughout with curtains of the same material and containing two large cupboards full of rubber garments, gas masks, photographic and other equipment. He has in the past visited prostitutes to play out some aspect of his fantasies, but now does not do so, feeling that he has all he needs for sexual satisfaction without leaving his house.

Stuff-fetishists who choose clothing rather than other items made of their preferred material can be difficult to distinguish from *clothing-fetishists* (described later). For stuff-fetishism, it is the material (its texture and scent, etc.) rather than the form of the object that is of primary interest; in clothing-fetishism, it is the form of the object (such as the shape of a women's shoe) that is of primary importance.

#### CLOTHING-FETISHISM

The garments chosen by clothing-fetishists are often emblematic of gender: high-heeled shoes, bras, or panties. The behaviors of clothing-fetishists include kissing and licking the garment, rubbing it against their genitals, and wearing it. A heterosexual male's wearing of a female-typical article of clothing, such as a shoe or pantyhose, resembles fetishistic transvestism; however, a clothing-fetishist dons the garment in order to interact with it physically, whereas a fetishistic transvestite employs garments in order to facilitate his mental imagery of having feminine characteristics. Clothing-fetishism also occurs among homosexual men; their erotic interests pertain to, for example, men's underwear or masculine footwear such as boots or wing-tip shoes (Weinberg et al., 1994). Unlike many activity paraphilias (described later), the expression of clothingfetishism does not itself involve any nonconsenting

persons; however, some individuals commit theft to obtain garments from people (e.g., Anonymous et al., 1976; Revitch, 1978). Because such behavior occurs despite the relative ease with which such garments could be purchased, such thefts may indicate that the process of the theft is part of such individuals' paraphilic interest or may represent an erotic interest specifically in clothing that has already been worn by someone (Weinberg et al., 1994). As noted in a case described by Grant (1953, p. 144),

If I buy the kind of shoes I prefer and ask a woman I know to wear them for me, it doesn't have the same appeal as if they were her own shoes. I guess this is because they don't seem to be as much a part of her.

#### TRANSVESTISM

Transvestism, also called fetishistic transvestism, refers to a male's erotic interest in wearing feminine attire, make-up, and wigs. There is sometimes an interest in being perceived as female in public; however, some men with fetishistic transvestism wear a single item, such as panties, underneath their regular attire when appearing in public. On phallometric testing, both fetishistic transvestites and clothing-fetishists show similar penile reactions to pictures of women's underwear (Freund et al., 1996). The great majority of men with fetishistic transvestism are heterosexual (e.g., Långström & Zucker, 2005). Although there exist homosexual male cross-dressers, their behavior is rarely, if ever, associated with sexual arousal and is instead employed for humor or entertainment.

#### PARTIALISM

In *partialism*, there is an erotic interest in a specific nonsexual portion of human anatomy, such as feet or legs. The interest in the body part is described as providing the same or greater sexual arousal as do the genitals (e.g., Kunjukrishnan et al., 1988). Interestingly, partialism involving the foot frequently co-occurs with clothing-fetishism focused on shoes, as illustrated by a case described by Kunjukrishnan et al. (1988, p. 821).

Mr. A had been masturbating regularly with fetish fantasies of smelling women's feet or sucking their toes. . . . He visited massage parlours and acted out his fetish fantasies with the masseuse. He usually got an erection while smelling or sucking women's feet and this was often followed by masturbation. He also asked several women that he met on the street if he could smell their feet. . . . When he and his wife had guests, he would often go downstairs to smell the shoes of female guests who would be upstairs talking to his wife or otherwise occupied.

There also exist homosexual male partialists, attracted to the feet, etc. of men (Weinberg et al., 1994, 1995).

#### UROPHILIA AND COPROPHILIA

Urophilia (also called urolangia) refers to the erotic interest in urine. Urophilic individuals express interests in being urinated upon, in clothing with urine stains or scents, and sometimes in consuming the urine of their sexual partners. Coprophilia (also called coprolagnia) refers to the analogous interest in feces. No studies have sampled urophilic or coprophilic individuals specifically; existing reports describe samples of persons who have several paraphilias, one of which is urophilia or coprophilia. Nonetheless, offers and requests for persons interested in engaging in these behaviors appear in personal ads and advertisements for prostitution or escort services. In a survey of several thousand gay men, 1% responded that they engaged in urophilic behaviors "always" or "very frequently," and 0.5% reported engaging in coprophilic behaviors that frequently (Jay & Young, 1977).

# Zoophilia/Bestiality

Zoophilia and bestiality are both used to refer to the erotic interest in nonhuman animals. Among 114 self-acknowledged zoophilic men in an Internet-based survey, sexual behaviors included orally stimulating the genitals of the animal (81%), vaginal penetration of the animal (75%), masturbation of the animal (68%), and being anally penetrated by the animal (52%) (Williams & Weinberg, 2003). Inducing the animal to lick the human's genitals and anal penetration of the animal have also been reported (Peretti & Rowan, 1983). On a similar survey of 82 male and 11 female zoophiles, the most commonly preferred animals were (in descending order): male dogs, female dogs, and male horses, followed by female horses (for men) or male cats (for women) (Miletski, 2001). Some zoophilics report being attracted only to certain species, to certain breeds of a species, or only to male or female members of a species (Williams & Weinberg, 2003).

Some persons who acknowledge repeatedly engaging in sex with animals describe the behavior as a form of masturbation during which they fantasize about sexual contact with humans (Peretti & Rowan, 1983). Other persons report that the behavior is part of an emotional and romantic bond with the animal, one that they believe the animal shares with them (Miletski, 2005; Williams & Weinberg, 2003). Moreover, some zoophiles report they would feel jealous if other humans or animals expressed an interest in "their" animal(s) (e.g., Earls & Lalumière, 2002; McNally & Lukach, 1991; Miletski, 2005). In describing their interviews with self-acknowledged zoophiles, Williams and Weinberg (2003) noted that some individuals professed an extreme affinity for nonhuman animals, "believing they had animal characteristics or that they felt like they were an animal" (p. 528). This suggests that there may also exist an autoerotic form of zoophilia.

## **Altered Partners**

#### ACROTOMOPHILIA

Acrotomophilia is the erotic interest in persons missing one or more limbs. Some acrotomophiles ask their (anatomically intact) sexual partners to mimic being an amputee during sexual intercourse (Dixon, 1983; Massie & Szajnberg, 1997; Money & Simcoe, 1986), and pornography depicting amputees in sexual or alluring poses exists both on the Internet and in print media (Elman, 1997; Waxman-Fiduccia, 1999). Dixon (1983) provided the results of a survey of individuals who subscribed to a service that distributed erotica depicting amputees: leg amputations were preferred over arm amputations; amputations of a single limb over double amputations; and amputations that left a stump over amputations that left no stump. Congenital malformations of limbs received the lowest ratings. Many people sexually attracted to amputees report that they recognized their interest for the first time as a child when they saw a person or a photograph of a person missing a limb (First, 2005).

#### GYNANDROMORPHOPHILIA

*Gynandromorphophilia* refers to the erotic interest in individuals who otherwise appear femaletypical but have a penis, or *gynandromorphs* (Hsu et al., 2016). (Earlier works employed broader definitions which included the erotic interest in crossdressed males; e.g., Blanchard & Collins, 1993.) Gynandromorphophilic men seek sexual encounters with partially transitioned male-to-female (MtF) transsexuals. Personal ads sometimes include persons seeking or offering encounters with feminized men, and pornography depicting "she-males" is readily available on the Internet (Blanchard & Collins, 1993; Escoffier, 2011). Indeed, most gynandromorphophilic men indicate that they came to realize their sexual attraction via such pornography (Rosenthal et al., 2017).

The penile responses of gynandromorphophilic men have been compared in the laboratory with those of heterosexual men and those of homosexual men while they viewed depictions of sex between two males, between a male and a female, and between a male and a gynandromorph (Hsu et al., 2016). The gynandromorphophilic group resembled the heterosexual group, responding strongly to the male-female pair, but not to the male-male pair. They differed from the heterosexual group only in that they additionally responded strongly to gynandromorphic stimuli, whereas neither the heterosexual nor homosexual groups did. On self-report, gynandromorphophilic men indicated subjectively experiencing the corresponding pattern: strong attraction to females, weak attraction to males, and strong attraction to gynandromorphs (Hsu et al., 2016; Rosenthal et al., 2017).

On surveys of gynandromorphophiles, roughly half refer to themselves as heterosexual and roughly half as bisexual, but many indicate that neither term exactly captures them (Operario et al., 2008; Rosenthal et al., 2017; Weinberg & Williams, 2010).

#### NECROPHILIA

The erotic interest in corpses is necrophilia. The phenomenon has also been called *vampirism* (e.g., Bourguignon, 1983; although others restrict "vampirism" to refer only to the erotic interest in drinking blood; e.g., Vanden Bergh & Kelly, 1964). The most extreme forms of the expression of necrophilia entail obtaining actual corpses or rendering an unwilling victim unconscious for copulation. Rosman and Resnick (1989) reviewed and tabulated the information available from 122 cases of necrophilia that were reported in the literature or made available to them by colleagues. The behaviors and behavioral fantasies of the cases included vaginal intercourse with the corpse (51%), its mutilation (29%), anal penetration of it (11%), kissing it (15%), performing fellatio or cunnilingus upon it (8%), and sucking or fondling the breasts of the corpse (8%). In some cases, mutilation of the body included cannibalism or the drinking of its blood. Thirty-four cases from the whole sample provided self-reports of their motivations: these included the desire to possess an unresisting and unrejecting partner (68%), reunions with a (presumably deceased) romantic partner (21%), sexual attraction to corpses (15%), comfort or overcoming

feelings of isolation (15%), or seeking self-esteem by expressing power over a homicide victim (12%). Stein et al. (2010) similarly tabulated information from FBI case files wherein the paraphilic nature of the offense was ascertained by the victim's attire (or the lack of it), exposure of victims' sexual anatomy, sexual positioning of the victim, or other features. This sample largely resembled that described by Rosman and Resnick; however, many of these cases showed evidence of the victim having been raped before being killed, contesting the claim that having an unresisting partner was a central motivation.

#### Erotic-Target Identity Inversion

The erotic fantasies of persons with erotic-target identity inversion (ETII) pertain less to imagery of sexual partners and more to transformed imagery of themselves, such as men fantasizing that they have the body of a woman (autogynephilia), have the body of a child or infant (infantilism), or are an amputee (apotemnophilia). This is often termed autoerotic. Such individuals sometimes describe their physical bodies as incorrect and their fantasized images as their ideal self (Lawrence, 2006). The expressions of these conditions range from covert visualization during masturbation or during sexual interactions with other people; to mimicking or approximating the erotic identity through clothing, costumes, and props; to seeking medical intervention for permanent body modification to resemble the image of the erotic identity more closely.

Erotic inversion does not always appear to be a complete reversal-such individuals often experience some amount of typical (noninverted) eroticism in addition to the ETII. ETII may represent a basic dimension of sexual attraction, independent of other dimensions of the erotic target, such as the target's sex and age (Freund & Blanchard, 1993; Hsu & Bailey, 2017). In this model, the sexual attraction to women (or gynephilia), when inverted, is the desire to be that woman rather than to have sex with her (i.e., autogynephilia; Blanchard, 1991; Ellis, 1928; Hirschfeld, 1918); the sexual attraction to children (pedophilia or hebephilia) when inverted becomes the desire to be a child rather than to abuse the child (i.e., infantilism or autopedophilia; Hsu & Bailey, 2017); and the sexual attraction to amputees (acrotomophilia) when inverted becomes the desire to be an amputee (i.e., apotemnophilia; Lawrence, 2006, 2013).

#### AUTOGYNEPHILIA

Autogynephilia refers to a male's erotic interest in the image or thought of himself as a woman (Blanchard, 1989a, 1991). During sexual intercourse with women, an autogynephilic male might imagine himself as a woman sexually interacting as a lesbian (Newman & Stoller, 1974) or imagine himself as a woman being penetrated by his partner, who is imagined as a man (Benjamin, 1966; Lukianowicz, 1959). Homosexual (and non-autogynephilic) men may also fantasize about being penetrated by a man, but the focus of their erotic imagery is on the masculine characteristics of their sexual partner, whereas the erotic imagery of autogynephilic men focuses on the feminine characteristics of themselves. Autogynephilia most frequently co-occurs with fetishistic transvestism; however, a male's erotic interest in being a woman can occur on its own, as illustrated in a case described by Blanchard (1993a, p. 70).

The earliest sexual fantasy [the patient] could recall was that of having a woman's body. When he masturbated, he would imagine that he was a nude woman lying alone in her bed. His mental imagery would focus on his breasts, his vagina, the softness of his skin, and so on—all the characteristic features of the female physique. . . . When questioned why he did not cross-dress at present—he lived alone and there was nothing to prevent him—he indicated that he simply did not feel strongly impelled to do so.

Some autogynephilic fantasies pertain to other aspects of being female, such as menstruating, being pregnant, lactating, or douching (Blanchard, 1991; Denko, 1976). Autogynephilia sometimes co-occurs with *gender dysphoria* (see the section on "Gender Dysphoria and Transsexualism" below).

Cases of *partial autogynephilia* have also been described: instead of envisioning themselves entirely as female, such individuals envision themselves with a mixture of male and female anatomy (Blanchard, 1993a, 1993b). Interestingly, autogynephilic male cross-dressers have shown strong penile responses to gynandromorphophilic stimuli—sex between a male and a gynandromorph, appearing as a female with a penis (Hsu et al., 2017). This supports models wherein partial autogynephilia represents the erotic inversion of gynandromorphophilia.

#### INFANTILISM

People with infantilism or autopedophilia are sexually aroused by behaving or imaging themselves as infants or children. (In earlier decades, the term "infantilism" was used to refer more generally to any arrest of psychosexual development in childhood, which was believed to be the cause the

paraphilias in general; e.g., Stekel, 1930.) Such individuals will crawl on all fours and employ (adultsize) baby clothes, bibs, feeding bottles, pacifiers, or other props as part of acting out the fantasy of being a young child, which is often accompanied by penile erection, masturbation, and ejaculation (e.g., Bethell, 1974; Pate & Gabbard, 2003). As part of expressing their fantasies, infantilists will often wear adult-sized diapers and urinate or defecate in them (often termed diaperism). Some individuals request that sexual partners mother them, as by rocking them, bottle-feeding them, or changing their diapers. Commercial websites have emerged that cater to individuals who refer to themselves as Adult Babies/Diaper Lovers (AB/DL) and supply adult-size baby clothes and nursery items (Pate & Gabbard, 2003). Consistent with the erotic-target inversion model, men reporting that they are sexually aroused by boys more often reported sexual interest in being boys, and men reporting sexual arousal in response to girls more often reported sexual interest in being girls (Hsu & Bailey, 2017). Moreover, self-reported sexual interests in older versus younger children corresponded to the interest in being a child of those ages.

When surveyed, AB/DL community member responses suggested the existence of one subgroup focused on role-playing and another focused on the associated sexual arousal (Hawkinson & Zamboni, 2014; Zamboni, 2019). It is not known if these individuals were hiding such imagery despite experiencing it or if these individuals had an incomplete form of infantilism (analogous to clothing-fetishism as an incomplete form of transvestism). The erotic component was much stronger among the males (89% of the sample), suggesting that males engage in the sexual behaviors to express their paraphilia whereas females engage in the role-play to serve nonsexual motivations.

#### APOTEMNOPHILIA

Apotemnophilia is the erotic interest in being or seeming to be an amputee (Blom et al., 2012; Money et al., 1977). Other terms, including "amputee identity disorder" (AID), "body integrity identity disorder" (BIID), and "xenomelia" have also been suggested (Barrow & Oyebode, 2019). Such individuals report that having four intact limbs makes them feel incomplete and that amputation is necessary in order for them to feel whole (Berger et al., 2005). Instances of desiring to possess other disabilities, such as deafness or blindness, have also been reported (Brugger et al., 2016). Communities

555

of people with apotemnophilia refer to themselves as "transabled" (Baril, 2015; Davis, 2014).

Some apotemnophilic individuals mimic amputeeism, in public or in private, using wheelchairs or crutches and by binding or concealing a healthy limb. Some have attempted or performed selfamputation of a limb, and others have purposefully injured a limb in hopes of forcing emergency medical teams to amputate it (Bensler & Paauw, 2003; Berger et al., 2005; Money et al., 1977).

Lawrence (2006) has argued that BIID derives from and is secondary to apotemnophilia, citing evidence that the majority of individuals who seek limb amputation do so with an explicitly sexual motivation. A convenience sample of 52 individuals who wanted a healthy limb removed was recruited from Internet groups; the great majority desired specifically to have a single leg removed, cut above the knee (First, 2005). Notably, the preference for this particular amputation is the same one that is reported by acrotomophiles (Dixon, 1983). In another, primarily Internet-recruited sample of 54 people with apotemnophilia, seven reported obtaining surgical amputation (Blom et al., 2012). All seven reported the surgical treatment was helpful and indicated significantly decreased levels of disruption to their happiness and to their work, social, and family lives. The similarities between BIID and gender identity disorder have been noted, as have those between apotemnophilia and autogynephilia, including in their age of onset (puberty), sex ratio (predominantly male), elevated rates of non-righthandedness, alleviation of dysphoria by externally approximating the internal identity, association with sexual arousal, and lack of remission with psychotherapy, as well as age at presentation (middle age), association with dysphoria, and willingness to risk harm for the corresponding surgical interventions (Barrow & Oyebode, 2019; Brugger et al., 2016; Lawrence, 2006).

There have been some small, preliminary neuroimaging studies of people with apotemnophilia employing a diversity of imaging technologies, including magnetoencephalography of selected regions of interest (ROIs) (n = 4; McGeoch et al., 2011); functional magnetic resonance imaging (fMRI) during tactile stimulation and motor tasks (n = 5; van Dijk et al., 2013); surface-based morphometry of the whole brain (n = 13; Hilti et al., 2013), with shape analysis of thalamus and basal ganglia in the same sample (n = 13; Hänggi et al., 2016); and voxel-based morphometry of T1-weighted scans of the whole brain adding the loci

Hilti identified as additional ROIs (n = 8; Blom et al., 2016). Unfortunately, neuroimaging analyses from samples as small as these are notoriously unreliable, and little can be deduced from the inconsistent findings and the diversity of techniques employed across them. Nonetheless, some authors have concluded that apotemnophilia represents a neurological rather than sexological phenomenon (e.g., Barrow & Oyebode, 2019). Such claims may represent a false dichotomy, however: atypical sexual interests are more than plausibly the result of atypical neuroanatomy, and the brain regions variously implicated in these studies overlap substantially with those involved in sexual response. Moreover, nonsexual explanations of apotemnophilia fail to account for why large proportions of such individuals report experiencing an erotic component, whereas the sexological explanations can account for people denying eroticism as their being too shy, fearful of the stigma of atypical sexualities, or hoping to benefit from the relatively greater social acceptability of having an identity differing from one's anatomy.

# **Activity Paraphilias**

#### Agonistic Sexual Behavior BIASTOPHILIA (PARAPHILIC RAPE)

The erotic preference for committing rape has been variously called biastophilia, paraphilic rape, and paraphilic coercive disorder. Rapists react to depictions of rape significantly more, on average, than do nonrapists on tests of penile tumescence responses, but respond significantly less than nonrapists to depictions of consensual sex (Lalumière et al., 2005). It is not known what proportion of rapists are biastophilic, however. Although some nonparaphilic men report experiencing occasional sexual fantasies that include elements of rape (Arndt et al., 1985; Crepault & Couture, 1980), biastophilic individuals prefer rape to sexual interaction with willing partners. Emphasizing this distinction, the paraphilic interest in rape has also been called preferential rape (Freund et al., 1983), pathological rape, or the deviant rape pattern. Rape as a primary erotic interest is illustrated by a case described by Freund (1990, p. 198).

A well-educated, well-built, and good-looking businessman used to go out at night and rape female strangers, whom he dragged into the lanes between houses. When one of his victims said she would gladly have intercourse with him if he would accompany her to her apartment, he said no, it must be here and now, and then he raped her. The manner by which the individual obtains sexual intercourse is a central component to the erotic interest. In clinical practice, it can be difficult to distinguish an individual who committed a rape to enact a biastophilic fantasy from one who committed a rape as a kind of theft.

## SEXUAL SADISM

Sexual sadism refers to the erotic interest in inflicting fear, humiliation, or suffering. Although both sadistic sexual offenders and biastophilic sexual offenders employ force, they do so with different motivations (Freund & Blanchard, 1986; Hirschfeld, 1938): biastophiles prefer sexual activities with unwilling strangers (who must therefore be coerced into compliance). For sadistic sexual offenders, however, it is the infliction of pain and suffering per se that carries erotic value. Thus, sadistic sexual offenders will continue to apply force, sometimes in increasing magnitude, regardless of the compliance of the victims. In extreme cases, this proceeds to the death of the victim (Dietz et al., 1990; Gratzer & Bradford, 1995), and, further still, to the mutilation of the victim's body. Sadistic rapes do not always include penile penetration of the victim: a review of case files in the US National Center for the Analysis of Violent Crime revealed that offenses included sexual bondage (77%), anal rape (73%), forced fellatio of the offender by the victim (70%), vaginal rape (57%), penetration of victim with a foreign object (40%), blunt force trauma (60%), and the offenders' retention of a personal item belonging to the victim (40%) (Dietz et al., 1990).

There also exist individuals who seek to inflict pain or humiliation, but only on willing partners (e.g., Gosselin, 1987); this has been called the *hyperdominance pattern* of sexual behavior (Freund et al., 1986). It is not known whether or to what extent hyperdominance is related to sadism. Hyperdominants often express the desire to provide sexual pleasure to their submissive sexual partner(s), who are sometimes acting out their own paraphilic interests, such as fetishism, klismaphilia, or masochism. Ernulf and Innala (1995) observed discussions among individuals with such interests, one of whom described the goal of hyperdominants (p. 644).

A good top is an empath who knows how to tell with the least possible feedback exactly what will blow the bottom's mind. The top enjoys his pleasure vicariously. He has a great time. The idea is to turn the body into a sexual response machine. Among sadistic sexual offenders, however, there is no obvious indication of a desire to provide pleasure. Although it is possible that hyperdominance and sadistic sexual offenses represent qualitatively different phenomena that resemble each other only superficially, it is also possible that such individuals (or a proportion of them) have the same erotic interests and differ in nonsexual psychological characteristics, such as antisociality, psychopathy, or the propensity to project or misinterpret the mental status of their sexual partners or victims.

# Masochistic Paraphilias SEXUAL MASOCHISM

Persons with sexual masochism experience erotic excitement from enduring humiliation or physical pain, often enacting such fantasies (or approximations of them) alone or with sexual partners. Sufficient numbers of individuals seek opportunities to engage in these behaviors to form stable subcultures, which have been repeatedly surveyed (e.g., Ernulf & Innala, 1995; Nordling et al., 2006). The majority of respondents to such surveys report the desire to undergo verbal abuse, slapping (either manually or with implements), being ordered to perform sexual acts, or being tied up or restrained. A smaller proportion of individuals seek to undergo very severe stimulation, however: these include torture through beatings that draw blood, branding or burning, and mummification (immobilizing the entire body with rope or other wrapping) and confinement for extended periods of time. Clinical and nonclinical samples of masochists (i.e, individuals with masochism and individuals diagnosable with DSM-5 masochistic disorder) report interests in the same activities (cf., Freund et al., 1995). Accidental deaths have been reported from engaging in some masochistic behaviors, such as through the selfapplication of electricity to the genitals or other parts of the body (Cairns & Rainer, 1981).

One of the most dramatic cases of sexual masochism was that of Mr. Bernd Brandes, which was widely reported in the media. Brandes answered a personal ad placed by Mr. Armin Meiwes, asking for young, well-built men who wanted to be slaughtered and consumed (Harding, 2003). After Brandes consumed a combination of alcohol and sleeping pills, Meiwes cut off Brandes' penis and fried it for both of them to eat. Meiwes then fatally stabbed Brandes, all of which Brandes consented to, on videotape. Notably, before he was arrested, Meiwes had met with five other men who responded to his personal ad.

#### AUTOEROTIC ASPHYXIA

Autoerotic asphyxia refers to the erotic interest in being suffocated, such as by being hanged or strangled. Some asphyxiophilics engage in such behaviors alone (sometimes called asphyxiophilia) using ropes suspended from beams or ligatures tied to doorknobs while they masturbate, whereas others engage sexual partners to purposefully restrict airflow to the lungs or bloodflow to the brain as part of their sexual activities (suggesting masochism focused on suffocation). When enacted in solitude, asphyxiophilia has led to accidental deaths (Hucker & Blanchard, 1992). Some cases of asphyxiophilic fatalities have come to the attention of clinicians by lawyers or insurance companies (e.g., Cooper, 1995, 1996), as life insurance claims are payable in the event of an accidental death but not of suicide. In some fatality cases, the body of the asphyxiophilic individual is discovered naked or with his penis exposed, with pornographic magazines nearby, with dildos or other sex toys nearby, or with evidence of his having ejaculated (Hucker & Blanchard, 1992; Janssen et al., 2005). The condition of such corpses also suggests that asphyxiophilia is frequently comorbid with other paraphilias: the corpse is sometimes cross-dressed or wearing make-up, the content of pornographic material is of a sadomasochistic nature, or the corpse is found with self-applied gags or bindings on his hands, feet, or genitals (Blanchard & Hucker, 1991). Asphyxiophilia has been called hypoxyphilia, under the presumption that hypoxia enhances sexual sensations (e.g., Uva, 1995). Such an association has not been established, however; the sexual interest might instead be focused on psychological associations with the actual behaviors, rather than with any physiological effects of hypoxia (Blanchard & Hucker, 1991).

#### Courtship Disorder

A specific set of the activity paraphilias voyeurism, exhibitionism, telephone scatologia, toucheurism, frotteurism, and biastophilia—has been hypothesized to be individual symptoms of a single underlying pathology, called *courtship disorder* (Freund, 1988). As detailed below, the courtship disorder hypothesis maintains that each of the paraphilias in this set is a disordered expression of a phase of human courtship (Freund, 1976; Freund et al., 1972). Biastophilia has already been described in the previous section together with sadism; the following describes the other paraphilias comprising courtship disorder.

#### VOYEURISM

Voyeurism is the erotic interest in viewing an unsuspecting person or persons in typically private situations. Viewed acts include dressing or undressing, sexual intercourse, urinating, and defecating. (In some cases, it is unclear whether these latter behaviors indicate voyeurism, with the urine and feces being incidental, or indicate urophilia or coprophilia with the urine or feces being central; e.g., Collacott & Cooper, 1995.) The increased availability of affordable and easily concealed electronic devices has broadened the range of opportunities available to voyeurs for viewing unsuspecting strangers (e.g., Simon, 1997). Some cases of voyeurism have included holding cellular telephone cameras over or under the partitions of public washroom stalls and hiding small cameras in the bedrooms of victims. Paraphilic voyeurism would not describe persons for whom the mere sight or image of a person were sufficient for eliciting sexual arousal; in paraphilic voyeurism, the means by which the individual achieves his view is an integral part of the paraphilic interest. That is, in some cases, the glance must represent a violation to be of erotic interest.

#### EXHIBITIONISM

The erotic interest in exposing one's genitals to unsuspecting strangers is exhibitionism. The paraphilia pertains to persons for whom there is sexual pleasure in doing so, not when the behavior is motivated by money (such as strippers) or other nonsexual reasons (such as pranks). The majority of exhibitionists masturbate to ejaculation as part of exposing their penis (Freund et al., 1988; Langevin et al., 1979). On a questionnaire given to a sample of 185 exhibitionists, Freund et al. (1988) asked, "How would you have preferred a person to react if you were to expose your privates to him or her?" (p. 256). Of the seven possible choices, the most common response was "Would want to have sexual intercourse" (35.1%), followed by "No reaction necessary at all" (19.5%), "To show their privates also" (15.1%), "Admiration" (14.1%), and "Any reaction" (11.9%). Few exhibitionists chose "Anger and disgust" (3.8%) or "Fear" (0.5%).

There is only limited research on the (typically male) behavior of sending unsolicited photographs of their genitals (Oswald et al., 2020). It remains unknown to what extent the behavior might represent a paraphilic or other motivation, or whether any paraphilic pattern might be related to exhibitionism or *telephone scatologia*.

#### TELEPHONE SCATOLOGIA

Telephone scatologia refers to the erotic interest in using a telephone to expose unsuspecting persons to vulgar or sexual language or to elicit it from them. Many scatologists masturbate during the call or masturbate subsequently while recollecting the call; some telephone scatologists cross-dress or pose as female when calling (e.g., Dalby, 1988; Pakhomou, 2006). Although it was not based on any systematic observation, Mead (1975) provided an intuitive taxonomy of obscene telephone call content: (a) the "shock caller," who immediately makes obscene remarks or propositions in order provoke an emotional response from the victims, (b) the "ingratiating seducer" who fabricates a plausible story to lure the victim into conversation, and (c) the "trickster" who poses, for example, as someone conducting a survey in order to elicit sexual history or other information about the victim. A survey of 1,262 Canadian women who were employed outside the home asked respondents about their experiences of receiving obscene phone calls (Smith & Morra, 1994); 83.2% of the sample had received such calls. Of those, 84.5% of the calls came from males, 86.8% came from adults, and 73.8% were reportedly from strangers (in 7.5% of the cases, the victim knew the scatologist, and in 18.6%, the victim was unsure whether she knew the caller).

Approximately 37% of rapists have been reported to engage in obscene telephone calls (Abel et al., 1988), but only 5–6% of apprehended telephone scatologists have been found to commit rape (Abel et al., 1988; Price et al., 2002). Because not all obscene telephone calls are reported to authorities, however, it is unknown how well these individuals represent all telephone scatologists. It is also unknown whether the content or other parameters of the calls predict an individual's likelihood of committing other sexual offenses.

Telephone scatologia is sometimes described as a variant of exhibitionism (e.g., Hirschfeld, 1938; Nadler, 1968), differing by being auditory rather visual. Indeed, telephone scatologia is highly comorbid with exhibitionism (e.g., Price et al., 2002). Although telephone scatologia necessarily involves obscene telephone calls, not all obscene telephone calls are motivated by telephone scatologia; the behavior may represent a prank with no erotic value to the caller (Pakhomou, 2006).

#### TOUCHEURISM AND FROTTEURISM

*Toucheurism* and *frotteurism* refer to the erotic interest in approaching unsuspecting strangers to

touch their (usually clothed) breasts, buttocks, or genital area. Toucheurism pertains to when contact is made using the hands, and frotteurism pertains to men who press their penis against the victim, especially against the buttocks, through clothing. Frotteurs typically target women in crowded public places (e.g., streetcars), whereas toucheurs will often grab at a woman while quickly moving across her path.

#### THE COURTSHIP DISORDER HYPOTHESIS

The courtship disorder hypothesis asserts that the usual male sexual activity cycle consists of four phases: (a) looking for and appraising potential sexual partners; (b) pretactile interaction with those partners, such as by smiling at and talking to them; (c) tactile interaction with them, such as by embracing or petting; and then (d) sexual intercourse (Freund, 1976; Freund & Blanchard, 1986). In normal courtship, each phase of the cycle leads to the next. In courtship disorder, however, one or more of these phases is exaggerated or distorted, and the cycle fails to progress from one phase to the next. According to the hypothesis, voyeurism is a rigid, isolated form of the searching phase; exhibitionism and telephone scatologia represent distortions of the pretactile phase; toucheurism and frotteurism represent pathologies of the tactile phase; and, in the preferential rape pattern, the first three courtship phases are altogether skipped.

The assertion that these six paraphilias all emerge from the same underlying disorder simplifies the interpretation of several observations. (a) The paraphilias in this set are highly comorbid with each other (Freund & Blanchard, 1986; Freund et al., 1983). (b) During laboratory testing of penile reactions to audiotaped stimuli, individuals who have shown one courtship paraphilia, but not another, nonetheless show an elevated response to stimuli representing other courtship paraphilias (Freund et al., 1983; Freund et al., 1986). (c) The paraphilias of courtship disorder share the propensity to target strangers (e.g., Freund et al., 1988; Gebhard et al., 1965; Mohr et al., 1964; Smith & Morra, 1994), whereas other paraphilias more often involve people known to the paraphilic individual (or involve no other person at all).

# Miscellaneous Paraphilias

*Klismaphilia* refers to the erotic interest in enemas. Klismaphilics will entertain sexual fantasies about enemas during masturbation, self-administer enemas for masturbatory stimulation, or engage their sexual partners to administer them. Some have reported experiencing sexual arousal upon administration of clinical enemas by nursing staff and feigning physical symptoms to justify the procedure (Denko, 1973). By contrast, the term would not apply when the enema provides a secondary rather than mandatory role-such as being forced to receive an enema as part of a masochistic fantasynor when only indirectly associated with sex, such as regular use in anticipation of anal intercourse. Twenty-two klismaphilics responded to an ad placed in sex-oriented periodicals as part of a survey of individuals with erotic interests in enemas (Arndt, 1991); the median frequency of enema use was twice per week, and approximately half the respondents engaged in the behavior together with their sexual partners. In describing a series of 15 cases, Denko (1976) reported that three male klismaphilics fantasized themselves as female during the enemas and that three such individuals experienced erotic enjoyment while eliciting enema-related conversation with female sales clerks (such as by asking for instructions).

#### TRIOLISM

*Triolism* or *cuckolding* refers to the erotic interest in watching one's romantic partner engage in sexual behavior with a third party. Triolism differs from voyeurism in that the romantic partner (but not necessarily the third party) is typically aware of being observed. Some triolists want to observe the sexual activity visually (sometimes while hidden; e.g., Hirschfeld, 1938), some audio or video record the activity, and some want only to listen to their partners describe encounters had while the triolist was absent (Wernik, 1990).

## Multiple Paraphilias and Blended Paraphilias

Individuals with one paraphilic interest often have other paraphilic interests (e.g., Abel et al., 1988; Abel & Osborn, 1992; Bradford et al., 1992; Freund et al., 1983). In some cases, these paraphilias function independently in the individual, such as in a man who will expose his genitals on certain occasions and who will grab the buttocks of females on other occasions. We refer to these simply as cases of *comorbid* or *multiple paraphilias*. Other individuals, however, possess erotic interests that deviate from typical in more than one aspect at the same time, such as men whose erotic fantasies entail being forced to cross-dress (e.g., Hucker, 1985) or a man who exposes his genitals to large dogs (McNally & Lukach, 1991).

#### **Prevalence and Sex Ratio**

Owing to their usually secretive nature, no meaningful prevalence or incidence data can be had for any of the paraphilias. Numbers of persons who are charged with or convicted of certain sexual offenses have been used as estimates for some paraphilias. It is unknown what proportion of such offenders is genuinely paraphilic, however. A more sophisticated estimation has been conducted for the prevalences of transvestic fetishism, exhibitionism, and voyeurism (Långström & Seto, 2006; Långström & Zucker, 2005). These investigations analyzed responses to a representative survey of 2,450 men and women in Sweden. A total of 3.1% of the respondents reported having been sexually aroused at least one time by exposing their genitals to a stranger; of that subset, 23.7% also experienced sexual fantasies about the behavior. Of the whole sample, 7.8% reported engaging in voyeurism at least one time; of that subset, 53.4% also experienced sexual fantasies about doing so. Of the males, 2.8% reported cross-dressing that was associated with sexual arousal; an insufficient number of women reported ever having done so to support any analysis. National forensic databases have suggested rates of autoerotic deaths by asphyxia at 0.1 per million population (Sweden) to 2-4 per million (United States) (Byard & Winskog, 2012), but the prevalence of nonfatal practitioners remains unknown.

As previously noted, most paraphilias appear to be phenomena restricted nearly entirely to males. Notwithstanding case reports in the literature, neither clinics, forensic institutions, nor social clubs for proponents of engaging in paraphilic behaviors report any substantial number of females with atypical erotic age preferences, courtship disorders, or fetishes. Sexual masochism is unusual among the paraphilias in that it shows a relatively high frequency of female practitioners. Breslow, Evans, and Langley (1985) surveyed subscribers to and advertisers in a periodical catering to individuals interested in masochism or hyperdominance. Of the 81 non-prostitutes who preferred or usually preferred masochistic behaviors (termed "submissive" in the survey), 49.4% were women. Similarly, Ernulf and Innala (1995) analyzed messages on an online discussion group catering to people with the same interests: of the 56 posts seeking to engage in masochistic acts (again termed "submissive"), 58.9% were purportedly from women.

Despite its close association with masochism, asphyxiophilia is usually viewed as a male phenomenon owing to the lack of women among individuals who suffered accidental asphyxiophilic death. For example, the Hucker and Blanchard (1992) sample consisted of all 118 known such deaths in Ontario and Alberta, Canada, from 1974 to 1987, and only one was female. It is plausible, however, that there are women who engage in the behavior, but that they are less likely to suffer accidental death. This might occur if more male asphyxiophilics engaged in the solitary form of the behavior and more female asphyxiophilics did so in the company of a sexual partner (thereby protecting against accident).

#### Associated Features

One may refer to the hypothetical factors that increase the probability of developing paraphilic interests as *paraphilogenic* factors. The existence of a biological predisposition to developing one or more paraphilias has been hypothesized for well over a century (e.g., Binet, 1887; Krafft-Ebing, 1886/1965), but few rigorous studies have been conducted. Some tentative conclusions can be proffered, however, primarily on the basis of investigations of individuals who have committed sexual offenses motivated by paraphilias, especially pedophilia.

#### IQ and Other Neuropsychological Testing

Pedophilic men and sexual offenders against children have lower IQs than nonpedophilic controls (Cantor et al., 2004; Cantor, Blanchard et al., 2005). The association between IQ and pedophilia appears to be independent of referral method; the same result emerges whether the pedophiles were referred by parole and probation officers, lawyers, or physicians or by self-referral (Blanchard et al., 2007). Consistent with these studies, pedophilic men are more likely to have repeated grades in school or to have required placement in special education classes (Cantor et al., 2006). Although several studies have administered batteries of neuropsychological tests to heterogeneous samples of sexual offenders, they have not reported results from homogeneous samples of paraphilic men. It remains unknown whether pedophiles have a general cognitive deficit (i.e., they would perform poorly on any neuropsychological test that correlates with IQ) or if they have a distinct pattern of cognitive strengths and weaknesses that might be detected by future investigations employing larger and more homogeneous samples.

It is also unknown whether and to what extent that poor cognitive functioning is a characteristic specific to deviant erotic age preference or a characteristic of several (or all) paraphilias. Communitybased samples of self-acknowledged paraphilics have repeatedly described highly educated and highfunctioning individuals (e.g., Alison et al., 2001; Croughan et al., 1981; Docter & Prince, 1997; Williams & Weinberg, 2003). Although it is possible that low IQ is specific to pedo- and hebephilia, it is also possible that paraphilics with higher IQs are more likely to participate in interest groups and research studies.

#### Handedness

Handedness is of interest due to its association with very early brain development. Fetuses demonstrate a hand preference when thumb-sucking in utero (Heppe et al., 1991), and that preference predicts handedness later in life (Hepper et al., 2005). Approximately 8–15% of the general population is non-right-handed (Hardyck & Petrinovich, 1977). Pedophilic men have been shown to be up to three times more likely to be non-right-handed (Cantor, Klassen et al., 2005). Nonhomosexual MtF transsexuals (who have been shown empirically to experience autogynephilia; Blanchard, 1985, 1988, 1989b) similarly show elevated rates of non-righthandedness (Green & Young, 2001). Very little is known regarding handedness in any of the other paraphilias.

Meta-analytic review has shown homosexual men, although they are not paraphilic, to have 34% greater odds and homosexual females to have 91% greater odds of non–right-handedness than their heterosexual counterparts (Lalumière et al., 2000). Recent research indicates that the association between non–right-handedness and homosexuality in men is limited to individuals with no or few older brothers (Blanchard, 2008). Considered together, the findings on hand preference and sexuality suggest that non–right-handedness might pertain to the development of all variant erotic-object interests (see Blanchard, 2008).

Non-right-handedness has commonly been interpreted as a marker for lesser than usual degrees of asymmetry between the left and right hemispheres of the brain. Therefore Blanchard (2008) conjectured that Klar's (2004) explanation for the association of non-right-handedness and homosexuality might apply to variant erotic-object preferences in general. Klar hypothesized that "less asymmetric hemispheres may allow additional
neuronal connections between different parts of the brain, thereby predisposing individuals to develop homosexuality, in contrast to the restricted possibilities allowed in the more common asymmetric hemispheric arrangement" (Klar, 2004, p. 254). Blanchard (2008) argued that the collective data on homosexual men and women, pedophiles, and transsexuals suggest that the hypothesized "additional neuronal connections" made possible by less asymmetric hemispheres might lead to an array of different psychosexual outcomes. The notion that erotic variations (paraphilic or benign) may result from atypical connections among brain regions, and not from anomalies in the brain regions themselves, is revisited in a different context in the next section.

### Brain Imaging

With only few exceptions, neuroimaging research on the paraphilias has been limited to pedophilia and hebephilia. Such studies continue to advance but must be considered carefully, as there exist powerful ascertainment biases in sampling: until recently, samples of people sexually attracted to children have been recruited from forensic centers studying sex offenders. Without appropriate handling, features of such samples can be confounded by antisociality, impulsivity, and other correlates of criminality (including having completed long-term confinement). More recently, people with pedophilia and no forensic history have begun to present themselves to clinics, seeking treatment or mutual group support and to participate in research studies. In contrast with forensic samples, these individuals would be predicted to be nonrepresentative in being higher functioning than typical. Neither source can yield representative samples, and both pose potential confounds. Different authors have employed different methods in the effort to compensate for the multiple factors in play, and it remains unknown to what extent each method is successful.

Contemporary studies aiming to identify neuroanatomic features associated with pedophilia and its development have coalesced into two camps: one implicating white matter differences yielding atypical connectivity among brain regions that otherwise serve to identity reproductively relevant social stimuli (e.g., Cantor et al., 2015) and one implicating gray matter differences that increase the risk of sexual offending rather than pedophilia per se (e.g., Lett et al., 2018). White matter and connectivity differences were detected in independent samples by several techniques, including voxelbased morphometry (Cantor et al., 2008), diffusion tensor imaging (Cantor et al., 2015), and independent component analysis (Cantor et al., 2016). Poeppl et al. (2015) conducted a meta-analysis of fMRI studies using activation-likelihood estimation, confirming functional dysconnectivity among sexually relevant brain regions, which those authors interpreted as confirmation of the dysconnectivity hypothesis of pedophilia.

Some initial reports instead implicated gray matter differences: Schiltz et al. (2007) reported differences in the amygdala, hypothalamus, substantia innominata, septal region, and bed nucleus of the stria terminalis, whereas Schiffer et al. (2007) reported them in the ventral striatum and nucleus accumbens, orbitofrontal cortex, and cerebellum. (Neither study examined white matter.) Subsequent imaging research employing larger samples disconfirmed the gray matter differences (Schiffer et al., 2017) and attributed the neural differences detected to be associated instead with criminality and the propensity to commit sexual offenses (Lett et al., 2018).

### Hormonal Assays

Studies of sexual offenders have measured the baseline levels of several hormones, including 5alpha-dihydrotestosterone, androstenedione, cortisol, dehydroepiandrosterone, dihydrotestosterone, estradiol, follicle-stimulating hormone, the freeandrogen index, luteinizing hormone, prolactin, sex hormone-binding globulin, and testosterone (Blanchard et al., 2006). Those investigations have failed to reveal any consistent association between paraphilic sexual offenses (primarily involving pedophilia, exhibitionism, or sexual sadism) and any hormone except, potentially, testosterone: greater levels of testosterone have been found among rapists relative to nonparaphilic controls (Giotakos et al., 2003; Rada et al., 1976). Other investigations have failed to detect such a difference, however (Haake et al., 2003; Rada et al., 1983). Lower levels of testosterone have been reported among pedophilic men by some studies (Gurnani & Dwyer, 1986; Seim & Dwyer, 1988), but no differences have been found in others (Gaffney & Berlin, 1984; Lang et al., 1990). It is possible that testosterone reflects the propensity to violence or aggression rather than any paraphilia.

### Intimacy/Social Skills Deficits

Sex offenders may seek out sex with children because they do not have the social skills to successfully interact with adult partners and they cannot fulfill their sexual and emotional needs in relationships with peers (Seto, 2008). Sex offenders lack the capacity for intimate relationships and report themselves to be lonely (Garlick et al., 1996; Seidman et al., 1994). Ward, Hudson, and Marshall (1996) found that sex offenders exhibited a wide range of insecure attachment styles, each associated with different psychological problems. Child molesters with a preoccupied attachment style were characterized by emotional neediness and profound doubts about their ability to elicit love and support from partners. Fearful-dismissively attached offenders tended to distance themselves emotionally in relationships because of their fear of rejection. Both groups experienced problems with intimacy and apparently turned to sex with children because their adult relationships were compromised or unsatisfactory. The primary causal mechanism underlying their deviant sexual behavior was seen to be their insecure attachments and subsequent problems establishing satisfactory relationships with adults (Ward & Seigert, 2002).

As reviewed by Smallbone (2006), in several studies, child sex offenders have reported less secure childhood attachments than nonsexual offenders (Marsa et al., 2004; Smallbone & Dadds, 1998) and nonoffenders (Marsa et al., 2004; Smallbone & Dadds, 1998). Similarly, according to Smallbone (2006), child sex offenders more frequently report an insecure rather than a secure adult attachment style (Jamieson & Marshall, 2000; Ward et al., 1996) and report less secure adult attachment than both nonsexual offenders and nonoffenders (Marsa et al., 2004; Sawle & Kear-Colwell, 2001; Smallbone & Dadds, 1998).

### **Onset and Course**

It is unknown whether the paraphilias share a common age at which their symptoms first manifest or if they vary in age of symptom onset. One should note that the age of onset of paraphilic symptoms does not necessary coincide with the age at which the paraphilogenic factors first operate. By way of analogy, typical (nonparaphilic) heterosexuality and typical homosexuality do not overtly manifest until puberty, but there is no reason to believe that the etiology of sexual orientation occurs at that time rather than earlier in development. The DSM-5 describes the age of onset for the paraphilias to be during adolescence, although some of paraphilic disorders may not be diagnosed until age 16 (in the case of pedophilic disorder) or 18 (in the case of voyeuristic disorder). These cutoffs are not meant to follow any etiological mechanism, however, and

instead reflect an attempt avoid false positives relative to typical sexual curiosity and experimentation during puberty and adolescence.

It is unknown to what extent information about age of onset is affected by the legal status of expressing paraphilic interests. It is plausible that individuals who experience paraphilia unassociated with sexual offending would be more willing to acknowledge awareness of their interests during childhood. The research literature supports the childhood onset of rubber fetishism (Gosselin & Wilson, 1980), cross-dressing (Brown et al., 1996), apotemnophilia (First, 2005), acrotomophilia (Dixon, 1983), homosexual or bisexual foot and shoe fetishism (Weinberg et al., 1995), and masochism and hyperdominance (Breslow et al., 1985). Moreover, paraphilics sometimes recall events from early childhood during which they became-and then remainedfascinated with the object(s) or behaviors of their future sexual interest (e.g., Dixon, 1983; Freund et al., 1995; Massie & Szajnberg, 1997; Weinberg et al., 1994, 1995).

### **Gender Dysphoria and Transsexualism**

Clinical contact with trans populations differs from social and public contact in that clinical contact often begins before any transition, when no outcome can be assumed, whereas social and public contact occur after transition, when people can explicate how they want to be treated. This can lead to conflicts in language: from the point of view of the post-transitioned, references to the pre-transitioned state represent reminders of a problematic situation. Clinically, however, to assume a transition at the start is to presume the answer to the very question client-patients present to their clinicians. To minimize ambiguity, this chapter will employ the full terms spelling out the trajectory of the (potential) transition-MtF or female-to-male (FtM)-rather than "single time point" terms that leave ambiguous if the gender named is the gender being transitioned from or the gender being considered to transitioned to.

The term "gender dysphoria" refers to a broad class of phenomena characterized by discontent with one's biological sex and/or social gender. In adults, it manifests as the persistent idea that one is, or should have been, a member of the opposite sex, and, in children, by pervasive patterns of behavior consistent with such a belief. The affective component of gender dysphoria is discontent with one's biological sex and the desire to possess the body of the opposite sex and to be regarded by others as a

563

member of the opposite sex. *DSM-5* introduced *gender dysphoria* as the formal diagnostic term (replacing the *DSM-IV-TR* term, *gender identity disorder*, which, in turn replaced the *DSM-III-R* term, *transsexualism*). Thus, "gender dysphoria" may now refer either to the broad term or the more narrowly defined diagnosis.

Gender dysphoria varies in severity and, at its most extreme (transsexualism) is accompanied by a desire for surgery to simulate (as much as possible) the reproductive organs of the opposite sex. Individuals with milder forms sometimes perceive themselves to be both male and female or fluctuate between seeing themselves as one or the other.

There appear to be two phenomena, unrelated and each capable of motivating discontent with one's biological sex. The two groups experiencing these phenomena differ in their age of onset, course, associated features, and sex ratio and, therefore, probably in their etiology (Blanchard, 1989a, 1989b). One is associated with autogynephilia, the aforementioned paraphilic interest (of biological males) in being female. Such individuals sometimes engage in erotic cross-dressing for many years before deciding to pursue permanent feminization. The other group lacks any obvious paraphilic interests but shows multiple, extremely strong or exaggerated features atypical for their biological sex. The other is related to homosexuality and occurs both in biological males and in biological females.

### Autogynephilic Male-to-Females

The autogynephilic type accounts for a substantial proportion of persons seeking sex reassignment in Europe and North America (e.g., Nieder et al., 2011; Smith et al., 2005). The exact nature of the relation between autogynephilia and gender dysphoria is unclear. Many autogynephilic transsexuals report that their desires to be women remained the same or grew even stronger after their initial strong sexual response to that ideation had diminished or disappeared.

Insofar as autogynephilic transsexuals are erotically oriented toward other persons, they may be attracted to women, to both sexes, or to neither sex. It is likely that those individuals attracted to women constitute the prototype and that bisexual and asexual individuals represent secondary variations. The asexual individuals represent those cases in which the autogynephilia nullifies or overshadows the person's erotic attraction to women, and the bisexual individuals represent those cases in which the autogynephilic disorder instead gives rise to some secondary erotic interest in men that coexists with the person's basic attraction to women (Blanchard, 1985). Blanchard (1989b) has suggested that the latter phenomenon need not reflect an equal attraction to the male and female phenotypes and would perhaps be better characterized as *pseudobisexuality*. Because autogynephilic MtFs express the belief that "inside" they really are women, those who are attracted to women may—paradoxically—describe their erotic interests in women as "homosexual" and refer to themselves as "lesbians trapped in a man's body" (Lawrence, 2013).

Autogynephilic MtFs are not conspicuously cross-gendered in childhood, although the private wish to be a woman may begin to occur before puberty. They are rarely labeled as "sissies" by their peers, and their cross-gender behavior is typically restricted to secret, solitary cross-dressing in garments surreptitiously borrowed from their mothers, sisters, or other females in their households. This type of gender dysphoria tends to develop more slowly and often has the character of a progressive disorder, with temporary or milder methods of expressing female traits preceding more permanent and dramatic ones. Autogynephilic MtFs usually present to clinicians in their mid-30s, and it is common for such individuals to seek professional help for the first time at age 50 or 60 years. Many autogynephilic MtFs marry women and father children before their wish to live as women becomes overwhelming, thus delaying their pursuit of sex reassignment (Blanchard, 1994).

### Androphilic Male-to-Females and Gynephilic Female-to-Males

MtF gender dysphorics who are sexually attracted to men (i.e., who are androphilic) exhibit multiple overtly feminine behaviors which were readily apparent in childhood. Such boys prefer girls' games and toys and female playmates and would rather be around adult women than adult men. They often or always take female roles in fantasy play (e.g., princess, ballerina), and they identify with glamorous female characters in television stories or other media. Some of these boys also dress up as women; however, their cross-dressing is not experienced as sexually arousing, either in childhood or later. Even when they are not engaging in any obvious crossgender behavior, boys with gender dysphoria are noticeably effeminate, which may manifest as feminine speech patterns, gestures, or gait.

Gender dysphoric FtMs who are sexually attracted to women (i.e., are *gynephilic*) show the corresponding

picture. In childhood, they express very strong preferences for boys' toys and games and a rejection of long hair and dresses in favor of short hair and trousers. They may imitate other male-typical behaviors, such as standing to urinate. Unlike ordinary "tomboys," they do not merely enjoy some activities stereotyped as male; rather, they systematically and vehemently reject all activities, clothes, etc. that would identify them to the world as female.

Gender dysphoric boys and girls may verbally express the wish to belong to the opposite sex or state the belief that they will become members of the opposite sex when they grow up. Claims of actually being members of the opposite sex are more common in younger than in older children, probably because older children have a better understanding of gender constancy. Older children are also less likely to communicate the desire to belong to the opposite sex, an inhibition attributable to their greater awareness of social sanctions (Wallien et al., 2009; Zucker et al., 1993, 1999).

The course of childhood gender dysphoria is unpredictable, and the outcome is highly variable. In many cases, the dysphoria resolves without clinical intervention, usually by puberty. That is, the individuals grow up to be ordinary, non-transsexual, androphilic men (i.e., gay men) or ordinary, nontranssexual, gynephilic women (i.e., lesbians), each content with their original, biological sex. In other cases, substantial cross-gender behavior remains, but the wish for a full transition to the opposite sex is weak or absent. These include gay male "drag queens," who cross-dress intermittently but extensively and who may take estrogenic medications to develop breasts, as well as biologically female "genderqueers," who may seek testosterone medication for its masculinizing effects (e.g., beard growth) but express no interest in mastectomy or pelvic surgery.

The remaining cases, who reach adulthood with their dysphoria unabated or intensified, may seek transsexual surgery and other interventions. Both androphilic MtFs and gynephilic FtMs (sometimes called in the literature *homosexual transsexuals*, relative to their biological sex) typically begin to seek sex reassignment surgery when they are in their mid-20s, by which time many of them have already begun living full-time as the opposite sex. For MtFs, the definitive operation is the construction of a vagina and vulva. For FtMs, the most urgent procedure is usually breast tissue reduction and construction of a male chest contour, followed by removal of the uterus and ovaries. They do not universally pursue construction of an artificial penis, which is expensive, technically difficult, and often disfiguring to the part of the body from which the donor tissue is taken.

### Androphilic Female-to-Males

There is a rare but distinct group of FtMs who are sexually orientated toward males and who say that they want to undergo sex reassignment so that they can become "gay men" (Blanchard, 1990; Dickey & Stephens, 1995). This makes the syndrome seem analogous to autogynephilic transsexualism in biological males. No one, however, has identified a distinct paraphilia (like autogynephilia) that accompanies or precedes heterosexual transsexualism in biological females; therefore the analogy seems incomplete.

#### Rapid-Onset Gender Dysphoria

A third profile has begun to present to clinicians or socially, characteristically distinct from the previously identified ones (Kaltiala-Heino et al., 2015; Littman, 2018). This group is predominately biologically female and presents in puberty or adolescence, but, unlike the androphilic FtM group, lacks the substantial history of cross-gender behavior in childhood. This feature has led to the term rapidonset gender dysphoria (ROGD; Littman, 2018). The majority of cases appear to occur within clusters of peers and in association with increased social media use (Littman, 2015) and especially among people with autism or other neurodevelopmental or psychiatric disorders (Kaltiala-Heino et al., 2015; Littman, 2018; Warrier et al., 2020). It cannot be easily determined whether the self-reported gender dysphoria is a result of other underlying issues or if those mental health issues are the result of the stresses of being a stigmatized minority (Boivin et al., 2020). Importantly, unlike other presentations of gender dysphoria, "coming out" in this group was often (47.2%) associated with declines rather than improvements in mental health (Biggs, 2020; Littman, 2018). Although long-term outcomes have not yet been reported, these distinctions argue against generalizing findings from the other presentations to this one.

#### Prevalence and Sex Ratio

The prevalence of full-blown transsexualism is easier to estimate than the prevalence of lesser degrees of gender dysphoria because transsexuals, almost by definition, must disclose their condition for medical or legal purposes. Estimates are about 1 in 12,000 for MtF transsexuals and 1 in 30,000–50,000 for FtM transsexuals (Bakker et al., 1993; De Cuypere et al., 2007; Wilson et al., 1999). The ratio of biological males to females is around 2:1 or 3:1 (Landén et al., 1996; Garrels et al., 2000).

### Neurological Correlates

Zhou, Hofman, Gooren, and Swaab (1995) and Kruijver et al. (2000) reported that a sex-dimorphic structure of the brain, the central subdivision of the bed nucleus of the stria terminalis (BSTc), was shifted in size toward that of the opposite sex in a small series of transsexuals examined postmortem. There are at least three reasons to be skeptical that this unconfirmed finding has conclusively identified a neurological substrate of cross-gender identity. First, significant sexual dimorphism in BSTc volume and neuron number does not develop in humans until adulthood (Chung et al., 2002), whereas many or most transsexuals report that their feelings of gender dysphoria began in childhood. Second, all of the subjects had undergone feminizing or masculinizing hormone treatment, and such treatment has profound effects on brain volume (Hulshoff Pol et al., 2006). Third, BSTc volume has been reported to be smaller among pedophilic men than among controls (Schiltz et al., 2007), which suggests that the structure may be related to sexual anomalies in general rather than to cross-gender identity specifically.

MRI has subsequently been employed in vivo to identify neuroanatomic features distinguishing transsexual from cissexual adults (other age groups have not yet been so studied). Unfortunately, many such studies confounded gender identity with sexual orientation (e.g., Rametti et al., 2011), contrasting MtF transsexuals attracted to men with cissexual males attracted to women (e.g., Spizzirri et al., 2018) or contrasting FtM transsexuals attracted to women with cissexual females attracted to men (e.g., Kim et al., 2015). Other reports failed to indicate the sexual orientations of the samples at all (e.g., Mueller et al., 2016). Thus, although some authors have attributed cross-sex shifts in sexually dimorphic neuroanatomy to transsexuality, the same findings are just as readily attributable to homosexuality when confounded in this way.

Another set of MRI studies explicitly controlled for sexual orientation, either by comparing transsexuals attracted to women with cissexuals also attracted to women (e.g., Savic & Arver, 2011), or by comparing a diverse group of transsexuals (some attracted to men, some attracted to women) with

two control groups of cissexuals, one attracted to men and one attracted to women (e.g., Burke et al., 2017; Manzouri & Savic, 2019). These analyses identified significant group differences, but not in neuroanatomic features known to represent cross-sex differences, correlates of homosexuality, or findings from samples of homosexual transsexuals. Rather, the implicated structures appear to represent "cerebral networks mediating self-body perception" (Manzouri & Savic, 2019, p. 2098). These findings remain consistent with the hypothesis that there is not a single neuroanatomic cause of gender dysphoria, but that there exist two phenomena in play, both of which can motivate gender dysphoria and each of which has its own neuroanatomic footprint: one related to homosexuality and another, independent one related to autogynephilia (Cantor, 2011).

### Suicidality

Reports of suicidality among trans populations vary widely (cf., Adams & Vincent, 2019; Wiepjes et al., 2020), owing primarily to which population subtypes were studied and how suicidality was defined (ideation vs. attempts vs. completions). Also differing across reports was the definition of trans, ranging from meeting diagnostic criteria to adopting self-described gender without clear definition (McNeil et al., 2017). Unfortunately, many reports also collapsed across groups or conflated gender identity with sexual orientation, leading to misattribution of conclusions across groups. Despite that this literature repeatedly emphasizes the interactions among sexuality, ethnicity, and other social stigmata with suicidality, few studies actually recorded or controlled for such variables (McNeil et al., 2017). This also has led to misattributing features across groups. Many features reported to reflect gender identity may instead reflect homosexuality.

In their comprehensive literature review, McNeil et al. (2017) found reported rates of suicidal ideation ranging from 37% to 83% and, for suicidal attempts, 9.8% to 44%. Rates reported by gender clinics were lower than those reported on surveys, and rates reported by gender clinics were lower still when assessed by a clinician than when indicated on self-report instruments. The reported rates of suicidal ideation and attempts differ appreciately from rates of completed suicide (e.g., Asscheman et al., 2011): the Amsterdam Cohort of Gender Dysphoria study examined the charts of all patients referred between 1972 and 2017, cross-checking them against the Dutch National Civil Record Registry and other sources (Wiepjes et al., 2020). This spanned 5,107 trans women (ages 4–81) and 3,156 transmen (ages 4–73). In total, 0.6% died by suicide, representing 0.8% of male-to-females and 0.3% of female-to-males.

The sex difference reported by Wiepjes et al. was significant and consistent with prior reports finding FtM's to show a greater risk of suicidal ideation and attempts than MtF's, whereas MtF's show a greater risk of completing suicide than FtM's (McNeil et al., 2017). The sex difference among the cis-gendered in rates of completed suicides versus ideation and attempts among the cis-gendered is widely documented: biological females are more likely to report suicidal ideation and attempts, whereas biological males are more likely to complete suicide (Fox et al., 2018). Thus, suicidality among trans populations would appear to follow biological sex rather than self-identified sex, the knowledge of which could help guide prevention efforts to where they are needed most.

### Hypersexuality

Multiple theory-laden terms have been used to describe sexual urges or behaviors whose frequencies are sufficiently high to produce distress or harm, the most common of which has been "sex addiction" (Carnes, 1983). The major competing theoretical perspectives of hypersexuality include addiction (Carnes, 1989; Goodman, 1997), compulsivity (Quadland, 1985; Coleman, 2003), the dual control model (Bancroft, 1999; Bancroft, Graham, Janssen, & Sanders, 2009), and desire dysregulation (Kafka, 2007). Although the theories make use of different terminology and treatment modalities, they contain many more similarities than differences. The word "hypersexuality" will be used to describe this condition in the following.

Elevation in sexual behavior is a symptom of several conditions, including hypomania, borderline personality disorder, and disinhibiting neurological trauma or disease. Hypersexuality as a syndrome unto itself has been receiving increasing attention, but there does not yet exist any consensus in definition or theoretical models.

### Prevalence and Sex Ratio

Estimating the prevalence of hypersexuality is hampered by the diversity of operational definitions and the lack of any meaningful distinction between typical and excessive rates of sexual urges or behaviors. Coleman (1992) offered an estimate of 5–6% of the population being affected by

"impulsive-compulsive" sexual behavior; however, it is unclear how such an estimate might be produced in the absence of reliable criteria, and it is likely that the problem may have increased following the readier access to pornography via the Internet. For comparison, a large cross-sectional study in the United States found 1.9% of males to masturbate daily and 1.2%, more than daily (Laumann et al., 1994). (The survey did not ask whether these individuals experienced problems due to the frequency of their sexual activity, however.) Similarly, 2-8% of men, including adolescents, experience more than seven orgasms per week (Mick & Hollander, 2006). Although such data might be imagined to be useful in identifying a clear cutoff, sexual frequency can interact with sexual context. For example, higher sexual frequency within a stable relationship correlates with higher psychological functioning, but frequency of solo or impersonal sexual behaviors does not (Längström & Hanson, 2006). A further impediment to accurate prevalence estimates is that hypersexuality also appears to often be confused with high-risk sexual behavior, which overlaps with, but is not the same as, out of control sexual behavior (Bancroft & Vukadinovic, 2004).

As with paraphilias, the reported samples consistently indicate a majority of males among individuals seeking assistance for potential hypersexuality, approximately three to five males per female (Black et al., 1997). Among studies that included both male and female referrals, 60–92% of each sample is male (Kaplan & Krueger, 2010).

### Comorbidities

From 83% to 100% of affected individuals also had one or more DSM-IV Axis I diagnoses (Black et al., 1997; Raymond et al., 2003). These included mood and anxiety disorders, substance abuse, impulse control disorders, and obsessivecompulsive disorder (Black et al., 1997; Kafka & Hennen, 2002; Kafka & Prentky, 1994, 1998; Raviv, 1993; Raymond et al., 2003; Shapira et al., 2000). Personality disorders are also common, with approximately half meeting criteria (Black et al., 1997; Raymond et al., 2003). Moreover, conditions for which hypersexuality is a symptom include dementia (Fedoroff et al., 1994), temporal lobe epilepsy (Remillard et al., 1983), and Tourette's syndrome (Kerbeshian & Burd, 1991), as well as bipolar disorder and borderline personality disorder.

Notwithstanding those associations, many individuals seeking help for hypersexuality show normal profiles on the Minnesota Multiphasic Personality Inventory (MMPI-2; Reid & Carpenter, 2009). Such discrepancies might reflect heterogeneous subtypes, the proportions of which differ between clinics or recruitment methods. The possibility that hypersexual phenomena consists of distinct subtypes has indeed been proposed (e.g., Cantor et al., 2013; Kafka, 2010; Raymond et al., 2003). In the most explicit attempt to identify clinically meaningful subtypes, referrals have been characterized as showing paraphilic hypersexuality, avoidant masturbation, and chronic adultery, with other phenomena being associated with genuine distress but not any behavioral excesses not already accounted for by other issues (Cantor et al., 2013).

Neuroimaging studies have compared patients with versus without hypersexual symptomatology (Black et al., 2005; Mendez & Shapira, 2013). For example, a study of patients with behavioral variant frontotemporal dementia found evidence of temporal lobe-limbic involvement as well as frontal lobe involvement in those patients who also had hypersexuality. The authors of that study concluded that individuals with hypersexuality may have developmental or genetic differences in the ability of the right anterior temporal lobe to inhibit limbic and subcortical areas for sexual arousal (Mendez & Shapira, 2013).

### Associated Features

Investigations of the role of testosterone have demonstrated that low levels of the hormone are consistently associated with low levels of sexual interest and behavior, suggesting that high levels would be associated with elevated sexual interest and behavior. This conclusion has not yet been examined, however (Berlin, 2008). Opioids may also play a role, as a study demonstrated a statistically significant release of internal opioids in the cingulate, the temporal cortex, and the frontal cortex during sexual arousal in men (Frost et al., 1986). Relatedly, individuals who have with Parkinson's disease and are prescribed dopamine agonists frequently display sexual acting out (Klos et al., 2005).

Reid, Karim, McCrory, and Carpenter (2010) found that a sample of treatment-seeking hypersexual males scored lower than controls on a self-report measure of executive functioning; however, that team subsequently found that such males scored no worse than an age-, education-, and full-spectrum IQ (FSIQ)-matched community sample when directly tested with executive functioning measures (Reid et al., 2011). That team concluded that executive functioning may be limited to situations in which there is an opportunity for sex, but it is also possible that such individuals simply perceive and rate themselves as having less self-control as a reaction to instead of a cause of their symptom. Both studies controlled for substance abuse and attention deficit hyperactivity disorder because these conditions are also known to affect executive functioning, and are often comorbid with hypersexuality.

Hypersexual behavior is frequently described as an addiction to sex. As a test of that comparison, Steele, Staley, Fong, and Prause (2013) used electroencephalography to record the P300 amplitude of hypersexuals in response to sexual stimuli. Instead of finding a diminished (downregulated) response as predicted by the addiction model, the hypersexuals showed an elevated response. Neuroimaging studies of sexual arousal in controls have demonstrated activation in areas including the prefrontal, orbitofrontal, insular, occipitotemporal, and anterior cingulate cortices, as well as in subcortical regions including the amygdala and substantia nigra (Stoléru et al., 2012), making these important areas to examine as potential mechanisms associated with sexually problematic behavior (Mendez & Shapira, 2013).

## Personality Disorders

## 25<sup>chapter</sup>

### The DSM-5 Level of Personality Functioning Scale

Johannes Zimmermann, Christopher J. Hopwood, and Robert F. Krueger

Personality disorders (PDs) are common in the general population and are associated with many negative consequences for both the person affected as well as their environment (Hengartner et al., 2018; Tyrer et al., 2015). The disorder is highly relevant for professionals from the healthcare system as it can severely affect their interactions with the patient as well as the success of medical and therapeutic interventions. A valid classification system is an indispensable prerequisite for the efficient diagnosis and treatment of and research into the causes of PD. Current classification systems for PD, such as the one in DSM-5 Section II, list purportedly distinct disorders; in the case of DSM-5, they are paranoid, schizoid, schizotypal, antisocial, borderline, histrionic, narcissistic, avoidant, dependent, and obsessive-compulsive PD. This categorical approach has come under criticism and is likely to be replaced in the long term by dimensional approaches. A central concept in this paradigm shift is the idea of a continuum in personality functioning, one ranging from healthy to extremely disturbed personality. This idea of PD severity has been exemplified in Criterion A of the alternative model for personality disorders (AMPD) in DSM-5 Section III, which is operationalized by the Level of Personality Functioning Scale (LPFS). The purpose of this chapter is to explain why and how the LPFS was developed, what measures are available based on its definition, and what empirical evidence exists on various aspects of the reliability, validity, and clinical utility of these measures. Additionally, controversies and open questions will be addressed.

### Arguments in Favor of Taking Severity of PD into Account

There are a number of arguments in favor of including a severity scale in a classification system

for PD. First, as with the vast majority of mental disorders, underlying individual differences in PD are continuously distributed and do not consist of two discrete groups of individuals with and without the disorder (Haslam et al., 2020). For example, the observed patterns of symptoms of borderline PD (Conway et al., 2012), narcissistic PD (Aslinger et al., 2018), and schizotypal PD (Ahmed et al., 2013) are all consistent with a dimensional rather than a categorical model. Overcoming the relatively arbitrary division into individuals with and without disorder and exploiting the multiple gradations of severity will significantly improve the reliability and validity of measurements (Markon et al., 2011). It will also make it possible to account for the substantial proportion of individuals who exhibit mild

### Abbreviations

AMPD	Alternative model for personality
g-PD	General factor of PD
GAF	Global Assessment of Functioning
GAPD	General Assessment of Personality

PDM	Psychodynamic Diagnostic Manual
SASPD	Standardized Assessment of
	Severity of Personality Disorder
SIPP-118	Severity Indices of Personality
	Problems
STiP	Semi-Structured Interview of
	Personality Functioning

personality problems that are nevertheless associated with diminished functioning (Karukivi et al., 2017; Thompson et al., 2019; Yang et al., 2010).

Second, it has long been known that PD diagnoses often co-occur, which is usually referred to as "comorbidity." For example, in a study of outpatients, it was found that of all patients who met criteria for PD, approximately 60% met criteria for at least one other PD (Zimmerman et al., 2005). Indeed, from a factor analytic perspective, there is considerable evidence for a general PD factor: when all PD diagnoses or criteria are considered together, they are shown to load not only on specific factors but also on a general factor (Conway et al., 2016; Hengartner et al., 2014; Paap et al., 2021; Ringwald et al., 2019; Sharp et al., 2015; Williams et al., 2018). Although the strength of the general factor varies across samples and assessment methods, it can be concluded that there is indeed a common construct underlying most of the individual PD criteria. This construct can be interpreted as the general severity of PD (g-PD), in a similar way as the g-factor of intelligence.

Third, g-PD, in terms of the total number of PD criteria met across all categories, has been repeatedly shown to be a good predictor of current and future problems in various life domains (Conway et al., 2016; Hopwood et al., 2011; Williams et al., 2018; Wright et al., 2016). Although other specific factors related to stylistic aspects or traits usually also contribute to prediction, g-PD is often the strongest predictor in relative terms. This suggests that a direct mapping of severity is highly relevant in terms of prognosis. Accordingly, proposals have now been developed on how to use PD severity to plan therapy (Bach & Simonsen, 2021; Hopwood, 2018). While a less-structured and -intensive treatment setting may be beneficial for a milder severity level (e.g., group therapy), a structured treatment setting with clear boundaries appears to be necessary for severe impairment, and the clinician must be very intentional about building the relationship, repairing ruptures, and preventing dropout. In general, due to its prognostic relevance, severity appears to be particularly useful for determining a patient's level of care.

Fourth, reanalysis of a longitudinal study of PD demonstrates that g-PD has much less absolute stability compared to the specific factors (Wright et al., 2016). For example, mean severity decreased by more than 1 standard deviation over a 10-year period, whereas scores on the specific factors (with the exception of compulsivity) changed little on average. This suggests that general severity captures not only a large part of interindividual differences

but also a large part of intraindividual changes in PD symptoms over time. This is relevant because change in PD symptoms is often the central endpoint for therapeutic interventions (e.g., Cristea et al., 2017).

Finally, the introduction of a severity continuum would also improve public recognition of the modifiable nature of PD and thus hopefully help destigmatize the diagnosis. For example, Tyrer et al. (2015) expressed the hope that treating experts might then be more willing to make the diagnosis even in adolescence (to enable early interventions) because it would in principle be seen as modifiable and not as a lifelong label. This is also in line with a recent meta-analysis on the relationship between a dimensional understanding of mental disorders and stigmatization: the more people assume a continuum between mental health and illness, the less they tend to have stigmatizing attitudes toward people with mental disorders (Peter et al., 2021).

### Arguments for the Central Role of Impairments in Self and Interpersonal Functioning

If one agrees that a classification system for PD should reflect general severity, the question arises as to how severity should be operationalized in concrete terms. Various proposals have been made, some long before the AMPD was developed (Crawford et al., 2011). For example, severity could simply be determined by the number of categorical PD diagnoses (Tyrer & Johnson, 1996) or measured separately using the Global Assessment of Functioning (GAF) scale (Widiger & Trull, 2007) or a list of negative consequences (Leising & Zimmermann, 2011). The latter options would map how severely a person is impaired in performing roles and activities of daily living, including social activities, school or work, recreation or leisure, and basic activities of self-care and mobility.

Opting for a different approach, the *DSM-5* workgroup based severity on the degree of impairment of internal abilities that underlie the perception and regulation of self and interpersonal relationships (Skodol, 2012). An important reason for this was to provide a substantive link to the general criteria for PDs, thus ensuring a relatively high degree of specificity for pathological *personality* processes (Bender et al., 2011). As the general criteria for PD introduced in *DSM-IV* were considered vague and ineffective (Livesley, 1998; Parker et al., 2002), a major goal of the *DSM-5* workgroup was to elaborate on the core substantive features of personality pathology.

Earlier research had suggested that the features common to all PD relate to problems of the self (e.g., identity disturbance, low self-direction) and to problems in interpersonal relationships (e.g., isolation, uncooperativeness, fear of rejection) (Gutiérrez et al., 2008; Hopwood et al., 2011; Svrakic et al., 1993; Turkheimer et al., 2008). These content domains also emerged in a factor analysis of several general criteria for PD (Parker et al., 2004). In recent studies of the factor structure of individual PD criteria, features such as emotional dysregulation, distorted thoughts about self and others, and problematic interpersonal behaviors were also found to exhibit high loadings on the g-PD (Sharp et al., 2015; Williams et al., 2018). This is especially true for borderline personality disorder (BPD) criteria, which often did not load on specific factors at all and, to that extent, can be considered particularly "pure" markers of g-PD. Based on such findings, some authors have suggested that "it may be more fruitful to reconceptualize BPD-and particularly the criteria tapping impairment in self and interpersonal pathology . . . as reflecting a broad, general dimension of PD-severity rather than a specific PD category" (Clark et al., 2018). Taken together, there is evidence from studies with different empirical approaches that problems in the domains of self and interpersonal relationships are key general indicators of PD.

A further argument for the relevance of these domains comes from an analysis of the normative assumptions underlying PD diagnoses in DSM-IV (Leising et al., 2009). In this regard, one must first realize that assigning a PD diagnosis to a person necessarily involves comparing the person's personality to an image of how people "normally" should feel or behave. Leising et al. (2009) addressed this issue by semantically reversing the 79 individual PD criteria in DSM-IV, resulting in a set of positive expectations regarding desirable behavior. Cluster analysis of the sorting data revealed 10 higher-order clusters of values that cut across the 10 PD categories. Many of these values can be categorized as being related to self-functioning (e.g., be self-reliant and independent; be self-confident, but in a realistic manner; have self-control) and interpersonal functioning (e.g., get along with others; connect with others emotionally and treat them fairly; enjoy social relationships and activities). It could thus be argued that the implicit normative assumptions that appear to have guided the development of the PD criteria in DSM-IV already include the foci of self and interpersonal relationships.

The relevance of these domains is also emphasized in many major theories of PD, including psychodynamic (Clarkin et al., 2020; Luyten & Blatt, 2013), interpersonal (Hopwood et al., 2013; Pincus et al., 2020), and attachment (Meyer & Pilkonis, 2005) theories. Another approach that brings this particularly into focus comes from Livesley (1998). According to his understanding, the core of PD is the failure to develop self and interpersonal capacities necessary to perform important life tasks. Last, such a definition of the general characteristics of PD also allows Wakefield's (1992) notion of "dysfunction" to be introduced into the definition of PD. Accordingly, PD is not merely a pattern of experience and behavior that is harmful or negative in terms of social values, but rather it emerges from an underlying dysfunction in which a psychological mechanism fails and no longer performs the natural function for which it was selected in the course of evolution (Krueger et al., 2007).

### Development of the DSM-5 Level of Personality Functioning Scale

These and similar considerations have led the *DSM-5* workgroup to develop a revised Criterion A that both requires the presence of significant impairments in self and interpersonal functioning for a diagnosis of PD and also can be used simultaneously to determine the severity of impairment (Skodol, 2012). The result of this development process is the LPFS, which is an operationalization of this new general Criterion A. Originally, it was envisioned that the revised criteria, including the LPFS, would replace the categorical PDs of *DSM-IV*, but in the end it was decided to add them as an alternative model in Section III of *DSM-5*.

The DSM-5 workgroup initially took a twopronged approach. First, data were reanalyzed on two self-report instruments available at the time that were designed to measure impaired personality functioning (Morey et al., 2011). The two instruments were the Severity Indices of Personality Problems (SIPP-118; Verheul et al., 2008) and the General Assessment of Personality Disorder (GAPD; Livesley, 2006). Item response theory (IRT) models were used to select items that measured the general factor well at different levels of severity. The item set was then validated using external data on severity (e.g., the presence of a PD diagnosis according to structured interviews or the total number of PD criteria met). The selected items covered the theoretically expected deficits in the domain of the self (e.g., identity integration, integrity of self-concept)

and interpersonal relationships (e.g., capacity for empathy and intimacy).

Second, although members of the DSM-5 workgroup emphasized the transtheoretical background of the LPFS (Bender et al., 2011), psychodynamically oriented models and measures have been particularly influential in its development (Blüml & Doering, 2021; Clarkin et al., 2020; Hörz-Sagstetter et al., 2021; Yalch, 2020; Zimmermann et al., 2012). It is one of the central assumptions of many psychodynamic models that maladaptive mental representations of self and others form the core of personality pathology and that the degree of disturbance can be assessed along different levels of functioning (Kernberg, 1984; Luyten & Blatt, 2013; Westen et al., 2006). Kernberg (1984) proposed, for example, that levels of personality organization are manifested in three domains of functioning: (a) integration of one's identity (i.e., the ability to develop nuanced and stable images of self and others), (b) maturity of defense mechanisms (i.e., the ability to process threatening internal and external stimuli in an adaptive manner), and (c) integrity of reality testing (i.e., the ability to distinguish between internal and external stimuli and make contact with a socially shared reality). Kernberg also distinguished three levels of severity based on the degree of impairment in these areas of functioning: namely, neurotic, borderline, and psychotic personality organization. More recent psychodynamic conceptualizations of severity, such as the Level of Structural Integration Axis of the Operationalized Psychodynamic Diagnosis-2 (OPD Task Force, 2008; Zimmermann et al., 2012) or the Mental Functioning Axis of the Psychodynamic Diagnostic Manual-2 (PDM-2; Lingiardi & McWilliams, 2017), are similar to Kernberg's model in that they refer to impairments in basic psychological capacities and distinguish between several prototypical levels of functioning.

Against this background, it is unsurprising that members of the *DSM-5* workgroup encountered only psychodynamically oriented measures in their search for relevant expert clinical assessment systems (Bender et al., 2011). To justify and streamline the initial LPFS proposal, the authors established methodological criteria for instruments to be considered in the broader *DSM-5* revision process. The instruments should (a) include important dimensions of psychological functioning; (b) have a self-other focus; (c) have been used in studies with general clinical samples, with personality disordered samples, or with both; (d) have concepts useful to a wide range of clinicians; (e) be appropriate for assessing clinical interview material; and (f) have published psychometric data on relevant domains of functioning. Using these criteria, Bender et al. (2011) identified the following five psychodynamically based instruments: the Quality of Object Relations Scale (QORS; Azim et al., 1991), the Personality Organization Diagnostic Form (PODF; Gamache et al., 2009), the Object Relations Inventory (ORI; Blatt et al., 1988), the Social Cognition and Object Relations Scale (SCORS; Westen et al., 1990), and the Reflective Functioning Scale (RFS; Fonagy et al., 1998). The final version of the LPFS can thus also be seen as an attempt to integrate existing psychodynamic rating scales of personality functioning while maximizing reliability and clinical utility.

In the final stage of development, the diagnostic threshold for the presence of PD was determined empirically. This was based on a pilot study of the AMPD in which 337 clinicians each assessed one of their patients using the categorical *DSM-IV* model and the new AMPD (Morey et al., 2013). The cut-off score of 2 on the LPFS scale of 0–4 achieved a sensitivity of 84.6% and a specificity of 72.7% in predicting the presence (vs. absence) of at least one diagnosable PD according to *DSM-IV*. This level was therefore set as the threshold for the diagnosis of PD.

### The DSM-5 Level of Personality Functioning Scale

Criterion A is used to determine the presence and severity of PD and can be assessed using the LPFS. The LPFS defines the severity of PD based on the degree of impairment in self and interpersonal functioning. This severity continuum is further specified by psychological characteristics considered typical of different degrees of impairment in the "components" (DSM-5, p. 772) of identity and self-direction (i.e., self-functioning) and empathy and intimacy (i.e., interpersonal functioning). Each of the four components is further broken down into three subcomponents. Intimacy, for example, means that a person (a) can form deep and lasting relationships with others, (b) wants to and can be close to others, and (c) treats others with respect. Table 25.1 summarizes all four components and 12 subcomponents. Note that despite these finegrained definitions, all components and subcomponents are intended to represent a general dimension of PD severity. The LPFS classifies this continuum into five different "levels" of impairment, beginning with little or no impairment (level 0), moving

Table 25.1	Components and subcomponents o
personality f	unctioning according to Criterion A

1	0
Component	Subcomponents
Identity	Sense of self Self-esteem and accurate self-perception Emotional range and regulation
Self-direction	Ability to pursue meaningful goals Prosocial internal standards of behavior Self-reflective functioning
Empathy	Understanding others' experiences and motivations Tolerance of differing perspectives Understanding effects of own behavior on others
Intimacy	Depth and duration of connections Desire and capacity for closeness Mutuality of regard

Note: Adapted from DSM-5, p. 762.

through mild (level 1), moderate (level 2), severe (level 3), and ending with extreme impairment (level 4). With level 0, the description of a healthy personality without impairments is explicitly provided for the first time in *DSM-5*. As mentioned above, moderate impairment (level 2) represents the threshold for the presence of PD.

To facilitate assessment, the LPFS operationalizes all 60 possible combinations of subcomponents and levels using prototypical descriptions (see the table on p. 775 of DSM-5). For example, the respective paragraphs for the first subcomponent within self-direction (i.e., ability to pursue meaningful goals) are "Sets and aspires to reasonable goals based on a realistic assessment of personal capacities" (level 0); "Excessively goal-directed, somewhat goal-inhibited, or conflicted about goals" (level 1); "Goals are more often a means of gaining external approval than self-generated and thus may lack coherence and/or stability" (level 2); "Difficulty establishing and/or achieving personal goals" (level 3); and "Poor differentiation of thoughts from actions, so goal-setting ability is severely compromised, with unrealistic or incoherent goals" (level 4). The diagnostician is asked to match these descriptions to the specific case and indicate on a global 5-point scale which level of functioning best corresponds to the patient's overall functioning (i.e., across all four components). In other words, each patient is assigned a single overall score on the LPFS.

### Measures Based on the DSM-5 Level of Personality Functioning Scale

Central to measuring PD severity in research and practice to date has been the use of the LPFS itself. Originally, this involved an expert rating on a single 5-point scale as described above (Morey et al., 2013). Other researchers have applied the LPFS in a more sophisticated way by having the four components (Dereboy et al., 2018; Few et al., 2013), the 12 subcomponents (Cruitt et al., 2019; Hutsebaut et al., 2017; Preti et al., 2018; Roche, 2018; Zimmermann et al., 2014), or the 60 prototypical descriptions (Zimmermann et al., 2015) assessed separately and then aggregating the ratings into an overall score. For the purpose of collecting self-report data, some researchers have asked individuals to self-report according to prototypical descriptions of the 12 subcomponents (Bliton et al., 2021; Dowgwillo et al., 2018; Roche et al., 2016, 2018). For the purpose of informant reports, it has been suggested that the 60 prototypical descriptions of the LPFS can also be individually assessed by laypersons (Morey, 2018; Zimmermann et al., 2015).

Following the publication of DSM-5, new measurement instruments have been developed to implement the operationalization of severity according to the LPFS (Birkhölzer et al., 2020; Zimmermann et al., 2019). These measures are summarized in Table 25.2, including references to validated translations. On the one hand, structured clinical interviews are available to systematically collect information relevant to applying the LPFS. For example, the Structured Clinical Interview for the Level of Personality Functioning Scale (SCID-AMPD Module I; Bender, Skodol, et al., 2018) has a funnel structure, starting with open-ended questions for each subcomponent to get an initial impression of severity and then going in-depth according to that impression with specific follow-up questions for the assumed level. The Semi-Structured Interview for Personality Functioning DSM-5 (STiP-5.1; Hutsebaut et al., 2017) has a similar funnel structure and can also be used on adolescents (Weekers, Verhoeff, et al., 2021).

On the other hand, several self-reports are available that build on the understanding of PD severity according to LPFS but use items that are easier for laypersons to understand. These measures differ in number of items and differentiation into subscales. For example, the Level of Personality Functioning Scale-Brief Form (LPFS-BF; Hutsebaut et al., 2016; updated version LPFS-BF 2.0; Weekers et al., 2019) comprises only 12 items in total, with

Semi-Structured Interview for Personality Functioning DSM–5 (STiP-5.1)	Hutsebaut et al. (2017)	Dutch German (Zettl et al., 2020); Czech (Heissler et al., 2021)	Structured interview	12	1/4
Structured Clinical Interview for the Level of Personality Functioning Scale (SCID-AMPD Module I)	Bender, Skodol, et al. (2018)	English German (Kampe et al., 2018); Italian (Somma et al., 2020); Norwegian (Buer Christensen et al., 2018); Danish (Meisner et al., 2021)	Structured interview	12	1/4

each item describing impairment in one subcomponent. The evaluation refers to the two subscales of impairments in self and interpersonal functioning as well as to an overall score. Because of its efficiency and compatibility with *ICD-11* (see below), the LPFS-BF 2.0 has recently been proposed to be used as part of a standard battery for patient-reported outcomes in PD (Prevolnik Rupel et al., 2021). In contrast, the Level of Personality Functioning Scale-Self-Report (LPFS-SR; Morey, 2017) comprises 80 items, each describing different levels of severity from all 12 subcomponents. Items are aggregated on a weighted basis according to severity, yielding four scales for impairments in the components of identity, self-direction, empathy, and intimacy, as well as a total score. Finally, one self-report measure, the Levels of Personality Functioning Questionnaire for Adolescents from 12 to 18 Years (LoPF-Q 12-18; Goth et al., 2018), was directly tailored to the target population of adolescents.

Further developments to measure severity according to LPFS include items that can be used in the context of intensive longitudinal designs. In this way, fluctuations and nuanced temporal dynamics in the components of identity, self-direction, empathy, and intimacy can be revealed (Roche et al., 2016, 2018). In addition, impairment scales have been developed to examine the validity of impairment criteria for the six specific PDs listed under the rubric of Criterion A in the AMPD (Anderson & Sellbom, 2018; Liggett et al., 2017; Liggett & Sellbom, 2018; McCabe & Widiger, 2020). What is not yet available but could be useful in higher-risk clinical settings are indices that indicate negligent or biased responses.

### Psychometric Properties and Empirical Findings Pertaining to the LPFS

Numerous reviews have summarized the theoretical underpinnings and current research findings on personality functioning in the AMPD (Bach & Simonsen, 2021; Bender, Zimmermann, & Huprich, 2018; Clark et al., 2018; Herpertz et al., 2017; Hörz-Sagstetter et al., 2021; Morey & Bender, 2021; Pincus, 2018; Pincus et al., 2020; Sharp & Wall, 2021; Sinnaeve et al., 2021; Sleep et al., 2021; Widiger et al., 2019; Zimmermann et al., 2019; Hopwood et al., in press). We provide here an updated comprehensive summary of research on the LPFS. We include only studies that applied the LPFS or one of the measures listed in Table 25.2, ensuring high specificity for AMPD definitions of severity. Results are organized according to the questions of (a) interrater reliability, (b) internal consistency and latent structure, (c) convergent validity, (d) discriminant and incremental validity, and (e) clinical utility.

### Interrater Reliability

Interrater reliability refers to agreement between judges of the same individual's level of personality functioning. Table 25.3 summarizes the studies that have examined the interrater reliability of the LPFS. Results suggest that interrater reliability is largely acceptable when using the LPFS based on case vignettes (Garcia et al., 2018; Morey, 2019), written life history data (Roche et al., 2018), personality or life story interviews (Cruitt et al., 2019; Roche & Jaweed, 2021), clinical interviews (Di Pierro et al., 2020; Few et al., 2013; Preti et al., 2018; Zimmermann et al., 2014), or unstructured clinical impressions (Dereboy et al., 2018), even among untrained and clinically inexperienced raters. Across these 10 studies including 676 targets and 3,451 ratings, the weighted intraclass correlation coefficient (ICC) for the LPFS total score was .55 (95% confidence interval [CI] .47, .63). However, training can increase interrater reliability (Garcia et al., 2018), and interrater reliability is usually significantly better when based on structured interviews that are explicitly tailored to collect the required information. Nine studies on such interviews have been conducted so far, including 276 targets and 662 ratings (Buer Christensen et al., 2018; Hutsebaut et al., 2017; Kampe et al., 2018; Meisner et al., 2021; Møller et al., 2021; Ohse et al., 2021; Somma et al., 2020; Thylstrup et al., 2016; Zettl et al., 2020). The weighted ICC for the LPFS total score across these studies was .83 (95% CI .75, .92), which is considered excellent (Cicchetti, 1994). An exception is the Clinical Assessment of the Level of Personality Functioning (CALF), where interrater reliability was at the lower limit, presumably because the interview does not probe closely enough the behaviors and experiences described in the LPFS and requires a higher degree of inference (Thylstrup et al., 2016). For the SCID-AMPD Module I, two studies are now available that use a more rigorous test-retest design in which patients are reinterviewed by a different person within a short period of time. Here, the ICC for the LPFS total score was .75 (Buer Christensen et al., 2018) and .84 (Ohse et al., 2021), respectively.

### Internal Consistency and Latent Structure

Internal consistency refers to the question of whether ratings of different aspects of a person's personality functioning result in similar test scores. In other words, the question is whether individual differences in these aspects are positively correlated and thus "consistent" and can be aggregated into a single construct. This can be considered at different levels in the LPFS and the derived self-report measures: For example, one can investigate whether the LPFS total score is internally consistent when looking at the ratings on the four components, or whether an LPFS-SR score regarding the component of empathy is internally consistent when looking at the ratings on the individual items. The results here are generally positive: for example, the internal consistency of the overall LPFS score has been shown to be acceptable when calculated based on ratings of the four components (Dereboy et al., 2018; Morey et al., 2013) and as very high when calculated based on scores of subcomponents (Bach & Hutsebaut, 2018; Cruitt et al., 2019; Dowgwillo et al., 2018; Hutsebaut et al., 2017) or individual items (Hopwood et al., 2018; Morey, 2017, 2018). Scores on the four components (Cruitt et al., 2019; Hopwood et al., 2018; Huprich et al., 2018; Morey, 2017, 2018; Zimmermann et al., 2014) and the 12 subcomponents (Zimmermann et al., 2015) also achieved fairly high internal consistency.

However, from the perspective of psychometric models such as IRT or factor analyses, high internal

Table 25.3 Studies on the interrater reliability of the LPFS

c We subsequently corrected this value to provide an ICC for single raters.

consistency is not sufficient to justify the formation of an overall score. It is also required to test the fit of a measurement model according to which different ratings can be explained by an underlying latent variable. The first comprehensive analysis of the latent structure of LPFS was conducted by Zimmermann et al. (2015). Data were collected through an online study in which 515 laypersons and 145 therapists rated all 60 prototypical descriptions of the LPFS. Laypersons were asked to rate one of their personal acquaintances, whereas therapists were asked to rate one of their patients. The results on latent structure were broadly consistent with the assumptions of the LPFS, although there were some discrepancies. First, it was possible to demonstrate, using so-called unfolding IRT models (Roberts et al., 2000; see below), that most subcomponents are indeed unidimensional. This means that the ratings on the five prototypical descriptions of a subcomponent (e.g., ability to pursue meaningful goals, see above) can be explained by a single underlying latent dimension. There were however exceptions, such as the second subcomponent within intimacy (i.e., desire and capacity for closeness), where the pattern of associations between ratings turned out to be more complex. This could be due to the fact that the individual descriptions from this subcomponent emphasize quite different signs and explanations of impaired capacity for closeness (e.g., inhibition in level 1, self-regulation needs in level 2, and rejection sensitivity in level 3), suggesting that the underlying construct is rather multidimensional.

Second, using exploratory structural equation modeling, it was shown that the structure of the 12 subcomponents was largely consistent with a model that included two strongly correlated factors of self and interpersonal functioning. There were some discrepancies here as well: for example, there was not much support for the theoretical differentiation of self-functioning into identity and self-direction on the one hand and interpersonal functioning into empathy and intimacy on the other. Crucially, however, the high correlation of the two factors of self and interpersonal functioning is consistent with a model that assumes a strong general factor for the 12 subcomponents. Indeed, the proportion of variance in the LPFS total score that could be attributed to the general factor was .78, suggesting that while individuals may differ to some extent in their specific type of impairment (i.e., whether their personality problems are more related to self or interpersonal functioning), the main source of differences is related to the general severity of impairments. Thus,

although forming an overall score may be difficult in some cases because impairment in self and interpersonal functioning differs too much, the use of a single score for the LPFS appears to be broadly acceptable in clinical practice.

Meanwhile, these findings on the latent structure of the subcomponents of the LPFS have been widely confirmed in other studies. Support for a model with two strongly correlated factors of self and interpersonal functioning has emerged in studies involving both self-reports based on the items of the LPFS (Bliton et al., 2021; Roche, 2018), the LPFS-BF (Bach & Hutsebaut, 2018; Bliton et al., 2021; Hutsebaut et al., 2016; Spitzer et al., 2021; Weekers et al., 2019) and the Personality Functioning Scale (PFS; Stover et al., 2020), as well as in expert ratings based on the SCID-AMPD Module I (Hummelen et al., 2021; Ohse et al., 2021) or STiP-5.1 (Heissler et al., 2021). Although this may challenge the theoretical differentiation into four components, it is consistent with the assumption of a strong general factor representing PD severity. Evidence for such a factor is also found in confirmatory factor analyses of SIPS items (Gamache et al., 2019) and principal component analyses of the four components of LPFS-SR (Hopwood et al., 2018; Morey, 2017) and LPFS (Cruitt et al., 2019). Item-level factor analyses of the LPFS-SR often deviate more from the theoretical structure or achieve poor model fit (Bliton et al., 2021; Hemmati et al., 2020; Sleep et al., 2019, 2020). This is at least partly due to the sheer size of the model (which can lead to biased fit statistics; Moshagen, 2012), as well as to method factors due to items with positive and negative valence. In any case, a strong general factor is also apparent in itemlevel analyses of the LPFS and LPFS-SR, which may justify the use of the overall score (Bliton et al., 2021; Leising et al., 2021). Interestingly, these analyses also indicated that loadings on the general factor were almost perfectly predictable from the social desirability of the items (Leising et al., 2021). This suggests that the impairments in personality functioning as defined by the LPFS and derivate measures are essentially guided by a social consensus of negatively valued experiences and behaviors.

Two other aspects of the LPFS are particularly challenging in the study of their latent structure aspects that seem less relevant for constructs such as personality traits. First, the LPFS involves not only a differentiation into different components and subcomponents, but also into different levels that are supposed to represent different degrees of severity. The question, then, is whether the five individual

descriptions of a given subcomponent are arranged in a theoretically consistent manner along the latent severity continuum. For example, the descriptions "Excessively goal-directed, somewhat goal-inhibited, or conflicted about goals" (level 1) and "Goals are more often a means of gaining external approval than self-generated and thus may lack coherence and/or stability" (level 2) should be located at different points on the latent severity continuum (i.e., the latter description should reflect a significantly higher severity level than the former description). In the study with informant ratings by Zimmermann et al. (2015), this assumption was tested using unfolding IRT models. In unfolding IRT models, a location parameter is estimated for each item, indicating where individuals are located on the latent dimension when they are most likely to agree with the item (Roberts et al., 2000). It was found that the relationship between the theoretically hypothesized severity levels and the empirically estimated location parameters was quite strong across all items. This largely supports the classification of the LPFS descriptions and confirms the results from surveys in which the items of the LPFS were directly assessed with respect to different severity concepts as well as social (un)desirability (Leising et al., 2018; Zimmermann et al., 2012). On the other hand, several location parameters emerged that deviated somewhat from this general pattern. For example, location parameters of the items for moderate, severe, and extreme impairment in subcomponents of identity (i.e., sense of self, self-esteem and accurate self-perception) and self-direction (i.e., self-reflective *functioning*) were all uniformly at the dysfunctional pole of the latent continuum, suggesting that, on average, raters did not capture the subtle differences in severity that the descriptions were intended to convey. Further studies are needed here to refine the LPFS descriptions accordingly, if necessary.

Second, strictly speaking, the AMPD does not mention clearly delineable factors in Criterion A, but rather "components" or "elements" that are described as "reciprocally influential and inextricably tied" (*DSM-5*, p. 772). This assumption is consistent with the high internal consistency of LPFS ratings, as interpenetrating elements should lead to strong positive correlations. However, the question arises whether factor analyses targeting relative stable differences between persons are sufficient or even appropriate to investigate such an assumption. Here, it would probably be useful to work with longitudinal studies to look at the reciprocal interrelationships of these elements within individuals over time; that is, to model the internal structure of personality functioning as a developmental process. To date, there is only one study using a 12-item version of the LPFS on a daily basis over 14 days that found clear evidence for a unidimensional latent structure at the within-person level (Roche, 2018). Studies that span longer time periods and test reciprocal, time-lagged effects between components do not yet exist.

### **Convergent Validity**

Convergent validity concerns the question of whether ratings of personality functioning are highly correlated with other measures of the same or similar constructs. The most obvious test for this is to assess personality functioning according to the LPFS with two different measures and determine their correlation. Here, substantial correlations have been shown in the vast majority of studies to date, both between LPFS expert or informant ratings and self-report measures (Heissler et al., 2021; Nelson et al., 2018; Ohse et al., 2021; Roche et al., 2018; Roche & Jaweed, 2021; Somma et al., 2020; Weekers, Verhoeff, et al., 2021) as well as between different self-report measures (Bliton et al., 2021; McCabe et al., 2021a; Roche & Jaweed, 2021; Somma et al., 2020). An exception with null findings is a study with forensic patients, although here the sample was very small (Hutsebaut et al., 2021).

Substantial associations with numerous measures of similar constructs were found for otherreports of the LPFS. These studies are summarized in the left column of Table 25.4. For example, strong associations were found with established measures of impairments in personality functioning and PD severity, including number of PD diagnoses according to DSM-IV or psychodynamic conceptualizations of personality dysfunction. Additionally, studies have examined associations with more-distant constructs and indicators that do not directly support convergent validity of the LPFS as an expert rating but highlight its scientific and clinical relevance. These include associations with short-term risk, proposed treatment intensity, and estimated prognosis (Morey et al., 2013) and prior treatment for mental health problems (Cruitt et al., 2019), as well as risk of dropping out of residential treatment (Busmann et al., 2019). There are also studies linking LPFS ratings to biological parameters, such as intralimbic resting-state functional connectivity (Traynor et al., 2021). By contrast, no associations emerged with various measures of **Table 25.4** Studies on the association between self- or other-reported impairments in personality functioningand measures of related clinical constructs

Other-reports	Self-reports
<ul> <li>Presence/number of PD diagnoses/criteria according to <i>DSM-IV</i> (Buer Christensen, Hummelen, et al., 2020; Cruitt et al., 2019; Dereboy et al., 2018; Di Pierro et al., 2020; Few et al., 2013; Hutsebaut et al., 2017; Morey et al., 2013; Preti et al., 2018; Zimmermann et al., 2014)</li> <li>Psychodynamic conceptualizations of personality dysfunction (Kampe et al., 2018; Ohse et al., 2021; Preti et al., 2018; Ruchensky et al., 2021; Zettl et al., 2020; Zimmermann et al., 2014)</li> <li>Self-reported personality pathology (Cruitt et al., 2019; Hutsebaut et al., 2017; Quilty et al., 2021)</li> <li>Impairments in psychosocial functioning (Buer Christensen, Eikenaes, et al., 2020; Morey et al., 2013)</li> <li>Complex posttraumatic stress disorder and disturbances in self-organization (Møller et al., 2021)</li> <li>Substance use history (Cruitt et al., 2019)</li> <li>Mental and physical health problems (Cruitt et al., 2019)</li> <li>Social and relational maladjustment (Cruitt et al., 2019)</li> <li>Symptom distress (Few et al., 2013; Hutsebaut et al., 2017; Zettl et al., 2020)</li> </ul>	Impairments in personality functioning and PD severity (Bach & Anderson, 2020; Brown & Sellbom, 2020; Gamache et al., 2019; Hemmati et al., 2020; Hopwood et al., 2018; Hutsebaut et al., 2016; Jauk & Ehrenthal, 2021; Morey, 2017; Oltmanns & Widiger, 2019; Sleep et al., 2019; Sleep et al., 2020; Weekers et al., 2019) Borderline PD symptoms (Gamache et al., 2019; Goth et al., 2018; Rishede et al., 2021) Low self-esteem (Gamache et al., 2019) Suicidality (Bach & Anderson, 2020; Roche & Jaweed, 2021) Subjective emptiness (Konjusha et al., 2021) Impairments in mentalizing (Müller, Wendt, Spitzer, et al., 2021; Müller, Wendt, & Zimmermann, 2021; Rishede et al., 2021) Low emotional intelligence (Jauk & Ehrenthal, 2021) Narcissism and aggression (Gamache et al., 2019) Psychopathy (Persson & Lilienfeld, 2019) Intimate partner violence (Munro & Sellbom, 2020) Eating pathology (Biberdzic et al., 2021) Childhood adversity (Back et al., 2020; Gander et al., 2020) Maternal bonding impairment (Fleck et al., 2021) Maladaptive schemas (Bach & Anderson, 2020; Bach & Hutsebaut, 2018) Immature defenses (Roche et al., 2018) Insecure attachment (Gander et al., 2020; Huprich et al., 2018; Roche et al., 2018) Interpersonal dependency (Huprich et al., 2018) Interpersonal problems, sensitivities, motives, and efficacies (Dowgwillo et al., 2018; Hopwood et al., 2018; Roche et al., 2018; Roche & Jaweed, 2021; Stone et al., 2020) Symptom distress and health problems (Bach & Hutsebaut, 2018; Gamache et al., 2019; Gamache, Savard, Lemieux, & Berthelot, 2021; Hutsebaut et al., 2016; Roche & Jaweed, 2021; Sleep et al., 2019; Sleep et al., 2020; Stover et al., 2020; Weekers et al., 2019; Sleep et al., 2020; Stover et al., 2020; Weekers et al., 2019) Low well-being (Bach & Hutsebaut, 2018; Gamache et al., 2019; Huprich et al., 2018; Nelson et al., 2018; Stover
	et al., 2020)

*Note*: Other-reports include LPFS ratings from experts, laypersons, and informants, partly based on structured clinical interviews. Self-reports include LPFS self-ratings or self-report measures summarized in Table 25.2. Note that studies on the association between impairments in personality functioning (Criterion A) and maladaptive personality traits (Criterion B) were omitted.

narrative coherence measured in life-story interviews (Dimitrova & Simms, 2021).

Initial validation studies of self-report measures based on LPFS also indicated substantial convergence with established measures of impairments in personality functioning and PD severity as well as with a number of constructs from the clinical literature (see right column of Table 25.4). Additionally, from the perspective of basic research in personality psychology, it is relevant that self-report measures assessing personality functioning generally exhibit a profile of correlations with Big Five personality traits that is typical for PDs in general (Saulsman & Page, 2004). This profile consists of negative correlations with emotional stability, conscientiousness, extraversion, and agreeableness, among which the negative correlation with emotional stability is usually the strongest (Hopwood et al., 2018; McCabe et al., 2021a; Oltmanns & Widiger, 2019; Sleep et al., 2020; Stone et al., 2020; Stricker & Pietrowsky, 2021). However, for informant reports, these correlations are sometimes extremely high (e.g., observed associations with low emotional stability and agreeableness approached .80; Morey, 2018), which corresponds to an overall less-differentiated personality description among informants (Beer & Watson, 2008). Also conceptually relevant are findings that impairment scores on self-report measures of personality functioning decrease with age in representative samples from the general population (Spitzer et al., 2021). This is consistent with theories and findings on the maturation of personality over the life span (Bleidorn et al., 2013). Finally, there are also initial studies exploring the correlates of impairments in personality functioning with intensive longitudinal designs in everyday life. For example, results across studies showed that individuals experience more negative affect and less positive affect in everyday life as self-reported impairment increases (Heiland & Veilleux, 2021; Ringwald et al., 2021; Roche, 2018). Additionally, individuals with high levels of personality dysfunction also reported corresponding problems in everyday life (Roche et al., 2016; Roche et al., 2018), experienced less affiliative and dominant behaviors and perceived less affiliation in others (Ringwald et al., 2021), and experienced more intense stressors and more invalidation by others (Heiland & Veilleux, 2021). One study found an indication that high levels of personality dysfunction are generally associated with more instability in experience and behavior (Ringwald et al., 2021), although this was not confirmed in another study (Roche et al., 2016).

### Discriminant and Incremental Validity

Discriminant validity refers to the question of whether ratings of personality functioning differ sufficiently from measurements that refer to other constructs. This aspect of validity is not so easy to assess. On the one hand, of course, some variables do not correlate with personality functioning. For example, associations between the LPFS-BF total score and gender were found to be approximately zero in representative samples (Spitzer et al., 2021), suggesting that different levels of severity are distributed independently of the gender of the person. On the other hand, numerous studies listed in Table 25.4 show that other-reports of LPFS, as well as corresponding self-report measures, are indeed substantially correlated with measures of a wide variety of other clinical constructs. Such correlations can make sense from a theoretical perspective: for example, it could be that impairments in personality functioning and

in physical health correlate because they share common causes or influence each other. In some cases, it is also the case that the other constructs are nothing more than subsets of personality functioning and, to that extent, overlap in their definitions (e.g., low self-esteem, impaired mentalization). Against this background, it becomes clear that it often makes little sense to expect low correlations with measures of other clinical constructs.

However, what might be an important test of discriminant validity from the perspective of the developers of the LPFS is to examine whether the LPFS ratings are specific to PD. This kind of question can be addressed in two ways: by ascertaining whether LPFS ratings are more pronounced in patients with traditional PD diagnoses than in both healthy controls and patients with other diagnoses and by ascertaining whether LPFS ratings correlate more strongly with the number of PD criteria fulfilled than with nonspecific symptomatic burden. There are now a few studies that have demonstrated specificity for PD for expert-based LPFS ratings (Di Pierro et al., 2020; Heissler et al., 2021; Hutsebaut et al., 2017; Ohse et al., 2021). However, this pattern is less clear for self-report measures as correlations with various symptom measures related to other mental disorders such as depression or anxiety are often only slightly lower (Sleep et al., 2019, 2020), or even equal (Spitzer et al., 2021) to correlations with PD measures. A similar conclusion was reached in a study by McCabe et al. (2021b), in which a general factor of PD (g-PD) defined using the LPFS-SR and DLOPFQ total scores, among other measures, was correlated with a broadly defined general factor of psychopathology ("p factor"). The authors found a latent correlation of .94, suggesting that, at least in self-reports, there is little specificity of the LPFS for PD. Put another way, the relevant self-report measures arguably capture impairments that are relevant to all mental disorders.

Incremental validity addresses the question of whether ratings of personality functioning provide additional information for predicting various clinically relevant experiences and behaviors (i.e., information that is not included in other measures). The question of the specificity of the LPFS for PD can also be formulated from the perspective of incremental validity: Here, it would then be necessary to examine whether LPFS ratings predict the presence and severity of PD when controlling statistically for nonspecific symptom burden or comorbid mental disorders. This has indeed been shown for other-reports of the LPFS (Preti et al., 2018; Zimmermann et al., 2014). Other important application scenarios for testing incremental validity include whether LPFS measures contain additional information relative to categorical PD diagnoses or general personality traits. For example, Morey et al. (2013) demonstrated that expert ratings of LPFS predicted psychosocial functioning, short-term risk, proposed treatment intensity, and estimated prognosis when categorical PD diagnoses were statistically controlled. This was confirmed by Buer Christensen, Eikenaes et al. (2020) with respect to self-reported and clinician-rated psychosocial functioning. In addition, one study suggests that the LPFS total score predicts several specific PDs according to DSM-IV as well as health- and relationship-related indicators when controlling for general personality traits (Cruitt et al., 2019). Incremental validity over general personality traits in predicting specific PDs according to DSM-IV was also confirmed for the LPFS-SR as a self-report measure (Sleep et al., 2020).

### Clinical Utility

A classification system for PD must be not only valid but also clinically useful in order to be applied in practice. Clinical utility is a complex concept that, when understood very broadly, also includes aspects of validity (e.g., meaningful conceptualization of the disorder and mapping of prognostically relevant information; First et al., 2004; Keeley et al., 2016). More narrowly, this refers to how easily the system can be used in practice by clinicians, to what extent it facilitates communication between different stakeholders (e.g., between different clinicians or between clinicians and patients or relatives), and also to what extent it supports clinicians' treatment planning (Mullins-Sweatt & Widiger, 2009). Such aspects have already been illustrated for the AMPD with numerous case reports (Bach et al., 2015; Pincus et al., 2016; Schmeck et al., 2013; Skodol et al., 2015; Weekers et al., 2020) and summarized in reviews (Bach & Tracy, 2021; Hopwood, 2018; Milinkovic & Tiliopoulos, 2020).

An important method for exploring clinical utility is to conduct consumer surveys that ask clinicians directly about aspects of a diagnostic system's utility after having used the system on case vignettes or real patients. Bornstein and Natoli (2019) conducted a meta-analysis of such studies, two of which also referenced the AMPD (Morey et al., 2014; Nelson et al., 2017). In the meta-analysis, dimensional approaches were found to be more useful than categorical diagnosis in DSM-IV or DSM-5 Section II in terms of communicating with the patient, formulating a therapeutic intervention, and describing the specific problems and overall personality of the patient. The study by Morey et al. (2014), which builds on assessments of utility from 337 clinicians and also allows specific statements about the LPFS as a severity rating based on a single item, seems particularly relevant. Here, the LPFS was found to be more difficult to apply and less useful in terms of communication with colleagues but at least on par with DSM-IV PD diagnoses in terms of the other aspects of clinical utility. Psychologists (but not psychiatrists) even perceived advantages with the LPFS over DSM-IV PDs. Positive evaluations were also obtained when asking students about clinical utility after they applied the LPFS to multiple case vignettes (Garcia et al., 2018).

A qualitative study of the learnability and usefulness of the SCID-AMPD Module I with Norwegian clinicians concluded that this interview was more likely to meet clinicians' interests and needs than were categorical diagnostic interviews (Heltne et al., 2021). For example, it was mentioned positively that the SCID-AMPD Module I provides dimensional assessments and focuses on important topics not explicitly asked elsewhere, thereby helping patients to feel seen and understood. At the same time, certain challenges and limitations were identified, including high requirements for theoretical knowledge and some interview questions that were difficult to understand or could be experienced as confrontational. The authors also recommended the development of more specific guidelines for training.

Additionally, there are other areas and methodological approaches to clinical utility that have not yet been explored for the LPFS. For example, Weekers, Hutsebaut, and Kamphuis (2021) have indicated that consideration of patient strengthslargely missing from traditional diagnostic systemsis a welcome aspect in terms of clinical utility. In this regard, the explicit description of a healthy personality in level 0 of the LPFS could be an advantage. It was also emphasized that patients themselves should be involved in the process of utility assessment. Here, complementary domains include, in particular, the extent to which the diagnosis is associated with less stigma (e.g., is respectful of the whole person and promotes self-acceptance) and is conducted collaboratively (Weekers, Hutsebaut, & Kamphuis, 2021). From a methodological perspective, it is also important to consider that consumer surveys are insufficient to demonstrate that a particular form of assessment actually improves clinical care (Kamphuis et al., 2021; Lewis et al., 2019). Future studies should therefore both examine aspects of client utility of the LPFS and employ stronger designs such as randomized clinical trials to demonstrate the utility of the LPFS for treatment.

### **Controversies, Questions, and Next Steps**

### Relationship to Maladaptive Personality Traits (Criterion B)

In the AMPD, in addition to Criterion A, there is also a Criterion B, which is used to determine the individual expression of PD (see Chapter 26 in this volume). To this end, a hierarchical model of maladaptive personality traits was developed based on empirical analyses (Krueger et al., 2012). At a higher level, the model includes five broad trait domains: negative affectivity, detachment, antagonism, disinhibition, and psychoticism. At a lower level, these domains are further specified by 25 trait facets. Disinhibition, for example, is subdivided into (a) irresponsibility, (b) impulsivity, (c) distractibility, (d) risk-taking, and (e) low rigid perfectionism. For a diagnosis of PD, in addition to moderate impairments in personality functioning, at least one maladaptive personality trait or facet must be clinically significant.

One controversy regarding the AMPD is whether impairments in personality functioning (Criterion A) and maladaptive personality traits (Criterion B) provide redundant information (for conceptual discussions, see Bender, 2019; Bornstein, 2019; Leising et al., 2018; Meehan et al., 2019; Sharp & Wall, 2021; Sleep et al., 2021; Widiger et al., 2019). From a semantic perspective, Criteria A and B share a focus on describing socially undesirable features (Leising et al., 2018), and differences appear to be primarily due to theoretical traditions and the level of inference (Mulay et al., 2018). From an empirical perspective, there is also strong evidence that measures of Criterion A and Criterion B are highly correlated, and, to that extent, discriminant validity tends to be low (Bach & Anderson, 2020; Bach & Hutsebaut, 2018; Few et al., 2013; Gamache et al., 2019; Garcia et al., 2021; Hopwood et al., 2018; Huprich et al., 2018; McCabe & Widiger, 2020; Nelson et al., 2018; Ohse et al., 2021; Roche et al., 2018; Roche & Jaweed, 2021; Sleep et al., 2019, 2020; Stover et al., 2020). Moreover, previous findings regarding incremental validity have been mixed and can be interpreted in various ways. On the one hand, there are numerous studies demonstrating

incremental validity of severity ratings compared to maladaptive traits, for example, in predicting PDs according to DSM-IV (Cruitt et al., 2019; Sleep et al., 2019, 2020; Wygant et al., 2016), personality dynamics in daily life (Ringwald et al., 2021; Roche et al., 2016; Roche, 2018), symptom distress (Bach & Hutsebaut, 2018; Roche & Jaweed, 2021), substance use and physical health (Cruitt et al., 2019), well-being (Bach & Hutsebaut, 2018; Huprich et al., 2018), maladaptive schemas (Bach & Hutsebaut, 2018), interpersonal dependence (Huprich et al., 2018), and physical violence (Leclerc et al., 2021). On the other hand, the effect sizes are, though statistically significant, often small, and some studies have found no incremental value for severity ratings in predicting PDs according to DSM-IV (e.g., Few et al., 2013).

Exemplary of these complex findings is the study on informant ratings by Zimmermann et al. (2015), described above. In this study, the 25 trait facets of Criterion B were analyzed together with the 12 subcomponents of Criterion A using exploratory structural equation modeling. A total of seven factors emerged, with two factors roughly mapping impairments in self and interpersonal functioning from Criterion A and another five factors mapping largely maladaptive traits from Criterion B. However, there were also deviations from the theoretical mapping in the AMPD: for example, impairments in self-functioning showed specific associations with the trait facets depressiveness and separation anxiety; impairments in interpersonal functioning showed specific associations with the trait facets grandiosity and callousness; and detachment showed specific associations with impairments in the personality functioning subcomponent depth and duration of connections. In later self-report studies, a similar differential pattern of association was found whereby components of self-functioning correlated particularly strongly with facets of negative affectivity and components of interpersonal functioning correlated particularly strongly with facets of antagonism (e.g., Sleep et al., 2019, 2020). An important implication of these findings is that the classification of some content under the rubric of Criterion A or B seems somewhat arbitrary, or at least cannot be justified on the basis of the pattern of empirical covariation. For example, the Criterion B facet depressiveness could also be understood as a specific impairment of the self, and the Criterion A subcomponent depth and duration of connections could be reinterpreted as an indicator of detachment.

The implications of these findings for a future revision of the classification system are controversial. A more conservative conclusion would be that the two criteria reflect the same phenomena from two different clinical perspectives and traditions, both of which are clinically useful and justified. However, there are also critical perspectives that find the lack of parsimony problematic: while some scholars argue that Criterion A can be dropped due to its low incremental validity (Sleep et al., 2019), other scholars suggest replacing the pathological personality traits of Criterion B with normal personality traits (e.g., the Big Five) to better capture the stylistic expression of personality regardless of the severity of the disorder (Leising & Zimmermann, 2011; Morey et al., 2020).

In our view, the results at least underscore the need for a clearer conceptual justification of how and why the phenomena currently described in Criteria A and B should be distinguished from one another and how they relate to one another. For example, if maladaptive traits are viewed as behaviorally anchored expressions of underlying impairments in basic internal capacities (e.g., Sharp & Wall, 2021), some degree of substantive overlap might be warranted as Criterion A would essentially serve as an explanation for Criterion B (e.g., a person tends to behave callously because his or her capacity for empathy is impaired; Zimmermann et al., 2015). However, other authors prefer conceptualizations that work the other way around; for example, by understanding dysfunctions as negative consequences or characteristic maladaptations of basic personality dispositions (cf. Clark & Ro, 2014; Leising & Zimmermann, 2011; Widiger & Mullins-Sweatt, 2009). These conceptual issues form the core of our understanding of personality pathology and have crucial implications for the selection of assessment methods. They are unlikely to be resolved completely with empirical studies and require conceptual clarity and argumentative precision.

### Relationship to Severity in ICD-II

Meanwhile, a new model for the classification of PD in *ICD-11* has also been finalized and will come into effect in 2022 (Reed et al., 2019). This model follows the AMPD in some key respects: for example, the general features of PD are again identified in terms of long-standing problems in self and interpersonal functioning; a primary classification of severity is made, ranging from subthreshold personality difficulties to mild and moderate to severe PD; and salient personality traits can be specified, including negative affectivity, detachment, dissociality, disinhibition, anankastia, and a borderline pattern (Bach & First, 2018; Mulder & Tyrer, 2019). Specifically related to the determination of severity, a high degree of substantive agreement with the LPFS can be observed: for example, severity in the *ICD-11* model is determined based on the extent and pervasiveness of dysfunction of the self (e.g., identity, self-esteem, accuracy of selfview, self-direction) and relationships (e.g., interest in relationships, perspective-taking, intimacy, conflict resolution).

There are, however, also a few minor differences. First, the extent, pervasiveness, and chronicity of additional maladaptive experiences and behaviors are to be considered, such as emotion perception and expression, accuracy of situational appraisals, decision-making ability under uncertainty, impulse control, and stress resistance. While some of these aspects are also considered in the LPFS (e.g., impairments in the experience and expression of emotions are understood as a subcomponent of identity in the LPFS), others are not explicitly listed there (e.g., stress resistance). Second, the ICD-11 model explicitly considers the degree to which these characteristics are associated with distress or impairment in different domains of life. Thus, in a sense, severity in the ICD-11 model is defined both in terms of impairments of internal abilities related to the self and interpersonal relationships and in terms of negative psychosocial consequences in everyday life. Finally, in the descriptions of the different severity levels of PD, the aspect of harm to self and others plays a greater role than in LPFS.

Research on the severity of PD according to ICD-11 is still in its infancy. Most studies to date on this topic have been based either on reanalysis of archival data (e.g., Tyrer et al., 2014) or on instruments or rating systems that were based on a preliminary version of the ICD-11 model (e.g., Kim et al., 2014; Olajide et al., 2018). One example is the Standardized Assessment of Severity of Personality Disorder (SASPD; Olajide et al., 2018), which should be understood as an index of PD complexity (in terms of exhibiting traits from different PD trait domains) rather than a unidimensional scale of functional impairment. In fact, there are currently only two studies in which severity has been assessed according to the final ICD-11 definition using new self-report measures (Bach et al., 2021; Clark et al., 2021). For the 14-item Personality Disorder Severity ICD-11 (PDS-ICD-11; Bach et

al., 2021) scale, there was a correlation of .68 with the total LPFS-BF score in a sample from the general population. When accounting for the influence of measurement error pushing this estimate downward, this initial result suggests that severity measures based on AMPD and *ICD-11* are highly overlapping in self-report and may be nearly impossible to differentiate. For a more definite evaluation of the conceptual and empirical similarities and differences of the two systems with respect to severity, further studies, preferably using multiple measures and methods, will be required.

### Further Development of Assessment Methods

As noted above, the inclusion of Criterion A in the AMPD has led to the development of several new self-report measures (see Table 25.2). Additionally, there are numerous other self-report instruments on personality functioning that have been developed previously (e.g., SIPP-118, GADP), that are aligned with the ICD-11 model for PD (e.g., SASPD, PDS-ICD-11), or that are based on psychodynamic concepts (e.g., OPD Structure Questionnaire; Ehrenthal et al., 2012). Although this is a comfortable situation that expands the choices available to researchers and practitioners, it has the disadvantage of an increasing lack of standardization. The new measures differ in a number of ways (e.g., underlying theoretical conceptualizations, emphasis on different aspects of the construct, length, precision, etc.), and one of the main challenges is that data obtained with different measures are difficult to compare. Despite their semantic similarities (Waugh et al., 2021) and their usually high intercorrelations, it is not clear whether these measures assess the same construct and how the scores obtained from them can be compared.

One possibility is to use IRT to calibrate different measures against a common metric. Zimmermann et al. (2020) followed such an approach in a sample from the general population. A common IRT model was estimated based on data from six widely used self-report measures or their short forms to link item responses to an underlying general factor. Measures based on Criterion A of the AMPD (i.e., LPFS-SR and LPFS-BF 2.0) were used, as well as a measure of Criterion B and measures based on psychodynamic concepts and on an early version of the ICD-11 model (i.e., SASPD). The results suggest that all measures capture a strong common factor and can therefore be scaled along a single latent continuum. The common factor was largely defined by impairments in self and interpersonal functioning, with a slight predominance of internalizing personality pathology (e.g., anxiety, low self-esteem). This suggests that the severity of PD based on psychodynamic concepts, Criterion A and Criterion B of the AMPD, and the *ICD-11* are largely consistent when implemented in a self-report format.

To be able to use the measures for the assessment of individual cases in routine practice, the development of norm values is crucial. The common metric study described above provides preliminary norms for each of the six measures based on the German general population (Zimmermann et al., 2020). For individual cases, practitioners can use the Web platform (http://www.common-metrics.org/) to estimate T scores, including 95% confidence intervals. In this way, an individual's general severity of PD can be interpreted as a deviation from the average case and measurement error can be explicitly accounted for. However, it is important to note that, in this study as in most other studies on the development of norm values, the representativeness of the sample could only be established to a limited extent (e.g., only with respect to age and gender). Other aspects such as education, regional origin, and use of medical and psychotherapeutic treatments may be biased, especially in online samples compared to the general population, which is why norm values from high-quality recruited random samples may differ significantly (Spitzer et al., 2021).

In addition to the development of norm values, there is also the possibility of empirically establishing thresholds based on external criteria. DSM-IV PD diagnoses in cross-sectional data have been mainly used for this purpose so far (e.g., Buer Christensen, Hummelen, et al., 2020; Gamache, Savard, Leclerc, et al., 2021). Indeed, as noted above, DSM-IV PD diagnoses were used in the development of the threshold of level 2 on the LPFS itself (Morey et al., 2013). This approach is understandable insofar as it ensures continuity with previous categorical systems. However, in light of the criticism of the arbitrary thresholds of the categorical system, there is also something circular about this approach. In our view, it would be desirable to use longitudinal studies to calibrate multiple cutoff values for severity based on the likelihood of future critical life outcomes and adverse consequences.

In addition to integrating and standardizing self-report measures, we should also be concerned with developing and optimizing other assessment methods. For example, the very high interrater reliability of LPFS ratings based on structured interviews such as SCID-AMPD Module I (see Table 25.3), as well as the sometimes very high agreement with self-reports, can be viewed critically. The very high interrater reliability is probably also due to the funnel structure of the interview, through which an outside person can easily guess the implicitly associated rating based on the interviewer's jumping to certain interview sections. The high degree of agreement with the self-report may also be due to the fact that some of the questions are very direct and the answers thus largely reflect the self-presentation of the interviewee. In this respect, further research should be conducted to determine the extent to which more open-ended interview strategies, as in CALF, are associated with lower interrater reliability but may have greater incremental validity in predicting clinically relevant outcomes compared to self-report. Finally, it would also be useful to give greater consideration to the possibility and appropriateness of maximal-effort tests to capture personality functioning. If one takes seriously the understanding of Criterion A in terms of impairments in internal mental capacities (Sharp & Wall, 2021), the development of a test battery to measure performance on tasks requiring self and interpersonal skills would be the logical next step (e.g., Jauk & Ehrenthal, 2021; Leising et al., 2011; Olderbak & Wilhelm, 2020).

### Conclusion

With the introduction of a severity scale for PD in the AMPD, several criticisms of the current categorical classification system for PD have been successfully addressed. A severity scale better captures the dimensional nature of individual differences in impairment, better accounts for empirical findings of high comorbidity and the substantial general factor in PD diagnoses, allows more efficient determination of prognosis and change, and contributes to destigmatization of the diagnosis. In particular, the LPFS as a concrete operationalization of severity ensures reference to the common denominator of all PDs in Criterion A, and the focus on impairments in the domain of self and interpersonal relationships builds on both empirical and conceptual arguments. Since the official publication of the AMPD in 2013, researchers have begun to explore the reliability, validity, and utility of the LPFS and derived measures. Results from numerous empirical studies are now available and are generally promising: interrater reliability is good for structured interviews, subcomponent ratings can be modeled by two highly correlated factors of impairments in self and interpersonal functioning (which is compatible

with the assumption of a strong general factor), ratings correlate highly with measures of similar severity measures in PD, there is evidence of incremental validity over categorical PD diagnoses, and clinical utility is mostly viewed positively by practitioners. At the same time, the issue of discriminant validity against nonspecific distress or other mental disorders, as well as against Criterion B, continues to be controversial and may also require conceptual clarifications or adaptations of the LPFS. For future empirical research, it is particularly desirable to move beyond the widely used monomethod studies that dominate the literature to date (Zimmermann et al., 2019). This includes the joint assessment of multiple constructs by multiple methods, allowing for the investigation of construct-level associations while controlling for shared method variance (e.g., multitrait-multimethod designs; Campbell & Fiske, 1959). Additionally, intervention studies should be conducted that focus on severity as a predictor, moderator, and endpoint of treatment effects. Currently, there is only one study showing that the LPFS-BF 2.0 can be used as an outcome measure in a 3-month residential treatment program (Weekers et al., 2019). In any case, with the prioritization of severity in the ICD-11 model for PD, there is no doubt that the DSM-5 LPFS and its derived measurement tools will continue to have an important place in PD diagnosis and research.

### Acknowledgments

We thank Bo Bach, Paul Blaney, Kirstin Goth, Benjamin Hummelen, Joost Hutsebaut, André Kerber, Anne Lehner, Sascha Müller, and Carina Remmers for helpful feedback on an earlier draft of this chapter.

# The DSM-5 Maladaptive Trait Model for Personality Disorders

Colin D. Freilich, Robert F. Krueger, Kelsey A. Hobbs, Christopher J. Hopwood, *and* Johannes Zimmermann

The classification system, or taxonomy, for personality disorders (PDs) has vast clinical significance. To explore just how pervasive the influence of the taxonomy is, consider what purpose an individual PD diagnosis serves. Diagnosis provides a common nomenclature between clinician and patient, prior clinician and new clinician, patient and support group, and many other transactions. In that way, diagnosis facilitates communication and allows for information retrieval. With a specific diagnosis, a clinician can quickly locate information about relevant treatment or illness course. Indeed, informing treatment may be the most fundamental clinical purpose of PD diagnosis.

More generally, diagnosis aids prediction. Not only should a diagnosis predict what treatment is likely to be efficacious, but also, for instance, what further risk factors should be avoided, what occupations may be suitable, or what outcomes should be expected. In addition, a diagnosis does not exist in a vacuum but rather in a complex sociopolitical landscape. For example, a diagnosis may serve administrative purposes, such as access to insurance coverage for specific interventions or requisite student accommodations.

Classification systems, such as *DSM-5*, must serve purposes beyond those directly relevant to an individual diagnosis. A taxonomy of PDs influences and organizes research by providing a descriptive basis for the science. Indeed, that descriptive basis frames research on the etiology, treatment, and course of similar cases, eventually leading to the development of scientific theories. These insights in turn influence the type of care that future patients with the relevant diagnoses receive. It stands to reason that a diagnostic system could be evaluated on how well it serves these various purposes. To what extent do the diagnoses within a taxonomy inform treatment decisions? How well do they predict meaningful outcomes? Do patients and clinicians find the common diagnostic language valuable and representative of their individual cases? How effective is the research built on these diagnoses at uncovering the etiology and course of pathological processes? Taxonomic choices affect patients on the smallest and largest possible scales.

#### PD Taxonomies of DSM-5

Reflecting the complexity of taxonomic decisions, *DSM-5* offers two distinct classification systems for diagnosing PDs. The first system is in Section II of the manual and "represents an update of text associated with the criteria found in *DSM-IV-TR*" (p. 645). The approach of the fourth edition of the *DSM* and its

	and Adaptive Personality

subsequent text revision (DSM-IV-TR) dates to 2000 and includes 10 putatively separate, categorical, and complex personality syndromes, each with its own criterion set. For instance, schizoid PD is defined as "a pervasive pattern of detachment from social relationships and restricted range of expression of emotions" indicated by four or more of seven symptoms, including "neither desires nor enjoys close relationships, including being part of a family," "almost always chooses solitary activities," and "takes pleasure in few, if any, activities" (pp. 652-653). In addition, the symptomatology must not be attributable to separate psychopathological diagnoses like schizophrenia. These diagnostic criteria are *polythetic*, meaning that the disorder is defined by multiple symptoms, and many different combinations of symptoms can be sufficient to meet the criteria for diagnosis. Similarly polythetic criteria are given for each of the nine other distinct syndromes: paranoid, schizotypal, antisocial, borderline, histrionic, narcissistic, avoidant, dependent, and obsessive-compulsive PDs. Finally, for cases in which symptoms are causing clinically significant distress but fail to meet the full criteria for one of the 10 specific PDs, clinicians can use the catch-all categories of "other specified" or "unspecified" PD.

*DSM-5*'s second system, the Alternative Model for Personality Disorders (AMPD), is in "Section III Emerging Measures and Models" of the manual. The AMPD is a dimensional approach built on efforts that arose primarily to address limitations of the traditional, categorical system of the *DSM-IV-TR* for classifying PDs (Zachar et al., 2016).

# Limitations of Traditional Approaches

Personality Traits as an Organizing Framework

The approach of Section II of DSM-5 has been the standard for PD diagnosis for decades, and considerable research has been generated in the interim that highlights its limitations. Perhaps the most fundamental flaw in this approach is that personality traits are not used as an organizing framework. In the first half of the twentieth century, scholars debated the importance of personality, but that period of skepticism is well behind us (Donnellan et al., 2009; Widiger, Sellbom et al., 2019). Personality traits are relatively enduring patterns of thoughts, feelings, strivings, and behaviors that distinguish individuals from each other, and they are now widely recognized as clinically significant, robustly impacting a host of outcomes like subjective wellbeing, physical health, longevity, relationship satisfaction, occupational choice and performance, values, and criminality (Ozer & Benet-Martinez,

2006; Soto, 2019). Personality psychologists have also extensively debated the structure of personality, and, by the turn of the century, it was widely agreed that the Five Factor Model (FFM) reflected a reasonable consensus regarding the broad outlines of the major organizing dimensions for understanding human personality variation. The FFM is a factor analytically derived system that describes variation in human personality in terms of the broad traits of neuroticism (vs. emotional stability), extraversion (vs. introversion), conscientiousness (vs. disinhibition), agreeableness (vs. antagonism), and openness to *experience* (or unconventionality vs. traditionalism). Although competing models of personality structure, such as the prominent six-factor HEXACO model, may differ in the number of dimensions, personality traits are widely accepted to exist along hierarchically arranged continua rather than in discrete categories (Lee & Ashton, 2016; Costa & McCrae, 1992).

Personality models like the FFM are intended to index normal, rather than pathological or "abnormal," ranges of personality, but the dimensional structure of personality appears to be largely overlapping in clinical and nonclinical populations (O'Connor, 2002). Nodding toward this research, *DSM-5* does appear to describe PDs in terms of personality traits: "when personality traits are inflexible and maladaptive and cause significant functional impairment or subjective distress do they constitute personality disorders" (p. 647). However, as in the schizoid PD example, the formal diagnostic criteria are notably written in terms of polythetic symptom lists rather than dimensional traits.

#### Continuous Distributions Versus Discrete Categories

Inherent to the tension between traditional approaches and one that uses personality as an organizing framework is the question of whether PDs are discrete entities or exist on a continuum with normal-range functioning. Evidence to date overwhelmingly supports the latter (e.g., Haslam et al., 2020). Structural research across multiple domains indicates that the structure of PD is dimensional (Trull & Durrett, 2005). As an example of this type of research, Bucholz et al. (2000) used an approach called latent class analysis (LCA), which is designed to identify the presence of classes (or types) that may underlie data indicators. They conducted a series of LCAs to assess the relative fits of categorical and dimensional models, respectively, for symptoms of antisocial PD, finding it is best measured by an underlying severity spectrum rather than by discrete

subtypes. Structural research like this has consistently shown that the boundaries in traditional diagnostic systems between pathology and normality are arbitrary (e.g., Ahmed et al., 2013; Aslinger et al., 2018; Conway et al., 2012).

#### Diagnostic Instability

In addition to creating arbitrary boundaries between pathology and normality, the imposition of categorical nomenclature (discrete PD syndromes) on naturally dimensional phenomena (maladaptive personality variation) results in diagnoses that have low reliability. Because PDs are defined to be "enduring patterns . . . exhibited in a wide range of social and personal contexts" (DSM-5, p. 647), diagnostic stability is a key concern. This is not meant to imply that personality is fixed; in fact, there is considerable evidence that personality is moderately responsive to intervention (Brown & Barlow, 2009) and general aging (Roberts et al., 2008). Although the common view that personality is unchanging across the life span has, indeed, been challenged, the short-term stability of personality traits is high (Chmielewski & Watson, 2009). Despite the high stability of personality traits, considerable PD diagnostic change is observed across all intervals, including those as short as 1 week (Clark, 2009), and, as a result, the test-retest reliability of traditional, categorical diagnoses has been demonstrated to be lower than that of dimensional assessments (Morey & Hopwood, 2013).

# Frequent PD Co-Occurrence

Unclear boundaries between disorders constitutes an additional concern. Traditional DSM-IV-TR PD syndromes have well-documented issues with comorbidity (for reviews Clark, 2007; Widiger & Samuel, 2005). An individual who meets criteria for one PD syndrome very frequently meets criteria for at least one other purportedly separate PD syndrome. Although the occasional co-occurrence of syndromes is not in and of itself problematic, the highly frequent comorbidity observed with PDs suggests that the individual symptoms or diagnostic criteria (e.g., "takes pleasure in few, if any, activities") are not assigned to syndromes based on their observed covariation in the population (Wright & Zimmerman, 2015), highlighting the need to reconsider boundaries.

# Heterogeneity Within Disorders and Clinical Utility

A consequence of using polythetic diagnostic criteria is that individuals who share the same diagnostic label may have drastically different symptom presentations. As was the case with comorbidity, this heterogeneity within disorders would not necessarily be troubling for the taxonomy if the shared label provided clinically relevant insights. In other words, a syndrome could theoretically have highly heterogenous presentations across patients as long as that diagnostic label informed treatment of these seemingly unique cases or represented an aspect of their shared etiology. However, this does not appear to be the case with traditional PD labels. Surveyed clinicians have a relatively low opinion of the clinical utility of diagnostic categories (Samuel & Widiger, 2006), further evidenced by the frequent usage of the "other specified" or "unspecified" PD diagnostic labels in many clinical settings (previously "not otherwise specified"; Verheul & Widiger, 2004). From a taxonomic perspective, the reliance on this catch-all category is troublesome as it suggests that the current diagnostic labels provide insufficient coverage and may not be valuable in informing treatment. In fact, for most traditional PDs there are no validated interventions, and there is no evidence that existing approaches have specific efficacy for individual diagnoses as opposed to general efficacy for a variety of psychiatric difficulties (Bateman et al., 2015).

#### Summary of Limitations

The issues surrounding PD categorization are not new. Indeed, Kupfer et al. (2002) summarized these limitations of the *DSM-IV-TR* approach in the *Research Agenda for DSM-V*.

Epidemiologic and clinical studies have shown extremely high rates of comorbidities among the disorders, undermining the hypothesis that the syndromes represent distinct etiologies. Furthermore, epidemiologic studies have shown a high degree of short-term diagnostic instability for many disorders. With regard to treatment, lack of treatment specificity is the rule rather than the exception. (p. xviii)

Others have been blunter in their calls to abandon traditional approaches. Widiger et al. (2002) stated, "Official diagnoses are substantially arbitrary, often unreliable, overlapping, and incomplete and have only a limited utility for treatment planning" (p. 435), and Tyrer et al. (2007) declared, "The assessment of personality disorder is currently inaccurate, largely unreliable, frequently wrong, and in need of improvement" (p. s51). The limitations of the traditional *DSM-IV-TR* PD taxonomy were well-documented in advance of the development of the fifth edition.

# **Developing an Alternative Trait Model**

As consensus developed on the limitations of traditional, categorical approaches to PD diagnosis, researchers began exploring dimensional alternatives that use personality traits as an organizing framework. Notably, Lynam and Widiger (2001) used the FFM domains and their underlying facets (e.g., gullible vs. cynical, meek vs. aggressive, soft-hearted vs. callous, and selfless vs. exploitative are facets within the domain of agreeableness vs. antagonism) to conceptualize each of the DSM-IV-TR PDs. They created trait profiles for each syndrome, and in general there was strong interrater agreement among experts on the trait translations of prototypic cases. Furthermore, these conceptualizations explained the problematic comorbidity among the PDs, in that the syndromes are comorbid to the extent to which they share FFM traits. Others explored the relations between the FFM and the PD syndromes, leading to Saulsman and Page (2004) concluding in their meta-analysis "that each disorder displays a five-factor model profile that is meaningful and predictable given its unique diagnostic criteria" (p. 1055). Building on this domain-level work, Samuel and Widiger (2008) conducted a meta-analysis at the more specific, facet-level of the FFM, further showing that the traditional PD syndromes can be understood as profiles of maladaptive variants of normal-range personality traits.

The paradigm shift from categorical diagnoses to dimensional trait conceptualizations for PDs became notable during the transition from DSM-IV-TR to DSM-5. The development of DSM-5 was preceded by three conferences that each proposed adoption of a dimensional trait model. The Nomenclature Work Group of the first "DSM-V Research Planning Conference" concluded that it would be "important that consideration be given to advantages and disadvantages of basing part or all of DSM-V on dimensions rather than categories" (Rounsaville et al., 2002, p. 13). Furthermore, they stated that PDs represented a promising initial domain that, given it is acceptable to clinicians, could lead to exploring dimensional conceptualizations elsewhere.

Subsequent conference discussions centered around how to integrate existing dimensional models. For instance, the Dimensional Assessment of Personality Pathology-Basic Questionnaire (DAPP-BQ; Livesley & Jackson, 2009) assesses

four domains, which can be readily understood as maladaptive variants of four of the five traits of the FFM (e.g., dissocial behavior as low agreeableness). Similarly, Clark's three-factor model, assessed by the Schedule for the Nonadaptive and Adaptive Personality (SNAP; Clark et al., 2017) includes a domain of negative affectivity (neuroticism) versus emotional stability, positive affectivity (extraversion) versus detachment, and constraint (conscientiousness) versus disinhibition. In addition to three domains conceptually similar to those of the SNAP, the DAPP-BQ includes a fourth domain of dissocial behavior/antagonism versus compliance (agreeableness). Widiger and Simonsen (2005) aimed to find a common ground among the various maladaptive personality trait models, arguing that they can be integrated within a common hierarchical structure with three to five broad domains, indicated by more specific facet traits. The four domains of the DAPP-BQ are representative of this integrated structure, and a fifth broad domain of unconventionality/ psychoticism versus closedness to experience (low openness) was proposed to ensure comprehensiveness.

In 2007, the APA appointed the *DSM-5* Personality & Personality Disorders Work Group, and they began to consider a wide-range of alternative PD classification approaches (Krueger et al., 2007). There was less consensus in the group than was present in the initial conferences, with various members committed to some of the *DSM-IV-TR* syndromes (Skodol et al., 2005) and others proposing an approach centered on a narrative prototype matching that had not yet been empirically studied (Samuel et al., 2012).

Simultaneously, there was still considerable interest in empirically deriving a new model that reflected the promise in the literature on dimensional trait conceptualizations. Advocates of this approach aimed to derive PD constructs based on data collected on fundamental individual difference constructs (e.g., tendencies to experience certain psychopathological states or to behave in specific maladaptive ways) rather than relying on a priori assumptions accrued through clinical experience or the collective wisdom of the group, as has often been the case in shaping psychiatric taxonomies (Krueger & Markon, 2014). The DSM-5 Maladaptive Trait Model was built in this way: first compiling constructs discussed by the Work Group, making them measurable, collecting data on their reliability and co-occurrence, and finally using that data to empirically discern the organization of the constructs through atheoretical taxonomic approaches.

The Work Group's initial literature review of a variety of instruments designed to capture pathological personality identified six broad domains of content (Krueger et al., 2011).

- Emotional dysregulation/negative emotionality/ neuroticism
- Detachment/low positive affectivity/ introversion
- Disinhibition (encompassing elements of low FFM conscientiousness)
- Antagonism (encompassing elements of low FFM agreeableness)
- Compulsivity (which has some elements of excessive FFM conscientiousness, but also appears to encompass significant elements of negative affectivity)
- Schizotypy/oddity/peculiarity/psychoticism (associated with FFM openness)

These domains are consistent with the four identified by Widiger and Simonsen (2005) and of the DAPP-BQ but also include *psychoticism* and *compulsivity* on a provisional basis subject to further empirical review.

Work Group members then generated provisional facets underlying each of these six domains. Thirty-seven potential traits were identified, and the group generated self-report items designed to measure them. Next, data were collected from three separate representative community-dwelling samples of adult participants (Krueger et al., 2012). In the first two rounds of collection, participants were sampled who reported that they had sought treatment from a psychiatrist or psychologist. In the third round, in order to examine community norms for the instrument, this inclusion criterion was not used. The research was designed to test and refine the ability to measure the facets and domains reliably in an iterative manner (via item response theory [IRT] modeling) and also to test if any highly correlated constructs could be combined. Subsequent analyses of these data led to a reduction of the 37 initial facets to a list of 25. All 25 "restructured" constructs were measured reliably by the third round of data collection, judged by both classical and modern (IRT) test theory approaches. The final version of the instrument contained 220 items with a preliminary exploratory factor analysis of the 25 facets corresponding to a five-domain structure. See Table 26.1 for the domains and underlying facet structure.

Table 26.1         DSM-5         Maladaptive Trait         Model		
Domain	Facets	
Negative affectivity	<b>Emotional Lability, Anxiousness,</b> <b>Separation Insecurity,</b> Submissiveness, Hostility <sup>a</sup> , Restricted Affectivity <sup>b</sup> , Perseveration	
Detachment	Withdrawal, Intimacy Avoidance, Anhedonia, Depressivityc, Suspiciousnessc	
Psychoticism	Unusual Beliefs and Experiences, Eccentricity, Perceptual Dysregulation	
Antagonism	Manipulativeness, Deceitfulness, Grandiosity, Attention-Seeking, Callousness	
Disinhibition	<b>Irresponsibility, Impulsivity,</b> <b>Distractibility,</b> Risk Taking, Rigid Perfectionism <sup>d</sup>	

*Note*: Boldface text indicates that items underlying this facet are used for calculating corresponding domain scores.

<sup>a</sup> Hostility cross-loads on Antagonism.

<sup>b</sup> Restricted Affectivity cross-loads on Detachment.

c Depressivity and Suspiciousness cross-load on Negative Affectivity.

<sup>d</sup> Rigid Perfectionism is keyed negatively for Disinhibition and cross-loads on Negative Affectivity.

In summary, after synthesizing existing approaches to create a preliminary questionnaire, the *DSM-5* Personality and Personality Disorders Work Group conducted analyses to arrive at an assessment instrument that encompasses the four major domains of maladaptive personality variation identified by Widiger and Simonsen (2005) and includes a fifth domain of *psychoticism* (see later section entitled "The Five Factor Model [FFM] of Personality" for further discussion on psychoticism). The instrument also includes multiple trait facets within all five domains. The 220-item instrument is named the Personality Inventory for *DSM-5* (PID-5; Krueger et al., 2012) and has been the primary tool for measuring the *DSM-5* Maladaptive Trait Model.

# Structure of the DSM-5 Alternative Model for Personality Disorders

The Work Group then aimed to develop a hybrid approach to diagnosis, integrating the maladaptive personality traits within a system that retains certain PD constructs of the *DSM-IV-TR*. Thus, the *DSM-5* Maladaptive Trait Model is just one aspect of the broader AMPD. The AMPD consists of seven criteria, listed A through G. In this model, a PD is defined as clinically significant difficulties in personality functioning (Criterion A) as expressed in high levels of at least one maladaptive personality trait (Criterion B) that are inflexible (Criterion C), stable over time (Criterion D), and not better explained by other causes (Criteria E, F, and G). The DSM-5 Maladaptive Trait Model was integrated into the AMPD as Criterion B, and thus the terms can be used interchangeably. The PID-5 operationalizes the Trait Model, but problems in functioning (i.e., a continuum of difficulties in selffunctioning, defined by identity and self-direction, and interpersonal functioning, defined by empathy and intimacy) are defined as the core of a PD and are usually measured by the Level of Personality Functioning Scale (DSM-5, p. 762).

The AMPD also provides a means for retaining 6 of the 10 diagnostic entities from the *DSM-IV-TR* PD list. Specifically, certain combinations of Criteria A and B are used to recreate and mirror antisocial, avoidant, borderline, narcissistic, obsessive-compulsive, and schizotypal PD (Table 26.2). The intent was to show how these traditional syndromes could be understood as combinations of difficulties in personality functioning and pathological traits.

In Section II, if a patient who clearly manifests a PD does not qualify for any of the 10 canonical PDs, no informative diagnosis is available as the only alternatives are "other specified," and "unspecified" PD in most cases. In contrast, the AMPD allows for an informative portrayal of every such patient under the rubric of PD "trait specified." Thus, if Criterion A is met, a "trait specified" PD designation allows the clinician to record the clinically significant trait elevations in the PID-5 domains or facets, even if the patient does not qualify for a specific Section II PD diagnosis. Personality functioning (Criterion A) and maladaptive traits (Criterion B) are conceptually distinguishable but can be challenging to separate empirically (Zimmermann et al., 2015), and their relations will be discussed in more depth later. Nonetheless, the PID-5 can stand on its own as an assessment of maladaptive personality traits and generally has been studied independently of the broader AMPD context.

Ultimately, the APA Board of Trustees had final authority over the content of the *DSM-5* and opted to retain the *DSM-IV-TR* PD criteria verbatim as the primary taxonomy (located in *DSM-5* Section II) to "preserve continuity with current clinical practice," while this AMPD was included in Section 
 Table 26.2 DSM-5 maladaptive trait constellations

 of traditional DSM-IV-TR personality disorders (PDs)

Traditional DSM-IV-TR disorder	Associated traits
Borderline personality disorder	Emotional lability, Anxiousness, Separation Insecurity, Depressivity, Impulsivity, Risk Taking, Hostility
Antisocial personality disorder	Manipulativeness, Callousness, Deceitfulness, Hostility, Risk Taking, Impulsivity, Irresponsibility
Avoidant personality disorder	Anxiousness, Withdrawal, Anhedonia, Intimacy Avoidance
Schizotypal personality disorder	Perceptual Dysregulation, Unusual Beliefs and Experiences, Eccentricity, Restricted Affectivity, Withdrawal, Suspiciousness
Narcissistic personality disorder	Grandiosity, Attention Seeking
Obsessive-compulsive personality disorder	Rigid Perfectionism, Perseveration, Intimacy Avoidance, Restricted Affectivity

*Note*: Not all of the associated traits are required to make a dimensional diagnosis; for most of the traditional PDs, just a subset of the associated traits is enough for the diagnosis. In addition to the associated traits, each traditional PD is associated with some type of impairment in personality functioning.

III for "Emerging Measures and Models" (p. 761). As a result, clinicians can use either the traditional categorical model or the newer dimensional model to diagnose patients with the DSM-5.

# **Assessing Maladaptive Traits**

The primary assessment tool for the Criterion B Maladaptive Trait Model is the PID-5. The 220item self-report PID-5 is freely available to any researcher or clinician who wishes to use it (https:// www.psychiatry.org/psychiatrists/practice/dsm/ educational-resources/assessment-measures). The inventory begins with these instructions.

This is a list of things different people might say about themselves. We are interested in how you would describe yourself. There are no "right" or "wrong" answers. So you can describe yourself as honestly as possible, we will keep your responses confidential. We'd like you to take your time and read each statement carefully, selecting the response that best describes you.

Participants are asked to choose if statements (e.g., "People would describe me as reckless") are "very false or often false," "sometimes or somewhat false," "sometimes or somewhat true," or "very or often true." Raw test responses are reversed-scored when needed and averaged to provide facet and domain scores on 4-point scales. The scores can be interpreted relative to observed norms based on the representative community samples recruited for the initial instrument development (Krueger et al., 2012). To obtain a more fine-grained understanding of the PID-5 domains and facets, full definitions for each are provided in a table on pages 779–781 of *DSM-5*.

The instrument has also been adapted into a 25-item brief form (PID-5-BF) and a 218-item informant report (PID-5-IRF) that are also freely available via the APA. In addition, it has been adapted into a 100-item short form (PID-5-SF), a 36-item modified form that includes an anankastia domain (intending to index compulsivity typically associated with obsessive-compulsive PD) that allows for compatibility with the PD taxonomy of ICD-11 (Bach et al., 2020), an adapted 100-item version that was tailored for use in forensic contexts (Niemeyer et al., 2021), and a shortened 75item informant report form (Zimmermann et al., 2015). There is also the possibility to measure the PID-5 traits from established measures such as the Personality Assessment Inventory (PAI) (Busch et al., 2017). Finally, for the purpose of expert ratings of maladaptive personality traits, researchers have developed a Personality Trait Rating Form (PTRF) that includes short descriptions of the facets to be rated on 4-point scales (Few et al., 2013). In the main form and most of the alternates, the PID-5 assesses five maladaptive trait domains and 25 underlying facets, provided in Table 26.1.

#### Empirical Research on the DSM-5 Maladaptive Trait Model

Since the PID-5 was made freely available in 2013, a vast body of research has accumulated while limited research on alternative operationalizations of the Trait Model exists. The PID-5's body of research has been summarized in at least six published reviews (Al-Dajani et al., 2016; Barchi-Ferreira Bel & Osório, 2020; Krueger & Hobbs, 2020; Krueger & Markon, 2014; Miller et al.,

2018; Zimmermann et al., 2019) and four metaanalyses (Clark & Watson, 2022; Somma, Krueger, Markon, & Fossati, 2019; Watters & Bagby, 2018; Watters, Bagby, & Sellborn, 2019). In addition, the PID-5 has been translated to and researched in at least 19 languages, including Brazilian Portuguese (Barchi-Ferreira et al., 2019), Chinese (Zhang, Wang et al., 2021), Danish (Bo et al., 2015), Farsi (Lotfi el al., 2018), Russian (Lozovanu et al., 2019), and Swedish (Kajonius, 2017). The instrument has clearly caught the interest of the field. Examination of its psychometric properties will help clarify the extent to which it measures distinct and homogeneous pathologies and, in turn, how effective it projects to be as a descriptive basis for research on specific etiologies and treatments.

# Structural Validity

The Trait Model's structural validity is integral to corresponding research on specific etiologies and treatments. Here, we analyze structural validity across three areas. First, we look at the higher order structure. Is it five rather than some other number of domains that fit the data best across a diversity of samples? Given the loadings of the items or facets, do the empirically derived latent factors resemble the proposed domains across samples? Second, we look at the lower order structure. Do the measured trait facets index a single construct (are they unidimensional)? Do they index those constructs with reasonable internal consistency? Finally, we look at how the lower order structure maps on to the higher order structure. Are the factor loadings of the facets onto the domains consistent across a diversity of samples? These types of questions represent an empirical approach to analyzing the extent to which the taxonomy accurately represents the structure of observed variation in personality pathology, or the structural validity of the Trait Model.

# **Higher Order Structure**

The 5-domain, 25-facet, factor structure of the PID-5 was derived in a representative US sample (Krueger et al., 2012). Somma, Krueger, Markon, and Fossati (2019) have noted that, through exploratory factor analysis or exploratory structural equation modelling, the 5-domain factor structure has been replicated six times in United States (e.g., DeYoung et al., 2016; Wright al., 2012) and 16 times in non-US samples, primarily using translated versions of the instrument (e.g., Lofti et al., 2018; Thimm et al., 2017). They then meta-analyzed these studies, finding highly similar factor loadings across US and non-US samples. Neither sample type, participant age, translation, nor geographic area had a significant moderating effect on model fit (Somma, Krueger, Markon, & Fossati, 2019). The 5-factor structure was also replicated in a mixed Middle Eastern sample (Al-Attiyah et al., 2017) and a Polish sample (Rowiński et al., 2019) that did not meet criteria for the meta-analysis, as well as more recent samples from Denmark (Bach et al., 2018), Singapore (Lim et al., 2019), Hungary (Labancz et al., 2020), Egypt (Aboul-ata & Qonsuo, 2021), Australia (Dunne et al., 2021), and the United States (Hyatt et al., 2021).

The factor structures of the alternate forms of the PID-5 have been studied less frequently. The fivedomain structure of the PID-5-BF was replicated in six studies and that of the PID-5-SF was replicated in three (Barchi-Ferreira Bel & Osório, 2020). Similarly, the original development of the PID-5-IRF (Markon et al., 2013) replicated the five-factor structure, but Morey et al. (2013) studied clinician ratings about their patients using the PTRF, deriving a fifth factor that resembled compulsivity rather than separate *antagonism* and *disinhibition* domains (both were subsumed under a single *externalizing* domain).

On the other hand, a four-factor solution fit the data best in a forensic sample (Niemeyer et al., 2021) using an adapted 100-item form. Once using the PID-5-BF and once using the primary 220-item form, a six-factor solution fit the data best in two Chinese samples (Zhang, Ouyang et al., 2021; Zhang, Wang et al., 2021). Finally, the five-factor solution did not display adequate fit in an Indonesian sample using the primary form (Adhiatma & Halim, 2021), indicating the need for further study in novel populations, notably in Eastern Asia. That said, the majority of evidence suggests that, in contrast to the three clusters (oddeccentric, dramatic-emotional, and anxious-fearful) which have shown limited structural validity for organizing the DSM-IV-TR PD syndromes (Sheets & Craighead, 2007), the five-domain structure of the PID-5 appears applicable and robust across US and Western European samples, with burgeoning evidence of its validity elsewhere.

# Lower Order Structure: Dimensionality and Internal Consistency.

The vast majority of PID-5 facets appear to be unidimensional across the majority of studies (Zimmermann et al., 2019), but certain facets have shown inadequate unidimensional fit in translated

forms. For instance, the risk taking facet (e.g., Somma et al., 2017) and the emotional lability facet (e.g., Gutiérrez et al., 2017) each failed to show adequate unidimensional fit across at least five samples. The manipulativeness facet failed to show adequate unidimensional fit across at least three samples (e.g., Labancz et al., 2020). Several facets were similarly heterogeneous in a Czech sample (Riegel et al., 2018), but the authors achieved adequate model fit by removing poorly discriminating items and proposed a 160-item instrument for use in Czechspeaking communities. Studies using the shortened versions are limited, but initial evidence for the unidimensionality of PID-5-BF domains is promising (Debast et al., 2017), whereas fit of the facets of the PID-5-SF was inadequate (Riegel et al., 2018). To summarize, most facets can be adequately represented as unidimensional constructs, but, without removing poorly discriminating items, some facets appear heterogeneous when applied across cultures.

After assuming a construct is unidimensional, it is important to then evaluate the extent to which several items that aim to measure the same construct produce similar responses, or its internal consistency. Across an initial literature review of 25 studies (Al-Dajani et al., 2016), a later review of 54 additional studies (Barchi-Ferreira Bel & Osório, 2020), and several studies from more diverse languages published since (e.g., Aboul-ata & Qonsua, 2021; Zhang, Wang et al., 2021), the PID-5 domain scores have demonstrated high internal consistency (indicated mainly by Cronbach's alpha coefficient) and the facet scores generally have demonstrated at least acceptable levels. Cronbach's alpha is positively influenced by the number of items in the instrument, so it is not surprising that those constructs with more indicators (the domains rather than facets) displayed higher reliability. In individual studies, certain facets do not reach acceptable levels of internal consistency (generally defined by Cronbach's alpha being under a certain threshold, which, in this case, we set at .70). However, there is little evidence that suggests a systematic pattern of low reliability of any specific facet, aside from possibly suspiciousness, which has failed to reach acceptable levels across at least five studies using translated forms of the PID-5 (e.g., Bastiaens et al., 2016; Lotfi el al., 2018).

The alternate forms of the PID-5 have been studied less frequently, but initial evidence is similarly promising. The internal consistency of domains and facets of the 100-item PID-5-SF has been evaluated across four studies each, and in only one study

611

did a facet (*impulsivity*) fail to reach acceptable levels (Ashton et al., 2017; Barchi-Ferreira Bel & Osório, 2020). The 25-item PID-5-BF only assesses domains, and it similarly had high internal consistency across nine studies (e.g., Barchi-Ferreira Bel & Osório, 2020; Zhang, Ouyang et al., 2021), with the exception of the *disinhibition* and *antagonism* domains in a study by Debast et al. (2017) and again *antagonism* in a study by Hyatt et al. (2021). Finally, the 218-item informant report (PID-5-IRF) was the subject of two studies where internal consistency was confirmed for all domains and facets apart from *impulsivity* once failing to reach acceptable levels (Ashton et al., 2017; Quilty et al., 2018).

In sum, the PID-5 seems to measure maladaptive personality traits represented in the Trait Model reliably at the domain and facet levels. Although individual facets may operate inconsistently across diverse samples, there is little evidence of systematically low reliability of any individual construct. Further work is needed to explore the reliabilities of the alternate forms of the PID-5 as well as measures of internal consistency that are less sensitive to number of items.

# Relations Between Higher and Lower Order Structure.

It is common for instruments such as the PID-5 to show interstitiality, which is evident when a facet loads on more than one domain (e.g., the facet hostility relates both to negative affectivity and antagonism). Whether or not specific patterns of interstitiality are consistent across research studies is an important window into the structural validity of the model on which the instrument is based. Watters and Bagby (2018) observed that some of the interstitial factor loadings vary significantly across samples, calling into the question the lower-order factor structure of the PID-5. For instance, Maples et al. (2015) reported that 19 of the 25 facets loaded substantively on at least two domains, whereas De Fruyt et al. (2013) found just six to be substantively interstitial. Watters and Bagby (2018) conducted a meta-analysis of the loadings across 14 samples and found that interstitiality decreased when samples were pooled, providing evidence that some of the inconsistency is likely the result of sampling error. At the same time, three facets consistently loaded more strongly onto a different domain than the original placement suggested by Krueger et al. (2012) during the construction of the instrument. These facets were hostility loading on to antagonism (rather than negative affectivity), restricted affectivity

loading on to *detachment* (rather than *negative affectivity*), and *rigid perfectionism* loading on to *negative affectivity* (rather than *disinhibition*) (Watters & Bagby, 2018).

In a follow-up analysis, *hostility* and *restricted* affectivity again loaded onto antagonism and detachment, respectively, leading the authors to recommend that they move to be considered primary indicators of those domains (Watters, Sellbom et al., 2019). Furthermore, the authors recommended that suspiciousness move from detachment to negative affectivity based on their results. Finally, the authors suggested the removal of the submissiveness facet entirely as it fails to substantively load on any domain. The findings for rigid perfectionism were mixed, so recommendations were not made. Many facets are expected to lie theoretically in between multiple domains, leading to interstitiality. As a result, only facets that are thought to be "cleaner" indicators of single domains are used to calculate domain scores. In other words, though antagonism is indicated by five underlying facets, only items that indicate the three facets that are the "cleanest" indicators of antagonism (manipulativeness, deceitfulness, and grandiosity) are used to calculate the antagonism domain score. See Table 26.1 for a summary of all "official" mappings, notable cross-loadings pointed out by Watters, Sellbom and colleagues (2019), and the facets that are used to calculate domain scores. Importantly, none of the five facets noted as potentially troublesome by Watters, Sellbom, et al. (2019) are included in the official scoring procedure for their respective domains (DSM-5, 2013), likely because of this known interstitiality.

Though more work is needed with alternate forms, the evidence suggests that the 5-domain structure of the Trait Model (measured by the PID-5) effectively parses variance in maladaptive personality traits across a wide range of populations. Although facets can sporadically be prone to differential loadings and lack of unidimensionality across diverse samples, it is difficult to identify patterns of particularly troublesome facets. That is to say, no individual facet has consistently displayed poor measurement properties or stood out as culturally bound. In addition, Riegel et al. (2018) demonstrated the promise of using IRT methods to modify translated forms for international use to overcome psychometrically troublesome facets.

# Temporal Stability

A lesser studied area is the temporal stability of the Trait Model. Recall that considerable PD diagnostic change was observed across short intervals using the traditional DSM-IV-TR taxonomy, so evidence of adequate temporal stability of the PID-5 is key for establishing a diagnostic system with test-retest reliability. Dimensional psychopathological constructs generally have displayed higher test-retest reliability when compared to categorical syndromes (Watson, 2003). In limited studies, the temporal stability of the PID-5 specifically was adequate or better in US samples (Chmielewski et al., 2017; Suzuki et al., 2017; Wright et al., 2015). For instance, Wright et al. (2015) estimated mean-level and rank-order change of the PID-5 domains and facets over two assessments separated by more than a year. For the five domains, mean-level change was measured by Cohen's d and ranged from -.17 to .00. Pearson's r measured rank-order change and ranged from .62 to .75 for the domains. These relatively high stabilities were replicated in international samples using the Arabic (Coelho et al., 2020), Portuguese (Pires et al., 2017), German (Zimmermann et al., 2017), and Indonesian (Adhiatma & Halim, 2021) translations. One study has validated the acceptable temporal stability of the PID-5-SF (Díaz-Batanerio et al., 2019), while two have done so for the PID-5-BF (Fossati, Somma, Borroni et al., 2017; Zhang, Ouyang et al., 2021). Overall, these findings are a promising development for the reliability of the Trait Model but require further replication.

#### Interrater Reliability

The unclear boundaries between DSM-IV-TR PDs made it very likely that if a patient saw two clinicians, they would receive two different diagnoses. The PTRF includes short descriptions of the PID-5 facets to be rated on 4-point scales for the purpose of expert ratings of maladaptive personality traits (Few et al., 2013). To collect this information systematically, the Structured Clinical Interview for Personality Traits (SCID-AMPD Module II) has also been developed (Skodol et al., 2018), but few researchers have used these resources to explore the interrater reliability of the PID-5. Although Trait Model materials yielded higher diagnostic reliability for case vignettes than categorical diagnoses (Morey, 2019b), overall, the PTRF has shown just fair to acceptable levels of interrater reliability (Few et al., 2013; Garcia et al., 2018). The SCID-AMPD Module II may allow for more reliable measurement, as evidenced by the excellent interrater reliability demonstrated in a study of psychotherapy outpatients (Somma et al., 2020). These initial results require further investigation but highlight the need for applying structured interviews such as the SCID-AMPD Module II for reliable measurement across raters.

# Measurement Equivalence Across and Within Cultures

The Trait Model has received considerable interest internationally, as evidenced by the plethora of PID-5 translations and psychometric research applying it to novel populations. This line of research has provided evidence that the trait domains and facets can be reliably measured and provide a reasonably valid account of the variance in responses internationally. Currently, most of the work has been done in Western Europe, but there is growing evidence of the applicability of the Trait Model in Eastern Europe, the Middle East, and Eastern Asia. However, testing for measurement invariance of the PID-5 is necessary to conclude that the same construct is being measured across groups and that scores are comparable cross-culturally.

Typically, measurement invariance is tested by comparing a sequence of increasingly restricted common factor models (Meredith, 1993). Traditionally, the first model in the sequence is a test of configural invariance. Next, a test of metric or weak invariance constrains factor loadings to equality across groups. Finally, a test of scalar or strong invariance constrains indicator intercepts to equality across groups. At each step, the fit of the nested, more constrained model is compared to the previous model. Evidence of weak invariance suggests that the latent factor or construct has the same meaning across groups because it is defined by the same indicators to same extent. Evidence of strong invariance suggests that group mean differences in indicators are attributable to differences in the latent construct because item intercepts are reasonably equivalent across groups.

In a comparison between Norwegian and US university samples, weak measurement invariance was found across all domains: that is, the factor loadings of the facets onto the domains were roughly equivalent across groups. Partial strong invariance was found, meaning the scores were invariant across groups after two facet intercepts were released from constraints (Thimm et al., 2017). Sorrel et al. (2021) built on this work, analyzing invariance across samples in Belgium, Switzerland, France, Spain, and Catalonia. Similarly, weak and partial strong invariance were found across the five samples. These results provide initial evidence that the PID-5 largely measures pathological personality

613

constructs in the same manner across the United States and Western Europe but requires replication. Examining invariance at the item level by considering if item loadings onto to facets are equivalent across populations is also necessary for valid crosscultural comparisons.

It is also important to demonstrate measurement invariance across diverse populations within a given culture. For example, strong invariance across community and clinical samples was demonstrated in Danish (Bach et al., 2018), Italian (with the Short Form; Somma, Krueger, Markon, Borroni, & Fossati, 2019), Czech (with the Czech shortened form; Riegel et al., 2018), and Chinese (with the Brief Form; Zhang, Ouyang et al., 2021) samples. Together, these findings give strong evidence that the PID-5 can be effectively used toward one of its primary goals: dimensionally measuring maladaptive traits in a manner that is comparable across severity levels. Measurement invariance across sex was established in American adult (Suzuki et al., 2019), Norwegian adult (South et al., 2017), and Italian adolescent samples, although only weak invariance was demonstrated in the latter group (Somma et al., 2017). Strong invariance was also demonstrated across a heterosexual group and a mixed homosexual and bisexual group in a US sample (Russell et al., 2017). Examinations of differential item functioning, or measurement invariance at the item level, across younger and older age groups have raised questions about whether all items are age-neutral, though many items have not displayed significant differential functioning (Debast et al., 2018; Van den Broeck et al., 2013). Thus, the limited initial evidence suggests that the PID-5 is largely invariant across age, sex, sexual orientation, sample type, and country, but each of these results requires replication. On the other hand, initial evidence suggests that the PID-5 may not be invariant across race in the United States. In a study of Black Americans and White Americans, a single-factor solution emerged for the Black American sample, indicative of covariation across all domains, thus raising questions about the instrument's applicability (Bagby et al., 2021). Additional studies should examine invariance across race and socioeconomic status within the United States.

Although it appears that most facets are applicable cross-culturally, certain facets like *suspiciousness* displayed some psychometric issues when translated and studied internationally, warranting further investigation to determine if they represent culturally bound constructs. Finally, Al-Dajani et al. (2016) note that

[i]t is important to consider that comparing translated versions of the PID-5 to the original measure for cross-cultural administration assumes that preexisting pathological personality dimensions hold the same relevance across cultures. As such, this etic approach to cultural description risks imposing pathological personality dimensions defined by Western traditions onto other cultures. (p. 69)

Indeed, etic approaches can confirm that an external structure is valid in a new culture but cannot disprove that additional or alternative domains would more parsimoniously represent traits within that culture if emically developed.

#### Convergent and Predictive Validity

Evidence of convergent validity, or how closely the Trait Model is related to other measures of the same theoretical constructs, is found by comparing the PID-5 to alternative inventories or methods. Zimmermann et al. (2019) reviewed the relevant studies and concluded that PID-5 scores have high associations with theoretically similar domains assessed by the DAPP-BQ, Computer Adaptive Test of Personality Disorder (CAT-PD), Minnesota Multiphasic Personality Inventory 2-Restructured Form (MMPI-2-RF), and Personality Assessment Inventory (PAI). The PID-5 has been found to be predictive of several clinically relevant outcomes, including self-harm (Evans & Simms, 2019), symptom distress (Zimmermann et al., 2014), disability (Díaz-Batanerio et al., 2019), quality of life (De Caluwé et al., 2019), physical illness (Waszczuk et al., 2018), child molestation (Ferretti et al., 2021), and many more (for a more comprehensive list, see Zimmermann et al., 2019). Finally, meta-analytic evidence suggests that patients and their therapists have a relatively high degree of agreement (selfother agreement) on PID-5 domain and facet scores (Oltmanns & Oltmanns, 2021). In sum, validity evidence for the Trait Model is seen in the PID-5's convergence with measures of similar domains and prediction of a wide range of clinically relevant outcomes.

#### Coverage of DSM-IV-TR PD Syndromes and Incremental Validity

Specific trait constellations of prevalent PD syndromes (e.g., borderline PD) were included in AMPD to demonstrate how a dimensional model theoretically could cover the same ground as traditional, categorical approaches. Table 26.2 displays these trait constellations. Still, consideration of a move to a dimensional trait approach raised concerns about whether any information from the existing set of PD syndromes would be lost. Accordingly, researchers have studied the extent to which the Trait Model covers the Section II or traditional DSM-IV-TR PD syndromes. For example, Morey et al. (2016) compared clinician-rated criterion counts for DSM-IV-TR PD syndromes with clinician-rated PID-5 facet and domain scores. The correlations were often quite substantial (e.g., *emotional lability* with borderline PD criteria = .75; manipulativeness and deceitfulness with antisocial PD criteria = .67 and .72, respectively). Given these associations, the authors concluded that traditional PD concepts can be adequately represented using PID-5 traits in combination with impairments in personality functioning (Morey et al., 2016). Similarly, Few et al. (2013) compared results from clinician-rated criterion counts for DSM-IV-TR PD syndromes, clinician-rated PID-5 scores, and patient self-report PID-5 scores and found that the traits explain substantial proportions of the variance in their respective traditional PD syndromes.

Rather than criterion counts for syndromes, Rojas and Widiger (2017) considered coverage of the individual diagnostic criteria. They examined correlations between the PID-5 facets and criteria for 6 of the 10 PD syndromes. For example, the *separation insecurity* facet correlated .77 with the "abandonment concerns" criterion for borderline PD. The authors concluded that the coverage was good to excellent for the borderline, antisocial, avoidant, dependent, and narcissistic PDs, but support was mixed for obsessive-compulsive PD. They also interpret their results as consistent with the relatively extensive literature confirming this strong coverage, with the exception of obsessivecompulsive PD.

Watters, Bagby, and colleagues (2019) built on this work, considering the results from 25 independent datasets. They found that the PID-5 traits showed moderate to large correlations with their traditional syndrome counterparts, with the notable exception again of obsessive-compulsive PD. This probably reflects the loss of some obsessivecompulsive traits when the *compulsivity* domain was deleted from the Trait Model (Krueger et al., 2012). These consistently strong coverages demonstrated by Watters, Bagby et al. (2019) applied to schizotypal PD and four of the five syndromes considered by Rojas and Widiger (2017): borderline, antisocial, avoidant, and narcissistic. Further evidence for the coverage of dependent PD by the PID-5 has also been demonstrated elsewhere (McClintock & McCarrick, 2017). Less frequently have researchers considered the coverage of paranoid, schizoid, and histrionic PDs, but there has been limited support for their retention (e.g., Blashfield et al., 2012), and the AMPD does not include specific diagnostic criteria for them (nor criteria for dependent PD).

Knowing that the Trait Model can largely cover many of the DSM-5 Section II PD syndromes, it is next important to consider its incremental validity (i.e., the extent to which it provides value over existing methods of assessment). Relative to the DSM-5 Section II PD syndromes, PID-5 traits have demonstrated stronger prediction of clinician treatment planning, treatment intensity, and long-term prognosis (Morey & Benson, 2016), as well PD severity (Fossati et al., 2016), psychosocial impairment (Simms & Calabrese, 2016), patient aggression (Somma, Krueger, Markon, Alajmo et al., 2019), measures of psychopathy (Anderson et al., 2014), and social cognition (Fossati, Somma, Krueger et al., 2017). The two approaches yielded about equally effective prediction of a measure of borderline personality traits (Anderson et al., 2016), while they were each more predictive of different aspects of a measure of disability (Chmielewski et al., 2017). Thus, initial evidence indicates that the Trait Model performs at least as well and usually better than categorical PD measures at predicting clinically relevant criteria.

# Clinical Utility

Morey et al. (2014) surveyed a US national sample of clinicians on various aspects of the clinical utility of the DSM-IV-TR and the Trait Model after applying both to their own patients. Clinicians rated the Trait Model to have significantly higher clinical utility across five of the six assessed domains. These domains were communication with patients, comprehensiveness, descriptiveness, ease of use, and utility for treatment planning. However, no significant differences were found regarding communication with other professionals. Nelson et al. (2017) built on this work, comparing trainee opinions about the clinical utility of four different PD diagnostic systems. They found that trainees rated the Trait Model significantly higher in most clinical utility domains, notably including the extent to which it provided a comprehensive understanding of their clients. Furthermore, initial evidence suggests that treatment-seekers have a high opinion of the accuracy and relevance of feedback they receive regarding maladaptive personality traits (Lengel & Mullins-Sweatt, 2017). Thus, initial evidence suggests that the Trait Model is thought to be useful by both clinicians and patients and provides mutually agreeable patient data.

Ease of use has been an especially pervasive concern with the Trait Model and the broader AMPD. Verheul (2012) has suggested that the AMPD's already high degree of complexity will prevent clinicians from adopting it for everyday use. On the other hand, Bach et al. (2015) and Bastiaens et al. (2021) have attempted to illustrate the PID-5's ease of use through case vignettes, qualitatively supporting the findings of Morey et al. (2014) and Nelson et al. (2017) that clinicians and trainees rate the Trait Model as easy to use relative to traditional *DSM-IV-TR* PDs and to some simpler approaches.

The PID-5 has been criticized as being heavily influenced by response styles or biases related to responders' tendencies to represent themselves in an indiscriminately positive or negative light (Ashton et al., 2017; Dhillon et al., 2017; McGee Ng et al., 2016). This relates to the fact that the PID-5 has relatively few "reverse-coded" items. Most items are positive indicators of the construct they measure. For instance, the item "I don't care if my actions hurt others" is a positive indicator for *callousness*, whereas "I would never harm another person" is a negative indicator, so it needs to be "reverse-coded" to index *callousness*. In this light, it is noteworthy that measures of symptom overreporting (Sellbom et al., 2018) and response inconsistency (Keeley et al., 2016) have been developed for the PID-5, which represent valuable additions for clinical use of the Trait Model. To further account for this limitation, Quilty et al. (2018) highlight the importance of multimethod assessment (using the informant report form) and use of the symptom overreporting scale.

Additional aspects of the clinical applicability of the Trait Model require further attention. For instance, do the 25 facets of the PID-5 adequately cover the range of pathological traits? Although seemingly providing an improvement in coverage over the polythetic categories, the Trait Model could be missing clinically relevant domains when applied to novel populations, such as domains like *Health Anxiety, Self-Harm*, and *Fantasy Proneness* captured in the CAT-PD (Yalch & Hopwood, 2016; Ringwald et al., 2021). In addition, the domain of *anankastia* is not explicitly present in most forms of the PID-5, which is an area that has

been emphasized as clinically relevant in ICD-11 (Bach et al., 2020) and may account for the poor coverage of obsessive-compulsive PD. Though there was limited support for their retention, it stands to reason that aspects of the traditional DSM-IV-TR PD syndromes that are not addressed in the Trait Model (paranoid, schizoid, histrionic, and dependent PDs) could have clinically relevant characteristics that are not captured. Finally, the traditional PDs that are addressed in the Trait Model have been demonstrated (e.g., Watters, Bagby et al., 2019) to be substantially covered by PID-5 traits (e.g., separation insecurity and submissiveness account for substantial portion of variance in dependent PD), but the portion that is not covered may also be clinically relevant and not simply the result of error variance.

Often, personality inventories, such as the PID-5, are administered to large community samples to establish normative values for each of the relevant domains (Krueger et al., 2012). These normative values, in turn, help to establish cutoff scores that ease interpretation of individual test scores in clinical practice. Rek et al. (2021) note that norms were mostly derived from samples that were not fully representative of the general population (e.g., regarding social status, education, or quality of health), and researchers have sometimes used "intuitive" cutoff scores for PID-5 domains and facets. To address this issue, they administered the PID-5 to a large representative German sample and proposed additional normative values for the domains.

Does the Trait Model enhance communication? Ease of communication has been a recurring argument against shifting to dimensional classification, as the manageable number of diagnoses in the categorical systems may be lost in a dimensional profile (First, 2005). A dimensional trait profile likely communicates more information than a single diagnostic label, but it is certainly easier to inform a colleague that a patient meets criteria for a specific syndrome. Surveyed clinicians have indicated that the Trait Model is favorable to DSM-IV-TR PD syndromes in communicating with patients, but significant differences did not exist regarding communication with other professionals (Morey et al., 2014). We theorize that communicating more information derives comparative value in many areas. For instance, with a wider array of options in their diagnostic profile, a patient may be more likely to feel accurately represented. Theoretically, this could improve therapeutic alliance, preventing the feeling of being shoehorned into a specific diagnostic box. It could also be argued, on the other

hand, that specific syndromes and support groups can create a feeling of community around a specific illness. The broader profile approach also provides (indirect) information about patient strengths, not just weaknesses. For instance, a highly agreeable, socially skilled, but disinhibited patient may score quite low the hostility and intimacy avoidance facets, highlighting that they may be able to use these interpersonal assets to compensate for maladaptive traits across other domains. At the same time, it could be argued that normal-range (rather than maladaptive) traits along with an independent measure of dysfunction (Criterion A) would provide a "fuller picture" of patient strengths and weaknesses. We discuss these issues further in the "Criterion A: Level of Personality Functioning" section.

# The DSM-5 Maladaptive Trait Model in the Context of Clinical Science

We briefly discussed the convergent validity of the Trait Model with regard to other prominent trait measures and clinical outcomes. However, this only scratches the surface. Vast bodies of research place the Trait Model in the context of other broad domains of clinical science, largely confirming that the model's maladaptive personality traits are theoretically complementary to well-validated constructs of psychopathology and normal-range personality, while their relationship to personality functioning (Criterion A) remains a contested empirical question.

# Non-PD Psychopathology

The distinction between psychopathological symptoms and maladaptive personality traits has been the subject of some debate. One view is that the fundamental difference is in timeframe: maladaptive traits are dispositional constructs related to persistent tendencies toward psychopathology, whereas symptoms are features of psychopathology during any specific time period (DeYoung et al., 2020). In response to diagnostic issues similar to those of PDs, efforts have been made to reorganize the taxonomy for all forms of psychopathology toward dimensional conceptualizations. A leading alternative approach is the Hierarchical Taxonomy of Psychopathology (HiTOP; Kotov et al., 2017). HiTOP is an evolving taxonomy, aiming to undergo revisions so that it always reflects advances in the literature on the structure of psychopathology. As of this writing, the current model includes five broad dimensional spectra of psychopathologythought disorder, disinhibited internalizing,

*externalizing, antagonistic externalizing,* and *detachment*—as well a sixth, provisional *somato-form* spectrum (Kotov et al., 2021).

The domains of the Trait Model are conceptually linked to these broad spectra. For instance, Wright and Simms (2015) conducted joint structural analyses of (non-PD) symptomatology and maladaptive traits to derive a five-factor meta-structure of psychopathology. In this model, the PID-5 domains corresponded with broad factors of psychopathology that resemble the HiTOP spectra (e.g., negative affectivity domain with internalizing, disinhibition with externalizing/disinhibition, antagonism with antagonism). Many lines of structural research have validated these broad spectra and their hierarchical organization (Kotov et al., 2017). As one such example, evidence from a large body of twin and family studies indicates that the higher order genetic structure of psychopathology aligns with the HiTOP framework (Waszczuk et al., 2020). Thus, contemporary models of psychopathology jointly organize maladaptive traits and psychopathological symptoms under broader dimensional umbrellas. The PID-5 fits neatly into this framework as a tool for measuring maladaptive traits and organizing research. Theoretical relations between the PID-5 domains, the HiTOP spectra, and the FFM are summarized in Table 26.3.

Although the Trait Model was originally conceptualized to aid in the diagnosis of PDs, this alignment suggests that it may also be useful regarding other forms of psychopathology more generally. For example, Heath et al. (2018) found that the PID-5 can aid in distinguishing between non-PD psychopathological diagnostic classes (e.g., mood disorders, substance use, psychotic disorders). Furthermore, antagonism and disinhibition are related to problematic alcohol use (Creswell et al., 2016; Zimmermann et al., 2014), while antagonism and detachment relate to risk for gambling disorder (Carlotta et al., 2015). These results are useful in explaining how broad personality dimensions underly the well-observed patterns of comorbidity between addictive syndromes and PDs, providing evidence that the Trait Model may have clinical utility regarding many forms of psychopathology.

The PID-5 traits have also been linked to internalizing psychopathology. James et al. (2015) found that *detachment* and *psychoticism* are predictive of posttraumatic stress disorder symptomatology, while *negative affectivity* and *detachment* are predictive of symptoms of major depressive disorder

Table 26.3 Theoretical relations between the PID-5, FFM, and HiTOP spectra				
PID-5 domain	FFM	HiTOP spectra		
Negative affectivity	Neuroticism	Internalizing		
Psychoticism	Openness	Thought disorder		
Detachment	Low extraversion (High Introversion)	Detachment		
Disinhibition	Low conscientiousness	Disinhibited externalizing		
Antagonism	Low agreeableness	Antagonistic externalizing		
		Somatoform (provisionally)		

*Note*: PID-5, Personality Inventory for *DSM-5* (Krueger et al., 2012); FFM, Five Factor Model (Costa & McCrae, 1992); HiTOP, Hierarchical Taxonomy of Psychopathology (Kotov et al., 2017).

(Naragon-Gainey & Simms, 2017; Zimmermann et al., 2014).

The PID-5's clinical utility also extends to psychotic disorders. Domain scores of higher psychoticism, lower negative affectivity, lower detachment, and lower disinhibition were found to discriminate effectively between individuals with a psychotic disorder from individuals with mood or substance use disorders (Bastiaens et al., 2019). Furthermore, evidence suggests that detachment and negative affec*tivity* are predictors of actually developing psychosis among individuals who are susceptible to psychosis (Drvaric et al., 2018). Thus, across many domains of psychopathology, the Trait Model is beginning to generate research that indicates its clinical value in differential diagnosis and understanding risk and resilience factors, thus aligning fields of research have too often operated in silos.

#### The Five Factor Model of Personality

As stated in the DSM-5, the five domains of the Trait Model are "maladaptive variants of the five domains of the extensively validated and replicated personality model known as the 'Big Five,' or the Five Factor Model of personality" (p. 773). Indeed, the strong associations between these systems have been demonstrated empirically. Barchi-Ferreira Bel and Osório (2020) review the literature linking the PID-5 domains with the FFM, concluding that associations that were, on average, strong. They report the following ranges of correlations observed in the literature: negative affectivity and neuroticism (r = .55 to .78); detachment and extraversion (r = -.73 to -.34); antagonism and agreeableness (r = -.71 to -.38); and disinhibition and conscientiousness (r = -.73 to -.12). However, they also noted associations between psychoticism and open*ness* were weaker, ranging from r = .14 to .43, with some nonsignificant associations observed. The FFM traits similarly align with the broad spectra of psychopathology, allowing Widiger, Sellbom and colleagues (2019) to argue that personality provides a "foundational base" for psychopathology more generally (Table 26.3).

Although somewhat heterogeneous across samples, the associations are, on average, strong, with the notable exception of openness with psychoticism. There are multiple interpretations of this weaker association. For instance, heterogeneity in relations between openness and psychoticism has been observed across inventories used to measure the FFM. Widiger and Crego (2019) observe that studies relying on a neuroticism, extraversion, and openness to experience (NEO) inventory (Costa & McCrae, 1992) or comparable measure (e.g., International Item Pool Inventory-NEO, Big Five Inventory) tend to obtain the weakest associations. They argue that the NEO inventories do not measure facets of openness related to unconventionality, imagination, and fantasy proneness to same degree as later Big Five inventories do, such as the FFM Rating Form (Thomas et al., 2013).

DeYoung et al. (2007) argue that the broad domain commonly referred to as "openness" is indicated by two specific aspects, *openness* and *intellect*, which are both equal parts of the broader trait domain. The specific *openness* aspect contains facets related to imagination and fantasy, while the *intellect* aspect contains facets related to curiosity and ingenuity. Joint factor analyses of the Big Five aspects and the PID-5 traits indicated that specific facet-level *openness* correlates strongly with facets underlying the *psychoticism* domain, while *intellect* is not strongly associated with any maladaptive traits (DeYoung et al., 2016). To summarize, the broad trait domain *openness* is multifaceted; different instruments tend to measure the underlying facets to different degrees; and facets related to unconventionality, imagination, and fantasy proneness appear to be closely related to *psychoticism*, while facets related to intellectual curiosity appear not to be.

Others have argued that the convergent association between *antagonism* and low *agreeableness* is only modest (Zimmermann et al., 2014). Zimmermann et al. (2014) note that in their sample, in the original sample (Krueger et al., 2012), and in others (e.g., Markon et al., 2013; Watson et al., 2013) the central facets of *antagonism*, like *manipulativeness* and *deceitfulness*, were less strongly associated with agreeableness than were peripheral facets like *hostility* and *callousness*. Though at a global level, there appears to be a relatively strong convergence between *antagonism* and low *agreeableness*, the heterogeneity at more specific levels makes the joint structure of these two domains an important issue to clarify in future research.

#### Criterion A: Level of Personality Functioning

The DSM-5 Maladaptive Trait Model is essentially one half of the AMPD. The other half, pertaining to Criterion A and involving clinically significant difficulties in personality functioning, is typically measured by the Level of Personality Functioning Scale (see DSM-5, pp. 775-779). Criterion B, measured by the PID-5, is thought to describe those functioning difficulties using maladaptive traits. While they are theoretically distinguishable, a key issue regarding the evaluation of the AMPD concerns overlap between Criterion A and Criterion B (Krueger & Hobbs, 2020). Criterion A and Criterion B assessments are indeed highly correlated (e.g., Few et al., 2013; Fossati, Borroni et al., 2017; Zimmermann et al., 2015). These high correlations raise the question of whether Criteria A and B do describe different constructs. While some have suggested that the overlap is not an issue, two possible responses have been posited: express Criterion B in normal-range (rather than maladaptive) personality traits, or somehow combine the two into a single criterion.

First, one could argue that strong overlap should be expected as Criterion A provides a basis for PD diagnosis, and Criterion B allows the clinician to delineate how that diagnosis is expressed. Furthermore, Criteria A and B reflect distinguishable traditions in PD scholarship, so considering them together in the AMPD represents an opportunity for intellectual rapprochement (Waugh et al., 2017). From that point of view, no major action need be taken regarding the structure of the first two criteria of the AMPD.

On the other hand, expressing Criterion B in terms of normal-range traits may reduce overlap. Morey et al. (2020) demonstrated that normalrange personality traits and Criterion A dysfunction contribute independently to understanding maladaptive traits. In other words, maladaptive traits can be represented as the combination of normalrange traits and global dysfunction (Criterion A). Thus, making Criterion B an index of normal-range traits would theoretically address the overlap issue without loss of information. Using normal-range traits would also keep the PD field consistent with the vast literature base on the FFM while providing a theoretical basis for distinguishing PD from other forms of psychopathology. In addition, it would allow for bipolar measurement of personality, including direct measurement of patient strengths. Finally, Hopwood et al. (2011) have argued for the clinical utility of separate severity and normal-range trait measurements in allowing clinicians to distinguish the person from their problems.

Widiger, Bach, and colleagues (2019) discuss relations between Criteria A and B in the framework of the structure of psychopathology. They suggest that Criterion A may approximate a general factor of psychopathology in a similar manner to Criterion B domains approximating broad spectra of psychopathology. There is support for the view that a general factor of psychopathology or "p factor" exists as a reflection of the correlations among various psychopathological symptoms and is associated with more life impairment (Caspi et al., 2014); recent evidence suggests that the p factor correlates very strongly (r = .94) with a proposed general factor of PD (g-PD), which is thought to be what Criterion A indexes (McCabe et al., 2021). Because both normal-range and maladaptive traits map cleanly onto broad spectra of psychopathology, either approach to Criterion B, in combination with Criterion A approximating a general factor, could be argued to make the AMPD consistent with the general structure of psychopathology.

Finally, it could also be argued that having two separate criteria is unnecessary. If one of the two lacks incremental validity, one could say that the classification system lacks parsimony, and separate assessment is inefficient. Zimmermann et al. (2019) discuss the incremental validity of the two criteria relative to each other in predicting domains like symptom distress, well-being, and Section II PDs. They conclude that "while some studies found support for the incremental validity of severity compared to maladaptive traits . . . the effect sizes were typically rather small. In contrast, the incremental validity of maladaptive traits when controlling for severity seems to be more robust" (p. 92). As a result, a simplified AMPD that combines features described in Criteria A and B may not result in loss of substantive information. These issues continue to be debated (Morey, 2019a; Sleep, Lynam, Widiger et al., 2019a, 2019b).

#### **Conclusion and Future Directions**

Given the clinical importance of classifying PDs and the well-documented limitations of traditional approaches, perhaps it should not be surprising that the DSM-5 Maladaptive Trait Model has accumulated considerable international interest and empirical research. This alternative approach was developed from a consensus of evidence that dimensional traits were a promising organizing framework for PDs. On that principle, the DSM-5 Personality and Personality Disorders Work Group nominated relevant trait facets and then empirically derived the structure of the Trait Model. The structural validity of the five-domain, 25-facet model has received considerable replication. While the temporal stability, interrater reliability, and cross-cultural measurement invariance of the approach require further research, the initial evidence in these domains is promising. The Trait Model appears clinically useful and to provide strong coverage of prior PD syndromes, thus quelling concerns about potential upheaval that a taxonomic shift would cause. It also neatly aligns with contemporary models of normalrange personality and psychopathology, providing further validity evidence.

These various lines of inquiry are likely to lead to revisions of the Trait Model. Future revisions should consider shifting the primary domains of some facets (e.g., hostility on antagonism rather than on *negative affectivity*), changing the items used to measure certain facets (e.g., in some samples, risk taking and emotional lability do not appear unidimensional), and the inclusion of additional traits (e.g., compulsivity to provide better coverage of obsessive-compulsive PD). Future research should continue to scrutinize the psychometric properties of the PID-5, especially when applied to novel populations within and outside of the United States and Western Europe, where most of the work to date has been completed. Additional research is also needed to better distinguish personality traits

from personality dysfunction, and that also utilizes clinician rating forms and structured clinical interviews of these traits to further demonstrate the model's applicability in clinical diagnostic settings. More generally, much of the research reviewed has been based on self-report data, so, moving forward, multimethod approaches will be key to overcoming concerns about shared method variance. Much work is still needed, but the *DSM-5* Maladaptive Trait Model has amassed an extensive body of literature demonstrating its strength as a taxonomy for personality disorders.

# Narcissistic Personality Disorder and Pathological Narcissism

Aaron L. Pincus

The concept of narcissism can be traced to the Greek myth of Narcissus and its retelling in Homeric hymns. Psychology has considered narcissism a characteristic of personality pathology for more than 100 years. Clinicians have been writing about narcissistic pathology and its treatment since Freud's (1914) initial discussion of narcissism through contemporary clinical models (Doering et al., 2021; Ogrodniczuk, 2013). Psychiatry classified pathological narcissism as narcissistic personality disorder (NPD) in DSM-III, and criteria for this diagnosis appears in all subsequent revisions including DSM-5. Despite more than a century of attention, the conceptualization, classification, and assessment of narcissistic personality pathology is in a state of significant flux (Dawood et al., 2020; Miller et al., 2017). Over a decade ago reviews recognized that the literature across disciplines was splintered, reflecting different approaches to conceptualizing and assessing narcissism (Cain et al., 2008, Miller & Campbell, 2008). Pincus and Lukowitsky (2010) concluded that "action must be taken to resolve disjunctions and integrate findings in future conceptualizations of pathological narcissism; otherwise continuing disparate efforts will impede progress towards a more sophisticated understanding of this complex clinical construct" (p. 422). Fortunately, this recognition has initiated renewed efforts to examine the construct validity and clinical utility of NPD and pathological narcissism and improve our understanding of one of the first recognized-yet most complex-expressions of personality pathology (Pincus, 2020; Pincus et al., 2020).

This chapter is organized in sections articulating the two main clinical perspectives on how to best conceptualize narcissistic personality pathology. First, I present the conceptualization of pathological narcissism as extreme expressions of grandiosity, reflected in *DSM* NPD. Next, I present a contemporary clinical conceptualization of pathological narcissism as states of grandiosity and vulnerability based on self-regulation theory (Morf & Rhodewalt, 2001). I then review important associated clinical features of NPD and pathological narcissism. The chapter concludes with a consideration of future theoretical, clinical, and empirical issues for research.

# DSM NPD: Pathological Narcissism as Extreme Grandiosity

The *DSM-5* NPD diagnosis exemplifies the conceptualization of pathological narcissism as excessive or extreme grandiosity.

# Criteria for NPD in DSM-III, DSM-III-R, DSM-IV, and DSM-5

The introduction of NPD in *DSM-III* was based on a review of the pathological narcissism literature published prior to 1980. The majority of the criteria reflected grandiose attitudes and behaviors, including a grandiose sense of self-importance or uniqueness; preoccupation with fantasies of unlimited success, power, brilliance, beauty, or ideal love; exhibitionism; entitlement; exploitativeness; and a lack of empathy. A minority of criteria reflected impairments in self- and emotion regulation including "a reaction to criticism characterized by rage, shame or

#### Abbreviations

NPD Narcissistic personality disorder PDM Psychodynamic Diagnostic Manual humiliation" and "alternating states of idealized and devalued views of self and others." Beyond the diagnostic criteria, the discussion and examples included dysregulated and vulnerable aspects of narcissism, noting that the grandiose sense of self-importance frequently alternates with feelings of unworthiness, and self-esteem is often fragile and contingent on successful achievements and receiving recognition and admiration from others. The implementation of *DSM-III* NPD diagnostic criteria assumed that grandiose behaviors, beliefs, and expectations existed in tandem with dysregulated, vulnerable states marked by low self-esteem and negative affectivity.

In an effort to improve the reliability and reduce the overlap among DSM PD criteria sets, notable changes to the NPD diagnosis from DSM-III to DSM-5 added a number of criteria explicitly emphasizing grandiosity (e.g., arrogant, haughty behaviors and/or attitudes; frequently infers others are envious of him/her) and eliminated criteria and text describing dysregulation and vulnerability (e.g., shameful reactivity or humiliation in response to narcissistic injury, alternating states of idealization and devaluation) (Gunderson et al., 1995). Although a major revision of the PD diagnostic system was proposed for DSM-5 (Skodol, 2012), it was rejected by the Board of Trustees of the American Psychiatric Association and placed in Section III of DSM-5 describing emerging measures and models in need of additional research.1 Therefore DSM-5 Section II retains the DSM-IV PD criteria sets unchanged, moving them from a separate diagnostic axis to one of 20 chapters describing all diagnoses.

DSM-5 Section II describes NPD as a pervasive pattern of grandiosity (in fantasy or behavior), a constant need for admiration, and a lack of empathy, beginning by early adulthood and present in a variety of contexts, operationalized as nine diagnostic criteria paraphrased here: (1) an inflated sense of self-worth; (2) preoccupation with fantasies of unlimited influence, achievement, intelligence, attractiveness, or romance; (3) belief that one is distinctive and elite and should only associate with others of similar stature; (4) excessive needs for respect, appreciation, and praise; (5) sense of privilege; (6) willingness to take advantage of others for personal gain; (7) lack of compassion; (8) jealousy of others; and (9) exhibition of conceited behaviors and attitudes. A patient must meet clinical threshold

for a minimum of five of these criteria to be diagnosed with NPD. A confirmatory factor analysis of these NPD criteria supported a one-factor solution (Miller et al., 2008). The *DSM-5* diagnosis of NPD reflects chronic expressions of excessive or extreme grandiosity. Self-esteem vulnerability and emotional dysregulation are only mentioned in the "Associated Features Supporting Diagnosis" section, where clinicians are also cautioned that patients with NPD may not outwardly exhibit vulnerable characteristics. *DSM-5* Section II diagnostic criteria are mainly limited to observable presentations of narcissism and omit the underlying features that maintain and unify heterogeneous clinical presentations of narcissism (Caligor et al., 2015).

#### Case Example: Mr. A

Mr. A was a single man in his late 30s who lived alone, met criteria for DSM NPD, and presented at a community mental health clinic twice for treatment within a 2-year period. He saw two different therapists and unilaterally terminated both therapies after 7 sessions and 18 sessions, respectively. He was a disabled veteran who reported feeling angry toward and envious of the Veterans Administration (VA), neighbors, women, and society as a whole. He also reported feeling very mistreated and disrespected by most other people and institutions. In therapy he regularly belittled, mocked, and challenged therapists, "I know I'm narcissistic and there's nothing you can do about it," "You can do your empathy thing, but it will have no effect on me," "You're just a trainee, you don't know enough to help me," and "I'm only here to get medication because the VA requires too much paperwork and makes me wait too long." In addition to deriding his therapists, Mr. A regularly threatened people he found parked in his apartment's assigned parking space and fantasized to his therapist about buying a gun and shooting the next person who parked there. A clinically relevant fact to note is that Mr. A did not drive or even own a car.

In treatment Mr. A reported that he felt his parents were cold and aloof, emphasizing that they had not helped him resolve highly competitive feelings he developed toward his older brothers. He recalled being treated frequently with strong allergy medicines that left him foggy and detached from others. As an adult Mr. A's contingent self-esteem

<sup>&</sup>lt;sup>1</sup> In contrast, the World Health Organization's (2018) recently revised *ICD-11* adopted a highly similar revised proposal for diagnosis of personality disorders (for reviews, see Huprich, 2020; Tyrer et al., 2019).

and unresolved competitive needs appeared compensated for by a distorted self-view that he was far more capable, powerful, and deserving than reality suggested. Mr. A exhibited chronic grandiosity and entitlement throughout his two therapies and never acknowledged receiving anything beneficial from them before unilaterally terminating treatment. In fact, it may very well be that Mr. A's main motivation for seeking help from the clinic was to bypass whatever he found intolerable about receiving treatment from the VA. This is a cycle that might repeat itself with numerous treatment providers.

#### Prevalence

Prevalence rates of NPD in the general population range of 0% to 5.3% (Ekselius et al., 2001; Mattia & Zimmerman, 2001; Torgersen et al., 2001). A nationally representative epidemiological study found that the lifetime prevalence (i.e., cumulative assessment across all time points) of NPD is 6.2% (Stinson et al., 2008). Overall, NPD exhibits the lowest prevalence rate of any DSM personality disorder; however, this is inconsistent with the frequency of patients with narcissistic personality pathology reported in clinical practice (Cain et al., 2008). Prevalence estimates among clinical samples range from 1.3% to 22% (e.g., Grilo et al., 1998; Zimmerman et al., 2005). Among personality disorders, NPD typically has among the lowest correlation between clinical interviews and self-report ratings (Oltmanns & Turkheimer, 2006), possibly due to a lack of insight into how behavior is perceived by others (Carlson & Oltmanns, 2015) or a disregard for the negative impact of their behavior on others (Carlson, 2013). This might particularly impact the accuracy of typical population-based epidemiological assessments as individuals with NPD may lack the insight or willingness to disclose narcissistic attitudes or difficulties (or even participate in such assessments). As the prevalence of the categorical NPD diagnosis is particularly difficult to accurately determine, dimensional approaches to conceptualizing and assessing narcissistic personality pathology provide important alternatives (Dawood et al., 2020).

#### Stability

The temporal stability of NPD is modest but varies depending on whether it is assessed by clinical interview or self-report. Ronningstam, Gunderson, and Lyons (1995) employed the Diagnostic Interview for Narcissism (DIN; Gunderson et al., 1990) on 20 patients diagnosed with NPD over a

3-year period. They found modest diagnostic stability, with only 33% of the patients continuing to meet the DIN criteria for NPD at follow up. The 3-year stability of DSM-III-R diagnoses (50%) and DSM-IV diagnoses (46%) were slightly higher. Lenzenweger, Johnson, and Willett (2004) conducted individual growth curve analyses of interviewerrated PD features over a 4-year period in a sample of 250 participants. Results revealed significant variability in PD features, including NPD features, over time. Nestadt and colleagues (2010) interviewed 294 participants on two occasions, 12 to 18 years apart and found that NPD had among the lowest temporal stability levels (ICC = 0.10), and NPD traits at baseline did not significantly predict those same traits at follow up. Self-reported NPD symptoms yielded a higher level of stability. Ball, Rounseville, Tennen, and Kranzler (2001) reported a 1-year temporal stability coefficient of 0.42 for the self-reported DSM-III-R NPD features in a clinical sample of 182 substance abusing inpatients. Samuel and colleagues (2011) examined the 2-year rank order and mean level stability of PDs using selfreport and interview-based assessments. They found the rank order stability for NPD was higher for self-report than for interview ratings, and the mean level decrease in symptoms over time was smaller for the self-report compared to the interview ratings. Supporting previous findings, Vater et al. (2014) found a 2-year remission rate for NPD diagnoses of 52%.

#### Comorbidity

Across several studies examining diagnostic comorbidity among DSM PDs, NPD consistently exhibits the highest rates of comorbidity with antisocial and histrionic PDs (Widiger, 2011). NPD also exhibits significant comorbidity with symptom syndromes (Simonsen & Simonsen, 2011). Stinson et al. (2008) used 34,653 participants enrolled in an epidemiological study to examine the comorbidity of NPD with Axis I psychiatric disorders. They calculated the odds ratios (i.e., the increase or decrease in likelihood of meeting NPD diagnosis given the presence of another 12month or lifetime non-PD psychiatric diagnosis), controlling for demographic variables. They found almost every psychiatric disorder was significantly related to having an NPD diagnosis. After controlling for other psychiatric disorders, many associations became smaller but remained significant. The diagnoses in the past 12 months that most strongly predicted comorbid NPD diagnosis were bipolar I

disorder (2.3 times more likely to have an NPD diagnosis), anxiety disorders (2.0 times more likely to have an NPD diagnosis), drug dependence (1.9 times more likely to have an NPD diagnosis), posttraumatic stress disorder (PTSD; 1.7 times more likely to have an NPD diagnosis), mood disorders (1.5 times more likely to have an NPD diagnosis), and substance use disorders (1.5 times more likely to have an NPD diagnosis). Comorbidity with lifetime diagnosis of psychiatric disorders yielded similar results, with the strongest predictors being a lifetime diagnosis of bipolar I disorder (1.9 times more likely to have an NPD diagnosis) and PTSD (1.9 times more likely to have an NPD diagnosis). These findings are consistent with clinical samples of NPD that cite the most frequent comorbid diagnoses as major depression or dysthymia (41–50%), substance abuse (24-50%), and bipolar disorder (5-18%) (Clemence et al., 2009; Ronningstam, 1996). Oulis, Lykouras, Hatzimanolis, and Tomaras (1997) found that among 102 recovered schizophrenic patients, 15% met criteria for NPD, and a clinical epidemiological study of 32 firstepisode psychotic patients revealed 16% met criteria for NPD (Simonsen et al., 2008).

Because NPD exhibits notable comorbidity with personality, anxiety, mood, and substance use disorders, novel research has explored the mechanisms driving comorbidity. Eaton and colleagues (2017) used a nationally representative sample to model NPD's transdiagnostic comorbidity structures through multivariate associations. Findings indicate that NPD is more strongly associated with a latent distress factor (vs. a latent fear factor) within an internalizing-externalizing model of psychopathology. Furthermore, they concluded that NPD is composed of unique facets; however, it remains unclear whether shared variance and comorbidity represents a general factor of pathology overlapping with other disorders or an NPD-specific manifestation of unique symptoms. Hörz-Sagstetter and colleagues (2018) identified unique patterns of functioning among patients diagnosed with comorbid NPD and borderline personality disorder (BPD) and patients only diagnosed with BPD suggesting that comorbid NPD may serve as a buffer against anxiety and other Axis I disorders and reduce number of hospitalizations. However, within the context of a BPD diagnosis, NPD may also increase the cooccurrence of severe personality pathology including paranoia, antisocial personality features, and distortions of reality. Taken together, NPD exhibits unique associations with other disorders, and the

basis for and impact of such relationships must be further investigated.

#### NPD Research

Due in part to the low prevalence of NPD, substantive research employing even modest samples of patients diagnosed with NPD is extremely rare. Most of this work has focused on examining empathy deficits and self-esteem in NPD. The best research of this nature involves a well-diagnosed sample of NPD patients in Germany. The investigators (Ritter et al., 2011) used both self-report and experimental methods to assess empathy and found that, compared to controls and patients with BPD, NPD patients exhibited deficits in emotional empathy (i.e., an observer's emotional response to another person's emotional state) but not cognitive empathy (i.e., the ability to take another person's perspective and represent others' mental states). This distinction could explain the NPD patient's tendency to successfully exploit others. In another study of these NPD patients (Schulze et al., 2013), the investigators used brain imaging techniques and found that, relative to controls, NPD patients had smaller gray matter volume in the left anterior insula. Importantly, gray matter volume in this area is positively correlated with self-reported emotional empathy. Supporting these conclusions, Nenadic and colleagues (2015) used voxel-based morphemetry to identify structural issues in the brains of six patients diagnosed with NPD and found gray matter deficits in the right prefrontal and bilateral medial prefrontal regions. Frontal gray matter loss is associated with emotion dysregulation and deficits in coping behaviors. Complementary wholebrain analyses yielded smaller gray matter volume in frontoparalimbic brain regions comprising the rostral and median cingulate cortex as well as dorsolateral and medial parts of the prefrontal cortex, all of which are implicated in empathic functioning (Schulze et al., 2013). Consistent with these findings, another group of investigators (Marissen et al., 2012), using a small independent clinical sample of NPD patients, found that they generally performed worse on a facial emotion recognition task compared to controls. In addition to this general deficit in emotion recognition, patients with NPD showed specific deficits in recognizing fear and disgust.

Empirical studies of self-esteem in NPD patients demonstrate mixed results. Investigators have found evidence supporting that, despite the grandiosity emphasized in the diagnostic criteria, NPD patients have lower explicit self-esteem than controls (Vater, Ritter et al., 2013; Vater, Schröder-Abé et al., 2013). However, Marissen and colleagues (2016) found that implicit and explicit self-esteem did not differ between NPD patients and control groups (e.g., patients with other PDs and healthy controls). This makes sense, considering NPD is commonly comorbid with anxiety disorders, mood disorders, and PTSD. Finally, current research efforts have focused on the role of shame in individuals with NPD. Notably, Ritter and colleagues (2014) investigated the association of NPD and explicit and implicit shame using self-report and performance measures, respectively. A small group of patients diagnosed with NPD reported higher levels of explicit shame than patients diagnosed with BPD and healthy controls. Implicit shame-self associations (vs. anxiety-self associations) were significantly stronger in NPD patients than in the control groups. Findings support continuing investigation of shame-related processes in NPD.

Research on treatment of NPD is limited to case studies. There are no published randomized clinical psychotherapy trials, naturalistic studies of psychotherapy, or empirical evaluations of community-based interventions for NPD (Dhawan et al., 2010; Levy et al., 2007). Thus, there are no empirically validated treatments for NPD; however, extensions of empirically validated treatments such as dialectical behavior therapy (Reed-Knight & Fischer, 2011), transference-focused psychotherapy (Diamond & Hersh, 2020), mentalization-based therapy (Drozek & Unruh, 2020), and schemafocused therapy (Dieckmann & Behary, 2015) are being developed and evaluated. General principles for treating narcissistic patients are also available (Crisp & Gabbard, 2020; Kealy et al., 2017; Weinberg & Ronningstam, 2020).

# Critiques of NPD

The lack of research on patients diagnosed with NPD renders the validity and clinical utility of the diagnosis questionable, and this was the primary reason NPD was initially recommended for deletion in the proposed PD revisions for *DSM-5* (Skodol et al., 2011). Currently, it is unclear whether the *DSM* NPD diagnosis serves its central purpose, which is to facilitate the accurate diagnosis of patients exhibiting pathological narcissism. Unlike what is seen with other PD diagnoses, the low prevalence rates of NPD reported in large-scale epidemiological studies (often 0%) are notably lower than the rates of narcissistic pathology being treated in psychotherapy based on surveys of practicing clinicians (Doidge

et al., 2002; Morey & Ochoa, 1989; Ogrodniczuk, 2013; Ronningstam & Gunderson, 1990; Westen, 1997). This indicates a possible limitation of the DSM criteria to identify patients whom clinicians consider to be exhibiting pathological narcissism (Pincus et al., 2009; Pincus & Lukowitsky, 2010; Ronningstam, 2009). The relatively low prevalence of NPD diagnoses in all populations could be due, in part, to the narrow range of content of the diagnostic criteria. NPD emphasizes grandiose attitudes and behaviors and lacks assessment of self-esteem vulnerability and impaired self- and emotion regulation found in clinical descriptions of pathological narcissism. It may be that many narcissistic patients seek therapists and encounter diagnosticians when they are in a vulnerable self-state with increased mood and anxiety symptoms and lower self-esteem (Kealy & Ogrodniczuk, 2012; Kealy & Rasmussen, 2012). In such instances, relying solely on DSM NPD diagnostic criteria may impede clinical recognition of pathological narcissism. The lack of sufficient NPD criteria assessing self-esteem vulnerability and impaired regulation has been a common criticism for more than a decade (Cain et al. 2008, Gabbard, 2009, Levy et al., 2007; Miller, Widiger, & Campbell, 2010; Pincus, 2011, Ronningstam, 2009).

In response to the initial proposal to eliminate NPD as a diagnosis in DSM-5, Pincus (2011) noted that the DSM is merely an imperfect operationalization of clinical knowledge, not the benchmark for evaluating it (Regier et al., 2009), and he argued that the performance of the DSM NPD criteria set should not be the sole or even primary basis for considering the ontological status of NPD. Problematic comorbidity, stability, and particularly validity may be a function of construct definition problems (e.g., Acton, 1998) with DSM NPD criteria themselves and criterion problems (McGrath, 2005) with DSM NPD research rather than an indication that pathological narcissism does not exist. The narrow construct definition of DSM NPD creates a fundamental criterion problem for research on the validity and clinical utility of the diagnosis (Pincus & Lukowitsky, 2010) as "the disparity between the diagnostic nomenclature and actual psychiatric phenomena is largely ignored, and extensive research is conducted to understand the psychosocial and treatment implications of the existing diagnostic categories" (McGrath, 2005, p. 114). In contrast to the limitations of DSM NPD criteria, a contemporary clinical model encompassing narcissistic grandiosity and narcissistic vulnerability is supported by an emergent, and more clinically informed, empirical research base that is discussed in the next section.

# Clinical Theory and Research: Pathological Narcissism as Grandiosity and Vulnerability

In contrast to the emphasis on extreme grandiosity in DSM NPD, clinical theory and observation has always included states of negative affectivity (e.g., shame, rage), fragile and contingent selfesteem, and behavioral dysregulation (e.g., suicidality, aggression, withdrawal) in the clinical portrait of pathological narcissism (Cain et al., 2008). The comorbidity of NPD with mood and anxiety disorders suggests there could be a more comprehensive conceptualization that moves beyond grandiosity and includes impairments in self- and emotion regulation that could better account for why individuals with a pathologically inflated self-image commonly enter psychotherapy reporting low selfesteem, depressed mood, and anxiety (Pincus et al., 2014, 2016).

# Clinical Theory and Observation: Psychodynamic Origins

Clinical conceptualizations of pathological narcissism have deep roots in early psychodynamic theories and clinical observations of personality (e.g., Freud, 1914; Rank, 2011). These early psychodynamic conceptions were influential in shaping future clinical theories of narcissism (Ronningstam, 2011c), including the contemporary object-relations and self-psychological perspectives that I review next.

Narcissism as a psychodynamic construct evolved from the theorizing of Rank and Freud, through the important reformulations of Otto Kernberg's object-relations theory (1984, 1988) and Heinz Kohut's self-psychology theory (1971, 1977). These reformulations stimulated worldwide interest in how narcissism should be conceptualized and treated (Levy et al., 2011). Object relations theories recognize that humans are social beings who experience much of life relating to others, and these theories emphasize the importance of understanding how people's mental representations of self and others positively or negatively impact their identity, emotions, and relationships. Early in development, a child is unable to attribute good and bad experiences to the same person, so she or he experiences the other as "all bad" or "all good." Similarly, the self is experienced as "all good," and any information to the contrary is pushed out of awareness (denial) or

located in another person (projection). Over time the child learns to integrate good and bad experiences into a complex and integrated view of self and others (Clarkin et al., 2006).

Kernberg's (1984, 1988, 2010) conceptualization of narcissism is embedded within this object relations model. Parental figures (some of the earliest "objects" one can relate to) are experienced as cold and harsh, and they may concurrently hold high (yet superficial) expectations for their child in hopes of vicarious fulfillment of their own failed ambition. These conditions lead to good and bad experiences remaining unintegrated in the form of idealized and devalued views of self and others. The narcissistic individual libidinally invests in a distorted self-structure based on immature real and ideal self-representations as well as ideal objectrepresentations. Devalued or aggressively determined self- and object-representations are split off or projected. A pathological grandiose self is constructed by combining all the positive and idealized characteristics of the self and others, leading to an unrealistic self-image that is hard to maintain. This grandiosity functions as an acquired defense against experiencing an enraged and empty self that is hungry for authentic recognition (Kernberg, 1970).

In contrast, Kohut (1971, 1977) defined narcissism as a normal stage of development. A primary narcissistic structure first exists where the self and other are both idealized (e.g., grandiosity). Through receipt of healthy support and empathic mirroring from parental figures, this structure is reinforced and leads the child to experience the world as secure and consistent. Parental figures will occasionally not support or gratify the child's needs, but such frustration is tolerable, not traumatic, and allows the child an opportunity to regulate their own needs. These experiences of support and opportunities for selfand emotion regulation coalesce into a new, healthier self-structure that is better equipped to navigate disappointments. This in turn transforms immature grandiosity into realistic ambition that energizes the individual to use their skills and talents to pursue realistic goals that validate an authentic positive self-concept (Kohut, 1977). Narcissistic pathology results when parental figures do not provide appropriate support or mirroring, or when parental support is excessive (e.g., overinvolved and enmeshed). Neither condition affords the child an opportunity to experience the appropriate and tolerable empathic failures needed to develop mature regulatory strategies and form realistic views of the self, others, and the world. Millon (1981) and Benjamin
(1996) noted that excessive parental indulgence and admiration that is unrealistic can also result in narcissistic pathology through social learning mechanisms, as the parental figures teach the child that success and admiration are not contingent upon effort and requisite achievements.

#### A Contemporary Clinical Model

Of course, clinical theories of pathological narcissism and descriptions of its phenotypic expression extend well beyond the psychodynamic literature. Recent efforts to synthesize the corpus of description, theory, and research on pathological narcissism across the disciplines of clinical psychology, psychiatry, and social-personality psychology<sup>2</sup> generated a contemporary model that conceptualizes pathological narcissism as a combination of maladaptive self-enhancement motivation (grandiosity) and impaired self- and emotion regulation in response to self-enhancement failures and lack of recognition and admiration from others (vulnerability) (Dawood et al., 2020; Pincus, 2013; Pincus & Lukowitsky, 2010).

#### SELF-ENHANCEMENT AND REGULATION

Narcissism can be defined as an individual's tendency to employ a variety of self-regulation, affectregulation, and interpersonal processes to maintain a relatively positive self-image. Thus, it is necessarily a complex personality construct involving (a) needs for recognition and admiration, (b) motivations to overtly and covertly seek out self-enhancement experiences from the social environment, (c) strategies to satisfy these needs and motives, and (d) abilities to manage disappointments and self-enhancement failures (Morf, Horvath, & Torchetti, 2011; Morf, Torchetti, & Schürch, 2011). Generally, such needs and motives are normal aspects of personality, but they become pathological when they are extreme and coupled with impaired regulatory capacities. It is normal for individuals to strive to see themselves in a positive light and to seek experiences of self-enhancement (Hepper et al., 2010) such as successful achievements and competitive victories (Conroy et al., 2009). Most individuals manage these needs effectively, seek out their gratification in culturally and socially acceptable ways and contexts, and regulate self-esteem, negative emotions, and interpersonal behavior when disappointments are experienced. In basing the definition of narcissism on the individual's needs, motives, and regulatory capacities, a definition of what pathological narcissism is (i.e., impairments in motivation, psychological structures, and regulatory capacities and processes) can be distinguished from how the symptoms present in thought, feeling, and behavior (i.e., its phenotypic expression).

Pathological narcissism involves impairment in the ability to regulate the self, emotions, and behavior in seeking to satisfy needs for recognition and admiration. Put another way, narcissistic individuals have notable difficulties transforming narcissistic needs (recognition and admiration) and impulses (self-enhancement motivation) into mature and socially appropriate ambitions and conduct (Kohut, 1977; Stone, 1998). Morf and colleagues have provided a compelling argument for conceptualizing pathological narcissism through regulatory mechanisms in their dynamic self-regulatory processing model (Morf & Rhodewalt, 2001; Morf, Torchetti, & Schürch, 2011). They suggested that early empathic failures by parental figures (see also Kohut, 1971) leave the child ill-equipped to regulate the self, and instead self-regulation is played out in the social arena (Dickinson & Pincus, 2003; Kernberg, 2010). However, the early negative parenting experience also leaves the self with a mistrust and disdain for others, resulting in a tragic paradox in which other people are needed for the narcissist to self-enhance, but the devalued and skeptical view of others limits the narcissist's ability to experience others' admiration, praise, and validation as selfenhancing. This leads to lingering self-doubt and increased vulnerability, re-energizing the self to continue seeking these self-enhancement experiences in increasingly maladaptive ways and inappropriate contexts (Morf, 2006; Morf & Rhodewalt, 2001). Thus, the fundamental dysfunction associated with pathological narcissism involves chronically unsatisfied needs for recognition and admiration that lead to an equally chronic preoccupation with the social status of the self and an unremitting prioritization of self-enhancement motivation. This heightens narcissistic individuals' sensitivity to the daily ups and downs of life and relationships (e.g., Besser & Priel, 2010; Besser et al., 2016; Dawood & Pincus,

<sup>&</sup>lt;sup>2</sup> This chapter focuses mainly on the clinical psychology and psychiatry literature. Social-personality psychology research supporting the contemporary clinical model is reviewed in several sources (e.g., Cain et al., 2008; Hermann et al., 2018; Miller et al., 2010; Pincus & Lukowitsky, 2010; Pincus & Roche, 2011).

2018; Ziegler-Hill & Besser, 2013) and impairs their regulation of self-esteem, emotion, and behavior (Roche, Pincus, Lukowitsky et al., 2013). Importantly, conceptualizing narcissism from a regulatory perspective, unlike *DSM* NPD, accounts for both narcissistic grandiosity and narcissistic vulnerability (Pincus, 2013).

#### NARCISSISTIC GRANDIOSITY AND NARCISSISTIC VULNERABILITY

To the layperson, narcissism is most often associated with conceited, arrogant, and domineering attitudes and behaviors (Buss & Chiodo, 1991), which are captured by the term *narcissistic grandiosity*. This accurately identifies some common expressions of maladaptive self-enhancement associated with pathological narcissism. Narcissistic vulnerability is reflected in experiences of anger, envy, aggression, helplessness, emptiness, low self-esteem, shame, avoidance of interpersonal relationships, and even suicidality (Kohut & Wolf, 1978; Krizan & Johar, 2012, 2015; Pincus & Roche, 2011; Ronningstam, 2005b). While grandiosity is the core feature of pathological narcissism according to surveys of clinicians, they also consistently recognize expressions of vulnerability in most narcissistic patients (Ackerman et al., 2017; Gore & Widiger, 2016).

The contemporary clinical model of narcissism combines maladaptive self-enhancement (e.g., grandiosity) with self, emotional, and behavioral dysregulation in response to ego threats or self-enhancement failures (e.g., vulnerability). A comprehensive hierarchical model of pathological narcissism is presented in Figure 27.1. Here, narcissistic grandiosity and vulnerability together make up the higher-order construct of pathological narcissism and are moderately intercorrelated (Wright et al., 2010), particularly at higher levels of grandiosity (Jauk & Kaufman, 2018; Jauk et al., 2021). Expressions of narcissistic grandiosity and vulnerability may be chronic, with each suppressing the other, or they may oscillate over time as distinct states within the same person (Edershile & Wright, 2021a, 2021b; Hyatt et al., 2018; Pincus & Wright, 2021). In recent years, recognition of both grandiose and vulnerable themes of narcissistic pathology has increasingly become the norm (Miller et al., 2017; Krizan & Herlache, 2018).

Reviews of clinical literature on narcissism and narcissistic personality pathology over the past 60 years identified more than 50 distinct labels describing grandiose and vulnerable phenotypes of pathological narcissism (Cain et al., 2008; Pincus & Lukowitsky, 2010). The authors concluded that two broad themes of narcissistic pathology, labeled "narcissistic grandiosity" and "narcissistic vulnerability," could be synthesized across the literature with varying degrees of emphasis. Clinical theorists have employed these themes to describe the core aspects of narcissistic dysfunction through defects in self-structure (Kernberg, 1998, Kohut, 1977), difficulties in the therapeutic relationship (Gabbard, 2009; Kernberg, 2007), and maladaptive coping and defensive strategies used in response to stressors (Masterson, 1993).

Ronningstam (2005a) identified subtypes of narcissistic personality based on similarities and differences in self-esteem dysregulation, affect dysregulation, and difficulties in interpersonal relationships. Grandiose themes are emphasized in descriptions of the arrogant narcissist and the psychopathic narcissist. The former copes with self-esteem dysregulation

Figure 27.1 The hierarchical structure of pathological narcissism.

Adapted with permission from Pincus, A.L., & Lukowitsky, M.R. (2010). Pathological narcissism and narcissistic personality disorder. Annual Review of Clinical Psychology, 6, 431.

by creating an exaggerated sense of superiority and uniqueness as well as by engaging in grandiose fantasies. These individuals exhibit entitlement, exploitativeness, and a lack of empathy, and they experience intense envy and aggression as a result of their affect dysregulation. The psychopathic narcissist copes with self-esteem dysregulation by engaging in antisocial behaviors to protect or enhance their inflated self-image. Such individuals will commit violent criminal acts to gain admiration from others, display extreme rage reactions to criticism, and are sadistic without experiencing remorse or empathy. Consistent with Akhtar's (2003) and Dickinson and Pincus's (2003) description of narcissistic vulnerability, Ronningstam's shy narcissist deals with self-esteem dysregulation by engaging in grandiose fantasy while also feeling intense shame regarding their needs and ambition. The dominant affect problem for the shy narcissist is shame rather than aggression, and they avoid interpersonal relationships because of hypersensitivity to ego threats and self-enhancement failures. Similarly, results of a Q-factor analysis of NPD patients' Shedler-Westen Assessment System (SWAP-II) profiles also described two pathological subtypes (Russ et al., 2008). The grandiose/malignant subtype is characterized by seething anger, manipulativeness, pursuit of interpersonal power and control, lack of remorse, exaggerated self-importance, and feelings of privilege. These individuals tend to be externalizing and have little insight into their behavior. In contrast, the fragile subtype fails to consistently maintain a grandiose sense of self such that when their defenses fail, narcissistic injury evokes shame, anxiety, depression, and feelings of inadequacy.

The *Psychodynamic Diagnostic Manual (PDM*; PDM Task Force, 2006) initially subdivided narcissistic personality disturbance into an arrogant/entitled (grandiose) subtype and a depressed/depleted (vulnerable) subtype. Most recently, the *PDM-2* (Lingiardi & McWilliams, 2017) integrated the grandiose and vulnerable subtypes into one coherent and potentially variable clinical presentation consistent with the contemporary clinical model of pathological narcissism presented here.

#### NOMOLOGICAL RESEARCH ON GRANDIOSE AND VULNERABLE NARCISSISTIC TRAITS

A number of self-report measures of narcissistic grandiosity and narcissistic vulnerability are now available, including the Pathological Narcissism Inventory (PNI; Pincus et al., 2009; Schoenleber et al., 2015), the Five-factor Narcissism Inventory

(FFNI; Glover et al., 2012), the Narcissistic Admiration and Rivalry Questionnaire (NARQ; Back et al., 2013), and the Narcissism Scale for Children (NSC; Derry et al., 2019). Other measures assess either grandiosity alone, such as the Narcissistic Personality Inventory (NPI; Raskin & Hall, 1981) and the Narcissistic Grandiosity Scale (NGS; Rosenthal et al., 2020), or vulnerability alone, such as the Hypersensitive Narcissism Scale (HSNS; Hendin & Cheek, 1997) and the Narcissistic Vulnerability Scale (NVS; Crowe et al., 2018). Research using these measures demonstrates that grandiosity and vulnerability exhibit convergent and divergent patterns of relationships with internalizing and externalizing psychopathology, self-esteem, self-conscious emotions, core affect, interpersonal functioning, and psychotherapy (Dowgwillo et al., 2016; Edershile et al., 2019; Kaufman et al., 2020; Pincus & Roche, 2011).

Narcissistic grandiosity and vulnerability exhibit distinct and meaningful patterns of associations, with internalizing problems and symptoms in both normal and clinical samples. This has been most extensively studied with depressive symptoms (Ellison et al., 2013; Erkoreka & Navarro, 2017; Kealy et al., 2012; Marčinko et al., 2014; Miller et al., 2010; Morf et al., 2017; Tritt et al., 2010). In addition, narcissistic grandiosity and vulnerability are associated with suicide attempts (Miller et al., 2010; Pincus et al., 2009), suicidal ideation (Jaksic et al., 2017), and nonsuicidal self-injury (Dawood et al., 2018).

Narcissistic grandiosity and vulnerability also exhibit distinct and meaningful patterns of associations with externalizing problems and symptoms in both normal and clinical samples. Numerous laboratory-based and correlational studies (Lobbestael et al., 2014; Reidy et al., 2010; Widman & McNulty, 2010) show that grandiosity and vulnerability are positively associated with all forms of aggression (e.g., reactive, proactive, unprovoked, sexual), as well as violent behavior and self-reported homicidal thoughts in psychotherapy inpatients and outpatients (Ellison et al., 2013; Goldberg et al., 2007). Grandiosity is also associated with increased criminal behavior and gambling (e.g., Miller et al., 2010), as well as alcohol and drug use (e.g., Buelow & Brunell, 2014; Welker et al., 2019). Moreover, vulnerability interacted with selfreported childhood sexual abuse to predict overt and cyber stalking in men (Ménard & Pincus, 2012).

Consistent with associations found for internalizing and externalizing psychopathology, narcissistic grandiosity and vulnerability exhibit distinct associations with self-esteem, self-conscious emotions, and core affect. Vulnerability is negatively related with self-esteem, whereas grandiosity is positively correlated with self-esteem (Maxwell et al., 2011; Miller et al., 2010; Pincus et al., 2009). Zeigler-Hill and Besser (2013) found that vulnerability is uniquely associated with day-to-day fluctuations in feelings of self-worth. Vulnerability is positively associated with shame and hubris, negatively associated with authentic pride, and unrelated to guilt. In contrast, grandiosity is positively correlated with guilt and unrelated to pride and shame (Pincus, 2013). Vulnerability is positively correlated with negative affectivity, rage, and envy and negatively correlated with positive affectivity, while grandiosity is only positively related to positive affectivity (Krizan & Johar, 2012, 2015).

Narcissistic grandiosity and vulnerability are also associated with specific types of interpersonal problems. Grandiosity is associated with predominately vindictive, domineering, and intrusive problematic behaviors (Ogrodniczuk et al., 2009). Similarly, vulnerability is associated with vindictive interpersonal problems but also shows positive associations with exploitable and avoidant problems (Pincus et al., 2009). Grandiosity and vulnerability also exhibit meaningful associations with interpersonal sensitivities, with grandiosity associated with sensitivity to others' remoteness, antagonism, and control, and vulnerability associated with sensitivity to others' remoteness, control, attention-seeking, and affection (Hopwood et al., 2011). Finally, a weeklong daily diary study (Roche, Pincus, Conroy, et al., 2013) indicated that narcissistic grandiosity and narcissistic vulnerability were related to individuals' behavior in social interactions in daily life. Specifically, narcissistic grandiosity was associated with responding to perceiving others as behaving dominantly with reciprocal dominant behavior. The authors concluded that narcissistic individuals may view the dominant behavior of others as a threat to their status and respond in ways to self-enhance and reassert their superiority (see also Wright et al., 2017).

Narcissistic grandiosity and vulnerability also show differential associations with the utilization of psychotherapy and psychiatric treatment. For instance, Ellison and colleagues (2013) found that narcissistic grandiosity was negatively correlated with treatment utilization (telephone-based crisis services, partial hospitalizations, inpatient admissions, taking medications) and positively correlated with outpatient therapy no-shows. Narcissistic vulnerability was positively correlated with use of telephone-based crisis services, inpatient admissions, and outpatient therapy sessions attended and cancelled. Results indicating that narcissistic vulnerability is positively associated with treatment utilization support the view that narcissistic patients are likely to present for services when they are in a vulnerable self-state (Pincus et al., 2014).

Finally, after many years of research relating the broad and general personality traits of the Five Factor Model to personality disorders (Widiger & Costa, 2013), a trifurcated trait model of narcissism that accounts for grandiosity and vulnerability has been derived (Crowe et al., 2019; Miller et al., 2016). Specifically, across multiple samples and multiple measures of narcissism, a three-factor solution was consistently identified. The first factor, labeled "self-centered antagonism" (i.e., low agreeableness), included the FFNI facets of manipulativeness, entitlement, empathy, arrogance, distrust, reactive anger, and thrill seeking. The second factor, labeled "narcissistic neuroticism," was comprised of the FFNI need for admiration, shame, and low indifference (i.e., high self-consciousness) facets. The third factor, labeled "agentic extraversion," was marked by the FFNI subscales of grandiose fantasies, acclaim seeking, exhibitionism, and authoritativeness. Existing measures of NPD are correlated with all three dimensions of the trifurcated trait model of narcissism. Moreover, measures of narcissistic grandiosity and vulnerability were strongly correlated with self-centered antagonism (i.e., a shared antagonistic core), but differentially related to the other two factors. Measures of narcissistic grandiosity (but not vulnerability) were correlated with agentic extraversion, while measures of narcissistic vulnerability (but not grandiosity) were correlated with narcissistic neuroticism.

# TEMPORAL RESEARCH ON GRANDIOSE AND VULNERABLE NARCISSISTIC STATES

In contrast to the emphasis on extreme grandiosity reflected in *DSM* NPD, clinical theory and empirical evidence supporting the contemporary clinical model suggest that a person's grandiose selfstates may oscillate with vulnerable self-states marked by low self-esteem and emotional and behavioral dysregulation. Ronningstam (2009) noted that "The narcissistic individual may fluctuate between assertive grandiosity and vulnerability" (p. 113). Similarly, Kernberg (2009) indicated that narcissistic personalities endure "bouts of insecurity disrupting their sense of grandiosity or specialness" (p. 106). Horowitz (2009) suggested that as narcissistic pathology negatively impacts relationships, creativity, and occupational adjustment, grandiosity cannot be maintained, and narcissists are "more vulnerable to shame, panic, helplessness, or depression as life progresses" (p. 126). Thus, narcissistic patients may be best differentiated from each other based on *relative* levels of grandiosity and vulnerability rather than making categorical distinctions based on grandiose or vulnerable subtypes (Lingiardi & McWilliams, 2017; Pincus et al., 2016; Pincus & Lukowitsky, 2010).

Recent research supports within-person temporal variability of grandiose and vulnerable narcissistic states. A series of studies focusing on grandiose states (Giacomin & Jordan, 2014, 2016a, 2016b) found that grandiose states varied over time, and state grandiosity was higher when people experienced more positive agentic outcomes (e.g., having power over someone) or more positive communal outcomes (e.g., helping someone with a problem). State grandiosity was lower on days people experienced greater stress, guilt, and shame, and less empathy. These relations held when controlling for state self-esteem,

gender, and trait narcissism. These findings suggest that grandiose narcissism has a meaningful process or state component. In another series of studies on narcissistic states (Edershile & Wright, 2021a, 2021b), both grandiosity and vulnerability exhibited state-like variability within persons over time. More grandiose individuals perceived others as colder and behaved more dominant and colder, on average. But in the moment, higher grandiosity was associated with perceiving others as warmer and more submissive, resulting in more dominant and warm behavior. Trait vulnerability was associated with perceptions of coldness and cold behavior, and this was amplified in the moment. Additionally, variability in narcissistic states from moment to moment was moderately associated with dispositional assessments of narcissism. Specifically, individuals who are dispositionally grandiose exhibited both grandiose and vulnerable states that varied considerably over time. In contrast, dispositionally vulnerable individuals tended to have frequent states of vulnerability and infrequent states of grandiosity. Temporal distinctions in patterning of grandiose and vulnerable narcissistic states are presented in Figure 27.2.

Figure 27.2 Patterns of grandiose and vulnerable narcissistic states over time.

#### Case Example: Mr. B

Mr. B is a patient I diagnose as suffering from pathological narcissism, but he may not meet *DSM* NPD criteria due to his pronounced vulnerability. I present his vulnerable characteristics first, and then follow this with his grandiose features. I chose this approach because narcissistic patients who seek outpatient treatment in community mental health centers typically present in dysregulated states in which more vulnerable symptoms are prominent and grandiosity is only detectable later in treatment after patient stabilization (Pincus et al., 2014).

Vulnerability. Mr. B was a 40-year-old single, college-educated man living with his parents after discharge from his most recent hospitalization. He presented for therapy as socially isolated with impaired intimacy. He had no friends or relationships except with his parents, had difficulty maintaining employment as a dishwasher, and expressed pessimism about his ability to improve his life. He wished to pursue permanent disability status and was interested in moving to a residential facility for the mentally ill. His most pronounced symptom was an empty depression characterized by agitation and anhedonia but an absence of sadness or melancholia. Mr. B was chronically suicidal and described waking up each day feeling "horrified" he was still alive. Early in treatment, he would commonly respond to therapist questions with long latencies where he lowered his head into his hands and repeatedly rubbed his head in anguish before responding with one or two words or "I don't know." Mr. B tried many different antidepressants with minimal effects and was admitted to the hospital 3 times in a 12-month period, one of which included a long course of electroconvulsive therapy (ECT) that was similarly ineffective. Clearly Mr. B's initial presentation was one of a vulnerable and anguished patient, and a diagnostician might reasonably consider a diagnosis of a mood disorder. Mr. B would not meet criteria for DSM NPD.

*Grandiosity*. Over the course of psychotherapy, the therapist learned about several other features of Mr. B's thoughts, feelings, and behaviors that suggest narcissistic grandiosity. But unlike in Mr. A, these expressions were at first subtle or unacknowledged by the patient and they oscillated with more common depressive states. Mr. B was a skilled keyboard player with a sizable home recording studio set up. But the instruments lay untouched, and he reported no intrinsic pleasure in playing them. He reported he only enjoyed it when people paid to hear him play. He tried playing with a few local bands, but

none was "serious enough" or "talented enough," and he even devalued his own musical interests as too "flawed and disappointing" to pursue. Mr. B also used to be an avid bicyclist. However, after excitedly purchasing a new high-quality model, Mr. B became obsessed with the various noises the bicycle made while riding it. He was unhappy and felt it was too noisy. He tried to stop the offending noises without success. With the encouragement of his therapist, Mr. B tried for some time to ride the bike despite his disappointment over its imperfections. However, like playing music, he eventually lost interest in riding his bike and felt depressed about that as well.

Mr. B also felt that daily responsibilities like buying groceries, finding a job, balancing his checkbook, filling out forms, and paying taxes were a "hassle" and that he should not have to do them. In fact, he continued to rely on his parents to do most of these things for him. When he was living in his own apartment, he lived off a trust fund and his mother still balanced his checkbook and took him on a weekly shopping trip. When the trust fund ran out, he strategically took an overdose to ensure his mother would find him when she arrived for their weekly grocery shopping. Despite all his parents' help (for better or worse), in therapy he expressed resentment toward them for aging and having decreasing resources. For example, he complained bitterly that his mother took much longer to balance his checkbook than she used to, and he was disappointed when they could not immediately buy him a car. The therapist learned the main reason Mr. B could not hold a job was because he resented the lack of control over his schedule. He would angrily quit jobs when asked to change his schedule to accommodate other employees' vacations or even his employers' changing needs. He had no friends because he saw relationships as meaningless and insisted he "can't tolerate listening to other people's shit." Ultimately, his grandiose expectations of self and others contributed to virtually all his social, occupational, and recreational activities becoming disappointing and flawed.

Mr. B was very depressed at times, but recognition that it was due to his personality pathology improved his treatment. He was told explicitly that the therapist did not expect medication or ECT to improve his depression and recommended transference-focused psychotherapy (Diamond & Hersh, 2020) for his narcissistic personality. Long-term psychotherapy helped Mr. B remain out of the hospital, improve his relationship with his parents, get off disability, resume work and playing music, and seek independent living arrangements. Treatments that did not take the patient's pathological narcissism into account were not effective.

# A Note on Overt and Covert Narcissism

I wish to alert students that they will occasionally come across the terms "overt" and "covert" narcissism when reading narcissism literature. Unfortunately, many incorrectly associate overt expressions of narcissism exclusively with grandiosity and covert expressions of narcissism exclusively with vulnerability. There is no empirical support for these linkages, nor is there empirical support for the view that overt and covert narcissism are distinct subtypes of narcissism. In fact, there are no existing interviews or self-report measures of overt and covert narcissism. DSM NPD criteria as well as items on various self-reports, interviews, and rating instruments assessing pathological narcissism include a mix of overt elements (behaviors, expressed attitudes, and emotions) and covert experiences (cognitions, private feelings, motives, needs) (e.g., McGlashan et al., 2005). Clinical experience with narcissistic patients indicates they virtually always exhibit both covert and overt grandiosity and covert and overt vulnerability. In Figure 27.1, the distinction between overt and covert expressions of narcissism is secondary to phenotypic variation in grandiosity and vulnerability.

# Clinically Important Associated Features of NPD and Pathological Narcissism

Research on the associated features of NPD and pathological narcissism typically examines correlational associations between relevant constructs and NPD symptom counts, scores on self-report measures of narcissism, or informant ratings. Research using the NPD diagnosis, NPD symptom counts, or scales based on *DSM* NPD effectively assesses grandiosity but not vulnerability. In other research, pathological narcissism is assessed through interviews or scales that can include vulnerable content. It is notable that both NPD and the broader conceptualization of pathological narcissism are associated with the three associated clinical features I review below.

# SUICIDALITY

Pathological narcissism and NPD are clinically and empirically recognized as significant risk factors for self-harm, suicidal ideation, and suicide attempts (Ansell et al., 2015; Dawood et al., 2018). It has

exhibit elevated NPD symptom counts (Apter et al., 1993; Brent et al., 1994) and that the presence of comorbid depression may accrue even greater risk of suicide in patients with NPD (Heisel et al., 2007). Although all (formerly) Cluster B personality disorders are associated with risk for suicide, individuals with NPD exhibit greater risk for more deliberate and lethal forms of suicidal behavior compared to histrionic, antisocial, and borderline personality disorders (Blasco-Fontecilla et al., 2009). Experiencing difficult life stressors increases suicide risk (e.g., Orbach, 1997), and certain stressors

been estimated that 4.7-23% of suicide completers

cide risk (e.g., Orbach, 1997), and certain stressors are particularly impactful for narcissistic individuals. In a sample of 375 suicide attempters, domestic stressors (e.g., arguing more with spouse) and significant life changes including employment termination, house foreclosure, and personal injury or illness preceded attempted suicide in individuals with NPD (Blasco-Fontecilla et al., 2010; see also Marttunen et al., 1993). Additionally, narcissistic personality was associated with increased suicide risk among depressed older (65+) adults, highlighting their difficulties with age-related life changes and transitions (Conner et al., 2001; Heisel et al., 2007).

Research on pathological narcissism demonstrates that an increased suicide risk is related to both narcissistic grandiosity and narcissistic vulnerability; however, the association with vulnerability tends to be stronger (Jaksic et al., 2017). Pincus and colleagues (2009) conducted a chart review of 25 patients and found that the report and number of suicide attempts was positively associated with both grandiose and vulnerable facets of the PNI. In contrast, the frequency of parasuicidal behaviors was uniquely predicted by narcissistic vulnerability. Grandiosity may catalyze suicidality by promoting a view of the self as indestructible, a preoccupation with one's physical appearance, and a detachment from one's emotional and physical self. In such cases, suicide may function as a means of complying with fantasies of invincibility or eliminating perceived imperfections of the body (Ronningstam & Weinberg, 2009). It may also serve an aggressive function to punish others or bolster an illusion of control over one's life and relationships with others (Kernberg, 1984; Ronningstam & Maltsberger, 1998). This would be consistent with suicidality following domestic arguments, for example. Vulnerability may catalyze suicidality by promoting the experience of narcissistic injury, leading to the deflation of grandiose self-views and the

experience of shame in recognizing imperfections, personal weaknesses, and defeat (Pincus et al., 2009; Ronningstam & Weinberg, 2009). It may also serve an aggressive function to punish the self in response to experiencing disappointments of entitled expectations and self-enhancement failures (Pincus, 2013). This is also consistent with the increased risk of suicidality in response to age-related life transitions, as one is confronted with one's increasing physical and socioeconomic limitations (see also Horowitz, 2009).

Narcissism confers a serious risk for suicidality in part because it may be difficult to detect. Usually suicidality will present with depression, but studies suggest narcissistic individuals have an increased risk for suicide, even when not in a depressed state (Ansell et al., 2015; Ronningstam & Maltsberger, 1998; Roningstam & Weinberg, 2009; Ronningstam et al., 2018). Similarly, Cross, Westen, and Bradley (2011) identified a narcissistic subtype of suicide attempters in an adolescent sample who were not characterized by mood or anxiety problems. Furthermore, the life stressors identified above for narcissistic individuals remained significantly associated with suicide when controlling for Axis I disorders, including depression (Blasco-Fontecilla et al., 2010). Information from case studies also suggests that suicide attempters with narcissistic features may be more likely to deny intent, minimize the risk of suicidal gestures, and ignore obvious identifiable stressors that ultimately trigger such events (Ronningstam & Maltsberger, 1998; Ronningstam & Weinberg, 2009). Together, this means the clinician may have a harder time detecting and treating narcissistic suicidality.

#### DEPRESSIVE EXPERIENCES

Although mood disorders, including depression and bipolar disorder, are common comorbid diagnoses with NPD, the phenomenology of depression in narcissistic patients may vary considerably. In a sample of 117 psychiatric outpatients (Kealy et al., 2012), researchers found that anaclitic/dependent themes of depression were positively associated with grandiosity, while introjective/self-critical themes of depression were positively associated with vulnerability. The authors suggested that patients with grandiose features may be more likely to suffer depressive states in the context of violated expectations of external validation, whereas patients with vulnerable features may be more likely to experience depressive exacerbations of their chronic sense of deficit. A similar study with 234 clinical outpatients (Marčinko et al., 2014) found that the relationship between vulnerability and depressive symptoms was partially mediated by dysfunctional perfectionistic attitudes. These findings suggest that the self-criticism and perfectionism commonly seen in depressed patients may involve deeper narcissistic issues (Nealis et al., 2016; Ronningstam, 2011a, 2012), potentially fueling further depressive episodes. In a sample of 235 undergraduate students assessed weekly for 8 weeks (Dawood & Pincus, 2018), the authors found that, at baseline, pathological narcissism was concurrently positively associated with multiple measures of depressive symptoms (e.g., general depression, anhedonic loss of interest, anhedonic lack of positive affect) and distinctively predicted the severity of anhedonic loss of interest over time. Pathological narcissism assessed at baseline also predicted higher variability and instability in both general depression and loss of interest (but not lack of positive affect), suggesting pathological narcissism is associated with more variable and episodic bouts of depression over time rather than a chronically depressed mood. Narcissistic individuals may be susceptible to depression because their self-worth depends on external affirmations from the social world, and their psychic cohesion can become threatened if these needs for recognition and admiration are not met (Kohut & Wolf, 1978; Morf, Horvath, & Torchetti, 2011; Morth Torchetti, & Schürch, 2011).

#### AGGRESSION

Clinical perspectives on narcissism observe that narcissistic individuals become angry and aggressive when their positive, grandiose self-image is threatened or when their entitled needs for admiration from others are unmet. More simply, narcissistic individuals become enraged when their ego is threatened. Recent meta-analyses (Du et al., 2022; Kjærvik & Bushman, 2021; Rasmussen, 2016) and narrative reviews (Lambe et al., 2018) support the association between aggression and ego threat in narcissistic individuals. Cross-sectional, experimental, and field studies all converge in linking narcissism and multiple forms of aggression. A few representative studies are detailed next.

In cross-sectional studies, pathological narcissism correlates positively and moderately with physical aggression and verbal aggression in university student, clinical, and community samples (e.g., Barnett & Powell, 2016; Houlcroft et al., 2012; Morf et al., 2017). Additional research demonstrated that narcissistic vulnerability relates

641

to uncontrolled anger, anger externalization, and anger internalization while narcissistic grandiosity only relates to anger externalization (Krizan & Johar, 2015). Moreover, vulnerable narcissism, but not grandiose narcissism, is associated with reactive aggression (retaliation against the original source of a provocation) and displaced aggression (retaliation against others who are not responsible for the original provocation), with angry rumination and mistrust accounting for these associations. Depressed patients with NPD show significantly more elevated levels of physical aggression, verbal aggression, anger, and hostility compared to depressed patients without any personality disorder (Fjermestad-Noll et al., 2020). Furthermore, research using undergraduate students shows a positive significant correlation between narcissistic vulnerability and physical aggression and verbal aggression, and this pattern remains significant when controlling for narcissistic grandiosity. Conversely, when controlling for narcissistic vulnerability, the relationship between narcissistic grandiosity and aggressive behaviors (physical, verbal) was no longer significant (Keene & Epps, 2016). Overall, cross-sectional results suggest narcissistic vulnerability as a key source of narcissistic rage.

Narcissistic grandiosity and vulnerability also predict aggressive responses in laboratory settings, particularly when following shame-inducing feedback (Bushman & Baumeister, 1998; Ferriday et al., 2011; Reidy et al., 2008; Twenge & Campbell, 2003). Grandiosity and vulnerability may also sensitize individuals to different triggers for anger. Grandiosity was associated with increased anger following an achievement threat, while vulnerability was associated with increased anger following an interpersonal threat (Besser & Priel, 2010). Krizan and Johar (2015) found those high in vulnerable narcissism, but not grandiose narcissism, respond to laboratory-based provocation with aggression, anger, depression, and mistrust. Similar experimental research on responses to provocation (Hart et al., 2017, 2018) found that vulnerable narcissism related to heightened negative emotionality (sadness, anger, hurt feelings), heightened aggression (combination of physical, verbal, and symbolic), hostile goals, and self-worth/defense goals. When combined with findings on depression (Kealy et al., 2012), this research suggests that narcissistic grandiosity may contribute to anger in response to self-enhancement failures and depression in response to relational difficulties, whereas narcissistic vulnerability may contribute to anger in response to relational difficulties and depression in response to self-enhancement failures. Therefore, pathologically narcissistic individuals are at risk for both aggression and depression when coping with social disappointments and selfenhancement setbacks.

Lambe and colleagues (2018) found that narcissism is related to a 1.2- to 11-fold increase in violence in clinical samples and is a significant predictor of more severe forms of violence (e.g., homicide). Similarly, narcissism predicted documented aggressive acts on an inpatient unit (Goldberg et al., 2007) and the endorsement of violence by outpatients seeking psychotherapy (Ellison et al., 2013). The association between narcissism and aggression also extends to incidents of intimate partner violence (Knight et al., 2018; Valashjardi et al., 2020), sexual aggression (Mouilso & Calhoun, 2012; Widman & McNulty, 2010; Zeigler-Hill et al., 2013), and stalking (Ménard & Pincus, 2012).

# The Future of NPD and Pathological Narcissism

Further theory and research is needed on how to best integrate NPD and pathological narcissism. Three areas of focus are noted below.

# Diagnosis

Four suggestions for revising the diagnosis of NPD have appeared in the literature. One suggestion is to revise the DSM criteria to include features reflecting narcissistic vulnerability (e.g., Ronningstam, 2009, 2011b). A second proposal is to consider narcissistic vulnerability a specifier for NPD diagnoses (e.g., NPD with vulnerable features) similar to specifiers used for other diagnoses (Miller et al., 2013). A third alternative is to consider pathological narcissism a facet of general personality pathology, representing a core feature of all PDs rather than a specific PD diagnosis (Morey, 2005; Morey & Stagner, 2012). A final suggestion, found in the DSM-5 Alternative Model for Personality Disorders, bases NPD diagnosis on severity of impairments in self- and interpersonal functioning (Criteria A) and elevated traits of grandiosity and attention-seeking (Criteria B), where Criteria A effectively incorporates both grandiosity and vulnerability (Pincus et al., 2016).

# Grandiose and Vulnerable Narcissistic States

Although the contemporary clinical understanding of pathological narcissism recognizes

its grandiose and vulnerable expressions, future research should take advantage of advancements in assessment technology and analytic methods to further investigate the within-person dynamics of grandiosity and vulnerability (Pincus & Wright, 2021). Clinical theory and observation suggest states of grandiosity and vulnerability as dynamically patterned, oscillating in ascension in relation to the outcomes of self-enhancement efforts and the receipt of social supplies of recognition and admiration. Recent research has examined variability in narcissistic states (e.g., Edershile & Wright, 2021b; Giacomin & Jordan, 2018). Such research can be extended to answer relevant clinical questions. Do shifts in grandiose and vulnerable narcissistic states occur rapidly or over long time periods? How are they triggered? How are they related to important associated features like suicidality, depression, and aggression? How do they impact patient presentation, diagnosis, and treatment?

#### Contextualized Mechanisms and Processes

Even more broadly, the next generation of clinical research should conceptualize narcissistic psychopathology as involving the dynamic interplay of individual differences, within-person (perceptual, affective, cognitive, behavioral, motivational, regulatory, etc.) processes, and contextual factors that unfold at varying time scales (Dotterer et al., 2020; Pincus, 2020; Ronningstam, 2020; Wright & Kaurin, 2020). Methods, analytics, and technology now allow for the empirical investigation of such contextualized dynamic processes. Beyond the interplay of grandiose and vulnerable narcissistic states, other processes that are relevant to narcissistic psychopathology include shifting perceptions of self and other; affect regulation impairments including anger, depression, and shame; shifts from self-awareness to rigid nonmentalizing modes or defensively split grandiose and devalued object relations; and variable levels of psychosocial functioning over time.

#### Conclusion

Consistent with current clinical interests, research on narcissism in all its forms is at an alltime high (Miller et al., 2017). This complex clinical phenomenon requires a sophisticated clinical science that reciprocally informs and is informed by the clinical enterprise (Pincus et al., 2020). That science has arrived, and significant advancements in conceptualization, diagnosis, and treatment of narcissistic psychopathology are now possible.

# CHAPTER **28**

# Borderline Personality Disorder: Contemporary Approaches to Conceptualization and Etiology

Timothy J. Trull and Johanna Hepp

#### **Historical Overview**

Borderline personality disorder (BPD) is a severe mental disorder associated with extreme emotional, behavioral, and interpersonal dysfunction (DSM-5). For historical context, Gunderson (2009) reviewed the ontogeny of the BPD diagnosis. Most scholars credit Adolph Stern (1938) and Robert Knight (1953) for introducing the term *borderline* to the psychiatric nomenclature to designate a condition that was believed to share a boundary with schizophrenia but was seen as more temporary and more likely to occur in the context of unstructured clinical situations. Later, Otto Kernberg's (1967) designation of "borderline personality organization" was applied to a group of patients who, on the one hand, showed features of psychotic personality organization (e.g., primitive defenses, fragmented sense of self) but, on the other hand, showed reality testing that was generally intact. As for the earliest empirical approach to the definition and characterization of borderline personality, Roy Grinker is credited with providing discriminating features of four subtypes of borderline personality and identifying four common features of the "borderline syndrome": anger, impaired intimate relationships, identity problems, and depressive loneliness (Grinker et al., 1968). These contributions, as well as that by John Gunderson in further delimiting borderline personality from other psychiatric conditions, have served as the basis for what we now know to be the BPD diagnosis (e.g., Gunderson et al., 2018; Gunderson & Singer, 1975).

Following the introduction of the formal BPD diagnosis in *DSM-III* in 1980, debates about

the boundaries of BPD continued. For example, instead of schizophrenia, critics argued that BPD was a variant of affective disorder (especially depression or bipolar disorder; Akiskal, 1981) or of posttraumatic stress disorder (PTSD; Herman, 1992). Complicating the debates and investigations into these boundary issues was the fact that BPD frequently co-occurred with mood disorders, PTSD, and other disorders characterized by emotional dysregulation and impulsivity. In addition, among more biologically oriented researchers, no specific biological etiology (e.g., a biomarker) was found that would distinguish BPD from other disorders. However, despite these questions, the validity of the BPD diagnosis is well-recognized by the general psychiatric and psychological communities. The diagnosis itself remains one of the most prevalent diagnoses in mental health settings, it continues to be associated with great impairment and increased mortality, and BPD is increasingly recognized as a major public health problem.

PAI-BOR	Personality Assessment
	Inventory–Borderline Scale

#### **Clinical Description**

Since the publication of DSM-III in 1980, the diagnostic criteria for BPD have remained relatively consistent, with the one exception being the addition in DSM-IV of a criterion for temporary, stress-dependent, quasi-psychotic experiences. Individuals with BPD have a maladaptive personality style that is present in a variety of contexts, emerges by early adulthood, and leads to distinct patterns of dysfunction in behavior and relationships (DSM-IV-TR and DSM-5). Those diagnosed with BPD frequently experience intense and unstable negative emotions that are easily triggered and that take a long time to recover from. One emotion that those with BPD are particularly prone to experience is intense anger that is difficult to control and often results in outbursts with verbal or physical aggression. At the same time, many individuals with BPD also experience feelings of aversive inner emptiness. Beyond these affect-related criteria, there are two criteria related to interpersonal relationships. Individuals with BPD tend to have unstable relationships and show a pattern of idealizing and devaluing others. When confronted with real or imagined abandonment by a close other, they may engage in frantic actions to avoid being abandoned. In addition to this instability in their concept of and behavior toward others, BPD individuals are also unsure of their self-image. At the behavioral level, they are prone to suicidal threats, gestures, or attempts and impulsive, potentially harmful behaviors, such as risky sexual behavior or substance use. Stressful situations may invoke transient paranoid ideation or dissociation. Associated features include a propensity for engaging in selfdefeating behavior (e.g., making a bad decision that destroys a good relationship), high rates of mood or substance use disorders, and premature death from suicide. Concerning the latter, it is estimated that approximately 3-10% of individuals with BPD will have committed suicide by the age of 30 (Gunderson, 2001).

Box 28.1 presents the nine individual criteria for BPD as defined by both *DSM-IV-TR* and *DSM-5*, in Section II. To receive a BPD diagnosis, at least five of the nine criteria must be present, and the symptoms must result in significant distress or impairment. A calculation of unique combinations of five or more items from nine total items reveals that there are 256 possible ways to meet *DSM-IV-TR* and *DSM-5* criteria for BPD! In the case of BPD, this heterogeneity in diagnosis **Box 28.1** Nine *DSM-IV* and *DSM-5* criteria for borderline personality disorder

- Extreme attempts to avoid real or imagined abandonment
- · Intense and unstable interpersonal relationships
- · Lack of a sense of self, or unstable self-image
- Impulsivity that is potentially self-damaging (e.g., excessive spending, substance abuse, binge eating)
- Recurrent suicidal behavior (i.e., threats, gestures) or self-mutilating behavior
- Chronic feeling of emptiness
- Anger control problems
- Dissociation (e.g., depersonalization or derealization) or paranoid thoughts that occur in response to stress

has been recognized for some time and has proved challenging for both etiological and treatment research.

#### Epidemiology

BPD affects 1-3% of the general population, and it is the most common personality disorder (PD) in clinical settings. It represents 10% of the patients in outpatient settings, 15-20% of the patients in inpatients settings, and 30-60% of the patients diagnosed with PDs (Gunderson, 2001; Lenzenweger et al., 2007; Paris, 2009; Tomko et al., 2014; Trull et al., 2010; Widiger & Trull, 1993; Widiger & Weissman, 1991). It is believed that significantly more women than men meet the criteria for BPD, but this belief is based primarily on clinical studies. It is important to distinguish BPD symptoms, which are more chronic and pervasive, from emotional and impulsive behaviors that may be exhibited for short periods of time in adolescence. Studies that have followed children and adolescents who initially received a BPD diagnosis typically find that only a small percentage retain a BPD diagnosis years later. This finding raises the possibility that BPD may be overdiagnosed in children and adolescents, and a more conservative approach to diagnosis in this age group is necessary.

Although BPD has been studied extensively in clinical and treatment samples, less is known about demographic features associated with BPD in the general population. One source of information on this is the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC). The NESARC is a nationally representative, face-to-face survey that evaluated mental health in the civilian, non-institutionalized (i.e., hospitals, prisons) population of the United States. BPD symptoms were assessed in wave 2 of this survey (2004-2005). Initial reports from NESARC indicated very high prevalence rates for the PDs (Grant, Stinson et al., 2004). However, these estimates were likely inflated because the original NESARC investigators only required the endorsement of extreme distress, impairment, or dysfunction for one (but not all) of the requisite endorsed PD items in order for a diagnosis to be assigned (Grant, Hasin et al., 2004; Trull et al., 2010). Trull et al. (2010) presented an alternative method for diagnosing PDs from the NESARC data, which resulted in prevalence rates much more in line with those from other, recent epidemiological studies.

A reanalysis of the BPD NESARC data (Tomko et al., 2014), taking into account distress and impairment for each requisite symptom, resulted in a weighted prevalence rate for BPD overall of 2.7% (instead of the original estimate of 5.9%; Grant et al., 2008a). The rate was also only slightly higher among women than among men (3.0% and 2.4%, respectively) (see Table 28.1). Elevated risk for BPD was suggested for individuals with a family income of less than \$20,000 per year (4.8%), people younger than 30 (4.3%), and individuals who are separated, divorced, or widowed (4.5%). Racial and ethnic differences were evident, with Native Americans (5.0%) and Blacks (3.5%) reporting higher rates of the disorder, on average, than Whites (2.7%) or Hispanics (2.5%), and Asian Americans having a significantly lower rate (1.2%). Individuals with less than a high school education also showed slightly elevated rates of BPD (3.3%) compared to those with at least a high school degree. Urban and rural respondents showed similar rates of the disorder. Regional differences were also minimal, and there were no significant region × sex differences. A recent analysis of data from the third wave of NESARC further demonstrated that lifetime prevalence of BPD is approximately twice as high in gay or lesbian individuals compared to heterosexual individuals (odds ratio [OR] = 1.9) and more than three times higher in bisexual than in heterosexual individuals (OR = 3.6) (Kerridge et al., 2017). Estimates of BPD prevalence for transgender individuals vary substantially between studies and may be affected by inaccurate assessment of the identity diffusion criterion (for an overview of prevalence estimates and a discussion how to distinguish gender minority stress and BPD, see Goldhammer

et al., 2019). Reliable data from large-scale crosssectional or cohort studies on the BPD prevalence in this population is currently lacking.

# Comorbidity

BPD is frequently comorbid with a range of *DSM-5* disorders, including other PDs. Overall, this comorbidity appears to be associated with

poorer outcome (Skodol, Gunderson, McGlashan et al., 2002).

# Comorbidity with Anxiety, Mood, and Substance Use Disorders

BPD is highly comorbid with a number of psychological disorders in both clinical and community samples (Coid et al., 2006; Lenzenweger et al., 2007; Skodol, Gunderson, Pfohl et al., 2002). Unlike many conditions, BPD has commonalities with both internalizing and externalizing disorders (e.g., Eaton et al., 2011). Concerning internalizing disorders, features of BPD such as affective instability, emptiness, and interpersonal difficulties may be driving the high rates of comorbidity between BPD and mood or anxiety disorders. Concerning externalizing disorders, previous research has established a strong link between BPD and substance use disorders (SUDs) (e.g., Sher & Trull, 2002; Trull et al., 2000). To the extent that BPD is associated with impulse control disorders, we might expect that BPD also shares genetic risk with both antisocial PD (ASPD) and SUDs and falls on an externalizing factor of psychopathology. However, BPD is not generally considered to be solely an externalizing disorder (Eaton et al., 2011). Thus, the BPD-SUD co-occurrence may be explained by a combination of impulsivity and negative emotionality (Sher & Trull, 2002; Trull et al., 2018; Trull et al., 2000).

High rates of comorbidity are the rule not the exception in clinical samples. Therefore, it is also of interest to investigate BPD comorbidity rates in the general population. Referring again to the NESARC study of the general US population, Table 28.2 presents the odds ratios for the association between BPD and a range of other psychiatric disorders (Tomko et al., 2014). BPD is significantly associated with almost every diagnosis, including all forms of anxiety, mood, and substance use disorder.

# Comorbidity with Other Personality Disorders

In addition to extensive comorbidity with anxiety, mood, and substance use disorders, BPD is highly comorbid with other PDs (Cohen et al., 2007; Lenzenweger et al., 2007; McGlashan et al., 2000). For example, Lenzenweger et al. (2007) found BPD to have an average correlation of .56 with Cluster A PDs (paranoid, schizotypal, and schizoid) and .55 with Cluster C PDs (avoidant, dependent, and obsessive compulsive). Although there were no instances of histrionic or narcissistic PD in this sample, the correlation with the remaining Cluster B PD, ASPD, was the highest at.64.

Trull et al. (2012) evaluated results from four large studies (at least 200 participants) that used structured diagnostic interviews to establish DSM-IV-TR PD diagnoses. This included comorbidity data from two major epidemiological studies, the NESARC and the National Comorbidity Survey Replication (NCS-R), as well as large clinical investigations of PD comorbidity. Despite different methods and sampling strategies, it is clear that a BPD diagnosis is significantly associated with the full range of other PDs but especially the other Cluster B diagnoses of antisocial, narcissistic, and histrionic PD (Trull et al., 2012). However, the comorbidity patterns in this study did vary to some degree depending on the sample. Thus, proclamations about specific BPD-other PDs comorbidity patterns should be offered with some caveats; these patterns do seem to be sample-specific.

# Somatic Illness Comorbidity

Data from the second wave of NESARC and other large-scale, representative samples found that BPD is associated with substantial overall physical disability (Fok et al., 2014; Grant et al., 2008b). Looking more closely at the types of somatic illnesses those with BPD tend to suffer from reveals a wide range of syndromes and chronic conditions. Some of the most prominent ones include strongly elevated rates of chronic pain and cardiovascular and gastrointestinal disease (e.g., Heath et al., 2017; Sansone & Sansone, 2012). Beyond cross-sectional studies that have established the co-occurrence BPD and somatic illnesses, some studies have also demonstrated that BPD increases the prospective risk of several somatic illness. For instance, Chen et al. (2017) assessed 5,969 BPD patients and 23,876 age- and sex-matched control participants in Taiwan and found that a BPD diagnosis at onset predicted stroke probability several years later. In addition to these major conditions, daily life studies suggest that individuals with BPD frequently experience minor health problems such as headaches, nausea, or general pain in their day-to-day lives (Carpenter et al., 2019; Hepp, Lane et al., 2020). For instance, Hepp, Lane et al. (2020) found that BPD participants reported an average of two health problems per measurement across a 4-week period (with 6 daily measurements).

The marked somatic illness comorbidity of those with BPD contributes to increased morbidity, healthcare usage, and associated primary and secondary cost of illness for this patient group (Frankenburg & Zanarini, 2004). The added 
 Table 28.2
 Odds ratios for lifetime borderline personality disorder and other lifetime psychiatric disorders associations

Psychiatric disorder	Total	Men	Women
	OR (99% CI)	OR (99% CI)	OR (99% CI)

Drug dependence	10.10 (7.69–13.33)	9.52 (6.41–14.08)	12.20 (8.26–17.86)
Any mood episode	14.93 (11.63–19.61)	13.51 (9.35–19.61)	17.54 (12.20–25.64)
Major depressive episode	11.76 (9.35–14.93)	11.36 (8.13–15.87)	13.16 (9.52–17.86)
Dysthymia	8.33 (6.62–10.53)	7.25 (4.76–10.99)	8.85 (6.67–11.76)
Manic episode	16.39 (13.33–20.41)	16.95 (11.90–24.39)	16.13 (12.20–21.28)
Hypomanic episode	3.70 (2.71–5.05)	2.62 (1.49-4.63)	4.69 (3.22-6.80)
Any anxiety disorder			
Panic disorder with agoraphobia	14.29 (10.87–18.87)	15.15 (10.20–22.22)	14.71 (10.00–21.72)
Panic disorder without	13.89 (10.20–18.87)	13.33 (7.19–25.00)	13.70 (9.71–19.61)
agoraphobia*	5.29 (4.12-6.85)	7.52 (4.88–11.49)	4.22 (3.09-5.78)
Social phobia	9.17 (7.41–11.49)	7.87 (5.49–11.24)	10.10 (7.63–13.33)
Specific phobia	5.03 (4.08-6.17)	5.08 (3.61-7.09)	5.03 (3.86-6.49)
Generalized anxiety disorder	11.11 (9.01–13.70)	11.36 (8.00–16.39)	11.11 (8.55–14.49)
Posttraumatic stress disorder	10.42 (8.47–12.82)	11.76 (8.40–16.67)	10.00 (7.63–12.99)
Any other personality disorder	15.87 (12.82–19.61)	14.93 (10.64–20.83)	18.18 (13.70–23.81)
Any Cluster A PD	20.83 (16.13–27.03)	21.74 (14.71–33.33)	20.00 (14.29–27.78)
Paranoid	12.20 (8.93–16.39)	10.87 (6.49–18.18)	12.66 (8.70–18.52)
Schizoid	14.29 (8.40–24.39)	11.90 (5.46–25.64)	17.24 (8.40–34.48)
Schizotypal	111.11 (66.67–200.00)	125.00 (55.56–250.00)	100.00 (50.00-200.00)
Any other Cluster B PD	13.16 (10.42–16.39)	13.89 (9.80–19.23)	16.67 (11.90–23.26)
Histrionic	14.49 (6.85–31.25)	14.29 (4.18–50.00)	14.93 (5.95–37.04)
Narcissistic	55.56 (40.00-83.33)	62.50 (40.00-100.00)	55.56 (33.33–90.91)
Antisocial	6.33 (4.76-8.40)	6.33 (4.31–9.35)	8.47 (5.46–13.16)
Any Cluster C PD	9.52 (7.19–12.66)	7.63 (4.72–12.35)	10.87 (7.63–15.38)
Avoidant	11.63 (7.87–17.24)	7.81 (3.47–17.54)	13.70 (8.70–21.74)
Dependent	20.41 (9.71-41.67)	12.82 (3.03–55.56)	23.26 (10.20–52.63)
Obsessive-compulsive	7.75 (5.65–10.64)	6.94 (4.15–11.63)	8.40 (5.56–12.66)

*Note:* \*Signifies significant gender differences in the odds ratios for this disorder (p < .01).

burden of somatic illness is also thought to contribute to the vastly reduced life expectancies for those with BPD, which have been estimated to be as many as 22 years shorter than those for the general population (Chesney et al., 2014).

# General Functioning and Mental Health Treatment Utilization in BPD

Longitudinal studies have provided some provocative findings about the course of BPD, some of which run counter to prevailing notions about the long-term stability of the BPD diagnosis (Morey & Hopwood, 2013). An early investigation of the longitudinal course of BPD was the Collaborative Longitudinal Personality Disorders Study (Gunderson et al., 2000), which includes 175 individuals with a formal BPD diagnosis. At the 10year follow-up assessment, 85% of those originally diagnosed with BPD no longer met diagnostic criteria for the disorder based on a 12-month definition of remission (Gunderson, Stout et al., 2011). Yet, compared to other diagnostic groups (major depression; Cluster C PDs), the rate of remission for BPD was slower over 10 years. Among those with BPD that did remit, the relapse rate was low (11%) and tended to occur in the first 4 years before leveling off. Data from another long-running study on the course of BPD, the McLean Study for Adult Development, parallel these findings. Zanarini et al. (2010) reported that, over 10 years, 86% of participants attained a sustained remission that lasted for at least 4 years. In a later reassessment of the sample at a 16-year follow-up, they confirmed this, demonstrating high rates of sustained remission (2-8 years), with infrequent relapses (e.g., only 10% among those with an 8-year remission). More recently, Choi-Kain et al. (2020) provide a detailed, up to date review of findings from both studies as well as evidence from two other studies assessing the trajectory of BPD symptoms from childhood to young adulthood. The authors conclude that longitudinal studies underline the fluctuating nature of BPD across the lifespan, the importance of identifying youth at risk and providing early interventions to prevent chronification, and the need to extend existing treatments to target functional improvement in addition to symptom reduction. The latter implication was derived based on participants in both longitudinal studies showing relatively low levels of psychosocial functioning after 10 years, suggesting continuing problems in both social and occupational functioning despite significant symptom remission. Zanarini et al. (2010) indicated that

only around a third of individuals who no longer met criteria for a BPD diagnosis after 10 years showed a "total recovery" including good social and vocational functioning. Typical areas of sustained impairment include functioning in social relationships, occupational, and leisure activities (Ansell et al., 2007; Skodol et al., 2005), as well as legal problems and financial difficulties (Coid et al., 2009).

Results from NESARC further indicate that individuals with BPD were significantly more likely to have reported separation or divorce over the preceding 12 months, having significant trouble with one's boss or employer, and having serious problems with neighbors, friends, or relatives (Tomko et al., 2014). Among those endorsing depression or low mood, a BPD diagnosis was also significantly associated with attempted suicide, presence of suicidal ideation, wanting to die, and thinking a lot about one's own death over the previous 3 years. Individuals with BPD also showed significant impairment in functioning on self-reported scales, even after controlling for the presence of other psychiatric disorders, sociodemographic risk factors (e.g., age, ethnicity or race, family income), and medical conditions (where relevant). BPD was a significant predictor of impaired social functioning, role emotional functioning, mental health, bodily pain, poorer general health, and decreased vitality (Tomko et al., 2014).

# Treatment Utilization and Treatment Cost

It is generally believed that those with BPD often seek out (perhaps excessively) health services, including emergency room (ER) services, while in crisis. ER visits for those with BPD are often precipitated by suicidal behavior, self-harm behaviors, or substance overdoses. Individuals with BPD frequent mental health treatment settings more than individuals with mood, anxiety, or other PDs (Ansell et al., 2007). For example, a large epidemiological study in Great Britain estimated that 56.3% of individuals with BPD had sought help from a professional for mental health concerns in the past year (Coid et al., 2009). Hörz et al. (2010) reported on the use of treatment modalities among 290 BPD patients and 72 patients with other PDs followed over a 10-year period. All were originally inpatients and between the ages of 18 and 35. There were five follow-up assessments, separated by 24 months. Overall, the percentage of those in individual therapy, taking regular medication, and being hospitalized decreased significantly over the followup period. Comparing those with BPD to those

with other PDs, a significantly higher percentage of BPD patients reported taking medications regularly and being hospitalized over the 10-year follow-up period. Furthermore, of those with BPD who terminated outpatient treatment at some point during the follow-up period, 85% of them resumed treatment at a later date. In contrast, rehospitalization was much less frequent and more sporadic. Even in the general population, individuals with BPD report high rates of lifetime mental health treatment utilization (Tomko et al., 2014). For example, in the NESARC study, individuals with BPD were highly likely to seek mental health services at some point in their lifetime, with 74.9% presenting to a physician, therapist, counselor, or other mental health professional for diagnosable mental health concerns. In addition, 63.1% of individuals diagnosed with BPD were prescribed medication for mental health issues.

As a result of these high rates of healthcare usage, the treatment of individuals with BPD accounts for large proportions of mental healthcare costs in countries around the globe (Bohus, 2007; Bourke et al., 2018; Feenstra et al., 2012; Frankenburg & Zanarini, 2004; Salvador-Carulla et al., 2014). For instance, data from Germany suggest that BPD accounts for as much as 25% of the total cost for psychiatric inpatient care per year (Bohus, 2007). Beyond direct health costs (costs directly incurred through primary and emergency care), BPD was also shown to create some of the highest secondary health costs of any mental illness in Germany (Bohus, 2007), the Netherlands (Soeteman et al., 2008; Van Asselt et al., 2007), and Norway (Østby et al., 2014). These include costs resulting from productivity loss and absence from work, disability pensions, and production losses due to premature mortality.

# Etiology

The etiology of BPD has been investigated and debated since the advent of the diagnosis itself. Almost all practitioners now agree that the causes of and contributors to the disorder are multifactorial and complex and comprise both a biological/ genetic predisposition and psychosocial factors, such as specific learning histories or early stressors. One of the most prominent models in the field today stems from a cognitive-behavioral tradition and was proposed by Marsha Linehan in 1993. Her *biosocial model* of BPD posits that biological vulnerabilities interact with psychosocial factors in the development of the disorder (Linehan, 1993).

Specifically, she proposes that individuals with BPD have a biological predisposition toward strong affective reactions and emotional sensitivity, which already manifests as a certain child temperament early in life. When this temperament interacts with a family environment in which emotions are invalidated, for instance by parents who do not take the child's emotions seriously or instruct suppression of emotions, the child is at risk for developing BPD. In addition to invalidating the child's emotions, Linehan describes that the family environments of those with BPD often lack adequate models for emotion regulation, thus keeping the child from developing adaptive ways to regulate intense emotions. The other symptoms of BPD (beyond affective instability) are largely seen as resulting from dysregulated states of negative affect.

A second theoretical model of BPD stems from a psychodynamically oriented tradition and has its roots in attachment theory (Bowlby, 1973). The mentalization-based model of BPD was proposed by Peter Fonagy and Anthony Bateman (Bateman & Fonagy, 2004, 2010; Fonagy et al., 2003) and posits that disorganized attachment styles are at the root of BPD. A disorganized attachment style can develop because of exposure to psychological trauma or noncontingent parental mirroring of emotions and later lead to affective dysregulation and a negative and incoherent representation of the self and others. The central piece of the model is the assumption that the mediating process between disorganized attachment and the symptoms of BPD is a failure to develop mentalizing capacities. Mentalizing is the ability to correctly infer one's own mental states and processes as well as those of others. This can include, for instance, inferring another person's general beliefs and goals, but also their current cognitive-affective state. Ultimately, unsuccessful mentalizing impedes affect regulation and adaptive interpersonal behavior and promotes the symptoms of BPD.

Relatively recently, a third model of BPD has sparked growing interest. Jeffrey Young proposed a *schematherapeutic model* of BPD, which integrates elements from cognitive behavioral models, object relations, and attachment theories, as well as ideas from Gestalt psychology (e.g., Young et al., 2003). Like the other two models, the schematherapeutic model of BPD places particular emphasis on the family environment. Specifically, it proposes that unstable, depriving, punitive and rejecting, or subjugating family environments contribute to the development of BPD. These environments are thought to lead to the development of negative schemas, in which early adverse experiences and the associated affects, cognitions, and physiological sensations are represented. The model further proposes that, in dealing with the adverse environment, the child develops coping modes that persist later in life but lose their adaptiveness outside of the adverse context and become symptomatic.

Because all theoretical models place a particular emphasis on childhood adversity, studies on the prevalence of adverse events within the BPD population are a central test to etiological models of BPD. A recent meta-analysis (Porter et al., 2020) summarized findings on the association between BPD and adverse childhood experiences and demonstrated that individuals with BPD are approximately 14 times more likely to report adverse childhood experiences than are healthy individuals (based on 42 reviewed studies). The largest effects were observed for emotional abuse (OR = 38.1), followed by emotional neglect (OR = 17.7), physical abuse (OR = 7.1), physical neglect (OR = 6.9), and sexual abuse (OR = 6.0). Compared to other clinical groups, individuals with BPD were approximately 3 times more likely to report adverse childhood experiences (based on 61 studies). This effect replicated when specifically comparing BPD to individuals with mood disorders, psychosis, or other PDs, thus underlining the importance of early environments for the etiology of BPD.

#### **Genetic Perspectives**

Although an increasing amount of attention has been paid to BPD in recent years, its specific etiology and development remain uncertain. Currently, most new work on the etiology of BPD focuses on genetic influences on the expression of the disorder. This is the focus in the remainder of this chapter. As will become clear in the following discussion, a genetic predisposition seems to play a significant role in the development of BPD, but the specific genes responsible for this have not yet been reliably identified.

#### **Twin Studies**

Several studies support the idea that BPD and BPD-related traits are familial, for instance demonstrating that the probability of BPD is 3.9 times higher in first-degree relatives of an individual with BPD than in the general population (e.g., Gunderson, Zanarini et al., 2011). However, family studies cannot disentangle the effects of genes from the effects of environment shared by family members. In contrast, *twin studies* can illuminate the effects of common environment and genes by modeling the different genetic relatedness of monozygotic (MZ) and dizygotic (DZ) twins. Amad et al. (2014) summarized the evidence from 10 twin studies and concluded that the average heritability of BPD ranges around 40% across studies. We highlight some of the studies included in the review that were of particular interest, aiming to provide an overview of heritability estimates from different countries.

Data from Norway were provided by Torgersen et al. (2008), who assessed PD traits in 1,386 Norwegian twin pairs between the ages of 19 and 35 years using a structured PD interview. The prevalence rate for BPD (0.4%) was too low to analyze the data categorically, so a dimensional representation based on subclinical criteria was used to study the degree to which genetic and environmental factors influence PDs. The heritability of BPD was estimated at 35%, with the remaining variance explained by unique environmental factors. Adding to this, Kendler et al. (2011) used structured diagnostic interviews to assess DSM-IV BPD criteria in 2,111 twins (669 MZ pairs and 377 DZ pairs) from the Norwegian Institute of Public Health Twin Panel (NIPHTP) to estimate the heritability of BPD liability. Because too few individuals met DSM-IV cutoff scores for a BPD diagnosis, the authors analyzed a dimensional count of level of BPD symptoms endorsed. Specifically, a score of "subthreshold" or above was used as a cutoff for the presence of each BPD criterion, and five categories of endorsement were used in the analyses. Results indicated a heritability estimate of .49 for BPD liability, and, in the context of multivariate genetic analyses of a range of Axis I and Axis II disorders, BPD liability was associated with genetic risk for both Axis I and Axis II externalizing disorders as well as with environmental risk for Axis II disorders and Axis I internalizing disorders.

Using a quantitative scale of BPD features Distel, Trull et al. (2008) assessed 5,496 twins (1,852 complete pairs) between the ages of 18 and 86 years from the Netherlands, Belgium, and Australia. Results indicated that genetic influences explained 42% of the variation in BPD features in both men and women. Interestingly, this heritability estimate was equal between the three countries, suggesting no interaction between genotype and country. The MZ correlation in all three countries, indicating that nonadditive genetic effects may explain part of the variation in BPD features. Finally, in a series of studies using a US sample, Bornovalova and colleagues conducted biometric analyses of questionnaire items judged to be relevant to BPD in 640 twin pairs at age 14 and age 18, as well as 1,382 twin pairs at age 24 (all part of the same longitudinal study). Heritability for BPD traits was estimated to be .25 at age 14, .48 at age 18, and .35 at age 24 (Bornovalova, Hicks et al., 2013; Bornovalova, Huibregtse et al., 2013).

#### **Twin Family Studies**

Twin family studies offer even more extended insight than twin studies because they combine data from twins and other family members. This allows studying several mechanisms that cannot be assessed in twin or family data alone (Boomsma et al., 2002), including cultural transmission of features from parents to offspring, passive  $G \times E$  correlation or covariance, social homogamy, phenotypic assortment, and social interaction. Concerning the latter, twin methods assume that the social interaction between MZ and DZ twins is approximately equivalent. Twin family studies, because of their extended sampling of family members, can test this assumption.

In a study by Distel, Trull et al. (2008), a maximum likelihood test of variance differences between MZ and DZ twins indicated no differences in variances between MZ and DZ twins and, thus, given the large sample size, did not suggest that social interaction between twin siblings is of significant importance. Distel, Rebollo-Mesa et al. (2009) examined the genetic and environmental influences on individual differences in BPD features using an extended twin-family design. Data were collected on BPD features in twins (N = 5,017), their spouses (N = 939), siblings (N = 1,266), and parents (N =3,064). Additive and nonadditive genetic effects, individual specific environmental influences, and assortment and cultural transmission were tested. Results indicated that resemblance among biological relatives could be attributed completely to genetic effects. Variation in borderline personality features was explained by additive genetic (21%) and dominant genetic (24%) factors, while environmental influences (55%) explained the remaining variance. Additive genetic variance refers to variance attributed to the additive effects of alleles segregating in the population, whereas dominant genetic variance refers to that attributed to nonadditive effects such that an allele can mask the effect of another allele at the same locus. In the Distel, Rebollo-Mesa et al. (2009) study, significant resemblance between spouses was observed, best explained by phenotypic assortative mating, but it had only a small effect on the genetic variance (1% of the total variance). There was no effect of cultural transmission from parents to offspring.

Multivariate twin family studies, in which more than one phenotype per person is analyzed, can shed light on the genetic and environmental causes of association between traits, comorbidity between disorders, or overlap between traits and disorder. Distel et al. (2010) investigated the extent to which the covariance among four important components of BPD (affective instability, identity problems, negative relationships, and self-harm) could be explained by common genes. The phenotypic correlations among the scales ranged from .21 to .56 and were best explained by a genetic common pathway model in which a single latent factor influenced all four components. Results indicated that a single genetic factor underlies most of the genetic variance in BPD, but each contributing component to BPD was also influenced by specific genetic factors which do not overlap with each other.

Another multivariate twin family study from this group examined the genetic etiology of the relationship between BPD features and the five factor model (FFM) of personality (Distel, Trull et al., 2009). Data were available for 4,403 MZ twins, 4,425 DZ twins, and 1,661 siblings from 6,140 Dutch, Belgian, and Australian families. Heritability estimates for neuroticism, agreeableness, conscientiousness, extraversion, openness to experience, and borderline personality were 43%, 36%, 43%, 47%, 54%, and 45%, respectively. The phenotypic correlations between borderline personality and the FFM personality traits ranged from .06 for openness to experience to .68 for neuroticism. Results from multiple regression analyses revealed that a combination of high neuroticism and low agreeableness best predicted borderline personality. Multivariate genetic analyses showed that the genetic factors that influence individual differences in neuroticism, agreeableness, conscientiousness, and extraversion account for all genetic liability to borderline personality. Unique environmental effects on borderline personality, however, were not completely shared with those for the FFM traits (33% was unique to borderline personality).

Recently, Skoglund et al. (2019) presented data from six different national registers that included 1,851,755 individuals born in Sweden between 1973 and 1993. Of these, 11,665 individuals met criteria for emotionally unstable PDs (F60.3 in ICD-10), which corresponds well to a diagnosis of BPD according to DSM-IV or DSM-5. Based on linking the data of these individuals with that of their relatives in the same pooled dataset, the authors obtained hazard ratios, marking the familial association along the level of genetic relatedness. They observed that hazard ratios decreased with increasing genetic distance. Specifically, they observed a hazard ratio of 11.5 for MZ, 7.4 for DZ twins, 4.7 for siblings, 2.1 for maternal half-siblings, 1.3 for paternal half-siblings, and 1.7 for cousins.

In sum, evidence from twin studies and twin family studies supports the idea that BPD has a substantial genetic component. The heritability of BPD likely ranges around 40%, and variation in BPD features is attributable to both additive and nonadditive effects with a common genetic pathway for the different symptoms of BPD.

#### Linkage Studies

To date, only one linkage study has been conducted to identify the genomic region(s) that may contain the quantitative trait loci (QTLs) that influence the manifestation of BPD features. Distel, Hottenga et al. (2008) conducted a family-based linkage study with 711 sibling pairs with phenotype and genotype data and 561 additional parents with genotype data. BPD features were assessed on a quantitative scale. Evidence for linkage was found on chromosomes 1, 4, 9, and 18. The highest linkage peak was found on chromosome 9p at marker D9S286 with a logarithm of the odds (LOD) score of 3.548 (empirical *P*-value = .0001). Results suggest that these regions may harbor risk variants, but more empirical work is needed to provide greater resolution at these regions.

# Candidate Gene Studies

Several approaches developed in recent years highlight the promise of transitioning from pure categorical diagnostic approaches of mental disorders to a more continuous, dimensional approach. These include the introduction of the National Institute of Mental Health (NIMH)'s Research Domain Criteria (RDoC) (Insel et al., 2010); the proposal of the Hierarchical Taxonomy of Psychopathology (HiTOP) as a dimensional alternative to categorical nosologies (Kotov et al., 2017); the release of DSM-5, which incorporates to some extent a dimensional approach to psychiatric classification; and the revision of the PD diagnosis in ICD-11. In contrast to the other dimensional approaches, RDoC (Insel et al., 2010) primarily focuses on the biological

and genetic underpinning of dimensions of psychopathology instead of studying heterogeneous phenotypes included in traditional diagnostic classifications. This offers a promising avenue by which to study etiological factors that may be common to a number of diagnostic phenotypes and may inform description, treatment, and prevention. This transition to a more dimensional, endophenotypic perspective has spurred many theorists and researchers to focus on common dimensions of dysfunction that may underlie many existing diagnostic categories, which is particularly relevant to PDs, including BPD (Regier, 2007). The transition has been reinforced by a methodological shift in the study of the genetics of BPD to more emphasis on the identification of endophenotypes related to this disorder (Siever et al., 2002). Although most examinations of BPD's genetic underpinnings have utilized categorical and diagnostic approaches, we now see more studies examining the heritability of individual borderline personality traits and not the diagnosis per se, based on the rationale that this approach may improve understanding of component phenotypes (McCloskey et al., 2009; Siever et al., 2002).

Several candidate gene association studies have been conducted for BPD. Their aim is to identify genetic variants associated with risk for BPD, for instance by comparing the frequency of certain alleles between individuals who meet criteria for BPD and a control group. Amad et al. (2014) conducted a meta-analysis on these studies. One group of studies they summarized assesses candidate genes related to the serotonergic system. The search for candidate genes related to serotonergic functioning was initially based on research implicating the serotonergic system in many traits that are central to BPD, such as anger (Giegling et al., 2006), aggression (Bortolato et al., 2013; Siever, 2008), suicidal behavior (Bah et al., 2008; Bortolato et al., 2013; Mann et al., 2009; Zaboli et al., 2006), emotion regulation (Canli et al., 2009), emotional lability (Hoefgen et al., 2005), and impulsivity (Passamonti et al., 2008). Candidate genes related to the serotonin system include, for instance, the tryptophan hydroxylase genes (TPH1 and TPH2). Tryptophan plays a role in the biosynthesis of serotonin (5-HT) and is thus expected to be related to dysfunction of the 5-HT system (Bortolato et al., 2013). Additionally, studies have considered serotonin receptor genes (e.g., HTR1A, HTR2A) and the serotonin transporter gene (5-HTT). While several of these genes were associated with BPD at the single-study level, none of them was significantly associated with BPD at the meta-analytic level (Amad et al., 2014). Another gene implied in serotonergic functioning that has been studied as a candidate gene for BPD encodes monoamine oxidase-A (*MAOA*), which degrades 5-HTT and dopamine. MAOA is suggested to be involved in BPD because it has been shown to be associated with aggression (Buckholtz & Meyer-Lindenberg, 2008), impulsivity (Manuck et al., 2000), and mood lability (Furlong et al., 1999). Yet, again, no significant associations between the MAOA gene and BPD emerged in the meta-analysis (Amad et al., 2014)

In addition to serotonergic dysfunction, there is some evidence that dopamine dysfunction may be associated with BPD. Dopamine dysfunction is associated with emotional dysregulation, impulsivity, and cognitive-perceptual impairment (Friedel, 2004)-three important dimensions of BPD. Studies have considered the dopamine transporter gene (DAT1), the dopamine  $D_4$  receptor gene (DRD4), the dopamine D<sub>2</sub> receptor gene (DRD2), and the COMT gene as potential candidate genes for BPD. The COMT gene encodes catechol-Omethyltransferase, which is an enzyme that breaks down dopamine. As with the serotonin-related genes, no significant associations were observed between dopamine-associated candidate genes and BPD at the meta-analytic level (Amad et al., 2014). All other reviewed candidate genes similarly failed to produce substantial associations with BPD in the metaanalysis. The remaining candidate genes included the BDNF gene, which encodes the brain-derived neurotrophic factor involved in serotonin regulation; the SCNA9 gene, which encodes a sodium channel expressed in the hippocampus; the AVPR1A gene, which encodes the expression of a vasopressin receptor; and the neurexin 3 gene NRXN3.

Thus, there are currently no candidate genes that were shown to be specifically associated with BPD across studies. This lack of consistency in findings could result from multiple factors. For one thing, the total number of available studies is still small, as are the sample sizes in most cases. Further restricting the available evidence base, studies typically only considered one or a small group of candidate genes; therefore the pool of studies that assessed the same candidate is also limited. Additionally, unlike with candidate gene studies in the medical sciences, there is the problem of unreliability in the phenotype. In other words, the assessment of BPD or BPD features itself may be affected by a level of unreliability which introduces additional error variance that other studies, where the phenotype is more directly observable (e.g., eye color), do not suffer from. Therefore, the necessity of recruiting large samples and conducting a careful, standardized assessment of the phenotype BPD becomes even more evident. Adding to this, there is the possibility that the selection of candidate genes has been limited by our restricted biological theory of BPD. Studies that were searching for candidate genes in "obvious places," so to speak (e.g., the serotonin system), may simply have been looking in the wrong place. As outlined in the following section, genome-wide association studies (GWAS) may help identify other likely candidate genes via a more bottom-up driven approach.

#### **Genome-Wide Association Studies**

GWAS are observational studies that rely on genotyping to determine genetic variants in a sample of individuals and assess whether different genetic variants are associated with a certain phenotype, for instance presence or absence of BPD (e.g., Manolio, 2010). GWAS typically focus on identifying single nucleotide polymorphisms (SNPs), which are positions within the genome where a single nucleotide that is common in the majority of the population is substituted for another nucleotide in a small proportion of individuals. GWAS often rely on case-control designs and compare the prevalence of all assessed SNPs between the case and the control group. If one SNP is found to be significantly more common in the case group, it is considered to be associated with the phenotype (e.g., presence of BPD) and qualifies as a possible genetic risk marker. In a next step, researchers typically investigate more closely in which genes the SNPs that differed in their frequency between the case and control group are located and which functions they have. For BPD, so far, there are only two GWAS, underlining a need for additional investigations in the coming years. The two GWAS on BPD also differ in that one of them focused on individuals with a formal BPD diagnosis and one on self-reported BPD features.

Lubke et al. (2014) assessed 8,426 individuals from three Dutch cohorts who self-reported on their BPD features using the Borderline Scale of the Personality Assessment Inventory (PAI-BOR; Morey, 1991). The PAI-BOR comprises 24 items within the four subscales of affective instability, identity problems, negative relationships, and selfharm, which map onto the core symptoms of BPD as proposed in the *DSM*. Genome-wide association analyses revealed seven SNPs as significantly associated with PAI-BOR total scores. Importantly, all of these SNPs were located in the serine incorporator gene (*SERINC5*) on chromosome 5. This gene expresses a protein that is responsible for incorporating serine (a polar, nonessential amino acid) into membrane lipids and is prevalent in myelin in the brain. Adding to this, the authors carried out a reverse regression and tested the association between these seven SNPs and the PAI-BOR total score in participants with low versus high levels of BPD features (via median split). In the low BPD group, none of the SNPs showed an association with the level of BPD features, whereas in the high BPD group, all associations were significant.

In addition to considering the association between these genes and the PAI-BOR total score, the authors also conducted post hoc tests for each of the seven SNPs, separately for each PAI-BOR item. Due to reduced reliability, they generally observed smaller associations than for the total score, but what stood out was that the associations for items from the negative relationships and self-harm scales were largely negligible in contrast to associations observed for items measuring affective instability and identity problems. In addition to assessing genome-wide associations, the authors also estimated heritability of the PAI-BOR total score using genome-wide SNPs. They estimated heritability at 23% (thus substantially smaller than the 40% estimated from twin studies) and again found substantial differences when looking at the individual item level. Particularly, they observed high heritability scores for affective instability items and very low to insignificant estimates for items from the other subscales.

Witt et al. (2017) conducted the only GWAS with a case-control design and diagnosed BPD patients. The sample comprised 998 BPD patients and 1,545 controls. They analyzed a total of 10,736,316 SNPs and tested 17,755 genes. However, and likely at least in part due to the sample size still being small for a GWAS and lacking statistical power, no SNPs reached genome-wide significance. They found no significant association for any individual SNP, but gene-based analysis yielded two significant genes: the gene coding for dihydropyrimidine dehydrogenase on chromosome 1 (DPYD) and the gene coding for Plakophilin-4 on chromosome 2 (PKP4). Moreover, gene-set analysis revealed exocytosis as a significant gene set. The authors discuss that because all three (DPYD, PKP4, and exocytosis) were previously linked to bipolar disorder and schizophrenia in other studies, there may be genetic overlap between BPD, bipolar disorder, and schizophrenia. Using LD-score regression, the authors tested this in their dataset and found significant genetic correlations between BPD, and bipolar disorder, schizophrenia, and major depressive disorder.

Although GWAS have opened exciting new pathways to studying the genetics of BPD, much larger samples will be needed to reliably identify SNPs that are specifically associated with the disorder (or features of it) in the future. A further investigation into the genes where these SNPs are located and their functions holds the promise of better understanding the biological basis for BPD and ultimately developing treatments more targeted to the biological mechanisms underlying the disorder.

#### **Epigenetic Studies**

Epigenetic studies on BPD focus on DNA methylation or, more precisely, the methylation of CpG sites. CpG sites are sections in the singlestrand DNA sequence where cytosine (C) is directly followed by guanine (G) and connected by phosphate (p). DNA methylation both a natural part of development, ensuring mitosis-persistent cell differentiation, but it can also occur as a result of environmental influences (Robertson, 2005). Therefore, the vast majority of CpG sites in the human DNA is already methylated, which means that cytosine has been converted to 5-methylcytosine through the enzyme DNA methyltransferase. Yet, there are certain "islands" in the DNA sequence, specifically in the promoter regions of genes, where GC is particularly rich but that are unmethylated. Epigenetic studies focus on the methylation level of these CpG islands, assuming a negative association between methylation level and transcriptional activity of the gene. In other words, methylation of CpG sites in gene promoter regions tends to be associated with gene silencing, and environmental factors, such as early trauma, are theorized to cause increased methylation (Klengel et al., 2014; Robertson, 2005).

Most of the available epigenetic literature for BPD was systematically reviewed by Gescher et al. (2018). Their review includes nine studies that focused on methylation in genes that were previously considered candidates for BPD. We highlight some of the findings from the review and summarize evidence from studies published more recently. The largest body of evidence is available for methylation of the promoter region of the glucocorticoid receptor gene (*NR3C1*). This gene has been a study focus because alterations in its expression could help explain hypothalamic-pituitary-adrenal (HPA) axis dysregulation and dysregulated stress responses that were observed for BPD (Drews et al., 2019).

Increased methylation of NR3C1 in individuals with BPD was observed in three studies (Dammann et al., 2011; Martín-Blanco et al., 2014; Perroud et al., 2011). Martín-Blanco and colleagues (2014) additionally demonstrated that NR3C1 methylation was associated with higher BPD severity and a higher number of hospitalizations. Contrasting this, two other studies found no association between NR3C1 methylation level and BPD. Prados et al. (2015) conducted a whole-genome methylation scan in 96 individuals with BPD and childhood maltreatment and 93 individuals with major depressive disorder. They found no significant associations between BPD severity and methylation sites within or near NR3C1, though this could be a result of limited statistical power due to their non-deductive approach. Likewise, Moser et al. (2020), found no difference in NR3C1 methylation levels between a group of 45 BPD patients and 45 matched HCs.

Two additional studies assessed whether methylation of candidate genes was affected by treatment for DBT and, thus, whether methylation level could serve as a marker for treatment outcome. One of these studies assessed methylation of the promoter region of the brain-derived neurotrophic factor gene (BDNF gene) pre- and post-treatment (Perroud et al., 2013). Specifically, the authors assessed BDNF methylation in 115 BPD individuals before and after a 4-week intensive DBT intervention. They observed increased methylation levels post-treatment in a group they categorized as nonresponders to DBT and decreased levels of methylation in responders. In a later investigation within the same sample, the authors investigated methylation of the serotonin receptor 3A gene (5HTR3A). They found increased methylation levels in BPD compared to individuals with attention deficit hyperactivity disorder (ADHD) or bipolar disorder (Perroud et al., 2016). The second study that assessed potential treatment effects on methylation levels focused on genes that were associated with BPD in a previous, genome-wide methylation analysis (Teschler et al., 2013). This study assessed genome-wide methylation in a very small sample of 24 women with BPD and 11 healthy controls and observed different levels of methylation between the groups for a range of genes, including APBA3, MCF2, and NINJ2. Knoblich et al. (2018) then assessed whether methylation levels of these genes differed between 44 individuals with BPD and 44 matched healthy control participants. They observed no differences between the groups at baseline and following 12 weeks of DBT.

Both studies (Knoblich et al., 2018; Teschler et al., 2013) are significantly limited by their small sample size and therefore the results need to be interpreted with caution. At the same time, they illustrate an approach that may be useful for future genetics research in BPD. Genome-wide studies (both GWAS and genome-wide methylation studies) could help identify new candidate genes for BPD in a bottom-up, data-driven approach. Further studies could then follow up on these candidates by assessing clinical and biological correlates and ultimately help inform our theory of BPD. Importantly, particularly genome-wide studies require very large samples (even the 8,426 individuals assessed by Lubke et al., 2014, constitute a small sample for GWAS) that likely demand increased cooperation between laboratories and collaborative recruitment. Likewise, studies following up on the candidates identified in genome-wide studies should pay careful attention to sufficiently power their studies. In that respect, studies should consider moving away from a case-control approach and take into account the dimensional nature of BPD by assessing BPD symptoms and their association with methylation levels in a continuous way.

# Summary of Genetically Informative Studies of BPD

Existing twin data make a strong case for the heritability of the BPD phenotype, suggesting a heritability that ranges around 40%. However, to date, the results of candidate gene studies have been somewhat inconsistent, and few replications of specific polymorphisms and BPD phenotypes have been reported. These inconsistencies are likely due to multiple factors but especially to very small sample sizes and to great variation in the nature of the target samples (e.g., psychiatric patients vs. general population, patients with comorbid conditions) and the control samples (e.g., clinical controls, healthy controls). Therefore, the task for the next generation of studies is to conduct larger-scale molecular genetic investigations or form major collaborations in order to obtain large pools of genetic data that will provide enough statistical power to detect what are likely to be small effects of genes on the BPD phenotype. However, the success of such investigations will be contingent not only on assessing extremely large numbers of participants to provide adequate statistical power but also on identifying and using reliable measures of the phenotype. In particular, it can be questioned whether adopting the DSM-IV-TR and DSM-5 definition of the phenotype and using the resulting categorical

diagnosis will be optimal (because there are 256 ways to obtain a BPD diagnosis). We now turn to a discussion of the evidence supporting different conceptualizations of the BPD phenotype, some of which are not tethered to the *DSM-IV* and current *DSM-5* Section II BPD definition.

#### Personality Traits and BPD

Up to this point, our discussion has focused on studies that have largely adopted the DSM-IV-TR and DSM-5 definition of BPD. However, there is reason to question whether the nine DSM BPD criteria are necessarily the best way to conceptualize the BPD phenotype. In particular, much is known about the universality and genetic and biological bases of major personality traits, and there is a clear conceptual and empirical connection between major personality traits and PDs (Widiger & Trull, 2007). Indeed, over the past 20 years, researchers have examined the correspondence between major personality traits and both symptoms and diagnoses of the DSM PDs (Trull & Widiger, 2008; Widiger & Trull, 2007). By far, the personality model that has received the most attention is the five-factor model (FFM) of personality (Costa & McCrae, 1992). The five broad FFM domains include Neuroticism (versus emotional stability), Extraversion (or surgency), Agreeableness (versus antagonism), Conscientiousness (or constraint), and Openness (or intellect, imagination, or unconventionality).

A description of each of the 10 *DSM-IV* PDs in terms of the 30 facets of the FFM was developed by Lynam and Widiger (2001) on the basis of a survey of PD researchers; these descriptions were then replicated by Samuel and Widiger (2004) in a subsequent survey of clinicians. The FFM description of BPD (Lynam & Widiger, 2001; see Box 28.2) includes high levels of Neuroticism (high anxiousness, angry hostility, depressiveness, impulsiveness, and vulnerability), high levels of Openness (high openness to feelings and to actions), low levels of Agreeableness (low compliance), and low levels of Conscientiousness (low deliberation).

Lynam and Widiger's (2001) FFM account of BPD has received empirical support at both the domain and facet levels (Samuel & Widiger, 2008; Saulsman & Page, 2004). For example, a metaanalysis of 16 empirical articles that examined the relations between FFM traits and BPD indicated a moderate, positive correlation between Neuroticism scores and BPD (.54), and negative correlations with Agreeableness (-.24) and Conscientious (-.29) scores, respectively (Samuel & Widiger, 2008). In addition, BPD was positively related to all Neuroticism facet **Box 28.2** Five-factor model of personalityborderline personality disorder (FFM-BPD) traits and *DSM-5* Section III borderline personality disorder elevated personality traits

#### FFM-BPD traits<sup>a</sup>

Neuroticism: anxiousness; angry hostility; depressiveness; impulsiveness; vulnerability Agreeableness: low compliance Conscientiousness: low deliberation Openness: feelings; actions

# DSM-5 borderline traits

Negative Emotionality: emotional lability; separation insecurity; anxiousness; depressivity Antagonism: hostility Disinhibition: impulsivity; risk taking

*Note:* <sup>a</sup>FFM-BPD predicted relations based on Lynam and Widiger (2001). Note that the FFM is a model. There are many measures available to assess the FFM traits in this particular model. We use the facet names of the NEO-PI-R (Costa & McCrae, 1992).

scores (i.e., anxiousness, angry hostility, depressiveness, self-consciousness, impulsiveness, and vulnerability) and negatively related to a range of Extraversion, Agreeableness, and Conscientiousness scores (i.e., warmth, positive emotions, trust, straightforwardness, compliance, competence, dutifulness, self-discipline, and deliberation). In general, these findings corresponded highly with predictions based on BPD pathology and personality styles (e.g., Lynam & Widiger, 2001; Widiger et al., 2002). Other more recent studies have also supported these FFM trait predictions for BPD diagnosis and features (Bagby et al., 2008; Davenport et al., 2010).

# Major Dimensions of Psychopathology Underlying BPD

Another approach to defining and understanding BPD is to focus on major dimensions of psychopathology that underlie the construct. Although this approach overlaps to some extent with a personality trait description of BPD, identifying major dimensions of psychopathology that presumably have biological underpinnings is perhaps more directly relevant to the NIMH's RDoC approach to psychopathology research (Sanislow et al., 2010). In this spirit, we can review and discuss what many believe to be the three major dimensions of psychopathology that account for the symptoms of BPD: *emotional dysregulation, impulsivity*, and *interpersonal hypersensitivity*. Although there is some debate over the predominance of one or two of these over the other(s) (as well as the names of these dimensions), most researchers agree that these three dimensions capture the essence of the disorder.

# Emotional Dysregulation

Emotional dysregulation is a core and perhaps the central feature of BPD (Linehan, 1993). Despite the prevalent use of the term, there is much confusion about the construct, and it seems best to conceptualize emotional dysregulation as a multicomponent process that includes but is not synonymous with the BPD symptom of affective instability (Carpenter & Trull, 2013). Affective instability refers to the highly reactive moods of borderline individuals. Those with BPD typically shift between different varieties (e.g., anger, depression, anxiety) and degrees (e.g., moderate to extreme) of negative affect. Therefore, in the context of BPD, a more accurate description of the process that includes affective instability might be negative emotional dysregulation. The contextualization of affective instability within the negative emotional dysregulation process distinguishes BPD from disorders such as bipolar disorder, in which a person may shift between both positive and negative affect (e.g., from depression to elation). Also, affective instability in BPD is unique in that the affect shifts occur in response to external stimuli in the person's environment. These extreme shifts in negative mood typically last a few hours to a few days and may occur as a result of factors such as interpersonal stressors, perceived rejections, or events prompting identity crises. This pattern differentiates BPD from major depression, for example, in which the shifts in affect may result more from internal cues (e.g., self-critical thinking, pessimism about the future). Specific BPD criteria that appear to arise directly from negative emotion dysregulation include affective instability, extreme anger, and emptiness.

The empirical literature on affective instability and negative emotion dysregulation in BPD is extensive; therefore, we can highlight only some of the important empirical contributions from the past years. One particularly important tool for studying affective instability in BPD has been ambulatory assessment (AA), which allows researchers to collect data at multiple time-points throughout the day, during participants' daily lives and in their natural environments. The AA research on affective instability and emotion dysregulation in BPD has been summarized in a number of literature reviews (Rosenthal et al., 2015; Santangelo et al., 2014; Trull, 2018). These conclude that AA research remains somewhat inconclusive about the specificity of affective instability to BPD. Instead, the differences between BPD and other clinical groups may be more subtle than previously assumed in that they only emerge for certain indices of acute and extreme change of affect, suggesting affective instability may be largely transdiagnostic (which would be in line with recent theoretical frameworks such as RDoC or HiToP).

Beyond AA research, a large number of studies have investigated the neurobiological processes that underlie negative emotion dysregulation in BPD using functional magnetic resonance imaging (fMRI). Schulze and colleagues have conducted two extensive meta-analyses on these studies. In their first meta-analysis, the authors analyzed studies comparing individuals with BPD to healthy control participants (Schulze et al., 2016). Results showed that when BPD participants processed negative versus neutral emotional stimuli, the activation of their left amygdala and posterior cingulate cortex increased while that of the bilateral dorsolateral prefrontal cortex decreased. The authors further observed that medication status moderated this association, such that only BPD individuals without medication showed amygdala hyper-reactivity, whereas those currently taking psychotropic medication did not. These findings seemed to support the notion that BPD is a disorder that is particularly marked by emotion dysregulation, reflected by limbic hyper- and prefrontal hypoactivation. When repeating the meta-analysis several years later, comparing studies on BPD, PTSD, and depression, the pattern that emerged was more fine-grained. The authors found that, compared to healthy controls, both BPD and PTSD participants showed increased limbic activation, whereas individuals with depression did not (Schulze et al., 2019). They also discovered that participants in all three clinical groups showed hyperactivation of the right median cingulate gyri and hypoactivation of the right middle frontal gyrus and the right middle occipital gyrus when processing negative (vs. neutral) material. This led the authors to conclude that the neurological correlates of emotion dysregulation may be largely transdiagnostic.

In addition to being a problem in and of itself, negative emotion dysregulation may also drive many of the other symptoms seen in the disorder (Carpenter & Trull, 2013). These can arise when BPD individuals use dysfunctional or simply ineffective regulation strategies to cope with negative emotions. A recent meta-analysis suggests that individuals with BPD are generally more likely to use emotion regulation strategies that have been associated with little or only short-lived regulation success, such as suppression, rumination, and avoidance (Daros & Williams, 2019). At the same time, they are less likely to use strategies that are typically more effective, such as cognitive reappraisal or acceptance. Linehan (1993) postulated that this inability to regulate emotions can lead to further maladaptive attempts to regulate negative affect through problem behaviors. Impulsive behavior (including suicidal behavior) may be seen as a maladaptive solution to painful negative affect. Identity disturbance may result from a lack of emotional consistency and predictability. As another example, it has been proposed that those with BPD may be especially vulnerable to developing substance use disorders because alcohol or drugs may be used to cope with negative affective states (Trull et al., 2018). This part of Linehan's theory has seen support from a large number of empirical studies that established a close association between dysregulated negative affect and the other symptoms of BPD. Specifically, a growing number of AA studies have highlighted positive associations between dysregulated states of momentary negative affect or indices of affective instability in daily life and almost all other symptoms of BPD. Findings include positive associations between negative affect/affective instability indices and impulsivity (Tomko et al., 2015), substance use (Wycoff et al., 2020), identity disturbance (Santangelo et al., 2017; Scala et al., 2018), interpersonal problems (Hepp et al., 2017; Hepp, Lane et al., 2018), nonsuicidal self-injury (for a review, see Hepp, Carpenter et al., 2020), and dissociation (Stiglmayr et al., 2008).

# Impulsivity and Behavioral Dysregulation

A second dimension of psychopathology that underlies BPD features is that of impulsivity or behavioral dysregulation. Individuals with BPD frequently engage in potentially harmful behaviors, such as substance abuse, promiscuity, excessive spending, gambling, binge eating, reckless driving, or shoplifting. In the *DSM-IV-TR* and *DSM-5* Section II, the major impulsivity criterion of BPD is defined as "impulsivity in at least two areas that are potentially self-damaging." Some argue that impulsivity is the single best defining feature of the disorder (Bornovalova et al., 2008; Links et al., 1999). Furthermore, this criterion is one of the most commonly occurring symptoms among BPD patients (McGlashan et al., 2005). Crowell et al. (2009) suggest that impulsivity is one of the earliest detectable features of the disorder, and they note that genetic and family studies show a significant increase in the rate of impulse control disorders among family members of individuals with BPD. In addition, some initial research suggested that impulsivity is the most stable BPD symptom and the strongest predictor of overall BPD pathology (Links et al., 1999). More recent research, however, has found that impulsivity generally decreases with age among BPD patients (Morey & Hopwood, 2013; Stepp & Pilkonis, 2008).

The impulsivity diagnostic criterion of BPD highlights overt, maladaptive, impulsive behaviors. However, the etiology of these behaviors is not well understood. A biological predisposition toward disinhibition is one potential mechanism underlying the impulsivity associated with BPD. From this viewpoint, impulsive behaviors are seen as manifestations of underlying personality characteristics. Others have suggested that impulsive behaviors may be maladaptive attempts to regulate negative emotions (e.g., Brown et al., 2002; Kruedelbach et al., 1993). From this perspective, impulsivity in BPD is secondary to affective instability and intense negative emotionality.

There are several avenues to studying impulsivity in BPD. One streak of research has aimed to learn more about impulsivity in BPD by investigating its comorbidity with ADHD and trying to pinpoint similarities and differences in the impulsivity profiles between the two conditions. The latest review of this literature argues that impulsivity in BPD is more strongly intertwined with, and driven by, emotion dysregulation and interpersonal hypersensitivity, whereas impulsivity in ADHD is more strongly rooted in deficits related to attention and cognitive control (Matthies & Philipsen, 2014). A second line of research has used self-report questionnaires to study impulsivity in BPD. Across studies, large differences tend to emerge between BPD individuals and healthy control groups when comparing self-reports. When comparing BPD groups to clinical control groups, the effects are smaller and often nonexistent when comparing BPD to ADHD (Sebastian et al., 2013).

A further major source of information on impulsivity in BPD are laboratory experiments. Many of these studies focus on facets of impulse *control* and include an fMRI assessment in addition to measuring behavioral outcomes. Sebastian et al. (2014) reviewed this literature and clustered findings based on different components of impulse control including stimulus interference, response interference, and behavioral inhibition. The authors conclude that there is some evidence for hypoactivation of orbitofrontal regions during behavioral inhibition in BPD. Moreover, they suggest that both stimulus and response interference are associated with a hypoactivation of the dorsal part of the anterior cingulate cortex (ACC), the dorsolateral prefrontal cortex (DLPFC). However, most of the included studies used paradigms that have also been used to assess emotion dysregulation in other contexts and that contain emotionally salient material, such as using negative words to operationalize stimulus interference in a Stroop task (Wingenfeld et al., 2009). Thus, more research is needed to investigate whether these findings are limited to emotional material. Adding to this, Paret et al. (2017) conducted a meta-analytic review of the literature on decision-making in BPD, some of which assessed delay of gratification, which can be seen as a form of impulse control. Meta-analytic results showed that individuals with BPD discounted delayed rewards more strongly than did healthy controls.

In general, few studies have succeeded at disentangling impulsivity from emotion dysregulation, and this problem has been discussed for many years now. One way studies have attempted this in recent years is to assess impulsive behavior in the laboratory following stress induction, for instance using interpersonal stressors. These studies suggest that dysregulated states of negative affect are predictive of impulsive behavior in various paradigms (e.g., Cackowski et al., 2014; Ernst et al., 2018; Krause-Utz et al., 2016). Another avenue toward studying impulsivity and its association with emotion dysregulation is to study both constructs outside the laboratory and try to assess their covariation and possible temporal precedence of one over the other in daily life. T-o date, - the only study on impulsivity and affect in daily live assessed momentary impulsivity in 67 BPD individuals and a control group of 38 individuals with depression 6 times a day over 28 days (Tomko et al., 2015). In addition to momentary impulsivity, the authors measured the level of negative affect and undifferentiated negative affect. The BPD group reported higher levels of momentary undifferentiated negative affect and impulsivity than the depressed group, and undifferentiated negative affect predicted momentary impulsivity in both groups. More research is needed to examine how impulsivity and emotion dysregulation may

interact to produce behaviors and actions characterizing BPD.

#### Interpersonal Hypersensitivity

In addition to difficulties in regulating both emotions and behaviors, BPD is associated with many interpersonal difficulties; some have even argued that interpersonal hypersensitivity could constitute a phenotype of BPD (Gunderson, 2007). Gunderson and Lyons-Ruth (2008) have presented a developmental model of interpersonal hypersensitivity in BPD. Their view suggests that negative interpersonal experiences combined with a biological disposition to be emotionally reactive may lead to an attribution bias toward perceived abandonment and rejection, resulting in excessive bids for attention and proximity seeking, which the recipient may find aversive. Two diagnostic criteria of BPD also directly reflect the importance of interpersonal dysfunction for BPD. First, frantic efforts to avoid abandonment relates to a general intolerance of being alone; the individual may react with fear or even anger at a time-limited separation or possible termination of a relationship. This criterion suggests that someone suffering from BPD may feel a strong desire to keep others close yet engage in aversive and at times destructive behaviors in order to maintain this closeness. The second interpersonal criterion for BPD, patterns of unstable and intense interpersonal relationships, reflects an initial strong idealization of another that may abruptly change to equally extreme devaluation of the same person. Finally, transient, stress-related paranoid ideation or dissociation, while not directly formulated as an interpersonal symptom, is believed to occur primarily in the context of real or imagined abandonment by others.

Interpersonal dysfunction in BPD has sparked increasing research interest in the past years, and the evidence base has grown considerably. First, we outline the different ways in which interpersonal dysfunction manifests in BPD before reviewing in more detail potential mechanisms behind interpersonal dysfunction. The first source of information on interpersonal dysfunction in BPD are studies that ask individuals to self-report on the quality of their social interactions and relationships. The general picture that emerges is that BPD individuals self-describe the quality of their relationships as poor (Daley et al., 2000; Miano et al., 2018). They perceive their social networks as generating low levels of social support (Clifton et al., 2007) and at the same time high levels of criticism and conflict (Beeney et al., 2018; Lazarus & Cheavens, 2017; Lazarus et al., 2016). This extends to all kinds of relationships, including romantic ones, in which verbal as well as physical fights and recurring breakups were shown to be common (Bouchard, Godbout et al., 2009; Bouchard, Sabourin et al., 2009; Hill et al., 2011). Daily life studies support this picture and underline that individuals with BPD experience interpersonal stressors and problems, such as conflicts, frequently in their day-today lives (Stepp et al., 2009). A recent meta-analysis of studies using the interpersonal circumplex model suggests that the interpersonal style of BPD individuals is characterized by a high degree of agency and low degree of communion, which can manifest in behavior that is vindictive, intrusive, domineering, and cold (Wilson et al., 2017).

BPD-related interpersonal problems have also been described within a framework of rejection sensitivity. Rejection sensitivity is a cognitive-affective trait that causes individuals to anxiously expect, readily perceive, and overreact to rejection cues in the environment (Berenson et al., 2009; Downey & Feldman, 1996). Those who are high in rejection sensitivity automatically perceive rejectionrelevant stimuli information as threatening, especially in ambiguous situations (Berenson et al., 2009; Downey et al., 2004). However, they seek to maintain social ties while avoiding potential rejection (Downey & Feldman, 1996). This cognitive and affective style has significant interpersonal consequences, including early termination of relationships, attributing negative intentions to partners, and avoiding relationship-threatening stimuli (Berenson et al., 2009). A recent meta-analysis has summarized the evidence on rejection sensitivity in BPD and suggests that there is a strong association between BPD and rejection sensitivity (Foxhall et al., 2019). Rejection and other types of interpersonal stressors also appear to be related to negative emotionality in the sense that they can trigger negative affective reactions. Lazarus et al. (2014) reviewed laboratory studies and concluded that individuals with BPD show a heightened emotional reactivity to interpersonal stressors, for instance induced rejection experiences. They also conclude that individuals with BPD show deficits in interpersonal trust and cooperation. Studies on cooperative behavior in BPD have also been extensively reviewed elsewhere (Jeung et al., 2016) and suggest that individuals with BPD have trouble establishing and maintaining cooperative behavior (especially after a rupture in cooperation). In addition to these laboratory studies, recent years have seen an increase in studies

assessing interpersonal stressors and their association with negative affect in daily life, which largely corroborates laboratory findings. Specifically, studies have demonstrated that perceived rejection and disagreements are associated with increased levels of negative affect at the same time of assessment and that they are also predictive of increased negative affect at the following assessment (Berenson et al., 2011; Hepp et al., 2017; Hepp, Lane et al., 2018; Lazarus et al., 2018; Sadikaj et al., 2013; Sadikaj et al., 2010). Thus, when faced with negative interpersonal events such as rejections or disagreements, a person with BPD may be likely to experience heightened negative affect. When accompanied by difficulties in regulating that affect, this can trigger reactive behaviors that an interaction partner finds harmful or aversive. Two daily life studies suggest that these interpersonal problems then themselves become predictive of further increases in negative affect, closing the vicious cycle of affective and interpersonal dysfunction in BPD (Hepp et al., 2017; Hepp, Lane et al., 2018).

As for mechanisms of interpersonal sensitivity in BPD, of major relevance are studies of social cognition, or the exchange of social signals between individuals (Roepke et al., 2013). The evidence on social cognitive deficits in BPD has been synthesized in several reviews and meta-analyses, with the majority of included studies focusing on facial affect recognition abilities (Daros et al., 2013; Domes et al., 2009; Mitchell et al., 2014). The evidence suggests a bias for attributing anger to ambiguous facial expressions and a general deficit for correctly categorizing various facial expressions and that these deficits become more pronounced in situations that involve more complex and more ecologically valid situations (i.e., not simply static pictures of faces). Moreover, a recent meta-analysis also concludes that individuals with BPD have deficits in theory of mind (Németh et al., 2018). There are also a small number of studies that have assessed how individuals with BPD perceive others based on short excerpts such as video clips or photos, so-called thin slices of behavior (Ambady & Rosenthal, 1992). These studies suggest that those with BPD tend to perceive others more negatively than do healthy control participants, participants with depression, and participants with a Cluster C PD (Arntz & Veen, 2001; Barnow et al., 2009; Sieswerda et al., 2013). A recent study further demonstrated that BPD individuals evaluate targets based on thinslice video sequences as specifically less trustworthy and less approachable than do healthy control

participants (Hepp, Kieslich et al., 2020). At the same time, some studies have also started to look at the other side of the coin and suggest that naïve raters also evaluate targets with BPD (based on thin slices of them) more negatively on a range of dimensions than they evaluated healthy control targets (Friedman et al., 2006; Hepp et al., 2019; Hepp, Störkel et al., 2018; Oltmanns et al., 2004). The finding that BPD individuals perceive others negatively and are, in turn, also perceived negatively by them could explain reduced approach behavior on both sides and the marked levels of loneliness that have been described for those with BPD (Liebke et al., 2017).

# The Future of the BPD Diagnosis

Our review of the various issues related to the best way to define the BPD phenotype begs the question: How is BPD likely to be conceptualized and defined in the future? The American Psychiatric Association Board of Trustees decided to maintain the same criteria and diagnostic rules outlined in DSM-IV for the PDs (including BPD) in Section II of the new DSM-5. This decision was made to preserve continuity with current clinical practice. The decision was based on an evaluation that there was not sufficient empirical evidence to justify a new trait-based approach to the PDs. Furthermore, many PD scholars and researchers decried the proposed changes and expressed concern that much of what we know about the PDs, based on a relatively stable set of diagnostic criteria, may not be applicable to these proposed newly defined PDs. Despite these concerns, DSM-5 Section III presents an alternative model for PDs in order to introduce an approach that seeks to address many of the shortcomings of previous categorical approaches to the diagnosis of PDs.

Specifically, the *DSM-5* Personality Disorders Work Group proposal for a BPD diagnosis requires (1) significant impairment in personality functioning (i.e., the domains of self-functioning and of interpersonal functioning); (2) elevated personality traits in negative affectivity, disinhibition, and antagonism; (3) stability and pervasiveness across situations; (4) these impairments and trait expressions are not normative or part of the person's culture; and (5) these impairments and trait expressions are not due to the effects of substances or medications (Mulay et al., 2019).

Here, we focus only on the first two components of the work group's proposed BPD diagnosis (assessing impairment in personality functioning

and assessing pathological personality traits associated with BPD), with special emphasis on the trait ratings included in this BPD conceptualization. The first step in assessing an individual for a Section III DSM-5 BPD diagnosis involves rating a patient's level of personality functioning-specifically, the level of self- and interpersonal functioning for each individual assessed. Self-functioning is defined in two areas (identity integration; self-directedness), as is interpersonal functioning (empathy and intimacy). A 5-point scale is used to rate overall level of personality functioning for this purpose (0 = no)impairment; 1 = some impairment; 2 = moderate impairment; 3 = severe impairment; and 4 = extreme impairment); examples for the ratings are provided (DSM-5, pp. 775-778). A moderate level of impairment of personality functioning in two or more of these four areas is required for a diagnosis of BPD. The clinician is reminded that the ratings must reflect functioning that is of multiple years in duration and must reflect patterns of functioning that are relatively inflexible and pervasive across a wide range of personal and social situations, not due solely to another mental disorder, physical condition, or effect of a substance, and not a norm within a person's cultural background.

The second step involves evaluating personality trait elevations in the individual. Section III *DSM-5* BPD personality traits include those tapping *negative affectivity* (emotional lability, anxiousness, separation insecurity, and depressivity), *disinhibition* (impulsivity, risk taking), and *antagonism* (hostility) (see Table 28.3). Section III calls on diagnosticians to decide whether these seven traits are elevated in the individual; this judgment can be made on the basis of clinical interview or questionnaire scores. It is required that an individual show elevations on at least four of these seven pathological personality traits, and at least one of these elevations must be on impulsivity, risk taking, or hostility.

The new alternative *DSM-5* model for PDs in Section III clearly represents an attempt to provide a more dimensional perspective on personality pathology in general and on BPD in particular. Furthermore, this trait-focused system is more consistent with the large body of research supporting the reliability and validity of using the framework of major dimensions of personality and personality pathology to conceptualize, describe, and study PDs (Widiger & Trull, 2007). However, a major challenge is convincing clinicians that such a framework is clinically useful, can be applied reliably, and can preserve what we have learned about BPD in the past using a traditional categorical system of symptom lists.

In contrast to DSM-5, which ultimately retained the categorical PD diagnoses, ICD-11 includes a dimensional PD diagnosis will be implemented in 2022. All currently existing categories of individual PDs will be replaced by a single dimensional diagnosis of PD that can be coded along a severity dimension of mild, moderate, and severe, and a level of "personality difficulty" (in the chapter "Factors Influencing Health Status and Contact with Health Services") that is below the threshold for a disorder (WHO, 2020). The two core criteria used for the severity scoring are the degree of interpersonal dysfunction (e.g., failure to fulfill social roles, lack of close relationships) and self-related dysfunction (e.g., instability of self-image, low self-worth) (Tyrer et al., 2015). Additionally, the ICD-11 allows for optional specification of the five trait qualifiers of negative affectivity, detachment, dissociality, disinhibition, and anankastia, and it includes a "borderline pattern" specifier. To code the borderline pattern, patients must show instability of interpersonal relationships, self-image, affects, and marked impulsivity and exhibit behavioral, cognitive, and emotional patterns that are essentially those detailed in the DSM-5 BPD criteria, such as frantic efforts to avoid real or imagined abandonment, self-harm, etc. (WHO, 2020). The borderline pattern was included to preserve an explicit representation of the BPD construct, acknowledging the vast body of research on this specific group and the need for a specific ICD-11 code to allow specialized treatment programs around the world to continue providing care to this patient group (Reed, 2018; Tyrer et al., 2019). At the same time, some criticized the inclusion of the borderline pattern as a redundant addition, arguing that BPD patients can be adequately represented by using multiple traits specifiers (Mulder et al., 2020). The proposal of the dimensional PD diagnosis met with some resistance (e.g., Herpertz et al., 2017), and the development and validation of instruments to measure the severity dimension (e.g., Olajide et al., 2018), trait qualifiers (e.g., Oltmanns & Widiger, 2019), and the borderline pattern (Oltmanns & Widiger, 2018) is still ongoing. In the end, the ICD-11 dimensional approach is likely to further facilitate the transition to dimensional models in future editions of the DSM.

#### Conclusion

It is very clear that clinicians and researchers deem BPD to be a syndrome that is quite important

given its prevalence in both clinical and nonclinical samples, its association with impairment and dysfunction, and its relationship to increased risk for suicidal behavior, interpersonal conflict, substance dependence, and early mortality. Despite the attention given to BPD by clinicians and researchers alike, its specific etiology remains largely uncharted. The causes of BPD are multifactorial and complex, involving some interplay between social, environmental, and genetic factors. However, the widely accepted DSM definition of BPD breeds great heterogeneity, and this will likely limit advances in uncovering etiological factors and in designing more effective treatments for BPD. It is recommended that scholars and researchers focus on the dimensions underlying BPD symptoms in order to identify the essence of the disorder, investigate both biological and environmental influences on these core dimensions, and ultimately develop better treatments.

# Schizotypy and Schizotypic Psychopathology: Theory, Evidence, and Future Directions

Mark F. Lenzenweger

#### Introduction

The role of genetic influences in schizophrenia (Henriksen et al., 2017; Gottesman, 1991) has long been established beyond dispute, and there is ample evidence implicating dysfunction in underlying neural systems (McCutcheon et al., 2020) and neural development. However, the precise etiology and pathogenesis of schizophrenia remain opaque. We continue to treat the signs, symptoms, cognition, and functioning impairments in the illness without an understanding of their etiology (Keepers et al., 2020). Illuminating the precise nature of the liability for schizophrenia and its various clinical and endophenotypic manifestations remains a high priority in psychopathology research. In this vein, schizotypic psychopathology, which is intimately connected to schizophrenia, has long intrigued researchers and clinicians for more than 100 years. In short, schizotypic psychopathology represents a unique and rich window on schizophrenia liability (Lenzenweger, 1998, 2010, 2018a, 2018b), and therein lies the heuristic basis for much of the scientific activity in this area of psychopathology research.

Beginning with early observations and speculations by Kraepelin (1919/1971) and Bleuler (1911/1950) in the early 1900s and continuing up through the most recent revision of the American Psychiatric Association's official diagnostic nomenclature (*DSM-5*) and the World Health Organization's *ICD-11*, schizotypic psychopathology has posed challenges to classification, theory, and experimental approaches. Some resolution has emerged recently as both the *DSM-5* and the *ICD-11* currently place schizotypic pathology within the schizophrenia blocks (Bach & First, 2018; Valle, 2020), which accords well with current research linking it to schizophrenia. The term schizotypic psychopathology has encompassed paranoid and schizotypal personality disorder (PD) as defined by the previous DSM nomenclatures (beginning in 1980), but, importantly, one must realize that definitions of schizotypic psychopathology are not solely reliant on the American Psychiatric Association's DSM nomenclature. Schizotypic psychopathology has been approached from a variety of theoretical and methodological vantage points, each offering useful insights into the fundamental nature of this class of psychopathology. In addition to these traditional approaches, newer contemporary dimensional approaches to psychopathology have emerged on

#### Abbreviations

APD	Avoidant personality disorder
BS	Benign schizotypy (model)
CNS	Central nervous system
IPDE	International Personality Disorder
	Examination
LSPD	Longitudinal Study of Personality
	Disorders
MIS	Magical Ideation Scale
PAS	Perceptual Aberration Scale
PPD	Paranoid personality disorder
RSAS	Revised Social Anhedonia Scale
SRPDs	Schizophrenia-related personality
	disorders
SPD	Schizotypal personality disorder
SPQ	Schizotypal Personality Questionnaire
SZD	Schizoid personality disorder

the research scene, each of which has relevance to schizotypy and schizotypic psychopathology (e.g., the hierarchical model proposed by the HiToP group (e.g., Kotov et al., 2018; the Alternative Model for Personality Disorders (AMPD) included in the DSM-5) (Krueger et al., 2018). The variation in these different approaches has generated alternative units of analysis for schizotypic psychopathology that have not always conformed to prevailing psychiatric diagnostic nomenclatures, thus yielding challenges to consistency, organization of findings, and other issues for the student of schizotypic psychopathology. On the other hand, theory and research in schizotypic psychopathology enjoy a spirited level of debate and development that remains exceptional in psychopathology.

Although relatively rare even through the early 1980s, research on schizotypic psychopathology grew in a meteoric fashion over the past 40 years and now represents one of the most active areas of inquiry in psychiatry, clinical science, experimental psychopathology, and developmental psychopathology. For example, as of early 2021, there were 2,459 published reports (according to a Web of Science—Science Citation Index search) that included the words *schizotypal* or *schizotypy* just in their titles. Accordingly, this review must be necessarily selective and makes no claim to be comprehensive.

The intention of this chapter's discussion is to introduce the reader to schizotypic psychopathology and identify several central theoretical and research issues and how they are confronted in this area of psychopathology research. Several empirical and theoretical reviews on this topic are available (Lenzenweger, 2010, 2018a, 2018b; Kerns, 2020; Kirchner et al., 2018; Raine, 2006; Rosell, Futterman, McMaster, & Siever, 2014). A collection of papers on schizotypal personality that covers research and theory up through the early 1990s remains well worth consulting by current students (Raine et al., 1995). An array of rich papers specifically on schizotypy can be found in two Special Issues of Schizophrenia Bulletin (Volume 41, Supplement 2, 2015 and Volume 44, Supplement 2, 2018) including commentary (Lenzenweger, 2015, 2018a, 2018b). Although this chapter discusses research findings relevant to the DSMdefined schizotypal (SPD) and paranoid PD (PPD), it does not focus solely on these diagnostic entities as defined in the various DSM systems. Indeed, a central organizing theme here is that observable schizotypic psychopathology reflects underlying schizotypy, and the range phenotypic expression of schizotypy extends beyond SPD and PPD, suggesting an expanded phenotype (Lenzenweger, 2010, 2018a, 2018b).

# Schizotypic Psychopathology: Definitional Issues, Terminology, and Relevant Distinctions

It is important to explicate and clarify several relevant distinctions regarding the meaning of the term "schizotypic." In this chapter, the terms "schizotypal" and "paranoid" are used to denote the PDs as defined by the DSM nomenclatures. SPD and PPD are, by definition, merely sets of descriptors (signs [observed] and symptoms [reported by patient]) that serve as diagnostic criteria; DSM systems (since 1980 [DSM-III] continuing to the *DSM-5*) eschew any relationship to an explanatory framework for these disorders. Moreover, given their relatively high degree of comorbidity, shared phenomenologic features (e.g., suspiciousness), and relationship to clinical schizophrenia, SPD and PPD are often referred to as the schizophrenia-related PDs (SRPDs) and are viewed as falling within the realm of schizophrenia spectrum disorders. In contrast, the term "schizotypic" can be used to describe signs and symptoms that are the phenotypic manifestation of schizotypy, or a latent personality organization that derives from a liability for schizophrenia as conceptualized in Meehl's classic model (1962, 1990; see Lenzenweger, 2010; e.g., Grant et al., 2013). The term can also serve as a generic shorthand descriptor of "schizophrenia-like" phenomenology that is stable and enduring but is fundamentally nonpsychotic, without necessarily referring to Meehl's model. The adjective nonpsychotic is critical here, for example an "idea of reference" is nonpsychotic, whereas a "delusion of reference" is psychotic from the standpoint of phenomenology.

SPD and PPD are conceived of as manifestations of schizotypy, but they are neither isomorphic with nor exhaustive of the breadth of the schizotypy construct. "Schizotypic psychopathology" serves as a generic term for this general class of mental disturbance. In this context, schizoid PD is generally not considered to be a schizophrenia-related PD in light of available evidence and, therefore, is not viewed as an example of schizotypic psychopathology in this discussion. The argument has been made that both schizoid PDs (SZD) and avoidant PDs (APD) could justifiably be included within the realm of schizotypic/schizophrenia spectrum pathology (Fogelson et al., 2007); however, the data supportive of this claim are limited. It is noteworthy that the "schizophrenia spectrum and other primary psychotic disorders" block in the *ICD-11* only includes SPD but not other PDs, which is similar to the situation with *DSM-5*.

# **A Clinical Vignette**

The following case vignette presents an example of a schizotypic person. Additional clinical vignettes of schizotypic cases can be found in Lenzenweger (2010).

Robin, a 24-year-old, single male graduate student in physics at a large midwestern research university, has a long history of exceedingly strong anxiety symptoms in response to social interactions. In fact, he describes his experience of social interaction as being similar to the feeling one has when one's "knuckles accidently scrape across a carrot grater." He has no interest in social interaction and leads a socially isolated life and does not seek out social contact; many see him as a "loner." He has but one friend with whom he has talks about only highly esoteric topics, and he refers to these discussions as "technicalizing." He frequently uses other words in a peculiar and vague manner. Aside from anxiety, he claims to feel no strong emotions such as joy or even sadness. He frequently thinks that neutral events have "special relevance" for him and often seems to misperceive aspects of his body (e.g., he misjudges the length of his arms or legs). Despite having adequate financial resources, Robin's attire is often best described as "odd" or "eccentric," though clearly not fashionably stylish or trendy.

## **Defining the Schizotype**

## Organization of Schizotypic Signs and Symptoms

As psychopathologists have come to learn that schizotypic psychopathology is likely to be related in a meaningful way to the liability for schizophrenia, some have sought to determine if the organization of schizotypic signs and symptoms bears any resemblance to what is known about the organization of actual schizophrenia phenomenology. In short, exploratory (see Andreasen et al., 1995) and confirmatory (Lenzenweger & Dworkin, 1996) factor analytic studies have suggested that schizophrenia symptoms are best organized into three factors: negative symptoms (flattened affect, avolition), reality distortion (hallucinations, delusions), and disorganization (thought disorder), with a

fourth possible factor consisting of premorbid social impairment (see Lenzenweger & Dworkin, 1996). Factor analytic studies of schizotypic signs and symptoms yield solutions or conform to models that are broadly consistent with the factorial structure observed for schizophrenia. For example, Raine (1991) found a three-factor model, consisting of cognitive/perceptual, interpersonal, and disorganization components, that provided a good fit to observed data. And for the most part, results from other factor and other latent structure analytic studies of schizotypy indicators have been rather consistent (Vollema & Hoitjink, 2000; cf. Kwapil et al., 2008; Kwapil et al., 2018). Thus, at the phenotypic level, schizotypic signs and symptoms appear not only as nonpsychotic attenuated schizophrenia manifestations, but also as being organized in a similar fashion at the latent level.

# Methodological Approaches to Assessing Nonpsychotic Schizotypic Psychopathology

Nonpsychotic schizotypic psychopathology can be defined in one of three ways: (1) clinically/ diagnostically, (2) in terms of deviance on reliable dimensional laboratory measures, or (3) by virtue of having a first-degree biological relative affected with schizophrenia (Lenzenweger, 2010, 2018a, 2018b). The clinical approach implied in psychiatric diagnostic schemes involves, quite obviously, the use of explicit diagnostic criteria to identify either SPD or PPD (e.g., the DSM systems). Note that SPD and PPD, though highly associated with each other, constitute coherent and relatively separable syndromes; however, a recent review raises questions about the viability of PPD as a diagnosis given the minimal interest shown in it by researchers (Triebwasser et al., 2013).

A second approach involves the use of reliable and valid psychometric (or other laboratory) measures of schizotypy to detect schizotypic psychopathology as defined by quantitative deviance on such measures. In this approach, psychometric scales designed to assess various schizotypic manifestations serve to define and measure the schizotypy construct; schizotypic status may be defined by deviance on one or more of such measures. The fundamentals of the psychometric high-risk approach have been discussed and reviewed extensively in other venues (Lenzenweger, 1994, 2010). The hypothetical relations among these alternative approaches in defining schizotypic psychopathology are depicted in Figure 29.1. Cases of schizophrenia are assumed to be direct reflections of true

**Figure 29.1** Hypothetical relations among schizotypy-related constructs. All cases of properly diagnosed schizophrenia (excluding phenocopies, such as drug-induced psychosis) are manifestations of "true schizotypy." *DSM* schizotypal (SPD) and paranoid (PPD) personality disorders, which themselves overlap, are fallible manifestations of true schizotypy. Psychometrically assessed schizotypy is also fallible and, therefore, partially overlaps with a true schizotypy as well as observed manifestations such as schizophrenia, SPD, and PPD.

schizotypy (discounting obvious and objectively classified phenocopies; e.g., PCP-induced psychosis). Schizotypy features assessed via psychometrics, as well as clinically assessed SPD and PPD, are not perfectly related to an underlying genuine schizotypy construct owing necessarily to imperfect measurement; thus they are considered fallible measures of true schizotypy. As depicted in Figure 29.1, SPD and PPD themselves overlap somewhat (see later discussion).

Finally, one can be concerned with the biological relatives of patients with schizophrenia and speak of "genotypic" schizotypes. Although many firstdegree relatives of patients with schizophrenia will not evidence their underlying genetic predisposition to the illness through schizotypic symptomatology, they are, as a group, at increased statistical risk for schizophrenia and can be spoken of as schizotypes. Some relatives of patients with schizophrenia will, indeed, display schizotypic symptomatology (e.g., Kendler et al., 1993), and some will go on to develop clinical schizophrenia. Of course, some relatives can carry the liability for schizophrenia quietly, giving little indication of its presence (Gottesman & Bertelsen, 1989). It is essential to note that not every biological relative of a schizophrenia-affected person will harbor liability for the illness (Hanson et al., 1977); that is, it is possible to be a noncarrier of schizophrenia liability.

In this context it is important to note that the subjects identified in "clinical high-risk" (CHR) studies of schizophrenia (often termed "prodromal studies") (see Fusar-Poli et al., 2013) are often deeply impaired and showing evidence of psychosis, albeit reduced in severity. Thus, CHR subjects do not display nonpsychotic schizotypic psychopathology as typically defined (see Lenzenweger, 2021).

# Prevalence of Schizotypic Psychopathology

### Epidemiology of Personality Pathology: General Considerations

Lenzenweger, Loranger, and colleagues (1997) estimated the point prevalence of diagnosed PD to be approximately 11% (95% confidence interval [CI] = 7.57%, 14.52%). The two-stage procedure for case identification coupled with advanced estimation procedures was subsequently used in the National Comorbidity Study-Replication (NCS-R) investigation (Lenzenweger, Lane, Loranger, & Kessler, 2007). In the NCS-R, which used welltrained screening personnel and clinically experienced diagnosticians using the International Personality Disorder Examination (IPDE, Loranger et al., 1994), a population prevalence of 9.0% for "any personality disorder" was found for the US general population (see also Lenzenweger, 2008).

### Epidemiology of Schizotypic Psychopathology

For most of the past century prevalence "estimates" for schizotypic psychopathology have been arrived at through indirect routes and considered at best to be educated guesses. The DSM systems have "suggested" prevalences for SPD of approximately 3% and for PPD at 0.5-2.5% in the general population. Such "guesstimates" were derived from relatively large clinical (psychiatric patient) samples. For example, Loranger (1990) reported, in a large series of consecutive psychiatric admissions to a university teaching hospital, 2.1% for DSM-III SPD and 1.2% for PPD. Zimmerman and Coryell (1990) reported that SPD was found in 3.0% of their respondents and PPD in 0.4%. In a more recent series of 859 psychiatric outpatients (university hospital), prevalence rates of .6% for SPD and 4.2% for PPD were reported (Zimmerman et al., 2005).

Since 1997, a number of community-based samples have been studied using epidemiological methods and state-of-the-art diagnostic interviews, and we now have reasonable estimates for SPD and PPD rates in the population. Lenzenweger (2008) summarized the prevalence data for SPD and PPD from five community studies (four US studies, two European studies) (see Table 28.1). For SPD, the prevalences ranged from 0.06% to 1.6% (median = 0.6%), whereas the prevalences for PPD ranged from 0.7% to 5.10% (median = 1.00%). In the NCS-R, Lenzenweger, Lane et al. (2007) found a prevalence of 5.7% (SE = 1.6) for Cluster A disorders (which included schizoid PD) for the US population. The median prevalence value for "any Cluster A PD" (including schizoid PD) taken across the six epidemiological studies was 3.45%. Quirk and colleagues (2016) similarly estimated the prevalence for SPD to be about 4%. Chemerinski et al. (2013) concluded that SPD remains best thought of as a relatively infrequent disorder, even in clinical settings.

One must, however, remember that "schizotypic psychopathology" is a broader construct than the contemporary definitions of *DSM-5* or *ICD-11* SPD and PPD. Therefore, useful guidance on the epidemiology of this "broader construct" should be considered as well. For example, Essen-Möller, Larsson, Uddenberg, and White (1956) reported from their landmark study of a rural Swedish population that schizoid personality, in the sense of "probably related to schizophrenia or to a schizophrenic taint" (p. 73), was found among 1.8% of women and 6.0% of men. Kety et al. (1994), in

a report from their Danish Adoption Study of Schizophrenia, found that among the biological relatives of normal control adoptees, 0.8% were paranoid personality, 3.3% were schizoid personality, and 2.5% were "latent schizophrenia," a pre-DSM-III diagnostic designation roughly akin to SPD. In a secondary analysis of the Kety et al. (1994) data, Kendler, Gruenberg, and Kinney (1994) found that, according to DSM-III criteria, from 3.1% to 3.7% of the relatives of the normal control adoptees had either SPD or a "schizophrenia spectrum" diagnosis (or, schizotypic psychopathology more generally). Generalization from family-based data to population prevalence must be done with great caution, however, owing to various constraints inherent in family data (Carey et al., 1980).

Finally, based on a consideration of familial risk rates among biological relatives, Meehl (1990) argued that approximately 10% of the population is genotypically schizotypic, though not all individuals manifest this predisposition in a highly visible manner. Meehl's conjecture is supported by empirical taxometric (Korfine & Lenzenweger, 1995; Lenzenweger & Korfine, 1992a; Linscott, 2007; Linscott & Morton, 2018; Meyer & Keller, 2001) and mixture modeling results (Lenzenweger, McLachlan, & Rubin, 2007).

## Comorbidity Among DSM-Defined SPD and PPD

In this context, it is useful to define the terms "covariation," "co-occurrence," and "comorbidity." Covariation concerns the degree to which measures correlate (e.g., the correlation or association between SPD and PPD features when both have been assessed in the same patients). Co-occurrence refers to the rate at which two conditions (e.g., diagnoses) appear together (e.g., the rate at which PPD and SPD diagnoses appear in the same patients). Finally, comorbidity, which is a term from epidemiology and medicine, concerns the presence of two or more illnesses in the same patients (e.g., heart disease + diabetes). Comorbidity as an issue for schizotypic psychopathology is usually concerned with the presence of SPD and PPD diagnoses in the same individuals, as observed in clinical samples. The pre-DSM-5 nomenclatures allowed (even encouraged) multiple diagnoses on what was then the Axis II of the multiaxial system. Therefore, that feature of the system complicates any discussion of comorbidity. Observed comorbidity for SPD and PPD may represent little more than an artifact of rules (or guidelines) of the then prevailing diagnostic system. Therefore, as opposed to the implication

that two diseases are actually present in the same person (genuine comorbidity), it may actually make greater sense to simply speak of "co-occurrence" of PD diagnoses within a *DSM* framework.

Available data indicate that PPD appears to be present in 0-60% of patients with SPD drawn from primarily clinical samples (Siever, Bernstein, & Silverman, 1991). SPD is present in 17-70% of patients diagnosed with PPD (Bernstein et al., 1993). Zimmerman et al. (2005) found that PPD and SPD diagnoses co-occurred frequently in their outpatient clinical series, and Lenzenweger, Lane, and colleagues (2007) found substantial covariation between PPD and SPD features in the NCS-R sample. It is essential to note that PPD is, in fact, rarely found alone in patients, often occurring with SPD (Triebwasser et al., 2013). In this context "covariation" refers to associations or correlations among the PDs, where the unit of analysis is typically the number of diagnostic criteria met for each of the disorders, whereas "co-occurrence" refers to the rate at which two disorders appear together in the same person in a sample of individuals assessed for the presence or absence of different PDs.

Therefore, these co-occurrence/covariation rates may reflect (1) a system that allows multiple diagnoses, (2) shared diagnostic criteria, (3) sampling bias (e.g., more individuals who are impaired tend to seek treatment), and/or (4) a common underlying substrate (e.g., schizotypy as a latent liability for schizophrenia). Regarding shared diagnostic criteria, PPD and SPD share the features of suspiciousness and paranoia, but PPD lacks the cognitive and perceptual distortions included in the SPD criteria. The sampling bias issue is especially relevant here given that most individuals diagnosed with SPD or PPD probably never present for treatment, but, when they do, they are likely to be in crisis, be more impaired, or both (Lenzenweger & Korfine, 1992b).

Available data also reveal that 33–91% of individuals diagnosed with SPD tend to also receive the diagnosis of borderline PD (BPD; Chemerinski et al., 2013), though fewer BPD-diagnosed cases have a co-occurring SPD diagnosis. Zimmerman et al. (2005) reported significant comorbidity between SPD and BPD as well as between PPD and BPD. Lenzenweger, Lane, and colleagues (2007) found a relatively strong association between PPD and BPD features, with a weaker association between SPD and BPD. This degree of co-occurrence/covariation may reflect, in part, the influence of the method used to derive the original SPD and BPD diagnostic criteria as well as less specific psychotic-like features that occur in both disorders and the sampling issue noted previously.

## Dimensional Measurement and Covariation Among Schizotypy Measures

The issue of comorbidity is not directly relevant to schizotypic psychopathology as assessed by dimensionally configured psychometric measures as these do not reflect a categorical approach to classification. Measures of schizotypy, however, do tend to be intercorrelated (Kwapil et al., 2008, 2018) as one would expect of valid indices tapping a common underlying construct. Inasmuch as the "psychoticism" dimension of the Alternative Model of Personality Disorder in the *DSM-5* can be considered to tap aspects of schizotypic psychopathology, the facets of unusual beliefs and experiences, perceptual dysregulation, and eccentricity are highly correlated with psychoticism, whereas (somewhat oddly) suspiciousness is not (Krueger et al., 2012).

# Longitudinal Course of Schizotypic Psychopathology

For many years, psychiatry and clinical psychology have assumed that personality pathology, including schizotypic psychopathology, was relatively stable over time. However, the data upon which that assumption of continuity or stability rested were relatively sparse—indeed, virtually nonexistent. Only within the past two decades have the data from multiwave, prospective, longitudinal studies begun to emerge to address this question. The available data from the four major prospective longitudinal studies of PDs have indicated that PDs are considerably more plastic and changeable than ever thought (Lenzenweger et al., 2018).

The Longitudinal Study of Personality Disorders (LSPD) (Lenzenweger, 1999a, 2006) reported that SPD and PPD, while maintaining rank order stability over time, showed evidence for nontrivial declines in mean level feature counts over a 4-year study period. However, when the LSPD data were examined in finer detail using individual growth curve analysis, the amount of individual change observed in PPD over time was insignificant, whereas the amount of individual change in SPD over time was appreciable. Johnson et al. (2000) found evidence for substantial rank-order stability of PPD and SPD features through time as well as rather substantial and significant declines in the mean level of PPD and SPD features over time in a large, community-based longitudinal study. Finally, in a clinical sample of schizotypal patients followed longitudinally, Shea et al. (2002) reported a comparable set of results showing maintenance of individual difference (rank order) stability for SPD features over time, yet clear evidence of a decline in SPD features over time at the level of group means (see also Sanislow et al., 2009). The overall longitudinal picture, therefore, is consistent across studies, yet complex. PPD and SPD appear to maintain rankorder stability over time in the context of diminishing features at the group and individual levels. The mechanisms and processes accounting for these changes have not been illuminated thus far.

# Historical Overview of Schizotypic Psychopathology

Variants of psychopathology thought to be related to schizophrenia, or schizotypic pathology, have been identified in different ways across the years (see Kendler, 1985, for historical review; see also Planansky, 1972). The difficult methodological and conceptual issues attending research in this area have been carefully reviewed by Gottesman (Gottesman, 1987; Shields et al., 1975) and Lenzenweger (2010, 2015, 2018a, 2018b).

Kraepelin (1919/1971, p. 234) and Bleuler (1911/1950, p. 239) made note of what they termed "latent schizophrenia," a personality aberration regarded as a quantitatively less severe expression of schizophrenia. Interestingly, because Kraepelin and Bleuler believed that the signs and symptoms of the so-called latent schizophrenia were in fact continuous with the "principal malady" (Kraepelin, 1896/1971, p. 234) or "manifest types of the disease" (Bleuler, 1911/1950, p. 239), neither of these master phenomenologists provided extended clinical descriptions of such cases. Both suggested one merely envision schizotypic conditions as characterized by diminished schizophrenia signs and symptoms. In attending to schizotypic pathology, however, Kraepelin and Bleuler foreshadowed subsequent efforts to delineate the phenotypic boundaries of schizophrenia through exploration of the schizotypic states.

In reviewing the history of psychiatric developments that culminated in the diagnostic criteria for SPD in *DSM-III*, Kendler (1985) persuasively argued that much of the clinical literature dealing with schizotypic states can be organized along two major historical trends. The "familial" tradition emphasizes phenomenological descriptions of nonpsychotic but aberrant personality states that occur in the biological relatives of individuals suffering from clinical schizophrenia. The second tradition was termed "clinical," as it emphasizes the work of clinicians who describe the symptomatology of their patients presenting schizotypic, or schizophrenialike, features. As detailed by Kendler (1985), workers within the familial tradition (e.g., Kraepelin, Bleuler, Kretschemer, Kallmann, Slater) frequently used terms such as "latent schizophrenia," "schizoid personality or character," or "schizoform abnormalities" to describe some family members of patients with schizophrenia. These early observers used terms like "eccentric-odd," "irritable-unreasonable," "socially isolated," "aloof/cold demeanor," and "suspiciousness" to describe the family members of schizophrenia patients (Kendler, 1985, p. 543, Table 29.1).

In contrast, researchers and clinicians working within the so-called clinical tradition (Kendler, 1985; e.g., Zilboorg, Deutsch, Hoch and Polatin, Rado, and Meehl) used terms such as "ambulatory schizophrenia," "as-if personality," "pseudoneurotic schizophrenia," and "schizotypal" to describe individuals who were severely affected but nonpsychotic. The patients described by these rubrics were observed to demonstrate "schizophrenia-like symptomatology" in their psychological and psychosocial functioning, and it was frequently hypothesized that a genuine schizophrenia-related process was driving the manifest pathology. Disordered ("primary process") thinking and the lack of deep interpersonal relations were the two features that occurred most frequently in the descriptions of schizotypic patients by clinical tradition workers (Kendler, 1985, p. 545, table 2). Kendler (1985) noted apparent basic agreement in the descriptions of schizotypic individuals across the two traditions in terms of interpersonal functioning impairments as well as broad overlap in other areas (e.g., disordered thinking, anxiety, anger, hypersensitivity).

Early depictions of schizotypic psychopathology, with the exception of those discussions by Rado and Meehl, were only *descriptive* and lacked any detailed etiological or developmental proposals. Although there was speculation about an association with schizophrenia and a possible hereditary connection, the precise pathway leading from the underlying liability for schizophrenia or schizophrenia-related pathology to the phenotypic expression of a clinical disorder was absent. Only Meehl (1962, 1964, 1990, 2001) offered a complex developmental model, setting him apart from other clinical researchers.

Perhaps the most influential early evidence that helped to establish a link between schizotypic

 Table 29.1
 Prevalence (percentage) of personality disorders in six nonclinical population/community studies using validated structured interviews

Study								
	Lenzenweger, Loranger et al. (1997)	Torgersen et al. (2001)	Samuels et al. (2002)	Crawford et al. (2005)	Coid et al. (2006)	Lenzenweger, Lane et al. (2007)

Cluster A	2.8	4.1	2.1	6.8	1.6	5.7		

*Note:* Instruments indicate the structured clinical interview used: International Personality Disorder Examination (IPDE); Structured Interview for *DSM-III-R* Personality Disorders (SIDP-R); Structured Clinical Interview for *DSM-IV* Axis II Disorders (SCID-II). Dashes indicate not applicable. All prevalences reported are weighted. In this context another epidemiological study, the National Epidemiologic Study of Alcohol and Related Conditions (NESARC; Grant et al., 2004), generated prevalence estimates for *DSM-IV* Cluster A personality disorders that are strikingly higher than those reported in most of the studies contained in this table (paranoid = 4.4%, schizotypal = 3.9%, schizoid = 3.13%). However, methodological limitations of the NESARC study (e.g., use of an unvalidated Axis II assessment instrument; use of census workers without clinical training to conduct Axis II assessments) urge substantial caution in any consideration of the NESARC prevalence data (thus, they are not included in this table).

phenomenology and clinical schizophrenia came from the Danish Adoption Study of Schizophrenia (Kety et al., 1968). Using a definition of "borderline schizophrenia" heavily influenced by the clinical tradition described here, Kety et al. (1968) found elevated rates of borderline or latent schizophrenia in the biological relatives of adoptees with schizophrenia. Kety et al. (1994) further confirmed these initial results through further study of adoptees from the entire Danish population. These early results provided compelling evidence derived from a rigorous adoption methodology for a genetically transmitted component underlying manifest schizophrenia and the less severe schizophrenia-like disorders. The hypothesized continuity between the conditions was thus not merely phenomenological but also genetic. The diagnostic framework used by Kety et al. (1968) to diagnose "borderline" schizophrenia was subsequently reexamined (Spitzer et al., 1979) for use in the Axis II section of what would become the DSM-III. However, Spitzer and colleagues were not attempting to distill from the Kety et al. framework only symptoms that identified biological relatives of individuals with schizophrenia; rather, they sought to determine if there was a reliable parsing of Kety's criteria that might map more narrowly defined and identifiable disorders. Spitzer et al. (1979) proposed the following eight symptoms and signs for SPD: magical thinking, ideas of reference, suspiciousness, recurrent illusions, social isolation, odd speech, undue social anxiety-hypersensitivity, and inadequate rapport (aloof/cold). These criteria were, in large part, adopted for use in the *DSM-III* and continue in use in the *DSM-5*. SPD was originally considered a PD, but in the *DSM-5* it is placed within the schizophrenia spectrum conditions, a move informed by decades of empirical research and theoretical argument (Lenzenweger, 1998). The *DSM* criteria for SPD were, and remain, essentially atheoretical in nature, reflecting merely a clustering of symptoms, denoted with no specification of etiology or development.

This overview provides a suggestion of the interest schizotypic conditions have enjoyed among clinical and research workers, especially since 1980. It is important to realize that with the advent of explicit diagnostic criteria for SPD in 1980 in the *DSM-III* and a simultaneous narrowing of the definition of schizophrenia, there was a marked decrease in the rate at which schizophrenia was diagnosed and a corresponding rise in diagnosis of Axis II schizophrenia-related PDs (Loranger, 1990). Such an effect generated by a shift in the nomenclature has surely facilitated the focus on schizotypic conditions. It is also reasonable to assume that interest in these conditions has been further augmented by the burgeoning of research work in PDs in general, which has been greatly facilitated by improvements in diagnostics (cf. Loranger, 1999). Clearly, this interest has been sustained through a rich descriptive tradition and supported by findings indicating that schizotypic pathology is related genetically to schizophrenia per se (see Torgersen, 1994). Indeed, recent evidence, done in the form of genome-wide scans for loci relevant to schizophrenia and schizotypic psychopathology dimensions, confirms shared genetic substrates for the two forms of psychopathology (Fanous et al., 2007; see also Avramopoulos et al., 2002; Lin et al., 2005; Siever et al., 2011; Walter et al., 2016).

# Classic Model of Schizotypic Psychopathology: Meehl's Integrative Developmental Model of Schizotypy

As already noted, many of the early depictions of schizotypic pathology were virtually all descriptive in nature. Although the peculiarities of the relatives of individuals with schizophrenia or the symptoms of outpatients with schizophrenic-like symptoms were noted and thought to be related to schizophrenia in some manner (Kendler, 1985), none of the early workers advanced a model that unambiguously posited a genetic diathesis for schizophrenia and traced its influence through developmental psychobiological and behavioral paths to a variety of clinical (and nonclinical) outcomes. Unlike his predecessors, Meehl (1962, 1990) proposed a model that was (and is) clearly developmental in nature and based on a hypothesized neurointegrative deficit.

# Insights Gleaned from the Earlier Observations of Sandor Rado

The roots of Meehl's model can be found in the observations and psychodynamic formulations of Sandor Rado (1953, 1960). As a clinician, Rado made initial strides toward an integrative model that sought to link genetic influences for schizophrenia and observed schizotypic personality functioning. He argued from a psychodynamic position informed by an appreciation for genetics that schizotypal behavior derived from a fundamental liability to schizophrenia. Rado, in fact, coined the term "schizotype" to represent a condensation of "schizophrenic *phenotype*" (Rado, 1953, p. 410; Rado, 1960, p. 87). It is interesting to note that Rado did not suggest schizotype as a condensation of the terms "schizophrenia" and "genotype" (cf. Siever & Gunderson, 1983). Rado (1960) referred to the individual who possessed the schizophrenic phenotype as a schizotype, while the correlated traits deriving from this "type" were termed "schizotypal organization" and the overt behavioral manifestations of the schizotypal traits were termed "schizotypal behavior" (see p. 87).

For Rado, the causes of schizotypal "differentness" were to be found in two core psychodynamic features of such patients, both of which were thought to be driven by "mutated genes." The two core defects present in the schizotype's personality organization were (1) a diminished capacity for pleasure, or pleasure deficiency, speculated to have a neurochemical basis deriving from an inherited pleasure potential coded in the infant's genes (Rado, 1960, p. 88), and (2) a proprioceptive (kinesthetic) diathesis that resulted in an aberrant awareness of the body (a feature giving rise to schizotypic bodyimage distortions; Rado, 1960, see pp. 88 and 90). Rado (1960) believed the physiological nature of the proprioceptive diathesis was obscure and remained to be explored (p. 88). According to Rado, integration of the "action self," a necessity of psychodynamic/psychological health, was endangered by the diminished binding power of pleasure (p. 90) and the proprioceptive diathesis found in the schizotype. Consequently, Rado (1960) described the schizotype as struggling to retain a sense of personality integration through several compensatory mechanisms (see p. 90), with such mechanisms frequently manifesting themselves as schizotypal traits and behaviors. An important feature of Rado's model concerned what he termed "developmental stages of schizotypal behavior," essentially a continuum view of clinical compensation (a view echoed later by Meehl, 1990, p. 25). Rado's continuum notion suggested that a common schizophrenia diathesis could lead to a variety of phenotypic outcomes ranging from compensated schizotypy to deteriorated schizophrenia; thus an etiological unity was proposed as underlying a diversity of clinical manifestations.

# Meehl's Proposal: Schizotaxia, Schizotypy, Schizophrenia

Influenced by Rado's (1953, 1960) hypotheses, Meehl's (1962) model of schizotypy was first articulated in a now-classic position paper titled "Schizotaxia, Schizotypy, Schizophrenia." In this paper, one that has been viewed as enormously transforming for schizophrenia research (Lenzenweger, 2010), Meehl laid out an integrative etiological framework for schizophrenia. The model not only encompassed genetic factors, social learning influences, and clinical symptomatology but also contained hypotheses about the precise nature of the fundamental defect underlying schizotypic functioning and its interactions with what he came to term "polygenic potentiators." Elaboration on and refinement of the original 1962 theory can be found in his later papers (e.g., Meehl, 1972, 1975, 1990, 2001). What follows is a distillation of the major points contained in Meehl's efforts to illuminate the development of schizophrenia. The reader is encouraged to consult Meehl's original position statement (Meehl, 1962), his 1990 treatise (Meehl, 1990), and additional refinements (Meehl, 2001, 2004; see also, Lenzenweger, 2010) to gain a full appreciation for his point of view.

In brief, Meehl's (1962, 1990) original model held that a single major gene (the schizogene) exerts its influence during brain development by coding for a specific "functional parametric aberration of the synaptic control system" in the central nervous system (CNS; Meehl, 1990, pp. 14-15). The aberration, present at the neuronal level, is termed "hypokrisia" and suggests a neural integrative defect characterized by an "insufficiency of separation, differentiation, or discrimination" in neural transmission. Meehl (1990) argued that his conceptualization of schizotaxia should not be taken to represent a defect in basic sensory or information retrieval capacities (p. 14), nor a CNS inhibitory function deficit (p. 16). The defect in neural transmission amounts to the presence of "slippage" at the CNS synapse, and such slippage at the synapse has its behavioral counterparts (at the molar level) in the glaring clinical symptomatology of actual schizophrenia. In other words, just as the synaptic functioning in schizophrenia is characterized by slippage, so, too, are the symptoms of associative loosening and cognitive-affective aberrations observed in the patient with schizophrenia. Hypokrisia was hypothesized to characterize the neuronal functioning throughout the brain of the individual who was affected, thus producing what amounted to a rather ubiquitous CNS anomaly (Meehl, 1990, p. 14) termed "schizotaxia." It is particularly fascinating that even today (e.g., Owen et al., 2005) models of synaptic dysfunction echo this conjecture about synaptic slippage. (In this context, it is important to note that many aspects of Meehl's model remain persuasive even in light of data indicating that multiple genes probably contribute to

schizophrenia liability, or schizotypy [see Sullivan et al., 2012; but see also Sekar et al., 2016; Yilmaz et al., 2021]).

Thus, according to the model, schizotaxia is the "genetically determined integrative defect, predisposing to schizophrenia and a sine qua non for that disorder" (Meehl, 1990, p. 35) and was conjectured to have a general population base rate of 10% (see Meehl, 1990, for derivation). Note that schizotaxia essentially describes an aberration in brain functioning characterized by pervasive neuronal slippage in the CNS; it is not a behavior or observable personality pattern. The schizotaxic brain, however, becomes the foundation that other factors will build upon and interact aversively with to possibly produce clinically diagnosable schizophrenia. The other factors that interact with the schizotaxic brain and influence individual development (as well as clinical status) are the social learning history of an individual as well as other genetic factors, termed "polygenic potentiators."

Meehl (1962, 1990, 2001) generally held that all (or nearly all) schizotaxic individuals developed schizotypy (i.e., a schizotypal personality organization) on essentially all existing social reinforcement schedules. Schizotypy, therefore, referred to the psychological and personality organization resulting from the schizotaxic individual interacting with and developing within the world of social learning influences. An individual who displays schizotypy is considered a schizotype. (Note that Meehl's "schizotypal personality organization" is not the same as the DSM SPD.) Meehl (1990) considered the possibility that a schizotaxic individual might not develop schizotypy if reared in a sufficiently healthful environment, but he viewed this outcome as unlikely. In short, there are multiple possible observable or measurable manifestations of schizotypy, where schizotypy is the latent construct and the observables are indicators (e.g., schizophrenia, schizotypic pathology, laboratory measures) (see Figure 29.2).

The second set of factors influencing the development of clinical schizophrenia in the schizotypic individual is a class of genetically determined factors (or dimensions) termed "polygenic potentiators." According to Meehl (1990), "a potentiator is any genetic factor which, given the presence of the schizogene *and therefore of the schizotypal personality organization* [emphasis in original], raises the probability of clinical decompensation" (p. 39). Potentiators include personality dimensions independent of schizotaxia, such as social introversion, anxiety proneness, aggressivity, and hypohedonia.

**Figure 29.2** Relationship between the latent construct schizotypy and indicators of schizotypy, such as clinical, psychometric, and laboratory measures. One should not speak of observed indicators of the latent construct as schizotypy; for example, schizotypal personality disorder features should be described as a schizotypy indicator. See Cronbach and Meehl (1955) and McCorquodale and Meehl (1948) for extended discussion of these points. Copyright 2010, Mark F. Lenzenweger. Used with permission of the author.

Such potentiators do not modify (in the technical genetic sense of the term) the expression of the putative schizogene but rather interact with the established schizotypic personality organization and the social environment to facilitate (or, in some cases, "depotentiate") the development of decompensated schizotypy, namely schizophrenia. Meehl (1990) stated, "It's not as if the polygenes for introversion somehow 'get into the causal chain' between the schizogene in DNA and the parameters of social reinforcement" (p. 38), rather the potentiators push the schizotype toward psychosis. In this context it is interesting to note that Meehl's modeling encompassed the idea of a "mixed" model of genetic influence: namely, a single major gene (i.e., an autosomal diallelic locus) operating against a background due to an additive polygenic (or cultural) component (Morton & MacLean, 1974). Thus, in this model, the development of clinically diagnosable schizophrenia is the result of a complex interaction among several factors: (1) a schizotaxic brain characterized by genetically determined hypokrisia at the synapse, (2) environmentally mediated social learning experiences (that bring about a schizotypal personality organization), and (3) the polygenic potentiators.

Although the modal schizotype does not decompensate into diagnosable schizophrenia, Meehl suggested that the latent diathesis is detectable through aberrant psychological and social functioning. This fundamental assumption has served as an organizing concept for decades of research on schizotypic psychopathology and schizophrenia (see Lenzenweger, 2010, 2021). Meehl (1962) described four detectable fundamental signs and symptoms of schizotypy: cognitive slippage (or mild associative loosening), interpersonal aversiveness (social fear), anhedonia (pleasure capacity deficit), and ambivalence. Later, in 1964, he developed a clinical checklist for schizotypic signs that included rich clinical descriptions of not only these four signs or symptoms but also several others that he suggested were valid schizotypy indicators. Basically, all aspects of the core clinical phenomenology and psychological functioning seen in the schizotype were hypothesized to derive fundamentally from aberrant CNS functioning (i.e., hypokrisia) as determined by the schizogene. For example, "primary cognitive slippage" gives rise to observable secondary cognitive slippage in thought, speech, affective integration, and behavior. He saw hypokrisia as the root cause of "soft" neurological signs as well as what he termed "soft" psychometric signs that could be detected among schizotypes. Finally, Meehl argued that hypokrisia also led to what he termed "primary aversive drift" or the steady developmental progression toward negative affective tone in personality functioning across the life span among schizotypes (see Meehl, 1990, figure 1 in original, p. 27). This primary aversive drift across the life span, according to Meehl, gave rise to social fear, ambivalence, and hypohedonia (Meehl, 2001). Figure 29.3 contains a depiction, inspired in large part by Meehl's

Figure 29.3 Developmental model relating the genetic diathesis for schizophrenia, schizotaxia, and schizotypy and implied levels of analysis (adapted from Meehl 1962, 1990), with modifications (Lenzenweger, 2010). Those factors to the left of the vertical broken line (i.e., plane of observation) are latent and therefore unobservable with the unaided naked eye, whereas those factors to the right of the plane of observation are manifest (or observable). A DNA-based (i.e., genetic) liability creates impaired central nervous syste,-based neural circuitry (schizotaxia) that eventuates in a personality organization (schizotypy) that harbors the liability for schizophrenia. Social learning schedules interact with schizotaxia to yield schizotypy. Psychosocial stressors and polygenic potentiators interact with schizotypy to vield manifest outcomes across a range of clinical compensation. Various possible manifest developmental outcomes are schizophrenia (assuming a "second hit," e.g., in utero exposure to maternal influenza), schizotypic psychopathology (e.g., schizotypal and/or paranoid personality disorders), or schizophrenia-related psychoses (e.g., delusional disorder). So-called prodromal features (withdrawal, reduced ideational richness, disorganized communication) may precede the onset of some (but not all) cases of schizophrenia. Endophenotypes (e.g., sustained attention deficits, eye-tracking dysfunction, working memory impairments, and/or psychometric deviance [PAS]; see Gottesman & Gould, 2003), which are invisible to the unaided, naked eye (but detectable with appropriate technologies), are found below the plane of observation. Epigenetic factors refer to nonmutational phenomena, such as DNA methylation and histone acetylation (modification), that alter the expression of the schizophrenia gene (or genes). Finally, all individuals represented across this range of manifest outcomes are considered schizotypes, which does not necessarily imply an ICD or DSM diagnosis. Copyright 2010, Mark F. Lenzenweger. Used with permission of the author.

thinking, of the relations between schizotaxia, schizotypy, schizophrenia, and related outcomes, including endophenotypes.

It is worth noting that the role anhedonia played in Meehl's model changed over the years. In the 1962 model, anhedonia was hypothesized to represent a fundamental and etiologically important factor in the development of schizotypy, actually falling somewhat "between" the genetic defect hypokrisia and the other schizotypic signs and symptoms of interpersonal aversiveness, cognitive slippage, and ambivalence. As of 1990, Meehl deemphasized anhedonia (then termed "hypohedonia"; but see also Meehl, 1964) as a fundamental etiological factor in the development of schizotypy and schizophrenia. In the 1990 revision, Meehl strongly suggested that associative loosening and aversive drift are those psychological processes (deriving from hypokrisia) that primarily determine the behavioral and psychological characteristics of the schizotype (see Meehl, 1990, p. 28). Hypohedonia was (is) now viewed as playing an etiological role in the development of schizotypy by functioning as a dimensional polygenic potentiator (i.e., not deriving from the core genetically determined schizophrenia diathesis). The reconfiguration of hypohedonia's role in the 1990 model was a major substantive shift and was discussed further in Meehl (1993, 2001). In overview, Meehl (1975, 1987, 1990) proposed that all persons displayed some level of hedonic capacity, which was conceived of as a normal-range, dimensional, individual differences construct, and

it functioned as the potentiator noted previously. However, Meehl (2001) made it clear that a pathological variant of hypohedonia, determined perhaps by a genetic defect and similar to that proposed by Rado, could also exist in some people. However, the etiological basis of such a hedonic defect may or may not be directly attributable to a "schizogene." He did not see these two possibilities-a normalrange quantitative system and an anhedonic taxon or class—as mutually exclusive. Meehl (2001) discussed the challenges posed to interpretation of results from latent structure analyses of phenotypic indicators of hedonic capacity with reference to his model of schizotypy and the possible etiology of deviations in hedonic capacity. Meehl viewed this specific terrain (i.e., hedonic capacity) as ripe for continued exploration and saw it as consisting of open questions with respect to schizotypy (e.g., Strauss & Gold, 2012; see also Strauss & Cohen, 2018). Recent taxometric evidence focused on hypohedonia and the distinction between hedonic capacity and experience, and thus social withdrawal, challenges the meaning of hypohedonia as a core process in schizotypy (Linscott, 2007).

A central, and perhaps the most important, assumption in Meehl's model is that schizotypy, as a personality organization reflective of a latent liability for schizophrenia, can manifest itself behaviorally and psychologically in various degrees of clinical compensation. Thus, following Rado (1960), Meehl (1962, 1990) argued that the schizotype may be highly compensated (showing minimal signs and symptoms of schizotypic functioning), or the individual may reveal transient failures in compensation, or may be diagnosably schizophrenic. Schizotypes, therefore, can range clinically from apparent normality through to psychosis, yet all share the schizogene and resultant schizotypic personality organization. A crucial implication of this assumption is that not all schizotypes develop diagnosable schizophrenia (i.e., one could genuinely be at risk yet never develop a psychotic illness); however, all schizotypes will display some evidence of their underlying liability in the form of aberrant psychobiological and/or psychological functioning. As noted, this particular implication of the model has guided nearly 60 years of research directed at developing methods for the valid and efficient detection of schizotypy endophenotypes (Gottesman & Gould, 2003; Lenzenweger, 1999c, 2013a, 2013b). Through clinical, psychometric, or other means it articulated the heart of the "diathesisstressor" model or approach for psychopathology

(Lenzenweger, 2010). In short, if valid schizotypy detection strategies could be developed, samples of "high-risk" individuals (i.e., schizotypes) could be assembled and examined in various efforts to better illuminate the nature and development of both schizophrenia and related schizotypic conditions (see Lenzenweger, 2021).

### Frequent Misunderstandings of Meehl's Model

In discussing Meehl's model of schizotypy, it is important to point out several misconceptions of the model and various misunderstandings (see Lenzenweger, 2010, for extensive details). There are five primary areas of misunderstanding:

- 1. Meehl's schizotypy construct is *not* the same as *DSM*-defined SPD. Schizotypy is a latent construct, whereas SPD is an observable phenomenological entity (Figure 29.2).
- 2. Schizotypy, as a latent construct, is *not* entirely genetic in origin. It reflects input from both genes (determining "schizotaxia") and environmental factors (e.g., social learning history) (Figure 29.3).
- 3. The terms "schizotype" and "schizotypy" are not reserved only for those cases identified by *DSM*-defined SPD features. It makes no conceptual sense to reserve the term "schizotypy" for *interview-based* assessments of schizotypic features, whereas the term "psychometric schizotypy" is used for psychometric assessments of schizotypic features.
- 4. Not all schizotypes are expected to develop schizophrenia. Some schizotypes will develop (or convert to) schizophrenia, some will show some continued nonpsychotic evidence of schizotypic features across the life span, and some schizotypes will remain quietly schizotypic (perhaps displaying evidence of their underlying personality organization on endophenotypic measures (Gottesman & Gould, 2003; Lenzenweger, 2013a, 2013b, 2021).
- 5. Some observers (mis)believe that Meehl's entire developmental model hinges on the presence of a proposed single, schizophrenia-specific gene (a "schizogene"). However, this is incorrect. Meehl did speculate on the possibility of a "schizogene" in his original formulations and used it as starting point. However, the cascade of processes and outcomes in the model is entirely compatible with *multiple* genes contributing to the underlying schizotaxic pathology, which then plays itself out developmentally as noted in

Figure 29.3. Meehl fully understood the state of modern genetics research in schizophrenia and the additive polygenic threshold model.

# What Determines Conversion to Schizophrenia from Nonpsychotic Schiztotypy in Meehl's Model?

There is interest in determining what is termed the "conversion to psychosis rate" among those persons deemed to be at risk for or in the early-onset stages of schizophrenia (with many prodromal cases appearing, at least, quasi-psychotic in terms of presenting phenomenology-some are already clinically psychotic for all intents and purposes; Fusar-Poli et al., 2013), however such interest is tempered by the fact that the vast majority (70% or more) of such clinical high-risk cases do not convert to psychosis on follow-up (see Lenzenweger, 2021, for extended discussion). On a related note, Siever and Davis (2004) have speculated that the schizotypic individual who does not develop schizophrenia may have reduced striatal dopaminergic activity and increased frontal capacity, assets that spare him or her from the emergence of schizophrenia. However, recent evidence shows relations between genetic polymorphisms known be associated with both dopaminergic functioning and schizophrenia to also be associated with schizotypic features (Grant et al., 2013; Mohr & Ettinger, 2014; Thompson et al., 2020).

What is the precise recipe of polygenic potentiators, life stressors, and random events in interaction with the schizotaxic brain that might lead one to move from being a compensated schizotype to clinical schizophrenia? Simply stated, the answer is not known. Meehl articulated the rich matrix of components and developmental processes that he believed could eventually yield schizophrenia in some instances, but he was not able to identify those specific factors (genetic or otherwise) that propel one to transition from the nonpsychotic schizotype to clear-cut schizophrenia (i.e., psychosis). Clearly Meehl (1962, 1990) viewed the polygenic potentiators noted earlier as playing an important role in this developmental process; however, he also stressed the importance of what he termed "unknown critical events" as well as the "random walk" (i.e., life histories may reflect divergent causality rather than the impact solely of well-known systematic factors such as social class or birth order) in the determination of schizophrenia (Meehl, 1978; cf. Meehl, 1971, 1972). In this context it is worth noting that although Meehl saw the polygenic potentiators as important, he argued that the polygenic potentiators "do not *in the least* 'modify' the schizogene's *endo*phenotypic expression as schizotaxia, a CNS parametric aberration" (Meehl, 1972, p. 380; emphasis in original), rather they simply alter the probability that a schizotype might move on to clinical schizophrenia. The precise manner whereby a schizotype moves on to schizophrenia, in those instances where it happens, remains an open issue and is ripe for life span developmental studies of schizotypy. Such research should also seek to understand those factors—polygenic potentiator or otherwise—that might buffer a schizotype from transitioning to schizophrenia.

Although various efforts have been made to expand upon and refine Meehl's basic framework (e.g., see examples in Lenzenweger & Dworkin, 1998), the core assumptions of contemporary liability models do not differ substantially from what he proposed in 1962 in terms of the importance of genetically influenced contributions to a liability impacted by environmental stressors. Contemporary quantitative genetic models, especially the simple polygenic model as well as the polygenic-threshold model, see all genetically influenced factors contributing to schizophrenia liability as summing (unlike Meehl who proposed what was essentially a "mixed model" in which a schizophrenia-specific, genetically influenced liability operated against a background of polygenic effects). Neurocognitive (Andreasen, 1999), neuroscientific (e.g., Grace & Moore, 1998; Owen et al., 2005; Phillips & Silverstein, 2003), and neurodevelopmental (Marenco & Weinberger, 2000; McGlashan & Hoffman, 2000; Sekar et al., 2016) models for schizophrenia, albeit not wed to hypothetical processes such as hypokrisia, are nevertheless quite consistent with many of the major tenets of Meehl's framework for schizotypic psychopathology and schizophrenia proper. In short, nearly all major models of the underlying pathological processes in schizophrenia emphasize a dysfunction in neural development (e.g., "overpruning" Sekar et al., 2016; Yilmaz et al., 2021) and neurobiologically driven dysregulation in neural transmission that impairs information processing and may lead to symptom formation, substantive views that echo Meehl's early conjectures (cf. Meehl, 1962).

# The Claridge View of Schizotypy: A Necessary Scientific Excursus on the Benign Schizotypy Model

As reviewed in Lenzenweger (2010, 2015), no discussion of contemporary views of schizotypic psychopathology and the schizotypy construct would be complete without an examination of the views of Gordon Claridge (Claridge, 1997; Mohr & Claridge, 2015). The most distinctive features of his approach to schizotypy concern his propositions regarding (a) the putative existence of "healthy" manifestations of schizotypy (also termed "benign schizotypy" [BS]), (b) schizotypy as a component of normal personality, and (c) the proposal that the schizotypy construct has a dimensional (quantitative) structure at the latent level.

Unlike the views of Meehl (1962, 1990) or those advocated here and elsewhere (Lenzenweger, 1998, 2010, 2015), Claridge sees schizotypy as a normal personality trait varying by degree along a continuum. In adhering to the methodological views of his mentor, the British personality psychologist Hans J. Eysenck and Eysenck's conceptualization of "psychoticism" as a personality trait, Claridge places his conceptualization of schizotypy squarely within the traditional dimensional view of normal personality. Indeed, Claridge's ideas regarding schizotypy have been introduced by his collaborators as consistent with those "writers who conceptualise the spectrum of schizophrenia-related characteristics as a continuous dimension, akin to other dimensions of personality," which represents a view "championed by writers such as Eysenck" (Eysenck & Eysenck, 1976; Rawlings et al., 2008, p. 1641). This view raises two questions: (1) Is schizotypy best thought of as a component of normal personality? (2) Does the available evidence support a dimensional view of schizotypy?

# Schizotypy as Part of Normal Personality and "Healthy" Psychosis

Is schizotypy best thought of as a component of normal personality? Unpacking this further, is schizotypy *normal*? Is schizotypy part of *personality*? These issues boil down to whether one views schizotypy as (a) the liability for schizophrenia (e.g., Meehl, Lenzenweger) or (b) a trait characterized by certain cognitive features and psychotic-like phenomena that are part of the general system of normal personality (Claridge, Bentall, Mason). As summarized recently by Rawlings et al. (2008), "Claridge and his colleagues have investigated schizotypy from many points of view. They have concluded that *psychotic*  traits constitute an essentially healthy dimension of personality, which in adaptive form contributes to psychological variations as creativity, non-threatening hallucinations, and rewarding spiritual and mystical beliefs and experiences" (p. 1670, emphasis added). Claridge and proponents of the BS model, which they argue yields "happy schizotypes," continue to assert their support for such a conceptualization (Grant & Hennig, 2020; Mohr & Claridge, 2015).

As pursued elsewhere (Lenzenweger, 2010, 2015, 2018b), the psychopathologist must ask, "What does it mean to argue that 'psychotic traits constitute an essentially healthy dimension of personality'?" In light of the observations of Kraepelin, Bleuler, Rado, Meehl, and others, one must consider critically the views on schizotypy held by Claridge, particularly as regards the term *psychosis*. What does it mean to designate an individual or behavior "psychotic"? In traditional psychiatric usage, "psychotic" as a descriptive term has typically one of three potential meanings, all suggestive of pathology: (1) the *impairment of reality testing* as indicated by the presence of particular psychopathology signs and/ or symptoms (hallucinations, delusions, thought disorder); (2) the depth or severity of an impairment (e.g., a psychotic depression, meaning a very deep or profound case of depression), and/or less frequently (3) a *degree of regression*, within a psychodynamic framework, to a developmentally primitive stage of psychological organization wherein thought and experience are characterized by primary process (i.e., not secondary process).

Given how the term "psychotic" is used in psychopathology, can we conceive of "psychotic traits" as being consistent with a "healthy dimensional of personality?" (Resorting to the locution "psychoticlike" does not get one out of this conceptual conundrum if one is serious about the notion that psychotic traits are representative of a healthy dimension of personality.) To do so, one must really confront the implication of this statement and consider the notion of "healthy psychosis." One impression gleaned from this juxtaposition of terms is that it reveals an insufficient appreciation for the clinical and research basis supporting the notion of schizotypy as schizophrenia liability. In short, those who see patients in intensive diagnostic or therapeutic capacities may find an eerie unfamiliarity in a concept such as "healthy psychotic" traits. Can one realistically speak of "healthy" schizophrenia or schizophrenia as a healthy dimension of personality? From the standpoint of clinical relevance, Claridge's theoretical position seems distinctly ungrounded in the clinical realities of schizotypic pathology. Moreover, from the research standpoint, the literature, by and large, does not support a view of schizophrenia (the illness) as reflective of an extension of normal personality. We must always remind ourselves that finding correlations between measures of schizotypy and measures of normal personality does not establish continuity with normality nor establish that schizotypy is akin to other measures of normal personality (e.g., extraversion, positive emotion, negative emotion, constraint). Rather, in the view of many, schizophrenia reflects a complex pathological disease process, not a deviation in a normal personality process or dimension, and schizotypy reflects liability for that illness. Raine (2006) proposes the notion of "pseudoschizotypy," which may reflect a more accurate appraisal that a group of persons might score highly on a measure of schizotypy for reasons other than latent schizotypy (rather than invoking strained constructions such as "happy schizotypy," "benign schizotypy," or "healthy psychosis").

An interesting issue for research is to determine how personality copes with the presence of schizotypy and how schizotypy shapes the personality. In short, it is likely that, when present, schizotypy (whether thinking qualitatively or quantitiatively) impacts and shapes personality manifestations. This view is consistent with a consideration of how the expression of schizophrenia, as a clinical illness, impacts the personality of one so diagnosed.

### Claridge's View of Schizotypy as a "Fully Dimensional" Construct

The second issue central to Claridge's view of schizotypy concerns the basic nature of the construct's underlying structure. Is it quantitative in nature at both the phenotypic level and the latent level? This issue received considerable discussion during the 1993 NATO workshop on schizotypy (see Raine et al., 1995). At that time, although Claridge maintained a strong commitment to a dimensional view, there were no empirical data available to support a view that the schizotypy construct was quantitatively distributed-varying by degree (not kind)-at the latent level. All empirical evidence marshaled by Claridge and colleagues in support of the dimensional latent structure of schizotypy came from analytic techniques (i.e., factor analysis) that could *not* determine whether a latent entity was quantitatively (dimensionally) or qualitatively (taxonically) structured at a deeper level. One can surely measure a psychopathological feature, symptom,

or character in a quantitative manner, but that, in and of itself, does not ensure or mean that the construct measured is dimensional at the latent level. For example, one could construct a quantitative measure of "maleness/femaleness" and acquire dimensional values on the "maleness/femaleness scale." However, the continuous variation in the scores on this scale would not mean that biological sex has a continuous (quantitative, "difference by degree") nature at the latent level (see below, regarding factor analysis).

The current empirical picture regarding the latent structure of schizotypy is one of discontinuity, which is either representative of a latent taxon (class, natural subgroup) or a severe step-function (threshold) in the structure of the schizotypy construct. As discussed later in this chapter, there is an abundance of evidence drawing on taxometric and finite mixture modeling studies that are supportive of the discontinuous underlying nature of schizotypy. The corpus of evidence drawn from empirical data is inconsistent with a fully dimensional view of schizotypy such as that argued for by Claridge and colleagues (e.g., Grant & Hennig, 2020; Nelson et al., 2013). Although Mason and Claridge (2006) state, "Suffice it to say that the evidence is strongly weighted in favour of the fully dimensional model" of schizotypy" (p. 205), this statement is simply incorrect in view of the available empirical corpus.

The bulk of the evidence that Claridge and colleagues interpret as supportive of the dimensionality of schizotypy comes from (a) a methodological position committed to dimensionality as proposed by Eysenck, (b) visual examination of the distributions of phenotypic psychometric values (recall that distributions of scores cannot resolve the latent structure question), (c) results of factor analyses of psychometric values (remember, factor analysis is a technique that always finds factors by organizing larger numbers of variables into a smaller number of large "factors"), and (d) a single taxometric investigation. Aside from evidence drawn from one taxometric study (Rawlings et al., 2008), which suffered from marked methodological artifacts (Beauchaine et al., 2008), the empirical picture painted overwhelmingly by results from latent structure analyses (taxometric, finite mixture modeling, latent class analysis) supports the existence of a discrete class of individuals harbored within large samples of persons who have completed schizotypy measures. Recent reviews arguing in favor of the dimensionality of schizotypy (e.g., Nelson et al., 2013) unfortunately fall short of establishing latent continuity through appropriate latent structure statistical methods;

instead, they tend to emphasize similarities between schizotypic psychopathology and schizophrenia (which are well known) and infer continuity. Ironically, much of the research marshalled to support a continuum view of schizotypy is done using distinct subject groups (e.g., schizotype vs. controls) rather than being conducted in a fully dimensional manner using correlational and/or regression techniques with a full range of schizotypy scale scores.

Eysenck, despite his preference for dimensional models and continuous measurement, stated that he "would not wish to dismiss the possibility or even the likelihood that in any random group of clinically diagnosed neurotics there would be found a small number of people who might 'constitute a group apart, different not in degree, but in kind, by reason of some specified biochemical error, which is highly predictable in terms of inheritance, and which operates in a manner quite different from anything observed' in the kinship relations of the remainder of that group" (Eysenck, 1958, p. 431). This view of Eysenck is actually quite commensurate with what is known about schizotypy from modern empirical studies of latent structure.

# Claridge's View of Meehl's Model as "Quasi-Dimensional"?

In this context one should also evaluate Claridge's view of Meehl's (1990) model of schizotypy as "quasi-dimensional," whereas he refers to his own model as "fully dimensional," as discussed above (Claridge, 1997; see also Nelson et al., 2013). What is meant by the term "quasi-dimensional"? If one takes the word "quasi" to mean "having a likeness to, having some resemblance to," we would say quasi-dimensional would logically mean "having a likeness to or resembling a dimension." One would be hard pressed to find an indication in Meehl's writing that schizotaxia (or, by definition, schizotypy) is in any manner dimensional, quasi or otherwise. The term "quasi-dimensional" as a descriptor is merely another way of saying "continuous latent liability with a threshold"—this not what Meehl proposed.

Meehl (1962, 1990) himself was quite clear about the latent structure of schizotypy as reviewed earlier: he saw schizotypy as having a taxonic (qualitative) latent structure. As noted, he did speak of "polygenic potentiators," which could have a dimensional nature; however, schizotypy, according to his model, was taxonically structured at the latent level. It may be the Claridge intended the notion of a "quasi-continuous" model of genetic influences, akin to a polygenic model with a distinct *threshold*  effect, when describing Meehl's model as "quasidimensional." In fact, behavior geneticists distinguish between a polygenic model with continuous variation in a phenotype (e.g., height, IQ) and one where there is some form of discernible demarcation in the phenotype (e.g., cleft palate, diabetes) (see Falconer, 1989). However, Meehl's model does not encompass the polygenic perspective (without thresholds) that embraces fully continuous variation or quasi-continuous variation. His model, rather, represents a "mixed model," whereby a single major schizophrenia-relevant gene operates against a background of polygenic modifier effects (his so-called potentiators). To review, Meehl was clear on this issue in advocating for a *taxonic* view of schizotypy. In Meehl's view there is no gradation or quantitative variation insofar as schizotypy is concerned at the latent level: one is either a schizotype or not, there is no in-between place. Claridge (1997; Mohr & Claridge, 2015), in contrast, advocates a fully dimensional view (latent level) with continuous variation at the phenotypic level; his model is most consistent with a polygenic model (without a threshold) that reflects a continuous additive model of genetic influences.

## Classification and Diagnostic Technology Assessment of Schizotypy and Schizotypal Phenomena

This section focuses on the assessment of schizotypy and schizotypic phenomena with a brief review of clinical interviews and psychometric inventories that have been developed for either clinical or research work. An evaluation of many psychometric measures conjectured to be putative schizotypy indicators developed before 1980 is available in Grove (1982); data bearing on psychometric measures through the early 1990s can be found in Chapman, Chapman, and Kwapil (1995). Recently, Kirchner et al. (2018) provide a useful overview of diagnostic and other assessment approaches to SPD, which has obvious relevance. Not all of the assessment devices discussed here have been designed with Meehl's (1964) early effort in mind, though most have been influenced by his work. Some emerged from the increased interest in personality pathology that followed the introduction of DSM-III in 1980. All of the measures discussed here have been shown to have strong reliability and a reasonable degree of validity.

# Clinical Interviews and Checklists for Schizotypic Psychopathology

Four interview-based procedures have been developed specifically to assess schizotypic phenomena. The following assessment devices are tailored specifically for schizotypic psychopathology. One could, of course, use the relevant diagnostic modules for SPD and/or PPD from an established Axis II structured interview (e.g., the IPDE; Loranger, 1999) as an alternative to these specialized instruments.

#### MEEHL'S CHECKLIST FOR SCHIZOTYPIC SIGNS

Meehl's (1964) Checklist for Schizotypic Signs is a treasure trove of clinical observation and phenomenological description for schizotypic psychopathology. The Checklist and the *Manual for Use with the Checklist for Schizotypic Signs* can be downloaded from Meehl's website (http://meehl.umn.edu/sites/ g/files/pua1696/f/061scchecklist.pdf). The checklist consists of 25 clinical features that Meehl argued were of diagnostic importance to the recognition and diagnosis of schizotypic features

#### SYMPTOM SCHEDULE FOR THE DIAGNOSIS OF BORDERLINE SCHIZOPHRENIA

The Symptom Schedule for the Diagnosis of Borderline Schizophrenia (SSDBS) was developed by Khouri, Haier, Rieder, and Rosenthal (1980) to assess the symptoms of "borderline schizophrenia" as defined by Kety et al. (1968). The schedule was administered in an interview format, with eight symptoms rated on a 3-point scale, including perceptual changes, body image aberrations, feelings of unreality, thought disturbances, ideas of reference, ideas of persecution, self-inflicted injuries, and preoccupation with perverse sexuality or violence.

#### SCHEDULE FOR SCHIZOTYPAL PERSONALITIES

Developed by Baron and associates (Baron et al., 1981), the Schedule for Schizotypal Personalities (SSP) was designed to assess the diagnostic criteria for *DSM-III* SPD. The SSP assesses illusions, depersonalization/derealization, ideas of reference, suspiciousness, magical thinking, inadequate rapport, odd communication, social isolation, and social anxiety. The SSP also assesses delusions and hallucinations.

#### STRUCTURED INTERVIEW FOR SCHIZOTYPY

Kendler and colleagues (Kendler, Lieberman, & Walsh, 1989) developed the Structured Interview for Schizotypy (SIS) to assess schizotypal signs and symptoms. The SIS consists of 19 sections, 18 to assess individual symptom dimensions and 1 to assess 36 separate schizotypal signs (Kendler et al., 1989). The SIS is intended to be given in conjunction with an Axis I assessment device. Results from the Roscommon Family Study of Schizophrenia (Kendler et al., 1993) provided additional validation of the SIS.

#### Psychometric Inventories for Schizotypy Detection

In this context, a comment is in order regarding a term one sees in some journals, namely "psychometric schizotypy." I see no conceptual gain in introducing idiosyncratic concepts such as "psychometric schizotypy" or "self-report schizotypy" into the empirical literature. If a measurement device is valid for the intended construct, then how does the method of assessment being included in the name of the construct advance scientific discourse? One does not speak of "structured clinical interview depression," "self-report panic disorder," or "observer-rated personality disorder." Relatedly, all interview assessments are essentially self-report in nature and presumably such interviews possess commendable psychometric properties, yet we do not call out these characteristics of the interviews.

# CHAPMAN "PSYCHOSIS PRONENESS" SCALES ("WISCONSIN SCALES")

Guided by Meehl's model of schizotypy and his rich clinical descriptions of schizotypic signs (Meehl, 1964) and in close accordance with construct validity principles (Cronbach & Meehl, 1955), L. J. Chapman and J. P. Chapman (1985, 1987) developed several objective self-report measures to assess traits reflective of a putative liability to psychosis, perhaps schizophrenia. For reviews of the early literature on these measures see J. P. Chapman et al. (1995). A brief and selective overview of leading instruments is provided here.

Two of these scales, the Perceptual Aberration Scale (PAS; Chapman et al., 1978) and the Magical Ideation Scale (MIS; Eckblad & Chapman, 1983), have been used extensively in recent research to detect schizotypy and assemble samples of respondents presumed to be at increased risk for psychosis from nonclinical populations. The PAS is a 35-item true-false measure of disturbances and distortions in perceptions of the body as well as other objects. Regarding the MIS, L. J. Chapman and Chapman (1985) defined magical ideation as a "belief in forms of causation that, by conventional standards of our society, are not valid but magical" (p. 164; emphasis added). The PAS and MIS tend to be highly correlated (r at .68 to .70). As a result, both measures are often used in conjunction to select schizotypic patients from nonclinical populations. The PAS and MIS have been used extensively in schizotypy

research and are associated with an impressive body of empirical literature supportive of their validity.

A third scale developed by the Chapmans, the Revised Social Anhedonia Scale (RSAS) (Mishlove & Chapman, 1985), has also been used with greater frequency because deviance on the scale was linked to later psychosis in the presence of elevated PAS/ MIS scores (Chapman et al., 1994). The extent to which the RSAS assesses "anhedonia" versus "social withdrawal" has become a focus of recent substantive discussion and empirical investigation (Linscott, 2007). Finally, abbreviated versions of the original Chapman scales (sometimes referred to as "Wisconsin Scales") have been published for research use (Winterstein et al., 2011).

#### SCHIZOTYPAL PERSONALITY QUESTIONNAIRE

The Schizotypal Personality Questionnaire (SPQ; Raine, 1991) is a 74-item true-false self-report questionnaire that assesses the features consistent with the symptoms for SPD as defined by the DSM-III-R. The SPQ has excellent psychometric properties (Raine, 1991). The SPQ generates three general factors that correspond conceptually to the reality distortion, disorganization, and negative symptom components that are well known in the schizophrenia research literature (Lenzenweger & Dworkin, 1996). The SPQ has become one of the most heavily used psychometric assessment methods in the schizotypy/schizotypal personality research area; a revised short form was published in 2010 (Cohen et al., 2010), and a child-focused version appeared recently (Raine et al., 2021). Importantly, the factor structures underlying the Chapman scales and the SPQ reveal distinct differences which suggest caution in assuming these measures are comparably structured at the latent level (Gross et al., 2014), which suggests also that they are not fungible.

#### OTHER PSYCHOMETRIC MEASURES OF SCHIZOTYPY

Several additional psychometric measures of schizotypy have been developed recently and should be mentioned. Unlike the PAS and MIS, these other measures have not yet been shown to be associated with a liability for schizophrenia (i.e., schizotypy) through systematic family, twin, or adoption studies; however, available validity data suggest that all are promising as schizotypy indicators. These measures include the Rust Inventory of Schizotypal Cognitions (RISC; Rust, 1988a, 1988b), the Referential Thinking Scale (Lenzenweger, Bennett, & Lilenfeld, 1997), the Social Fear Scale (Raulin & Wee, 1984), the Schizotypal Ambivalence Scale (Kwapil et al., 2002; Vaughn et al., 2008), the Schizotypal Personality Scale (STA; Claridge & Broks, 1984) and its close cousin, the Oxford-Liverpool Inventory of Feelings and Experiences (O-LIFE, Mason et al., 1995; see also Claridge, 1997; Grant et al., 2013), and the Schizophrenism Scale (Venables, 1990). A potentially promising psychometric approach designed specifically for the detection of schizophrenia liability (i.e., schizotypy) can be found in the Schizophrenia Proneness Scale (Bolinskey et al., 2003).

Recently, Kwapil et al. (2018) introduced a newly constructed multidimensional psychometric measure that taps positive, negative, and disorganized components of schizotypic deviance. Additionally, from a broader perspective, Krueger et al. (2012) have introduced an inventory geared toward the AMPD and that taps psychoticism in a manner compatible with the nature of schizotypy; their measure is also compatible with the thought disorder and detachment spectra in the hierarchical model advocated Kotov and colleagues (Kotov et al., 2020).

Also available for consideration are the schizoid, schizotypal, and paranoid PD scales derived from the original Minnesota Multiphasic Personality Inventory (MMPI) (Morey et al., 1985). The MMPI-2-RF (Ben-Porath & Tellegen, 2008) and the MMPI-3 (Ben-Porath & Tellegen, 2020) continue to contain useful measures of thought disorder, ideas of persecution, aberrant experiences, and psychoticism that are useful in the assessment of schizotypic psychopathology and likely tap schizotypy.

#### Etiology, Development, and Pathogenesis

There have been two major research vectors in schizotypic psychopathology research. First, many investigators have examined the correlates of schizotypic psychopathology through the study of either clinically defined SPD and/or PPD, psychometrically defined schizotypic persons, or first-degree biological relatives of patients with schizophrenia. The second thrust, which is a consistent theme through much of the research in this area, has been directed at illuminating the relationship between schizotypic psychopathology and schizophrenia per se (Lenzenweger, 2010; in press), as well as theoretical and empirical study of the nature of the latent liability construct.

Given that the theme of relating schizotypic pathology to schizophrenia is so prominent in this area and that one of the guiding assumptions in this work concerns the theoretical notion of latent liability, it seems appropriate to begin with a review of the need for such a construct. Following this discussion, empirical research related to schizotypic psychopathology is discussed from the vantage points of (1) family history, (2) laboratory findings, (3) clinical phenomenology, and (4) follow-up studies. This section is followed by a discussion of the delimitation of schizotypic psychopathology from other disorders at the latent (i.e., unobservable with the naked eye) level.

### On the Need for a Latent Liability Construct Formulation

The preceding discussion has assumed a common underlying liability for schizotypic psychopathology and schizophrenia (see Figures 29.2 and 29.3). What is the empirical basis for such an assumption? As argued previously (Lenzenweger, 1998, 2010), there is ample evidence in support of a latent liability conceptualization in schizophrenia that includes expanded phenotype schizotypic psychopathology manifestations. First, it was conjectured by Meehl (1962, 1990) and others that schizotypic psychopathology was linked, presumably via genetics to schizophrenia (e.g., Kendler, 1985, Kendler et al., 1993) (see later discussion). Perhaps the most influential early evidence that helped to establish a genetic link between schizotypic phenomenology and clinical schizophrenia came from the Danish Adoption Study of Schizophrenia (Kety et al., 1968), in which there were elevated rates of schizotypic psychopathology beyond schizophrenia in the biological relatives. These results provided compelling evidence for a genetically transmitted component underlying manifest schizophrenia and the less severe schizophrenia-like disorders. Moreover, confirming the early Kety et al. findings, numerous family studies have found an excess of schizotypic disorders in the biological relatives of individuals with schizophrenia (see Kendler et al., 1993). As noted, genomic work (Avramopoulos et al., 2002; Fanous et al., 2007; Grant et al., 2013; Lin et al., 2005; Siever et al., 2011; Walter et al., 2016) has provided important confirming data linking schizotypic psychopathology indicators to genetic loci that have been implicated in schizophrenia. Clearly, the boundaries of the phenotypic expression of schizophrenia liability extend beyond manifest clinical schizophrenia. Thus, liability manifestations are not isomorphic with expressed psychosis.

Second, the existence of a "clinically unexpressed" liability for schizophrenia has been confirmed

(Gottesman & Bertelsen, 1989; Lenzenweger & Loranger, 1989a). Thus, liability can exist without obvious phenotypic, or symptomatic (i.e., psychotic), manifestations. Third, a well-established biobehavioral marker, namely eye-tracking dysfunction (Holzman et al., 1988; Levy et al., 2010), which bears no immediately discernible phenotypic connection to overt schizophrenia, is known to be associated with a latent diathesis for the illness. Liability can thus manifest itself in an alternative phenotypic form (Lenzenweger, 1998, 2010). Finally, if the base rate of schizophrenia liability (or the schizotypy taxon) is in fact 10%, as conjectured by Meehl (1990), then perhaps well over 50% of those carrying liability for schizophrenia may go clinically "undetected" across the life span (i.e., derived from the estimated combined prevalence of schizophrenia, SPD, and PPD of roughly 5%; cf. Loranger, 1990; see also Lenzenweger, Lane et al., 2007). Taken together, theoretical and empirical considerations argue strongly for the plausibility of a complex latent liability construct in schizophrenia.

Given that most persons vulnerable to schizophrenia may never show flagrant psychosis or easily detectable signs and symptoms of schiztoypic personality functioning, researchers have sought ways to detect schizotypy using more sensitive laboratory and psychometric measures. Efforts have been made to discover valid objective indicators of schizotypy that function efficiently across a range of clinical compensation as well as mental state and are capable of detecting liability even in clinically unexpressed (nonsymptomatic) cases. Such indicators, psychometric and otherwise, are thought to assess an "endophenotype" (not visible to the unaided, naked eye; see Gottesman, 1991; Gottesman & Gould, 2003; Lenzenweger, 2013a, 2013b). Their inclusion in research investigations of the genetics and familiality of schizophrenia is likely to enhance those efforts through increased power and precision, even when the putative indicators are only modestly correlated with the latent liability (Fanous & Kendler, 2005; Smith & Mendell, 1974).

# Empirical Findings Relevant to Development and Pathogenesis

#### FAMILY HISTORY OF SCHIZOPHRENIA

Overall, it is now generally established that schizotypic psychopathology does indeed occur in the biological first-degree relatives of persons with schizophrenia at rates much higher than the population rate (for reviews see Kendler et al., 1993; Webb & Levinson, 1993 Walter et al., 2016). There is also evidence supportive of the familiality of schizophrenia and schizotypic psychopathology from studies that have found elevated rates of schizophrenia among the first-degree biological relatives of schizotypic patients (Battaglia et al., 1991 1995; Kendler & Walsh, 1995). The connection between schizotypic psychopathology and schizophrenia is now well established from the family study perspective (Chemerinski et al., 2013; Lenzenweger, 2010).

Three studies have reported a significant excess of PPD in the relatives of schizophrenia probands (Baron et al., 1985; Kendler & Gruenberg, 1982; Kendler et al., 1993; see also Webb & Levinson, 1993). However, PPD appears to be more prevalent in the first-degree relatives of those patients with Axis I delusional disorder, a psychotic illness (Kendler, 1985). One could argue that these data suggest a stronger link between PPD and the Axis I delusional disorder as opposed to schizophrenia, but more data would be required to resolve this issue.

From the "psychometric schizotypy" vantage point, Lenzenweger and Loranger (1989a) examined the lifetime expectancy (morbid risk) of treated schizophrenia, unipolar depression, and bipolar disorder in the biological first-degree relatives of 101 nonpsychotic psychiatric patients (probands) who were classified as either "schizotypypositive" or "schizotypy-negative" according to the Perceptual Aberration Scale (PAS). The relatives of schizotypy-positive probands were significantly more likely to have been treated for schizophrenia than the relatives of schizotypy-negative probands; the morbid risk for treated unipolar depression or bipolar disorder among the relatives of the two proband groups did not differ. Berenbaum and McGrew (1993) also reported that PAS deviance is familial. Of related interest, Battaglia et al. (1991) found in a study of the relatives of schizotypal patients that recurrent illusions (akin to perceptual aberrations) were found in every patient with SPD with a positive family history of schizophrenia. Finally, Calkins, Curtis, Grove, and Iacono (2004) reported that the primary dimensions of psychometrically assessed schizotypal personality, particularly social-interpersonal deficits, derived from the Raine (1991) SPQ, can differentiate the first-degree relatives of patients with schizophrenia from controls.

#### TWIN AND ADOPTION STUDIES

That schizophrenia, based on a long tradition of twin studies, is established as a complex, genetically influenced phenotype represents a scientific statement of fact (Cardno & Gottesman, 2000; Gottesman, 1991; Sullivan et al., 2003). However, for years, there had been no extensive twin studies of clinically defined schizotypic psychopathology beyond an initial study conducted by Torgersen (1994), which supported a heritable component to SPD (subsequently confirmed in a later study by Torgersen et al., 2000). There were no known twin studies of PPD. Miller and Chapman (1993) demonstrated that the PAS has a substantial heritable component, and Kendler and Hewitt (1992) found that "positive trait schizotypy" (of which perceptual aberration, among other features, is a component) is substantially heritable. More recently, Jang, Woodward, Lang, Honer, and Livesley (2005) reported a twin study that used a psychometric dimensional assessment of schizotypic features and found all components to be subject to substantial genetic influences (i.e., heritable). Kendler, Myers, Torgersen, Neale, and Reichborn-Kjennerud (2007) reported on a twin study of dimensionalized representations of the Cluster A disorders (SPD, PPD, and schizoid PD) and found evidence of heritability for all three disorders, with SPD showing the highest heritability.

In terms of adoption studies, the most relevant research comes from the Danish Adoption Study conducted by Kety and colleagues (Kety et al., 1968, 1994) and the subsequent secondary analyses of these data by Kendler and colleagues (e.g., Kendler et al., 1994). In short, whether working from the original data (Kety) or from secondary analyses (Kendler), schizotypic psychopathology is found at greater rates among the biological relatives of the adoptees with schizophrenia. These data are also consistent with the family and twin data supporting the familiality of schizotypic psychopathology and a heritable component to the pathology. There are no adoption studies of *DSM-III-R*, *DSM-IV*, *DSM-5* SPD or PPD.

#### MOLECULAR GENETIC STUDIES

The field of psychiatric genetics has moved well beyond the model-fitting research approach to assessing genetic factors in schizophrenia (e.g., Bipolar Disorder and Schizophrenia Working Group of the Psychiatric Genomics Consortium, 2018; Dennison et al., 2020; Sullivan et al., 2018). Some very exciting molecular genetic work has begun to appear, which, as noted earlier, provides tangible links between schizotypic psychopathology and schizophrenia. This pattern of results goes some distance in the direction of confirming the basic schizotypy model as developed here. Avramopoulos et al. (2002) found that individuals who carried the high-activity catechol-Omethyltransferase (COMT) gene showed elevations on the PAS and SPQ (see also Steiner et al., 2019). Lin et al. (2005) found that elevations in PAS scores were associated with a variant of the neuregulin-1 gene that is thought to be a susceptibility locus for schizophrenia. Fanous et al. (2007) reported the results of a genome-wide scan showing that a subset of schizophrenia susceptibility genes are also related to schizotypy. Vora et al. (2018) reported on dimensional schizotypy measures and the GLRA1 polymorphism, which has implications for treatment. Siever et al. (2011), Grant et al. (2013), and Walter et al. (2016) have all reported findings linking SPD or deviations in schizotypy measures with genetic polymorphisms of considerable interest in schizophrenia.

This emerging body of research should prove powerfully transformative for schizotypy research in the coming decade. At the same time, despite the high heritability of schizophrenia ( $h^2 = .80$  or higher), one must keep in mind that relatively few genes have been shown to be consistently related to schizophrenic illness and they account for a tiny proportion of the likely overall genetic contribution to the illness (Sullivan et al., 2012; Bipolar Disorder and Schizophrenia Working Group of the Psychiatric Genomics Consortium, 2018), although promising signals have emerged for C4 genes (Sekar et al., 2016; Yilmaz et al., 2021). In short, there is much work to be done in terms of the molecular genetics of schizotypy and schizophrenia.

#### Laboratory Studies of Schizotypic Psychopathology

There have been a large number of laboratory studies of schizotypic psychopathology. These studies have examined either clinical schizotypes (e.g., SPD/PPD), psychometrically identified schizotypes, or the first-degree relatives of patients with schizophrenia. Only those findings related to the biobehavioral and neurocognitive processes that have received the greatest attention in the schizophrenia literature in recent years are reviewed here, namely sustained attention (Cornblatt & Keilp, 1994; Cornblatt & Malhotra, 2001), eye tracking (Levy et al., 2010), and various forms of executive functioning mediated by the prefrontal cortex (e.g., Gold & Harvey, 1993; Piskulic et al., 2007). Siddi et al. (2017) provide a useful overview of neuropsychological correlates of schizotypy across a variety of other measures/constructs.

A deficit in sustained attention, a leading endophenotype for schizophrenia liability, has been found in clinically defined schizotypic individuals (e.g., SPD) (e.g., Condray & Steinhauer, 1992; Harvey et al., 1996). Similar deficits were found among psychometrically identified schizotypic individuals by Lenzenweger, Cornblatt, and Putnick (1991). Replication of the Lenzenweger et al. (1991) results, using the same measure of sustained attention, have been reported by Obiols, Garcia-Domingo, de Trincheria, and Domenech (1993) (see also Gooding et al., 2006; Rawlings & Goldberg, 2001). Grove et al. (1991) have also reported a significant association between high PAS scores and poor sustained attention performance among the first-degree biological relatives of individuals with diagnosed schizophrenia (see also Chen et al., 1998). Finally, Cornblatt, Lenzenweger, Dworkin, and Erlenmeyer-Kimling (1992) found that attentional dysfunction that is detected in young children who are at risk for schizophrenia is correlated with schizotypic features in adulthood (assessed nearly 20 years later). There are no studies that have explicitly examined sustained attention in patients with PPD. Whereas many prior studies have examined the relationship between sustained attention deficits and schizotypy in carefully constructed samples (i.e., clinical SPD; psychometric high-risk schizotypyes), Bergida and Lenzenweger (2006) showed that schizotypic features are indeed related to deficits in sustained attention within a quasi-random, unselected population sample. The neural signature of sustained attention anomalies in relation to schizotypy has been studied by Sponheim, McGuire, and Stanwyck (2006). Clearly, sustained-attention deficit remains an endophenotype of great interest in the study of schizotypic psychopathology (Fusar-Poli et al., 2013; Snitz et al., 2006). Moreover, careful consideration of the processes (e.g., working memory, context processing, vigilance) involved in alternative sustained tasks remains an area of open investigation (Lee & Park, 2005, 2006).

In terms of eye-tracking dysfunction (ETD) among individuals with schizotypic psychopathology, such deficits are clearly found among clinically defined schizotypes (e.g., Lencz et al., 1993; Siever et al., 1994; cf. Thaker et al., 1996) and psychometrically identified schizotypes (Gooding et al., 2000; O'Driscoll et al., 1998; Thomas et al., 2021). ETD has also been found to aggregate in the biological family members of patients with schizophrenia across numerous studies (Levy et al., 2010; Sponheim et al., 2003). Finally, although most prior research on ETD was conducted on highly selected samples (which can exaggerate relations between ETD and criterial groups), Lenzenweger and O'Driscoll (2006) showed that an increased rate of catch-up saccades as well as impaired gain (poor pursuit) can be found in relatively unselected adult patients from the general population and that these deficits are indeed related to increased schizotypic features. It is important to note that, just as sustained attention and ETD do not occur in all cases of schizophrenia, not all schizotypes evidence the dysfunctions (cf. Lenzenweger, 1998). Nonetheless, not only does the consistency in findings across patients with schizophrenia and individuals with schizotypic psychopathology inform us of the informationprocessing and psychophysiological deficits found in schizotypes, but these very deficits further link the schizotype to schizophrenia. To date, there are no reported studies of ETD or smooth pursuit performance specifically in patients with PPD.

Considerable attention has been focused on difficulties in abstract reasoning, executive functioning, and novel problem-solving in schizophrenia (Gold & Harvey, 1993), all processes that are hypothesized to be mediated by the prefrontal cortex. Moreover, early evidence was presented that suggested some schizophrenic symptoms might reflect a dysfunctional frontal brain system (e.g., Goldman-Rakic, 1991; Levin, 1984a, 1984b; Weinberger et al., 1986). Much of this research employed the Wisconsin Card Sorting Test (WCST) as a measure of abstraction ability and executive functioning. Schizotypic patients, identified through either a clinical or psychometric approach, have been found to display deficits on the WCST (Gooding et al., 1999; Lenzenweger & Korfine, 1991, 1994; Park et al., 1995; Raine et al., 1992) though not in all studies (Condray & Steinhauer, 1992). WCST findings for the biological relatives of schizophrenia-affected probands are mixed (Franke et al., 1993; Scarone et al., 1993; cf. Snitz et al., 2006). Clearly, the situation for WCST performance is somewhat inconsistent across mode of definition used in selecting patients, and the research corpus also shows some variability in the WCST performance variables on which deviance has been found (e.g., categories completed vs. percent of perseverative errors vs, failure to maintain set). Finally, in a more fine-grained assessment of the cognitive functions thought to be mediated frontally, Park et al. (1995) reported that psychometrically identified schizotypes revealed poorer "spatial working memory" performance, which is consistent with WCST deficits. Park, Holzman, and Levy (1993) have found that about half of the healthy relatives of patients with schizophrenia also displayed impaired spatial working memory. In general, it is safe to conclude that executive function and spatial working memory deficits are also of considerable interest in this area, both as clues to early pathological processes of schizophrenia as well as endophenotypes (Piskulic et al., 2007; Snitz et al., 2006) There are no reported studies of working memory performance in patients with PPD.

#### Other Endophenotypes of Interest

As this chapter is necessarily limited in scope, one cannot address all processes and factors studied in the domain of schizotypy research. The scope of inquiry in the field continues to expand, and new processes are being studied (e.g., context processing, see Barch et al., 2004; antisaccades O'Driscoll et al., 1998; Thomas et al., 2021). In our laboratory, we have taken a focus on more basic processes, such as motor function (Lenzenweger & Maher, 2002) and somatosensory processing (Chang & Lenzenweger, 2001, 2005; Lenzenweger, 2000). There are two themes guiding this work: (1) simpler processes may be easier to dissect and understand genomically, and (2) we seek to "count" rather than "rate" the things we are interested in studying, thus avoiding the pitfalls associated with rating-based data. We also continue to study ecologically meaningful processes such as the impact of stress on spatial working memory (Smith & Lenzenweger, 2013), social cognition (Miller & Lenzenweger, 2012), theory of mind (Wastler & Lenzenweger, 2019; see also Bora, 2020), and cone of gaze functioning (Wastler & Lenzenweger, 2018). Finally, while much of the experimental psychopathology work on schizotypic psychopathology has emphasized neurocognitive processes, there is a resurgence of interest in hedonic capacity in schizophrenia and schizotypy (e.g., Strauss & Cohen, 2018; Strauss & Gold, 2012), which echoes the early insights of Meehl (1962, 1975, 2001).

# Schizophrenia-Related Deviance on Psychological Tests

Patients with SPD and PPD are by definition schizotypic at the level of phenomenology, and one would not necessarily anticipate using other measures of pathology to verify the presence of phenomenology already required by virtue of the *DSM* diagnostic criteria. However, psychometrically identified schizotypes have been selected as a function of deviance on a schizotypy measure, and other measures of psychopathology have been used to inform the validity of their schizotypic "status." This literature is voluminous and cannot be thoroughly reviewed here; however, highlights can be illustrated (see Siddi et al., 2017). For example, PAS-identified schizotypes reveal schizophrenia-related deviance on the MMPI (Lenzenweger, 1991), schizophreniarelated PD features (Lenzenweger & Korfine, 1992b), and thought disorder (Coleman et al., 1996; Edell & Chapman, 1979). Lenzenweger, Miller, Maher, and Manschreck (2007) have found that PAS-identified schizotypes reveal hyperassociative language processing, consistent (albeit attenuated) with that seen in schizophrenia, and individual differences in hyperassociation are related to levels of reality distortion and disorganization. This study provides experimental evidence for mild thought disorder in schizotypes, thereby buttressing earlier findings based on ratings of thought disorder. See Chapman et al. (1995) for extensive reviews of the early studies that reported on the correlates of the Chapman psychosis-proneness scales (see also Lenzenweger, 2010).

## Neuroimaging and Neurobiology of Schizotypic Psychopathology

In recent years, the corpus of neuroimaging studies of schizotypic psychopathology has expanded dramatically. In the mid-1990s, the literature was quite limited, and it was premature to highlight major trends in the area (see Flaum & Andreasen, 1995; Gur & Gur, 1995), but the imaging corpus has grown and trends are evident (Dickey et al., 2002; Fervaha & Remington, 2013; Hazlett et al., 2012). Dickey, McCarley, and Shenton (2002), in their review of structural findings in schizotypal PD (using either computed axial tomography or magnetic resonance imaging), revealed many areas of abnormality in SPD (see their table 2, p. 11), and they note many areas of similarity between the SPD brain abnormalities and structural abnormalities found in patients with first-episode schizophrenia. Dickey et al. (2002) noted the relative absence of medial temporal lobe abnormalities in SPD (vs. their presence in clinical schizophrenia), and they speculate, with caution, that the absence of such abnormalities in SPD might help to suppress psychosis in those with SPD. A particularly exciting new finding concerns reduction in gray matter volumes in SPD patients who have never been exposed to neuroleptics (Asami et al., 2013). With respect to functional neuroimaging studies, Siever and Davis

(2004), in their review of SPD as a spectrum disorder, concluded that patients with SPD reveal many of the same disturbances in neural circuitry that are seen in clinical schizophrenia, albeit attenuated in severity (see also Lenzenweger & Korfine, 1994; Mohanty et al., 2005). Siever and Davis (2004), at that time, speculated that greater frontal capacity (along with somewhat reduced striatal reactivity) in the patients with SPD might spare them from psychosis. Consistent with this observation, Fervaha and Remington (2013) noted the evidence of increased frontal volumes as well as reduced volumes in subcortical structures (cf., Hazlett et al., 2012). As of 2021, however, functional neuroimaging of schizotypic psychopathology still lags behind the structural neuroimaging work in quantity.

The neurobiological modeling of schizophrenia has undergone major revisions within the past 50 years in response to greater knowledge regarding basic neurobiology (see Grace, 1991; Grace & Moore, 1998; Guillin et al., 2007; McCutcheon et al., 2020), developmental neurobiology, and psychopharmacology (Keepers et al., 2020). A more contemporary view of the dopaminergic dysfunction in schizophrenia emphasizes multiple processes and their dysfunction (Goto & Grace, 2007; Guillin et al., 2007; McCutcheon et al., 2020). Some time ago, Weinberger (1987), among others, suggested that there is a two-process dopamine dysfunction in schizophrenia, with one process implicating the mesocortical dopamine pathway, underactivity in the prefrontal cortex, hypo-dopaminergia, and negative symptoms, and the other involving mesolimbic dopamine pathways, the striatum and related structures, hyper-dopaminergia, and positive symptoms. Grace (1991; see also Goto & Grace, 2007) further refined this model of dopamine dysfunction in schizophrenia by suggesting that a glutamatergic dysfunction emanating from the prefrontal cortex affects "tonic" and "phasic" dopamine processes in the striatum (cf. Bustillo et al., 2019; McCutcheon et al., 2020). Additionally, though there is a continued focus on the role of dopamine in schizophrenia, there is a robust and developing interest in the role that serotonin (Abi-Dargham, 2007) and glutamate (Javitt, 2007) play in schizophrenia as well, particularly onset of the illness (Bossong et al., 2019). Systematic efforts to determine the precise correspondence between the neurobiological models for schizophrenia and schizotypic psychopathology have been undertaken, and they are providing interesting clues about the underlying neural circuitry and neurobiological dysfunction in schizotypes (Abi-Dargham et al., 2004; Mohr & Ettinger, 2014). The fascinating results from Park's group (Woodward et al., 2011) point to amphetamine-induced dopamine release rate as a potential endophenotype for schizotypy, based on findings showing that dopamine release in the striatum was strongly associated with level of schizotypic features in nonpsychotic subjects (not unlike the findings of Howes et al. [2009] in the study of prodromal schizophrenia cases).

### Clinical Phenomenology

Patients with SPD and PPD are, by definition, schizotypic at the level of phenomenology, and one would not necessarily anticipate using other measures of pathology to confirm the phenomenology of such patients. However, as noted previously, alternative methods of detecting schizotypes have been validated, in part, by examining the relations between schizotypic phenomenology as clinically assessed and psychometric measures of schizotypy. For example, Lenzenweger and Loranger (1989b) found that elevations on the PAS were most closely associated with schizotypal PD symptoms and clinically assessed anxiety. Others have found that nonclinical patients, identified as schizotypic through application of the psychometric approach, also reveal schizotypic and "psychotic-like" phenomenology (cf. Chapman et al., 1995; Chapman et al., 1980; Kwapil et al., 1999). Regarding first-degree biological relatives of patients with schizophrenia, Kendler et al. (1993) have shown that schizotypic features are found at higher levels among the relatives of schizophrenia cases than among the relatives of controls. However, it is important to note that not all psychometrically identified schizotypes or biological relatives of patients with schizophrenia will display levels of schizotypic phenomenology that would result in a diagnosis by DSM-5 criteria for SPD or PPD.

Although it has long been known that there is no meaningful connection between autism and schizophrenia at the level of genetics (Gottesman, 1991; I. I. Gottesman, personal communication, May 19, 2007), correlations have been observed between self-report measures of schizotypy and Asperger's syndrome (a putative autism spectrum condition) (Hurst et al., 2007). The meaning of such crosssectional correlations, however, remains obscure, and the trend in diagnosis and classification is to consider Asperger's disorder as separate from schizotypic psychopathology (including schizoid pathology) (Raja, 2006).

Finally, an area that has received increased attention in recent years concerns the nature of emotion and affective processing in schizotypes, particularly in light of Meehl's (1962, 1975) original conjectures regarding hedonic capacity (see also Meehl, 2001). Lenzenweger and Loranger (1989b) reported significant associations between measures of anxiety and depression with PAS scores. Berenbaum et al. (2006) reported that negative affect, not surprisingly, was related to interpersonal as well as cognitive schizotypic personality dimensions, whereas attention to emotion was less consistently related to schizotypic pathology (cf. Lewandowski et al., 2006). An important focus for this line of research in the future will be to find some way to resolve whether negative affect among schizotypes hails from the core schizotypy personality organization or whether it represents a secondary development, resulting from what Meehl (2001) has termed "aversive drift." The newly proposed Strauss and Gold (2012; see also Strauss & Cohen, 2018) model of hedonic capacity and anhedonia in schizophrenia may represent a new source of fruitful hypotheses for extension to the schizotypic realm in helping to address this and other questions.

## Follow-Up Studies of Schizotypic Psychopathology

There are few long-term follow-up data (10 years or longer) available on schizotypic samples that would help to determine how many schizotypes move on to clinical schizophrenia. Moreover, given the relative absence of large-scale longitudinal studies of PDs that involve multiple assessments, with the exception of the study being conducted by Lenzenweger's group, it is difficult to examine the stability of schizotypic features over time. Fenton and McGlashan (1989) conducted a follow-up study of patients who had been nonpsychotic at admission to the Chestnut Lodge Psychiatric Hospital, Rockville, Maryland. They found that 67% (12/ 18) of patients with a diagnosis of schizophrenia, located after a 15-year follow-up, were schizotypic (and nonpsychotic) at their initial admission.

The L. J. Chapman et al. (1994) 10-year followup of their "psychosis-prone" (i.e., schizotypic) patients showed that high scorers on the PAS and MIS revealed greater levels of psychotic illness and schizotypic phenomenology at follow-up. Partial replication of the L. J. Chapman et al. (1994) findings was reported by Kwapil, Miller, Zinser, Chapman, and Chapman (1997). Such schizotypic subjects are also known to have greater impairment in psychosocial functioning over time (Kwapil et al., 2013; Kwapil et al., 2020; Minor et al., 2020). Interestingly, psychoticism, as a general schizotypyrelevant construct, does not predict heightened risk for psychosis (J. P. Chapman, 1994); psychoticism as described by Eysenck shares little in common with psychoticism as defined, for example, in the DSM-5 AMPD or the MMPI-2-RF/MMPI-3 approaches. Finally, Lenzenweger (2021) has recently reported elevated rates of psychotic features in subjects, who initially displayed deviance on the PAS at age 18 (with no prior history of psychotic features), 17 years later at age 35. These associations could not be explained by mental state factors such as anxiety or depression at baseline assessment (Lenzenweger, 2021). The precise factors (e.g., cannabis) that serve to move a nonpsychotic schizotypic individual to a psychotic state are a focus intense research efforts (Flückiger et al., 2016; Hiorthøj et al., 2018). Schizotypy as a predictor of suicidal ideation and worry over the life course is also an emerging trend (Linscott et al., 2020).

The relatively new but maturing field of CHR (prodromal) research, which owes much to the schizotypy research vector, is another arena in which conversion from schizotypic states to psychosis is being studied (Fusar-Poli et al., 2013; see also Nordentoft et al., 2006). The gist of the prodromal studies seeking to specify those clinical and symptom feature predictive of conversion to psychosis is that they generally point to attenuated positive psychotic-like features, especially paranoia, suspiciousness, and thought disorganization (Fusar-Poli et al., 2013; see also Barrantes-Vidal et al., 2013; Lee et al., 2018). However, given that CHR studies of schizophrenia are focused on samples that are extremely enriched for partially psychotic subjects (at baseline), it remains important to determine if such psychotic-like symptoms, in previously nonpsychotic persons, in the population predict risk for nonaffective psychosis (see also Fusar-Poli et al., 2016; Sullivan et al., 2020). Werbeloff et al. (2012) provide important data on this issue from a stratified full-probability population-based sample that show self-reported attenuated psychotic symptoms do in fact predict risk for nonaffective psychosis later in life. The Lenzenweger (2021) 17-year followup study provides evidence that subtle perceptual aberrations in those persons who have never been psychotic do predict a higher rate of psychotic features later in life, which provides context for CHR studies wherein the majority of the subjects are already quasi-psychotic at study entry.

A common question in this area of research is "How many schizotypes go on to develop fullblown schizophrenia, and how many stay compensated (nonpsychotic) to one degree or another across the life span?" Meehl's model suggests that the modal schizotype never develops schizophrenia; this fascinating question awaits more empirical data from long-term follow-up study of schizotypic cases (see Lenzenweger, 2021). Other outcomes in schizotypy are clinically salient and just beginning to be explored, such as the social cost of schizotypy (Hastrup et al., 2021; Kwapil et al., 2020) and, importantly, suicidality (Linscott et al., 2020).

Another important contemporary question concerns the extent to which endophenotypes (Gottesman & Gould, 2003), assessed using laboratory procedures, predict psychotic outcomes downstream in those initially identified as schizotypic. This approach has the benefit of using objective measures to define endophenotype status, thus being free of the difficulties associated with determining risk or prodromal status as a function of clinical ratings. At this time, only one prospective longitudinal study using this approach has data available, namely that being conducted by Lenzenweger (2021). Preliminary results from this study are promising and indicate considerable utility in using multiple endophenotypes (assessed at baseline) in the later prediction of psychosis, schizotypic psychopathology, psychosocial dysfunction, and other psychological characteristics suggestive of impaired functioning (Lenzenweger, in preparation).

#### **Delimitation from Other Disorders**

Research on the delimitation of schizotypic psychopathology from other disorders has proceeded at phenotypic and latent levels. Phenotypic delimitation studies have typically taken the form of factor analytic studies and generally focused on data drawn from *DSM* Axis II symptoms. In short, Cluster A symptoms (i.e., schizotypal, paranoid, schizoid) typically hang together. The meaning and direction that can be extracted from such studies, however, is limited by the fact that method-related variance (e.g., structure of interviews) and overlapping definitions of the disorders are complicating factors. The issue of delimitation at the latent level is discussed here.

Assuming that schizotypy, as conceptualized by Meehl (1962, 1990, 1992, 2004), represents a latent liability construct and that current schizotypy indexes are construct valid, a basic question about the fundamental structure of schizotypy remains. Is

703

it continuous (i.e., "dimensional"), or is it truly discontinuous (or "qualitative") in nature? For example, at the level of the gene, Meehl's model (1962, 1990) and the latent trait model (Holzman et al., 1988; Matthysse et al., 1986) conjecture the existence of a qualitative discontinuity. The polygenic multifactorial threshold model (Gottesman, 1991), while positing a continuous distribution of levels of liability (although at the level of individual genes contributing to polygenic influence qualitative discontinuity must exist), does predict a marked threshold effect. Clarification of the structure of schizotypy may help to resolve issues concerning appropriate genetic models for schizophrenia, and such information may aid in planning future studies in this area. Nearly all investigations of the structure of schizophrenia liability done to date have relied exclusively on fully expressed, diagnosable schizophrenia (see Gottesman, 1991), and the results of these studies have left the question of liability structure unresolved (i.e., unexpressed, but at-risk cases are not accounted for in such studies). How best to explore the continuum notion? One cannot reason with confidence that a unimodal distribution of phenotypic schizotypic traits supports the existence of a continuum of liability (e.g., Kendler et al., 1991). In recent years, however, it has been proposed that a possible "expansion" of the schizophrenia phenotype to include other schizophreniarelated phenomena, such as ETD (Holzman et al., 1988), might be helpful in efforts to illuminate the latent structure of liability in schizophrenia. In my laboratory, we have pursued such an approach, complementary to the "expanded phenotype" proposal, through the psychometric detection of schizotypy (see Lenzenweger, 1993, 2010). Thus, we have undertaken over the past four decades a series of studies that begin to explore the latent structure of schizotypy. Our work has drawn extensively from the formulations of Rado and Meehl, and we have used a well-validated measure of schizotypy, the Chapmans' PAS, in these efforts.

We explored the latent structure of schizotypy through application of Meehl's maximum covariance analysis (MAXCOV) (Meehl, 1973; Meehl & Yonce, 1996) procedure to the covariance structure of scores on the PAS. Our samples have been randomly ascertained from nonclinical university populations, and they have been purged of invalid responders and those with suspect testtaking attitudes. Using the MAXCOV procedure, we (Korfine & Lenzenweger, 1995; Lenzenweger & Korfine, 1992a) have found evidence that suggests

that the latent structure of schizotypy, as assessed by the PAS, is taxonic (i.e., qualitative) in nature. Moreover, the base rate of the schizotypy taxon is approximately 5-10%. The taxon base rate figure is relatively consistent with the conjecture by Meehl that schizotypes can be found in the general population at a rate of 10%. In our work we have also conducted a variety of control analyses that have served to check the MAXCOV procedure and ensure that the technique does not generate spurious evidence of taxonicity. We (Korfine & Lenzenweger, 1995) have demonstrated that (1) MAXCOV detects a latent continuum when one is hypothesized to exist, (2) MAXCOV results based on dichotomous data do not automatically generate "taxonic" results, and (3) item endorsement frequencies do not correspond to our taxon base rate estimates (i.e., our base rate estimates are not a reflection of endorsement frequencies). Finally, Lenzenweger (1999b) applied MAXCOV analysis to three continuous measures of schizotypy, and this revealed results that were highly consistent with our prior research in this area. These data, taken in aggregate, though they do not unambiguously confirm that the latent structure of schizotypy is qualitative, are clearly consistent with such a conjecture. The suggestion that schizotypic psychopathology is discontinuous in its latent structure raises interesting possibilities for future genetic research in this area (see excellent recent work by Linscott and colleagues: Morton et al., 2017).

Most recently, latent structure work has moved from a consideration of psychometric values to analysis of actual ratio-scale laboratory measures of well-established endophenotypes, sustained attention, and smooth pursuit eye movement, and the results, using taxometric analysis and state-of-theart finite mixture modeling, support the existence of a qualitative discontinuity in the latent structure of such liability measures (Lenzenweger, McLachlan et al., 2007). Although there has been some interest in the underlying structure of social anhedonia measures, recent taxometric work suggests that hedonic capacity, when measured using fine-grained assessments, appears to have a dimensional latent structure (Linscott, 2007). Issues worthy of careful consideration in the study of the latent structure of psychopathology and/or liability have been detailed recently and are recommended for review to avoid common pitfalls and errors in interpretation that have appeared in the literature (Lenzenweger, 2003, 2004; Meehl, 2004; Waller et al., 2006). As noted, aside from one taxometric study (Rawlings et al., 2008), which was marred by any number

of methodological artifacts (see Beauchaine et al., 2008), the overwhelming picture from latent structure analyses (numerous studies across independent laboratories done with techniques that can discern between dimensional and categorical alternatives) supports the presence of some form of latent discontinuity in the distribution of schizotypy measures. This discontinuity is consistent with either a latent taxon (Meehl) or a severe step-function/ threshold (Gottesman) harbored within schizotypy measure data.

Finally, before leaving the issue of delimitation, it is worth noting that in recent years considerable energy has been thrown into arguing that the underlying liability of schizotypy must be continuous or dimensional in structure due to (a) the appearance of psychotic-like experiences (PLE) in the population (Johns and Van Os, 2001; Kelleher & Cannon, 2011; Nordgaard et al., 2019; see Lawrie et al., 2010 for alternative viewpoint), (b) the results of factor analysis studies or depiction of values in histograms, and/or (c) conceptual commitments to a dimensional model. What can PLEs tell us about the latent structure of schizotypy (i.e., schizophrenia liability)? In short: not that much, unless we know a great deal about the subjects in question. There could be many reasons for people to report PLEs in the general population-ranging from liability to schizophrenia, liability for bipolar illness, through anxiety states, borderline PD, drug-related experiences, alcohol-related experiences, religious experiences, sleep paralysis, and so on. That one can find PLEs among individuals in the general population does not necessarily tell us anything about the latent structure of schizotypy (schizophrenia liability). Consider some thought exercises. Imagine we are interested in viral spinal meningitis, which is associated with high fever. We could easily find a range of levels of elevated body temperatures (fever) in 10,000 people drawn randomly from the general population for any number of reasons (e,g., influenza, common cold, Lyme disease, COVID-19, and so on), but such instances of varying fever (phenotypic quantitative variation) would not imply that the latent structure of the cause of spinal meningitis was continuous in nature (see Lenzenweger, 2015). Murray and Jones (2012) similarly argue that many PLEs observed in the population, especially among young people, are better explained by common mental disorders such as anxiety or depression, not proneness to psychosis. Regarding statistical analysis, the informed reader will understand that factor analysis always extracts

dimensions (continuua) from data, and histograms can mislead the naked eye with ease, although results from both approaches have been invoked often to support continuity/dimensionality. Factor analysis applied to a sample of 10,000 subjects (50% female) using indicators such as height, weight, hair length, bicep size, baseball throwing ability, and so on will extract dimensional representations of these indicators, but such results do not make biological sex continuous in latent structure. Issues of continuity and dimensionality must be addressed using appropriate statistical procedures that are up to the task; "dimensionality," furthermore, cannot be the default model or the null hypothesis in whatever statistical approach is chosen. Finally, one is free to argue for whatever conceptual model one wants to embrace for the structure of schizotypy, but such a position should obviously be supported by proper empirical evidence, not merely a preference for how one thinks nature operates. Alternatively, "Whether or not the entities, properties, and processes of a particular domain (such as psychopathology, or vocational interest patterns) are purely dimensional, or are instead a mix of dimensional and taxonic relations, is an empirical question, not to be settled by a methodological dogma about 'how science works'" (Meehl, 1992; p. 119).

#### Conclusion

In summary, as discussed in Lenzenweger (2010), the benefits of the schizotypy model approach in the search for the causes of schizophrenia are fivefold. First and foremost, the study of schizotypic psychopathology provides a "cleaner" window on underlying schizophrenia liability. A cleaner window means an opportunity to study, in the laboratory, genetically influenced, neurobiologically based processes (neurocognitive, affective, personality) that are uncontaminated by "third-variable" confounds, such as medication, deterioration, and institutionalization. Second, the schizotypy model approach to schizophrenia also provides a rich opportunity to discover endophenotypes for schizophrenia liability. Endophenotypes (Gottesman & Gould, 2003; Lenzenweger, 1999c, 2013a, 2013b) represent genetically influenced manifestations of the underlying liability for an illness that are invisible to the unassisted or naked eye. Third, incorporation of valid schizotypy indicators (e.g., schizotypic psychopathology) into genomic investigations directed at etiology and development of schizophrenia will enhance the power of such studies. Fourth, via longitudinal investigations, study of schizotypic
psychopathology can elucidate *epigenetic* factors that might relate to the differences in outcome of schizotypes (i.e., stable SPD vs. conversion to schizophrenia). Finally, the study of schizotypes provides an opportunity to home in on relatively specific deficits, should they exist, prior to the deterioration in schizophrenia that can give rise to generalized deficit, or the deficient functioning shown by many schizophrenia-affected patients. While generalized deficit remains an area of discussion in schizophrenia (Gold & Dickinson, 2013; Green, Horan, & Sugar, 2013), the schizotypy research model potentially represents a powerful methodological end run on generalized deficit.

Schizotypic psychopathology has long held the interest of researchers and clinicians alike, and it has been the subject of considerable theoretical discussion and empirical investigation. Continued study of this class of mental disturbance through the methods of experimental psychopathology, cognitive neuroscience, genetics, epidemiology, classification, and neurobiology will help to provide clues to the nature of schizophrenia, as well as to the schizotypic disorders themselves. In this context it is worth noting that future work in this area should find methods for embracing and resolving the heterogeneity in performance patterns, symptom features, and life history factors that are known to characterize schizotypy and schizophrenia (as well as hobble research in the area) (Lenzenweger, Jensen, & Rubin, 2003). Furthermore, as has long been advocated by Brendan Maher (1966, 2003), one should "count" rather than "rate" phenomena of interest in this area, thereby bringing greater precision to the research enterprise (see also Lenzenweger, 2010 for other "methodological morals"). The multiplicity of vantage points that have been brought to bear on schizotypic psychopathology has helped to move this area of inquiry further, and the continued existence of alternative vantage points in psychology and psychiatry in connection with these disorders will only serve to advance our knowledge.

### Psychopathy and Antisocial Personality Disorder

Christopher J. Patrick, Laura E. Drislane, Bridget M. Bertoldi, and Kelsey L. Lowman

Among mental disorders classified as disorders of personality, psychopathy (psychopathic personality) and the related condition of antisocial personality disorder (ASPD) have been of particular interest to researchers and practitioners because of the serious harm they cause to individuals and the high costs they exact on society. In this chapter, we review what is known about these conditions and how they are represented in DSM-5, which includes both categorical-diagnostic (Section II) and dimensionaltrait (Section III) systems for characterizing personality pathology. In doing so, we highlight elements that these clinical conditions have in common as well as important features that distinguish them and consider how they relate to other forms of psychopathology in relation to an integrative conceptual framework: the triarchic model of psychopathy. We describe how the triarchic model framework can be useful for guiding and coordinating research directed at advancing developmental and neurobiological understanding of psychopathy.

#### **Historical Background**

The earliest accounts of psychopathy emphasized extreme behavioral deviance in the context of intact reasoning and communicative abilities. French physician Philippe Pinel (1801/1962) used the term *manie sans delire* ("insanity without delirium") to describe individuals who engaged repeatedly in impulsive acts injurious to themselves and others despite ostensible awareness of the irrationality of such actions. An American contemporary of Pinel's, Benjamin Rush (1812), documented similar cases and postulated absence of guilt ("moral weakness") as the root cause. Rush's description placed emphasis on features of manipulativeness and deception. British physician J. C. Pritchard (1835) used a similar term, "moral insanity," but applied it to a wide range of clinical conditions including drug and alcohol addiction, sexual deviations, mood disorders, and conditions likely to be classified today as intellectual disability or schizophrenia. Some years later, German psychiatrist J. L. Koch (1891) introduced the term "psychopathic" to denote chronic forms of mental illness presumed to have an underlying organic (physical, brain) basis. Like Pritchard, Koch applied this term to a much broader array of conditions than would be recognizable today as ASPD or psychopathy. Operating from a similar perspective of biological causality, Kraepelin (1915) used the term "psychopathic personalities" for

#### **Abbreviations**

AMPD	Alternative Model of Personality
	Disorders
APSD	Antisocial Process Screening Device
ASPD	Antisocial personality disorder

EPA	Elemental Psychopathy Assessment
ESI	Externalizing Spectrum Inventory
HSRP	Hare Self-Report Psychopathy (scale)
I/CP	Impulsive/Conduct problems
LSRP	Levenson Self-Report Psychopathy
	(scale)
MPQ	Multidimensional Personality
	Questionnaire
PCL-R	Psychopathy Checklist-Revised
PPI	Psychopathic Personality Inventory
TriPM	Triarchic Psychopathy Measure
YPI	Youth Psychopathic Traits Inventory

a somewhat narrower set of conditions that included sexual deviations, other impulse-related problems, and obsessional disorders—along with conditions he labeled "degenerative" personalities, which included "antisocial" (callous-destructive) and "quarrelsome" (hostile-alienated) subtypes that would be classifiable today as ASPD.

Countering this trend toward broad application of the term, Cleckley (1941/1976) argued that psychopathy should be diagnosed using a set of explicit diagnostic criteria that would identify a distinct clinical condition with a coherent etiological basis. Cleckley's criteria for the disorder included ostensibly healthy features (social adeptness, coherent speech, lack of psychotic or anxious/neurotic symptoms, "immunity" to suicide) that "masked" a severe pathology marked by persistent, reckless, impulsive behavior without regard for personal consequences or the feelings/welfare of others. One of the specific pathological features he listed was "inadequately motivated antisocial behavior," by which he meant acts such as "theft, forgery, adultery, [and] fraud" committed "in the absence of any apparent goal at all" (p. 343). Cleckley viewed such behavior as a part of a larger pattern of unrestrained deviancy that also included lack of planning, irresponsibility, impersonal sex, and a failure to learn from adverse experience. The criteria that Cleckley proposed for the disorder included features of three types: (1) indications of psychological stability (social charm and good intelligence, absence of delusions or irrationality, absence of nervousness, disinclination toward suicide), (2) tendencies toward emotional insensitivity and shallow or insincere relationships with others (self-centeredness and incapacity for love, lack of social reciprocity, deceitfulness, deficient affective reactivity, impaired insight), and (3) salient behavioral deviancy in the form of repeated antisocial acts (often without obvious motivation), irresponsibility, promiscuity, and absence of any clear life plan. According to Cleckley, the outward appearance of psychological stability in individuals of this type functioned as a convincing "mask of sanity," concealing the underlying interpersonalaffective deficits and deviant behavioral tendencies (for a recent detailed discussion, see Patrick, 2018).

Turning to ASPD, the first edition of the *DSM*, published in 1952, included a category termed "sociopathic personality disturbance," encompassing (in line with early, broad-ranging conceptions of psychopathy) a range of problems including sexual deviations, addictions, and a distinct syndrome labeled

"antisocial reaction" marked by persistent aggression and criminal deviance. In DSM-II, published in 1968, the term "reaction" was eliminated, and sexual deviations, addictions, and delinquent personality types were grouped together under "personality disorders and other non-psychotic mental disorders," which included an "antisocial personality" condition that featured some of the affective-interpersonal symptoms described by Cleckley (e.g., selfishness, untrustworthiness, callousness, and absence of guilt). However, a serious limitation of the first and second editions of the DSM was that diagnoses were assigned through reference to prototype case descriptions rather than through use of explicit behavioral criteria. As a result, the reliability of diagnostic decisions was poor. This problem was addressed in the third edition by providing more specific, behaviorally oriented criteria for diagnoses. The criteria in DSM-III, published in 1980, were influenced in particular by the work of Lee Robins (1966, 1978) on characteristics predictive of the persistence of delinquency from earlier to later ages and focused predominantly on symptoms of behavioral deviancy in childhood and adulthood, including truancy, stealing, vandalism, other delinquency acts, aggressiveness, impulsivity, irresponsibility, recklessness, and lying.

With this shift to explicit behavioral criteria, the diagnosis of ASPD within DSM-III proved highly reliable. However, concerns about its validity were quickly raised (e.g., Frances, 1980; Hare, 1983), given its omission of many of the features identified by Cleckley as being essential to psychopathy, including superficial charm, lack of anxiety, absence of remorse or empathy, and general poverty of affect. Some effort was made to address these criticisms in DSM-III-R, published in 1984, through the addition of lack of remorse as an adult criterion for ASPD. Further changes along this line, directed at increasing coverage of interpersonal-affective features of psychopathy, were considered for DSM-IV, published in 2000, but ultimately rejected (Widiger et al., 1996). Consequently, the diagnostic criteria for ASPD in DSM-IV remained much the same as those in DSM-III-R, and these criteria were carried over without modification to the main diagnostic section of DSM-5 (Section II). However, as discussed below under the heading "Psychopathy in DSM-5," a new dimensional-trait approach to the diagnosis of ASPD is included in DSM-5 as an alternative to the traditional criterion-based version of the diagnosis.

#### Psychopathy: Current Conceptions and Empirical Findings

Alongside research on ASPD as defined in successive versions of the *DSM*, an extensive literature on psychopathy has accumulated over the years using assessment instruments based directly or indirectly on Cleckley's classic clinical characterization. In this section, we review major approaches to the assessment of psychopathy in use today, highlighting ways in which they differ and ways in which they converge. Following this, we describe a conceptual framework, the triarchic model (Patrick et al., 2009), for reconciling contrasting conceptions of psychopathy embodied in these various assessment devices and integrating findings across studies that have relied on particular ones.

#### Psychopathy in Forensic Samples: Hare's Psychopathy Checklist-Revised (PCL-R) DESCRIPTION

The assessment instrument that has dominated contemporary research on psychopathy is Hare's (1991, 2003) Psychopathy Checklist-Revised (PCL-R), which was developed to identify the condition as described by Cleckley in incarcerated offenders. The PCL-R contains 20 items, each rated on a 0-2 scale (absent, equivocal, or present) using information derived from a semi-structured interview and institutional file records. Item scores are summed to yield a total psychopathy score, with scores of 30 or higher considered indicative of psychopathy (Hare, 2003).

The original 22-item version of the PCL (Hare, 1980) evolved out of a global (7-point) rating system that directly referenced Cleckley's diagnostic criteria. Items for the PCL were selected from a larger pool of candidate indicators on the basis of their effectiveness in discriminating between offender participants judged to be high versus low on the Cleckley global rating system. Two items were dropped in the subsequent revised version. Notably, the interpersonal-affective deficits and behavioral deviance features described by Cleckley are represented directly in the PCL-R, but the positive adjustment features he emphasized (social efficacy and intelligence, absence of psychosis, lack of anxiety or neurotic symptoms, disinclination toward suicide) are not. Features of this type were likely excluded because items selected for the original PCL were required to correlate as a whole with one another, based on the implicit idea of psychopathy as a unitary condition (Patrick, 2006). Because the majority of Cleckley's criteria (12 of 16) reflect propensities toward deviance, indicators of positive adjustment would have been excluded over the course of scale refinement because of their failure to coalesce with the larger contingent of (pathological) indicators.

The relations that overall scores on the PCL-R show with criterion measures of various types reinforce the notion that the PCL-R conception of psychopathy is more purely pathological than Cleckley's. PCL-R total scores correlate very highly with overall symptoms of ASPD (Patrick et al., 2007; Skilling et al., 2002) and show robust positive associations with various behavioral indices of aggression (Hare, 2003) and scale measures of substance problems (Reardon et al., 2002). With respect to personality variables, PCL-R total scores exhibit especially robust relations with trait measures of impulsivity and aggression (Lynam & Derefinko, 2006; Verona et al., 2001) and, in contrast with Cleckley's portrayal of psychopathic individuals as low-anxious, correlate either minimally or somewhat positively with measures of anxiety, neuroticism, and negative affectivity (Hare, 2003; Lynam & Derefinko, 2006; Hicks & Patrick, 2006). Also at odds with Cleckley's conception, PCL-R total scores show positive rather than negative associations with indices of suicidality (Verona et al., 2001, 2005).

#### PCL-R FACTORS

While developed to operationalize psychopathy as a unitary condition, structural analyses of the PCL-R's items have revealed distinctive subdimensions or factors that exhibit differential relations with criterion measures of various types. Initial work (Harpur et al., 1988; Hare et al., 1990) indicated two correlated (r - .5) factors: an Interpersonal-Affective factor (Factor 1) marked by items indexing superficial charm, grandiosity, conning/deceptiveness, absence of remorse or empathy, shallow affect, and externalization of blame; and an Impulsive-Antisocial factor (Factor 2) encompassing early behavior problems and delinquency, boredom proneness, impulsivity, irresponsibility, lack of long-term goals, parasitism, and hot-tempered aggressiveness. Cooke and Michie (2001) proposed an alternative three-factor model in which Factor 1 was parsed into separate "Deficient Affect" and "Arrogant/Deceitful" factors, and items of Factor 2 considered most trait-like (n = 5) were included in a third "Impulsive-Irresponsible" factor. Subsequent to this, Hare (2003; Hare & Neumann, 2006) advanced an alternative four-facet model in which Factor 1 was parsed into "Interpersonal" and

"Affective" facets mirroring Cooke and Michie's first two factors, and Factor 2 was partitioned into a "Lifestyle" facet mirroring Cooke and Michie's "Impulsive-Irresponsible" factor, and an "Antisocial" facet including the antisocial behavior items from Factor 2 along with a "criminal versatility" item.

Most published work on subdimensions of the PCL-R has focused on the factors of the original two-factor model. These factors show differential relations with a variety of criterion measures, particularly when their shared variance is accounted for (e.g., through structural analysis, regression modeling, or partial correlation; Hare, 1991, 2003; Harpur et al., 1989; Hicks & Patrick, 2006; Patrick et al., 2005, 2007; Verona et al., 2001, 2005). Variance unique to Factor 1 correlates negatively with measures of anxiousness and internalizing problems and positively with measures of social dominance and (in some studies) positive affectivity and achievement, suggesting that the positive adjustment features of psychopathy specified by Cleckley are embodied to some extent in the variance of Factor 1 that is distinct from impulsive-antisocial tendencies. The interpersonal items of Factor 1 in particular account for its associations with indices of emotional stability and adjustment (Hall et al., 2004; Patrick et al., 2007). PCL-R Factor 1 also shows negative relations with scale measures of empathy and positive relations with measures of narcissistic personality, Machiavellianism, and proactive (instrumental) aggression. By contrast, variance unique to Factor 2 correlates positively with trait anxiety and internalizing problems and is strongly predictive of both child and adult symptoms of ASPD as represented in DSM-IV (and Section II of DSM-5). Factor 2 also shows selective positive relations with scale measures of impulsivity, aggressiveness, general sensation-seeking, and substance dependence, and interview- or record-based indices of impulsive aggression (e.g., fighting, assault charges, partner abuse) and suicidal behavior.

These differential associations for Factors 1 and 2 of the PCL-R are notable for variables considered to be facets of a single higher-order construct (e.g., Hare, 1991, 2003). Especially noteworthy are cases in which opposing relations of the two PCL-R factors with criterion measures become stronger once their covariance (overlap) is removed—a phenomenon known as *cooperative suppression* (Paulhus et al., 2004). As an example of this, Hicks and Patrick (2006) reported that correlations for each factor of the PCL-R with measures of negative affectivity (i.e., fearfulness, distress, and depression) increased,

in opposite directions, when scores on the two factors were included together in a regression model. This result indicates that distinct opposing relations of the two PCL-R factors with indices of negative affectivity were partially concealed by the variance they share. A similar result was reported by Frick, Lilienfeld, Ellis, Loney, and Silverthorn (1999) for the two factors of the Antisocial Process Screening Device (Frick & Hare, 2001), an inventory for assessing psychopathy in children and adolescents that is patterned after the PCL-R (see next section). Effects of this type are conceptually important because they indicate that the items of the PCL-R, although intended to index a single underlying construct, are in fact indexing separate constructs. In particular, the finding of suppressor effects for the two PCL-R factors in relation to variables such as anxiety, depression, and suicidality appears consistent with Cleckley's view that psychopathy entails the convergence of contrasting dispositions toward psychological resiliency and behavioral deviancy.

#### ADAPTATIONS OF THE PCL-R USED WITH YOUNG CLINICAL SAMPLES

The dominant inventories used for assessing psychopathy in child and adolescent clinical samples consist of adaptations of the PCL-R and include the youth version of the PCL-R (PCL:YV; Forth et al., 2003), the Antisocial Process Screening Device (APSD; Frick & Hare, 2001; Frick et al., 1994), the Child Psychopathy Scale (CPS; Lynam, 1997; Lynam et al., 2005), and the Child Problematic Traits Inventory (CPTI; Colins et al., 2014). The most widely used of these, the 20-item APSD, was devised for use with children aged 6-13 referred for treatment of behavioral problems and is rated by either parents or teachers. The APSD has two distinguishable factors: a Callous-Unemotional (CU) factor reflecting emotional insensitivity and exploitative disregard for others and an Impulsive/ Conduct Problems (I/CP) factor encompassing impulsive tendencies, reckless or delinquent behavior, and inflated sense of self-importance (Frick et al., 1994; Frick & Hare, 2001)-with some research (e.g., Frick et al., 2000) suggesting distinguishable impulsive and narcissistic or attentionseeking components to the I/CP factor. Children who score high on the I/CP factor but not the CU factor exhibit reduced levels of intellectual ability, elevated anxiety and negative emotional reactivity, and proneness to angry-reactive (but not proactiveinstrumental) aggression (Frick & Marsee, 2018; Frick et al., 2014). By contrast, children who score

high on both factors of the APSD appear to have normal intellectual ability, exhibit reduced levels of anxiety and neuroticism, are underreactive to distressing stimuli and learn less readily from punishment, and tend to be attracted to activities entailing novelty and risk. These children also show heightened levels of both proactive and reactive aggression and greater persistence of such behavior across time.

#### PREVALENCE OF PCL-R-DEFINED PSYCHOPATHY

The PCL-R was developed for use with male correctional and forensic samples, and thus prevalence estimates have been available mainly for samples of this type. The estimated prevalence of PCL-R-defined psychopathy (total score of 30 or higher) in male correctional and forensic populations is 15-25%, compared with 50-80% for DSM-IV-defined ASPD (Hare, 2003), with most of those who score as psychopathic also meeting criteria for ASPD. Because the PCL-R is designed for offender samples and limited efforts have been made to assess PCL-R psychopathy in community samples (for exceptions, see Ishikawa et al., 2001; Gao et al., 2011), the prevalence of PCL-R-defined psychopathy in community adults is less well-established. Based on median prevalence rates for male prisoners (20% for psychopathy and 65% for ASPD), and assuming a similar ratio of high PCL-R scorers among adults diagnosable as ASPD in the general community, the estimated prevalence of PCL-R psychopathy among community men (3% of whom are expected to meet criteria for ASPD) would be approximately 1% (i.e., 20/65 × 3%). Using an abbreviated, screening version of the PCL-R (the PCL:SV; Hart et al., 1995), Farrington (2006) reported the prevalence of psychopathy to be around 2% (i.e., 8 cases out of 411) in a large sample of community boys followed up to age 48. Combining these figures, the prevalence of PCL-R psychopathy among men in the community is likely somewhere in the range of 1-2%. However, this estimate does not include individuals who exhibit salient interpersonal-affective symptoms of psychopathy without sufficient overt behavioral deviancy to warrant a diagnosis of ASPD-cases that Cleckley referred to as "incomplete manifestations" of the condition. Because the field lacks accepted criteria for diagnosing psychopathy in noncriminal adults, population prevalence estimates for cases of this type remain uncertain.

Women are incarcerated at much lower rates than men, and the prevalence of ASPD among women in the population at large is only a third of that in men (DSM-IV-TR). Regarding PCL-Rdefined psychopathy, some studies of incarcerated women have reported prevalence rates similar to those for incarcerated men, but others have reported lower rates (Verona & Vitale, 2018). Studies of psychopathy and related constructs in nonincarcerated adult samples have also demonstrated lower rates or levels in general for women than for men (Verona & Vitale, 2018). Given these findings, the prevalence of PCL-R-defined psychopathy among adult women in the community is likely no more than one-third the rate for community men (i.e., .3-.7%). Combining the midpoint of this range (.5) with that for men (1.5, as noted above) results in an overall estimated prevalence of approximately 1% in the general adult population. In line with this figure, a recent study by Sanz-García, Gesteira, Sanz, and García-Vera (2021) estimated the prevalence of PCL-R psychopathy among adults in society as a whole to be around 1.2%. Again, this estimate omits individuals exhibiting interpersonal-affective features of psychopathy without salient antisocial behavior.

With regard to race and ethnicity, an initial study of incarcerated men by Kosson, Smith, and Newman (1990) yielded evidence that overall PCL-R scores were higher among African American than European American offenders. A meta-analysis of this and subsequent work by Skeem, Edens, Camp, and Colwell (2004) revealed a small but significant effect size along this line. However, considerably more research is needed to clarify the contribution of factors such as poverty, discrimination, and adjudication inequities to reported racial-group differences. With regard to culture, there is evidence that American prison samples score higher in general on the PCL-R than do European prison samples (Sullivan & Kosson, 2006).

#### COMORBIDITY WITH DSM DISORDERS

The *DSM* disorder associated most closely with PCL-R-defined psychopathy is ASPD. However, the relationship between the two is asymmetric. Within offender samples, most individuals who meet the PCL-R criterion for psychopathy (total score  $\geq$ 30) also meet diagnostic criteria for *DSM-IV*ASPD, but the majority who meet criteria for ASPD fall below the PCL-R criterion for psychopathy. Additionally, the two PCL-R factors show differential relations with ASPD. On one hand, the behaviorally based child and adult criteria for ASPD overlap substantially with the impulsive-antisocial features of psychopathy indexed by PCL-R Factor 2. By contrast,

only 1 of the 15 child criteria for ASPD (lying) and only 2 of the 7 adult criteria (deceitfulness, lack of remorse) intersect with the interpersonal-affective features of psychopathy embodied in PCL-R Factor 1, resulting in a weaker observed association for Factor 1 that is largely attributable to its overlap with Factor 2 (Patrick et al., 2005).

Factor 2 of the PCL-R also shows selective associations with measures of substance abuse and dependence (Reardon et al., 2002; Smith & Newman, 1990) and borderline personality symptoms (Shine & Hobson, 1997; Warren et al., 2003). By contrast, scores on Factor 1 relate more to measures of narcissistic and histrionic personality disorder (Harpur et al., 1989; Hart & Hare, 1989; Hildebrand & de Ruiter, 2004). Also, as noted earlier, the two factors of the PCL-R show opposing, mutually suppressive relations with measures of anxiety and depression (Hicks & Patrick, 2006). The fact that the unique variance in Factor 1 is negatively associated with anxiety and depression indicates that this component of the PCL-R (its Interpersonal facet, in particular; Hall et al., 2004) captures something of the positive adjustment and resiliency that Cleckley described as characteristic of psychopaths. The positive relations for Factor 2, on the other hand, converge with data indicating that the DSM diagnosis of ASPD is associated with an increased prevalence of anxiety and mood disorders (e.g., DSM-IV-TR, 2000, p. 702; Krueger, 1999b).

#### NEUROBIOLOGICAL CORRELATES

Neurobiological correlates of psychopathy in adult offender samples have been studied mainly in relation to overall scores on the PCL-R or on the earlier Cleckley rating system that served as the referent for the PCL-R. Historically, one of the most consistent findings-beginning with Lykken's (1957) seminal multimethod investigation of anxiety and continuing with the autonomic reactivity studies of Hare in the 1960s and 1970s (cf. Hare, 1978)-has been that individuals high in overall psychopathy show reduced skin conductance reactivity to stressors of various types, in particular cues signaling an upcoming aversive event (for reviews, see Arnett, 1997; Hare, 1978; Lorber, 2004; Siddle & Trasler, 1981). This finding has been interpreted as reflecting a basic deficiency in anxiety or fear (Fowles, 1980; Hare, 1978; Lykken, 1957).

Another reliable finding in the literature, also consistent with the idea of a negative emotional reactivity deficit, is that individuals diagnosed as psychopathic using the PCL-R fail to show

normal augmentation of the startle blink reflex during viewing of aversive visual stimuli (e.g., Herpertz et al., 2001; Patrick et al., 1993; Sutton et al., 2002; Vanman et al., 2003). This reactivity deficit has been tied specifically to elevations on the Interpersonal-Affective factor of the PCL-R (Patrick, 1994; Vanman et al., 2003; Vaidyanathan et al., 2011). The selective association with PCL-R Factor 1 is notable because the startle reflex is a protective response known to increase with activation of the amygdala, a key structure in the brain's defensive (fear) system (Lang et al., 1990). The lack of aversive startle potentiation therefore suggests a weakness in reactivity at this basic subcortical level among individuals exhibiting the core interpersonalaffective features of psychopathy. Consistent with this notion, participants with high PCL-R scores show deficits on behavioral tasks believed to be sensitive to amygdala function (Blair, 2006). Neuroimaging studies have demonstrated reduced amygdala activity during aversive conditioning and fear face processing, respectively, in high PCL-R-scoring adults (Birbaumer et al., 2005; Veit et al., 2002) and in youth with conduct disorder who exhibit callous-unemotional traits (Jones et al., 2009; Marsh et al., 2008).

Additionally, other lines of work, including cerebral asymmetry, brain potential, and neuroimaging studies (for reviews, see Hare, 2003, pp. 124-126; Patrick, 2014; Patrick, Venables, & Skeem, 2012), have provided evidence for brain abnormalities in high PCL-R-scoring individuals. However, studies have not reliably demonstrated impairments on neuropsychological tests of frontal lobe function (for a review, see Rogers, 2006) or in P300 brain response (cf. Patrick, 2014). This contrasts with evidence that ASPD is reliably associated with deficits on tests of frontal lobe dysfunction (Morgan & Lilienfeld, 2000) and with reduced amplitude of P300 brain potential response (Bauer et al., 1994; Patrick, Bernat et al., 2006). Given that PCL-R Factor 2 is associated more strongly with ASPD and that Factor 1 (after controlling for overlap with Factor 2) shows positive relations with indices of psychological adjustment, it could be the case that the two factors of the PCL-R are differentially related to frontal lobe task performance and P300 brain response. Evidence in support of the latter of these possibilities was provided by a recent study demonstrating reductions in P300 response amplitude specifically in relation to Factor 2 of the PCL-R in a sample of male offenders (Venables & Patrick, 2014).

#### Psychopathy in Community Samples: Self-Report–Based Operationalizations

Most research on psychopathy in noncriminal samples has utilized self-report assessment inventories. Whereas older inventories of this type emphasized measurement of the impulsive-antisocial (Factor 2) component of psychopathy, which relates most to ASPD, newer measures such as the Psychopathic Personality Inventory (PPI; Lilienfeld & Andrews, 1996), Levenson et al.'s (Levenson et al., 1995) Self-Report Psychopathy Scale (LSRP), Hare's Self-Report Psychopathy Scale (HSRP; Paulhus et al., 2016; Williams et al., 2007), the Youth Psychopathic Traits Inventory (YPI; Andershed et al., 2002), the Elemental Psychopathy Assessment (EPA; Lynam et al., 2011), and the Triarchic Psychopathy Measure (TriPM; Patrick, 2010; Sellbom & Phillips, 2013) include coverage of interpersonal-affective (Factor 1) features as well as impulsive-antisocial features.

The LSRP, HSRP, and YPI were all patterned after the PCL-R and provide coverage of factors or facets specified by alternative structural models of the PCL-R. The LSRP includes "primary" and "secondary" subscales intended to parallel the factors of the original two-factor model (Hare et al., 1990; Harpur et al., 1989), the YPI contains subscales that align with Cooke and Michie's (2001) three-factor model, and the subscales of the HSRP align with Hare's (2003) four-facet model. In contrast with these PCL-R-based inventories, the EPA was developed as an extension of prior work (Lynam & Widiger, 2007; Miller et al., 2001) undertaken to characterize psychopathy in terms of lowerorder traits of the five-factor personality model as indexed by the Neuroticism-Extraversion-Openness (NEO) PI-R inventory (Costa & McCrae, 1992). The EPA assesses maladaptive variants of the set of NEO PI-R traits that appear most relevant to psychopathy. Although it is comparatively new, several published reports have appeared on the psychometric properties and correlates of the EPA's full (e.g., Miller et al., 2011; Miller, Hyatt et al., 2014) and short-length versions (Lee & Sellborn, 2021). The TriPM, another newer inventory developed to assess biobehavioral trait constructs specified by the triarchic model of psychopathy (Patrick et al., 2009), is described in a later section focused on this model.

The PPI is the self-report psychopathy inventory that has been used most widely over the past two decades. It was developed to index psychopathy in terms of dispositional tendencies (traits) considered relevant to this clinical condition by historical writers (Lilienfeld & Andrews, 1996). Factor analyses of the PPI's eight subscales (e.g., Benning et al., 2003; Ross et al., 2009) revealed distinguishable factors that exhibit relations with external criterion variables similar to those for the PCL-R factors (Poythress et al., 2010). Findings for these distinct factors of the PPI, along with those of the PCL-R and its affiliates, served as important referents for formulation of the triarchic model of psychopathy, described below. For these reasons, we focus the remainder of this section on research that has utilized the PPI to index psychopathy in community and offender samples.

#### THE PSYCHOPATHIC PERSONALITY INVENTORY AND ITS FACTORS

The original PPI (Lilienfeld & Andrews, 1996) consisted of 187 items; its revised version (PPI-R; Lilienfeld & Widows, 2005) includes 154 items. The PPI's items are organized into eight scales that tap distinct dispositional constructs relevant to psychopathy. In contrast with the PCL-R, the PPI includes specific coverage of nonanxiousness and low fear through its Stress Immunity and Fearlessness scales, along with coverage of interpersonal dominance (Social Potency scale), impulsivity (Carefree Nonplanfulness), oppositionality (Rebellious Nonconformity), alienation (Blame Externalization), aggressive exploitativeness (Machiavellian Egocentricity), and lack of empathic concern (Coldheartedness).

As noted above, factor analyses of the PPI's eight scales have revealed two higher-order factors, the first defined by scales assessing Social Potency, Stress Immunity, and Fearlessness subscales, and the second by ones indexing Carefree Nonplanfulness, Rebellious Nonconformity, Blame Externalization, and Machiavellian Egocentricity scales. Benning, Patrick, Blonigen, Hicks, and Iacono (2005) labeled these two higher-order factors Fearless Dominance and Impulsive Antisociality; Lilienfeld and Widows (2005) proposed Self-Centered Impulsivity as an alternative label for the latter of the two. The remaining PPI subscale, Coldheartedness, does not load appreciably on either of these factors, indicating that it taps something distinct. In contrast with the interrelated factors of the PCL-R, the two higher-order factors of the PPI are uncorrelated (Benning et al., 2003).

#### PSYCHOLOGICAL AND NEUROBIOLOGICAL CORRELATES OF THE PPI FACTORS

The two factors of the PPI show conceptually meaningful and often diverging patterns of relations

with various criterion measures (Benning, Patrick, Blonigen et al., 2005; Blonigen et al., 2005; Patrick, Edens et al., 2006; Ross et al., 2009). Scores on the Fearless Dominance factor (PPI-FD) are associated with social efficacy and emotional stability (e.g., higher assertiveness and well-being; lower anxiousness and depression) as well as with narcissism, thrill seeking, and reduced emotional empathy. In contrast, scores on the Impulsive Antisociality or Self-Centered Impulsivity (SCI) factor are more uniformly associated with maladaptive tendencies, including impulsivity and aggressiveness, child and adult antisocial behavior, substance problems, high negative affect, and suicidal ideation and acts.

The two PPI factors also show differing neurobiological correlates. In a study of young men from the community, Benning, Patrick, and Iacono (2005) found that participants with very high scores on PPI-FD showed a deviant pattern of startle reactivity resembling that of offenders with high scores on PCL-R Factor 1 (i.e., lack of startle potentiation during viewing of aversive picture stimuli, indicating a lack of normal defensive mobilization). By contrast, participants scoring high (as compared to low) on the PPI's Self-Centered Impulsivity factor (PPI-SCI) showed reduced electrodermal reactivity to picture stimuli in general (i.e., whether affective or neutral), suggesting reduced sympathetic arousability (cf. Raine, 1997). Extending the result for PPI-FD, Vaidyanathan, Patrick, and Bernat (2009) reported a lack of aversive startle potentiation for participants low in dispositional fear as defined by scores on PPI-FD and other scale measures of fear and fearlessness (see also Kramer et al., 2012). The finding of reduced electrodermal reactivity in high PPI-SCI-scoring participants has also been replicated. For example, Verschuere, Crombez, de Clercq, and Koster (2005) reported that PPI-SCI was related to smaller skin conductance responses to critical items in a concealed information lie detector test. Additionally, mirroring the findings of reduced P300 brain response in relation to ASPD and externalizing proneness more broadly, Carlson, Thái, and McLaron (2009) found scores on PPI-SCI (but not PPI-FD) to be inversely associated with P300 response in a visual oddball task paradigm.

Other work has used functional magnetic resonance imaging (fMRI) to test for brain reactivity differences in relation to the two factors of the PPI. Gordon, Baird, and End (2004) reported reduced fMRI blood oxygen level dependent (BOLD) activation in the right amygdala and affiliated regions of frontal cortex during processing of affective faces in participants scoring high but not low on PPI-FD. By contrast, individuals scoring high as compared to low on PPI-SC showed increased amygdala activation when processing affective faces. Related to this latter finding, Buckholtz et al. (2010) reported enhanced bilateral activation in the nucleus accumbens for high versus low SCI-scoring individuals during anticipation of monetary rewards. These results may indicate a more immediate affectdriven response style in high SCI-score individuals. Another fMRI study by Harenski, Kim, and Hamann (2009) reported reduced activation in medial prefrontal cortex during viewing of scenes depicting moral violations in individuals scoring high on the PPI as a whole, with evidence of reduced amygdala activation for those scoring high on PPI Coldheartedness specifically.

#### An Integrative Framework for Investigating and Understanding Psychopathy: The Triarchic Model

The triarchic model (Patrick et al., 2009) was formulated to reconcile alternative conceptions of psychopathy represented in historical writings and contemporary assessment instruments and address persisting unresolved issues in the field. The model proposes that contrasting perspectives and apparent contradictions in the existing literature can be reconciled by conceiving of psychopathy as encompassing three distinct but intersecting trait dispositions: disinhibition, boldness, and meanness. In contrast with other contemporary factor- or facetoriented perspectives (e.g., Cooke & Michie, 2001; Frick & Hare, 2001; Hare & Neumann, 2006), the triarchic model is a construct-based framework not bound to any specific assessment instrument or approach, designed to serve as an organizing framework for reconciling alternative instrument-based conceptions and integrating findings from studies using them. Different psychopathy inventories are viewed as indexing the triarchic constructs to varying degrees and in differing ways. The next section describes the three trait constructs of the triarchic model.

## Triarchic Model Traits: Description DISINHIBITION

The term "disinhibition" refers to a general proneness toward impulse control problems,

entailing lack of planfulness, a focus on immediate versus delayed gratification, difficulty in controlling emotions and urges, and weak behavioral restraint. Related concepts in the literature include disinhibitory psychopathology (Gorenstein & Newman, 1980; Sher & Trull, 1994), externalizing proneness (Achenbach & Edelbrock, 1978; Krueger et al., 2002), and low inhibitory control (Kochanska et al., 1997). Vis-à-vis conventional personality concepts, disinhibition represents the conjunction of impulsivity and negative emotionality (Krueger, 1999a; Sher & Trull, 1994). Behaviorally, it is manifested by impatience, impulsive action leading to adverse consequences, irresponsibility, distrust and alienation, aggressive behavior (angry or reactive aggression, in particular), repeated rulebreaking (and often law-breaking) acts, and proclivities toward abuse of alcohol and other substances (Krueger et al., 2007).

Historical accounts of psychopathy have emphasized this disinhibitory facet to varying degrees, with some writers broadening the diagnosis to encompass alcohol and drug addiction along with other nonnormative conditions such as sexual deviancy (e.g., Prichard, 1835), and others characterizing psychopathy in terms more characteristic of externalizing individuals (e.g., Arieti, 1963; Partridge, 1928) or describing psychopathic subtypes with irritableimpulsive behavior indicative of high externalizing proneness (e.g., Craft, 1966; Kraepelin, 1915). In particular, the traditional notion of the "symptomatic" or secondary psychopathy (Karpman, 1941; Lykken, 1957) appears consistent with the clinical presentation of the highly disinhibited-externalizing individual. Research has shown that variance unique to PCL-R Factor 2 reflects externalizing proneness to a large extent (Patrick et al., 2005), as do scores on the corresponding SCI factor of the PPI (Blonigen et al., 2005). Similarly, research on the factors of the APSD child psychopathy inventory demonstrates that the I/CP factor in particular indexes disinhibitory or externalizing tendencies (Bertoldi, Perkins et al., 2022; Drislane et al., 2014).

Despite its importance to conceptions of psychopathy, however, investigators in the area would not equate disinhibition with psychopathy. In contrast with the condition as described by Cleckley, externalizing proneness is associated with higher rather than lower levels of negative affectivity (Krueger, 1999a), elevated rather than reduced rates of internalizing problems (Achenbach & Edelbrock, 1978; Krueger, 1999b), and heightened rather than diminished tendencies toward suicidal behavior (Verona & Patrick, 2000; Verona et al., 2004). In contrast with the excessive, poorly regulated emotion that is characteristic of high-externalizing individuals, psychopathy is marked by salient "emotional detachment" (i.e., affective insensitivity and lack of social connectedness; Cleckley, 1941/ 1976; Lykken, 1995; McCord & McCord, 1964; Patrick, 1994; Patrick et al., 1993). The triarchic model proposes that this distinguishing component of psychopathy reflects the presence of boldness or meanness, or both. Stated another way, it is the occurrence of disinhibitory or externalizing tendencies in conjunction with high levels of dispositional boldness and/or meanness that signifies the presence of psychopathy.

#### BOLDNESS

This disposition encompasses characteristics of social assurance and self-confidence, calmness and poise in the face of stress or danger, rapid recovery from aversive experiences, and tolerance or preference for uncertainty and risk. Related terms include "fearless temperament" (Kochanska, 1997; Lykken, 1995), "fearless dominance" (Benning, Patrick, Blonigen et al., 2005), "hardiness" (Kobasa, 1979), and "resiliency" (Block & Block, 1980). In personality terms, boldness reflects the intersection of dominance, stress immunity, and thrill-adventure seeking (Benning et al., 2003; Benning, Patrick, Blonigen et al., 2005; Kramer et al., 2012). Behavioral expressions include social assertiveness, persuasiveness, imperturbability, venturesomeness, and courageous action. As conceptualized in the triarchic model, boldness is not identical to fearlessness. Fearlessness is viewed as a biologically based (genotypic) disposition, entailing diminished sensitivity of the brain's defense-mobilization system to signals of danger or punishment (Fowles & Dindo, 2009; Kramer et al., 2012; Patrick, Durbin, & Moser, 2012). Boldness is one way in which genotypic fearlessness can be exhibited phenotypically, but, as discussed next, this underlying disposition may also contribute to phenotypic meanness.

Cleckley's case histories and diagnostic criteria highlighted features of boldness in conjunction with disinhibitory (externalizing) tendencies (Crego & Widiger, 2016; Patrick, 2006, 2018). Boldness was represented directly in characteristic features of social charm, absence of anxiety or neurotic symptoms, lack of affective responsiveness, insensitivity to punishment ("failure to learn by experience"), and disinclination toward suicide. Other historical writers who focused on psychiatric patients as opposed to criminal offenders (e.g., Kraepelin, 1915; Schneider, 1934) also described bold-externalizing variants. Unresponsiveness to punishment and lack of fear were also emphasized in early psychophysiological research on psychopathy (cf. Hare, 1978) and in empirically based theories of psychopathy (Fowles, 1980; Lykken, 1995).

The Fearless Dominance (FD) factor of Lilienfeld's self-report-based PPI, demarcated by subscales of Social Potency, Stress Immunity, and Fearlessness, can be viewed as directly indexing boldness (Patrick et al., 2009; Patrick, Kramer et al., 2019). As mentioned earlier, scores on PPI-FD are uncorrelated with impulsive-antisocial tendencies tapped by PPI-SCI. Given this, boldness as operationalized by PPI-FD can be viewed as indexing a more adaptive expression of dispositional fearlessness-one distinct from aggressive externalizing deviancethat is likely to be of importance for conceptualizing psychopathy in nonviolent, noncriminal samples (Lilienfeld et al., 2018; Lykken, 1995). Boldness also appears to be tapped by Factor 1 of the PCL-R (Benning, Patrick, Blonigen et al., 2005), in particular, by its Interpersonal facet items (Patrick et al., 2007; Venables et al., 2014; Wall et al., 2015). However, the Interpersonal facet of the PCL-R indexes boldness less directly and distinctively than PPI-FD, given its overlap with the PCL-R's Affective, Lifestyle, and Antisocial facets.

#### MEANNESS

The triarchic trait of meanness encompasses features of deficient empathy, lack of closeness to others, uncooperativeness, exploitativeness, and self-empowerment through cruel and destructive acts. Related terms in the literature include "callousunemotionality" (Frick & Marsee, 2018), "antagonism" (Lynam et al., 2018), and "coldheartedness" (Lilienfeld & Widows, 2005). From the standpoint of interpersonal traits (Leary, 1957; Wiggins, 1982), meanness entails high dominance in conjunction with low affiliation and nurturance (Blackburn, 2006; Harpur et al., 1989). Saucier (1992) documented a construct similar to meanness (represented by adjective descriptors such as tough, unemotional, and insensitive) entailing the conjunction of low affiliation, high dominance, and low neuroticism. From this standpoint, meanness can be viewed as disaffiliated agency-an orientation involving active pursuit of goals and resources without concern for and at the expense of others. Unlike social withdrawal, which is marked by passive disengagement ("moving away"; Horney, 1945) from people, meanness involves active exploitation of ("moving against"; Horney, 1945) people. Affiliated behavioral expressions include disdain toward others, arrogance, rebellious defiance, lack of close relationships, harsh competitiveness, exploitation of others for personal gain, proactive (predatory or instrumental) aggression, cruelty toward people or animals, and engagement in destructive acts for excitement.

Meanness is emphasized in historical accounts of psychopathy based on observations of criminal and delinquent individuals (McCord & McCord, 1964; Quay, 1964; Robins, 1966, 1978). The Affective facet of the PCL-R comprises items that capture McCord and McCord's lovelessness (item 7, "shallow affect," and item 8, "callous/lack of empathy") and guiltlessness (item 6, "lack of remorse or guilt," and item 16, "failure to accept responsibility for own actions"). The Interpersonal items of the PCL-R also include elements of meanness: Item 1 ("glibness and superficial charm") refers to excessive slickness and toughness; item 2 ("grandiose sense of self-worth") includes arrogance and a sense of superiority over others; item 4 ("pathological lying") refers to deceptiveness in social interactions and enjoyment in deceiving others; and item 5 ("conning/manipulative") entails active exploitation for gain without consideration of the effects on victims. The best-established psychopathy inventories for children and adolescents (PCL:YV, CPS, and APSD), patterned after the PCL-R, also emphasize meanness in their interpersonal-affective items.

Although psychopathy is frequently operationalized with reference to antisocial acts and attitudes that reflect tendencies toward disinhibition as well as meanness, research by Krueger et al. (2007; see also Patrick, Kramer et al., 2013) on the structure of externalizing problems and traits demonstrated that these dispositional facets of psychopathy could be indexed separately. Specifically, these investigators reported a bifactor structure for the 23 content scales of the Externalizing Spectrum Inventory (ESI), an instrument developed to measure diverse elements and expressions of externalizing proneness. All of the ESI's scales loaded onto a superordinate disinhibition factor, but certain scales also loaded onto subordinate factors reflecting callous-aggressiveness (meanness) and substance abuse. The scales that loaded most strongly and exclusively onto the general disinhibitory factor were those indexing problematic impulsivity and irresponsibility. The best indicators of the callousaggressive subfactor were scales indexing presence versus absence of empathy and interpersonal expressions of aggression.

The findings of this work showed that tendencies toward meanness could be separated from proclivities toward disinhibition. Along with scales tapping empathic concern and interpersonal aggression, other scales that have helped to demarcate the callous-aggressive subfactor included ones indexing excitement seeking, rebelliousness, and dishonesty. Notably, these scale indicators of the ESI's callous-aggressive factor paralleled the item content of the APSD's callousunemotional (CU) factor, which reflects disregard for the feelings of others, shallowness and insincerity, lack of guilt, and lying and manipulativeness (Frick et al., 1994; Frick et al., 2014). Also in line with the ESI findings, youth with conduct problems who score high on the CU factor of the APSD show elevated rates of proactive aggression and enhanced excitement seeking in comparison to those low on the CU factor (Frick & White, 2008; Frick et al., 2014). Although early ideas about the biobehavioral basis of callousunemotionality (meanness) focused on dispositional fearlessness (e.g., Frick & Marsee, 2006; Frick & White, 2008), the triarchic model postulates that a weakness in the capacity for affiliation gives rise to the qualities that distinguish this facet of psychopathy from its boldness facet-namely, lack of empathic concern, disregard for others' welfare, and aggressive exploitativeness. Recent years have shown a growing emphasis on the role of affiliative deficits in dispositional callousness or meanness, both in younger-aged (Viding & McCrory, 2019; Waller & Wagner, 2019) and adult samples (Palumbo et al., 2020).

#### Operationalizing the Triarchic Model Traits

This section describes various self-report scales that have been developed to operationalize the three dispositional constructs of the triarchic model. The first of these, the Triarchic Psychopathy Measure (TriPM), consists of items selected to index broad factors of two inventories that served as referents for the triarchic model-the general disinhibition and callous-aggressive factors of the ESI (Krueger et al., 2007) and the fearless dominance factor of the PPI (Lilienfeld & Widows, 2005). A number of other triarchic scale measures have been developed using items from (1) preexisting psychopathy inventories, (2) normative and maladaptive personality inventories, and (3) construct-relevant scales available in etiologically informative (twin, longitudinal) archival datasets.

#### TRIARCHIC PSYCHOPATHY MEASURE

The 58-item Triarchic Psychopathy Measure (TriPM; Patrick, 2010) indexes the disinhibition, meanness, and boldness facets of psychopathy as separate dimensions. Items comprising the TriPM Disinhibition and Meanness scales (20 and 19 items, respectively) are from Krueger et al.'s (2007) ESI. The Disinhibition scale is composed of items from facet scales of the ESI that exhibit strong, selective loadings on the inventory's general disinhibition factor (i.e., Problematic Impulsivity, Irresponsibility, Boredom Proneness, Impatient Urgency, Alienation, Theft, Fraudulence, Dependability [-], Planful Control [-]). Scores on this scale correlate very strongly (r > .9) with regressionestimated scores on the general factor of the ESI (Patrick, Kramer et al., 2013). The TriPM Meanness scale consists of items from ESI scales that function as indicators of the inventory's callous-aggression subfactor (i.e., Empathy [-], Relational Aggression, Excitement Seeking, Destructive Aggression, Physical Aggression, Honesty [-]). Scores on this scale, after controlling for overlap (r - .5) with scores on the TriPM Disinhibition scale, correlate very highly (r > .8) with scores on the callousaggression subfactor of the ESI bifactor model (Patrick, Kramer et al., 2013). The 19-item TriPM Boldness scale consists of items that index fearless tendencies in the realms of interpersonal behavior (persuasiveness, social assurance, dominance), perceived emotional experience (resiliency, self-assurance, optimism), and venturesomeness (courage, thrill seeking, tolerance for uncertainty; cf. Kramer et al., 2012). Its items were selected to index the general factor of the Boldness Inventory (Patrick, Kramer et al., 2019), a multi-scale measure developed to flesh out distinct facets of this construct and characterize their structure. Scores on this scale correlate very highly (~.8) with the FD factor of the PPI, but only modestly (r~ .2) with the TriPM Meanness scale and negligibly with the TriPM Disinhibition scale (Drislane et al., 2014; Patrick, Kramer et al., 2019).

The TriPM has been employed in many different studies since the first report of its use by Sellbom and Phillips (2013), and evidence for the convergent and discriminant validity of its subscales exists in relation to a broad range of external criteria including measures from domains of personality, clinical symptomatology, behavioral performance, and psychophysiology/neuroimaging (for reviews, see Patrick & Drislane, 2015; Patrick, 2018; Sellbom, 2018; Sellbom et al., 2018). The inventory is freely available online, and a number of foreignlanguage translations (including Dutch, Finnish, French, German, Italian, Japanese, Mandarin Chinese, Portuguese, Spanish, and Swedish) exist, resulting in growing evidence for its validity across nations and cultures.

An issue that has been raised regarding the TriPM is that its scales are not strictly unidimensional according to confirmatory factor analytic criteria (Roy et al., 2021; Shou et al., 2018). This is because the TriPM's scales were developed to index broad factors identified by scale-level analyses of multifaceted inventories and thus include items from distinct content domains; in such cases, the recommended analytic method for characterizing structure is exploratory structural equation modeling (ESEM; Hopwood & Donnellan, 2010; Wright, 2020). A three-factor ESEM model of the TriPM item set has been shown to exhibit good statistical fit (Bertoldi, Tuvblad et al., 2022; Patrick et al., 2021).

#### OTHER TRIARCHIC SCALE MEASURES

The triarchic model was advanced to provide a general framework for ongoing work on conceptualization and assessment of psychopathy through a focus on core dispositional constructs-presumed to reflect biobehavioral propensities-that transcend specific assessment instruments or modalities of measurement. Importantly, the components of the triarchic model are conceived of as "open constructs" (Meehl, 1986), subject to modification over time based on accumulating empirical evidence from different measurement modalities. While the TriPM provides one approach to operationalizing the constructs of the model, other psychopathy measures, or inventories known to predict substantial variance in psychopathy measures, can also serve as vehicles for operationalizing these constructs.

Hall et al. (2014) undertook to develop itembased scale measures of the Triarchic constructs using items from the PPI. A construct-based rating approach was used rather than a criterion-oriented approach (e.g., selection of items with reference to the TriPM scales) to allow constructs distilled from the psychopathy literature as a whole to guide scale formation rather than binding scales to a particular operationalization of the triarchic model. All items of the PPI were rated for relevance to each construct of the model as described by Patrick et al. (2009), and items were selected for inclusion in scales based on their preferential relevance to one triarchic construct over the others. Scales were further refined based on considerations of overall content coverage, internal properties of the scales (i.e., inter-item correlations and internal consistency), and correlations of items within and across scales. The resultant PPI Triarchic (PPI-Tri) scales indexed boldness, meanness, and disinhibition in a manner complementary to but distinct from the TriPM. In particular, the PPI-Meanness scale (composed mainly of items from the PPI's Coldheartedness and Machiavellian Egocentricity subscales) correlated less strongly (r = .37) with the PPI-Disinhibition scale (composed mostly of items from scales loading onto the PPI's SCI factor) than their TriPM counterparts ( $r \sim .5$ ). Hall et al. reported evidence for criterion-related validity of the PPI-Tri scales in undergraduate and offender samples. PPI-Boldness and Disinhibition exhibited strong convergence with their TriPM counterparts (rs = .79 and .64, respectively) in the undergraduate sample, for which both inventories were available. Convergence between PPI and TriPM Meanness was somewhat lower (r = .54), suggesting that the decreased overlap between PPI Meanness and Disinhibition (vs. their TriPM counterparts) was attributable more to a shift in the former. In the forensic sample, for which scores on the PCL-R were available, all three PPI-Tri scales contributed to prediction of PCL-R total scores, with PPI-Boldness and PPI-Meanness contributing to prediction of Factor 1 scores, and PPI-Meanness and Disinhibition contributing to prediction of Factor 2 scores. With regard to the PCL-R's four facets, PPI-Boldness contributed distinctively to prediction of the Interpersonal facet, PPI-Meanness contributed to prediction of both the Affective facet and the Antisocial facet, and PPI-Disinhibition contributed distinctively to prediction of the Lifestyle facet.

A second triarchic scale development effort was undertaken by Drislane et al. (2015) using items from a psychopathy questionnaire designed for use with adolescents, the Youth Psychopathic Traits Inventory (YPI). The YPI-based Boldness scale consists of items from scales that define the YPI's Grandiose/Manipulative factor, along with some items from its Thrill-Seeking and Unemotionality scales; the YPI-Disinhibition scale consists mostly of items from scales associated with the YPI's Impulsive/Irresponsible factor; and the YPI-Meanness scale consists entirely of items from scales related to the YPI's Callous/Unemotional factor. Drislane et al. (2015) presented evidence for convergent and discriminant validity of the YPI-Tri scales in relation to psychopathy-relevant criteria, including the TriPM and PPI-Tri scales.

The foregoing studies demonstrated that effective scale measures of the triarchic trait constructs could be constructed from items of existing psychopathy inventories, thus supporting the idea that these constructs are embodied in different models and measures of psychopathy (Patrick et al., 2009). Inspired by published work demonstrating robust associations for the TriPM scale operationalizations with scores on omnibus inventories of normal-range personality and maladaptive personality, triarchic scales have also been developed using items from inventories of these types. The availability of these scales creates opportunities to extend knowledge of the nature and correlates of the triarchic traits in large existing datasets that contain such inventories-including epidemiological, longitudinal-developmental, genetically informative (i.e., twin), and neurobiologically informative datasets (for specific examples of such datasets, see Wygant et al., 2018). Along this same line, efforts have also been made to develop and validate triarchic scales using construct-relevant items from specific questionnaires available in large specialized datasets, such as those of the European IMAGEN project (Schumann et al., 2010) and the USC Risk Factors for Antisocial Behavior (RFAB) study (Baker et al., 2013). Table 30.1 lists all triarchic scale sets that have been developed to date, noting source(s) of items and original published reports for each.

In addition to providing a powerful means to further characterize the nomological networks of the triarchic trait constructs, the availability of alternative scales for assessing these traits provides a basis for bridging different datasets in order to address key questions not amenable to analysis with a single existing dataset (Friedman et al., 2014). Specifically, latent variable models employing alternative triarchic scale sets as indicators can be used to harmonize datasets along biobehavioral-trait lines. The next section describes efforts that have been made to model the triarchic traits as latent variables, using different scale sets from among those listed in Table 30.1.

#### LATENT VARIABLE MODELING OF THE TRIARCHIC TRAITS

The first latent variable model of the triarchic traits, which utilized data for a mixed-sex sample of undergraduates (N = 567; 46.4% male), was reported by Drislane and Patrick (2017). The indicators for the model consisted of the boldness, meanness, and disinhibition scales of the TriPM and the PPI, along with the meanness and disinhibition scales of the YPI and an index of boldness computed from construct-relevant trait scales of

the Multidimensional Personality Questionnaire (MPQ; Tellegen & Waller, 2008). A confirmatory factor analysis (CFA) specifying three correlated factors with three scale indicators each, and including correlated error terms between the meanness and disinhibition scales of the TriPM and those of the YPI, fit the data well, with all scale indicators loading very highly (> .70) onto their target factors. Tests of model invariance revealed equivalence of factor loadings and indicator intercepts for male and female participants, although mean-level differences were evident for two of the model factors (boldness and meanness; males > females for each). In addition, the authors reported that regressionbased scores for the three factors of the model strongly predicted overall scores on self-report psychopathy inventories patterned after the PCL-R (i.e., HSRP, LSRP, APSD), with multiple *R*s in each case exceeding .75.

CFA models like this have been used in subsequent research to demonstrate similarity of measurement for newly developed triarchic scale sets relative to previously validated scale sets. Drislane et al. (2018), employing data for an undergraduate sample, developed triarchic scales from items of the NEO PI-R five-factor questionnaire (Costa & McCrae, 1992) and demonstrated good fit for a three-factor triarchic model using the new NEO-Tri scales as indicators along with counterpart scales of the TriPM and PPI. The NEO-Tri scales loaded very highly onto their target factors, at levels comparable to loadings for the TriPM and PPI-Tri scales (> .80 in all cases). Using data for a mixed undergraduate/ community sample, Drislane et al. (2019) likewise demonstrated good fit for a counterpart threefactor model using triarchic scales composed of items from the Personality Inventory for DSM-5 (PID-5; Krueger et al., 2012) as indicators along with TriPM and MPQ-based triarchic scales (Brislin et al., 2015). This model is depicted in the upper part of Figure 30.1. As shown in the figure, the PID-5 Disinhibition scale emerged as the strongest indicator of the latent disinhibition factor, and the PID-5 Boldness and Meanness scales loaded onto their target factors at levels comparable to the TriPM and MPQ-Tri scales.

An important question, given evidence for differing latent structures of psychopathic traits as indexed by the PPI in criminal offenders as compared to nonoffenders (Ruchensky, Edens et al., 2018), is whether latent triarchic factors could be modeled effectively in an offender sample. Drislane, Sica et al. (2022) addressed this question using data

(in press)	S <sub>14</sub>

*Note*: Entries in right-most column correspond to sources for sequentially numbered self-report indicators (square boxes labeled " $S_1$ ," " $S_2$ ," " $\ldots$ ," " $S_{13}$ ") of biobehavioral threat constructs (cloud shapes labeled "Threat Sensitivity," "Affiliative Capacity," "Inhibitory Control") in Figure 30.2. Boldness scales from sources labeled  $S_1$  to  $S_{12}$  operate as reversed indicators of threat sensitivity (Patrick, Kramer et al., 2019). The thirteenth indicator of Threat Sensitivity in main Figure 30.2 (box labeled " $S_{13}$ ") is a scale measure of dispositional fear/fearlessness (Yancey, Venables, & Patrick, 2016; see also Kramer et al., 2012) that correlates to a high negative degree ( $\sim$  -.8) with scale measures of boldness (Brislin et al., 2015; Patrick, Kramer et al., 2019).

for a mixed-sex Italian prisoner sample (N = 356; 76.7% male). The indicators for the model consisted of the boldness, meanness, and disinhibition scales of the TriPM and the PPI, along with Minnesota Multiphasic Personality Inventory (MMPI)-based boldness and disinhibition scales (see Table 30.1) and a meanness scale composed of items from the Agreeableness domain of the short form NEO PI-R (NEO-FFI; Costa & McCrae, 1992). This latent triarchic trait model, depicted in the lower part of Figure 30.1, exhibited adequate statistical fit, with all scale indicators loading at strong, comparable levels onto their target factors. Tests of model invariance across sexes could not be performed due to the low n for female participants; however, the factor loadings for a model employing data only for males matched closely with those for the full-sample model (Tucker congruence coefficient > .99), indicating consistency of measurement for males alone relative to both sexes combined.

Findings from these studies illustrate how latent variable models of the triarchic traits using previously validated scale measures as indicators can be

used to evaluate the measurement effectiveness of new scale measures of these traits. Latent triarchic trait models utilizing established scale indicators can also provide an alternative to the construct-rating approach employed in previous scale development projects to date, beginning with Hall et al. (2014). Specifically, items from inventories such as Lynam et al.'s (2011) EPA or Clark's (1993) Schedule for Nonadaptive and Adaptive Personality (SNAP) could be selected to index, as effectively and efficiently as possible, latent triarchic trait dimensions from models like those reported by Drislane and colleagues (Drislane & Patrick, 2017; Drislane et al., 2022). Latent variable models of the triarchic model traits could also be used as harmonizing referents (see, e.g., Bilder et al., 2013; Friedman et al., 2014) for interfacing large-scale specialized datasets along triarchic-dimensional lines (see final section below, titled "Neurobiological Systems and Processes").

From a more conceptual standpoint, these latent-variable modeling efforts serve to illustrate the "open" (Meehl, 1986) quality of the triarchic

**Figure 30.1** Three-factor latent-variable models of the triarchic traits, showing standardized parameter estimates. Upper model is for the undergraduate-community sample (N = 210) of Drislane et al. (2019); lower model is for the incarcerated offender sample (N = 356) of Drislane, Sica, et al. (2022). TriPM, Triarchic Psychopathy Measure; PID-5, Personality Inventory for DSM-5; MPQ, Multidimensional Personality Questionnaire; PPI, Psychopathic Personality Inventory; MMPI, Minnesota Multiphasic Personality Inventory; NEO, NEO Five Factor Inventory.

model constructs. Rather than using the TriPM scales as fixed referents for developing alternative scale operationalizations from items of other inventories, alternative scales have been developed using a conceptual, rating-based approach not bound to any particular measurement device. This approach permits the content coverage of scales to vary from operationalization to operationalization, as a function of differences in thematic coverage of items within particular inventories compared to others. Observed variations in content across differing scale operationalizations can serve to highlight previously untapped, underrepresented, or perhaps less essential aspects of target constructs and thereby help to refine ideas about the nature and scope of the constructs themselves.

#### Psychopathy in the DSM-5

In addition to providing categorical diagnostic criteria for personality disorders, equivalent to those in *DSM-IV*, the fifth edition of the *DSM* includes a new trait-based system for these conditions (the Alternative Model of Personality Disorders [AMPD]) that entails (1) assessing for the presence of personality disturbance, as indicated by dysfunction in areas of self (identity, directedness) and social relations and (2) characterizing the specific nature of the disturbance in terms of maladaptive traits from five thematic domains (negative affect, disinhibition, antagonism, detachment, and psychoticism). As a link to the categorical system, the AMPD includes counterparts to six of the categorical PDs: antisocial, borderline, narcissistic, obsessive-compulsive, avoidant, and schizotypal. As shown in Table 30.2, ASPD is defined in the AMPD by the presence of distinct disturbances in self-concept and social relations, together with elevations on six of seven designated traits from the domains of disinhibition and antagonism, corresponding to meanness and disinhibition in the triarchic model. Four of the seven designated traits are from the antagonism domain, ensuring that persons assigned the diagnosis exhibit a balance of proclivities toward meanness and disinhibition-in line with historical conceptions that have focused on criminal expressions of psychopathy (Patrick, 2018; Patrick et al., 2009). This represents a shift from the categorical diagnosis of ASPD, which emphasizes disinhibition more than meanness, particularly in its adult criteria (Kendler et al., 2012; Venables & Patrick, 2012). The diagnostic importance of meanness is also recognized by the addition of a "limited prosocial emotions" specifier to the categorical diagnosis of conduct disorder (CD) in DSM-5, to distinguish a variant of this condition exhibiting salient callous-unemotional traits as described in the youth psychopathy literature (Frick et al., 2014).

A further innovative feature of the diagnosis of ASPD in the DSM-5's AMPD is the inclusion of a "psychopathic features" specifier, encompassing three other traits-[low] anxiousness, [low] withdrawal, and [high] attention seeking-from the domains of negative affect, detachment, and antagonism, respectively (see Table 30.2). This specifier provides for the designation of a classically low-anxious, socially efficacious (i.e., bold) variant of ASPD (cf. Cleckley, 1941/1976; Crego & Widiger, 2016; Karpman, 1941; see also Hicks et al., 2004; Skeem et al., 2007). The specifier is particularly important in light of research demonstrating the importance of boldness in distinguishing psychopathy as defined by the PCL-R from the criterion-based diagnosis of ASPD (Venables et al., 2014; Wall et al., 2015).

A self-report-based operationalization of the AMPD, the Personality Inventory for *DSM-5* 

(PID-5; Krueger et al., 2012), has been widely used in research over the past decade. Evidence for its convergent and discriminant validity has been reported in relation to symptoms of categorical PDs as defined in DSM-IV and DSM-5 (Hopwood et al., 2012). In addition, the PID-5 has been used to evaluate the effectiveness of the Section III diagnosis of ASPD and its specifier for capturing the distinct facets of psychopathy described by the triarchic model. One study by Strickland, Drislane, Lucy, Krueger, and Patrick (2013) administered the PID-5 along with the TriPM to a mixed college and community adult sample. Another study by Anderson, Sellbom, Wygant, Salekin, and Krueger (2014) administered the PID-5 along with both the TriPM and the PPI to separate samples of college students and community adults, with the latter sample recruited to overrepresent individuals with psychopathic tendencies. Findings from these two studies demonstrated that the AMPD-designated traits for ASPD (operationalized via the PID-5) provided highly effective coverage of the disinhibition and meanness facets of psychopathy (as indexed by the TriPM) and that the traits of the psychopathy specifier provided effective coverage of the boldness facet.

Taken together, the findings of these studies provide evidence that adult psychopathy as described in classic historical writings and investigated empirically over the years can be indexed effectively using the new dimensional-trait system of the DSM-5. Dovetailing with this evidence is work by Drislane et al. (2019), cited in the preceding section, showing that highly effective triarchic scales could be developed using items of the PID-5-most of them from PID-5 scales that assess traits related to ASPD and the psychopathy specifier in the AMPD. Of note, the AMPD in DSM-5 is organized around maladaptive trait domains that resemble higher-order factors of a dimensional model for psychopathology as a whole, namely, the Hierarchical Taxonomy of Psychopathology (HiTOP; Kotov et al., 2017). The next section describes how facets of psychopathy specified by the triarchic model relate to factors of this general psychopathology model.

## Psychopathy and the Hierarchical Taxonomy of Psychopathology Model

Traditionally, psychopathy has been viewed as a discrete psychopathological syndrome with a distinct underlying cause, and there has been a long-standing inclination to study it unto itself rather than in relation to other mental disorders. However, empirical evidence has resulted in a shift

Table 30.2         Criteria for diagnosis of antisocial personality disorder in Section III of DSM-5			
Criterion category	Summary description of criterion indicator(s)		
A. Significant impairments in personality	1. Identity (egocentric; self-esteem derived from power or pleasure)		
functioning, manifested in two or more of the following areas:	2. Self-directedness (lack of internalized prosocial values; goals based around hedonism or dominance)		
	3. Empathy (lacks concern for others; lacks remorse)		
	4. Intimacy (exploitative or controlling; lacks mutually intimate relationships)		
B. Elevations on six or all of the	1. Antagonism:		
following traits, from domains of:	a. Manipulativeness (controls or exploits others through persuasion)		
	b. Deceitfulness (dishonest, distorts truth, misrepresents self)		
	c. Callousness (lacks concern for others; lacks guilt for harmful acts)		
	d. Hostility (frequently irritable or angry; sensitive to slights; vengeful)		
	2. Disinhibition:		
	a. Irresponsibility (disregards or lacks respect for obligations and agreements)		
	b. Impulsivity (spontaneous; lacks planfulness; acts on immediate urges)		
	<ul> <li>c. Risk taking (acts recklessly without considering consequences; disregards danger; easily bored)</li> </ul>		
C. Temporal stability criterion	Impairments in self or interpersonal functioning and expression of pathological traits persist across time and occur across situations.		
D. Non-normativity criterion	Impairments in functioning and expression of pathological traits are atypical vis-à-vis developmental age and sociocultural milieu.		
E. Physiological/medical criterion	Impairments in functioning and expression of pathological traits are not due to effects of substance use or a general medical condition.		
Psychopathic Features Specifier for ASPD			
Low scores on the following two traits:	<ol> <li>Anxiousness (domain of negative affect)</li> <li>Withdrawal (domain of detachment)</li> </ol>		
AND			
Elevated score on the following trait:	3. Attention seeking (domain of antagonism)		

*Note*: The Psychopathic Features specifier is used to designate a classically low-anxious, socially assertive (i.e., "bold"; Patrick et al., 2009) variant of antisocial personality as described in the adult psychopathy literature (Cleckley, 1941/1976; Crego & Widiger, 2016; Hicks et al., 2004; Karpman, 1941), with high attention seeking and low withdrawal capturing the social assertiveness aspect.

toward viewing psychopathy as dimensional and multifaceted – that is, as a disorder encompassing distinct symptom subdimensions that relate in turn to distinct trait dispositions. There has also been growing interest in understanding psychopathy's associations with other forms of psychopathology. An important recent development in this regard is the formulation of an integrative dimensional framework for mental health problems encompassing episodic clinical conditions as well as personality disorders. This framework, the HiTOP model (Kotov et al., 2017), organizes mental disorders and their affiliated symptoms into a multilevel structure that reflects empirically observed patterns of covariation among them. The levels of the HiTOP model range from specific symptom dimensions at the lowest level to a general psychopathology factor at the highest level—with symptom clusters, disorders ("syndromes"), and disorder dimensions ("spectra") in between. The model considers syndrome- and spectrum-level dimensions within the psychopathology hierarchy to be related to broad dimensions of normative personality.

The comorbidity of psychopathy and its factors with disorders of certain types, described earlier, can be understood in relation to two major HiTOP disorder dimensions (spectra): the externalizing spectrum and the internalizing spectrum. The externalizing spectrum encompasses disorders involving deficient impulse control (Krueger et al., 2002, 2007, 2021) and is represented in the HiTOP model by a higher-order dimension with subdimensions reflecting "disinhibited" and "antagonistic" expressions of externalizing (Krueger et al., 2021). Substance-related problems (e.g., alcohol use disorder, other drug disorders) load predominantly onto the former dimension, whereas conditions involving callous disregard and exploitativeness (e.g., narcissistic PD, histrionic PD) load mainly on the latter. Antisocial conditions (e.g., CD, adult ASPD), which include both impulsive/rule-breaking and aggressive/exploitative symptoms, load onto both. The internalizing spectrum is represented in the HiTOP model by a higher-order dimension with subdimensions reflecting pathological fear conditions (e.g., specific phobia, social anxiety disorder, panic disorder) and conditions marked by dysphoria and pervasive distress (e.g., major depression, dysthymia, posttraumatic stress disorder [PTSD]). Psychopathy's associations with this psychopathology spectrum are important to clarify given notable discrepancies in the literature. For example, Cleckley described psychopathic individuals as lacking in nervousness and free from "psychoneurotic" symptoms, and early studies using his diagnostic criteria (e.g., Hare, 1978; Lykken, 1957) produced findings consistent with this description. In contrast with this, overall scores on the PCL-R and other PCL-based inventories show weak and inconsistent relations with measures of anxiety and internalizing problems (Widiger & Crego, 2018).

Regarding psychopathy's relations with the externalizing spectrum, Patrick (2022) reported findings from a structural modeling analysis undertaken to characterize relations of the triarchic traits with disinhibited and antagonistic subdimensions (subfactors) of this spectrum. The analysis utilized data from a mixed-gender sample of college students and community adults (N = 212) preselected to ensure broad representation of triarchic trait scores. Indicators of the two externalizing subfactors were symptom scores for DSM-IV disorders assessed using clinical interview (SCID-I and SCID-II) protocols: alcohol use disorder, other drug disorder, and nonaggressive CD symptoms for the disinhibited subfactor, and aggressive CD, aggressive ASPD, and narcissistic PD symptoms for the antagonistic subfactor. The triarchic traits were also modeled as latent dimensions using different validated scale measures as indicators (i.e., TriPM, MPQ-Tri, and PID-5-Tri scales, as described in the preceding section). In the structural model, which exhibited acceptable fit, the two externalizing factors were regressed onto the latent triarchic traits in order to evaluate distinct relations for the traits as concurrent predictors. The disinhibited externalizing factor was predicted very strongly by triarchic disinhibition (*B* coefficient = .63) and to a lesser unique extent by boldness (*B* = .25), with meanness predicting minimally. The antagonistic externalizing factor, on the other hand, was predicted most strongly by triarchic meanness (*B* = .40) and to lesser degrees by disinhibition and boldness (*B*s = .24 and .17).

Regarding relations with the internalizing spectrum, Latzman, Palumbo et al. (2020) examined relations between latent-variable representations of the triarchic traits and fear versus distress subfactors of this spectrum. The participant sample was the same as that employed in the above-described model for disinhibitory and antagonistic factors of externalizing, and the same self-report scales were used to index the triarchic trait dimensions. Indicators of the fear-disorder subfactor of internalizing were SCID-I-assessed symptom scores for specific phobia, social phobia, agoraphobia, and panic disorder; indicators of the dysphoria/distress factor were symptom scores for major depressive disorders, dysthymia, and PTSD. As in the model for the externalizing spectrum subfactors, unique predictive relations for the latent triarchic traits were evaluated via regression. The fear factor of internalizing showed a strong negative relationship with latent boldness (B = -.65), a weaker positive relationship with disinhibition (B = .21), and a negligible association with meanness. By contrast, the dysphoric/distress factor showed comparable negative associations with latent boldness and meanness (Bs = -.26 and -.24) and a strong positive relationship with disinhibition (B = .58).

These findings for externalizing and internalizing spectra of psychopathology are depicted schematically in the lower part of Figure 30.2, which illustrates how the triarchic model traits are linked to subdimensions of these spectra within the HiTOP framework. These associations for the triarchic traits shed light on patterns of observed relations of the PCL-R and its factors with clinical conditions of different types, as described earlier. PCL-R Factor 2 relates positively to both substance-related problems and anxious-depressive symptoms because it largely reflects externalizing proneness (disinhibition; Patrick et al., 2005, 2007). Factor 1 relates positively to self-centered narcissism and proactive aggression and negatively

**Figure 30.2** Schematic depiction of a conceptual-empirical framework for interfacing neural systems constructs (defensive motivational, social bonding, and executive regulatory; upper level) with triarchic trait and clinical symptom dimensions (lower level), through use of multimodal representations of biobehavioral traits of threat sensitivity, affiliative capacity, and inhibitory control (middle level). Ovals = triarchic trait and symptom dimensions that can be modeled as latent variables using report-based indicators (scale scores, clinical ratings) with documented covariance patterns. "Cloud" shapes = hypothesized biobehavioral trait dimensions for which provisional indicators from different modalities have been identified (for listings of these indicators, see Table 30.3), but whose covariance patterns need to be fully delineated in order to establish effective latent-variable models. Indicators of target biobehavioral traits from the self-report modality operate also as indicators of latent triarchic factors that link directly to internalizing and externalizing symptom dimensions; unbolded plus or minus sign between triarchic trait and symptom dimension indicates a predictive association (*B*) of  $\geq |0.4|$ . Biobehavioral trait indicators from the physiological and task-performance modalities link directly to neural systems constructs. Conceptualizations of biobehavioral traits will be shaped by accumulating knowledge of covariance patterns among replicable indicators of these traits from different measurement modalities. The right-side arrow denotes the important role of development in this framework, as discussed in the main text.

to both fearful and anxious-depressive symptoms (particularly when controlling for its overlap with Factor 2) due to its selective representation of meanness and boldness, respectively.

#### The Triarchic Model as a Framework for Understanding Developmental Pathways and Neurobiological Processes in Psychopathy

As a trait-based framework for psychopathy, the triarchic model connects to other established models of normative and pathological personality traits, which connect in turn to broad symptom dimensions of the HiTOP model (Kotov et al., 2017). The triarchic constructs of boldness, meanness, and disinhibition, as indexed by the TriPM and other scale sets, show clear and robust relations with normative trait inventories such as the MPQ and the NEO PI-R (Drislane et al., 2014; Poy et al., 2014) as well as with maladaptive trait inventories including the PID-5 and the MMPI-2 (Latzman, Tobin et al., 2020; Sellbom et al., 2016; Strickland et al., 2013). However, the broad dimensions of these inventories that appear most related to boldness, meanness, and disinhibition (e.g., neuroticism, agreeableness, and conscientiousness in the NEO PI-R; negative affect, antagonism, and disinhibition in the PID-5) do not correspond directly to the dimensions of the triarchic model, making it necessary to configure lower-level traits of these inventories differently to approximate triarchic disinhibition and meanness more closely (Drislane et al., 2018, 2019; see also

Bowyer et al., 2020). This raises the question: Why configure lower-level traits along triarchic model lines, as opposed to PID-5/AMPD or NEO-PI R/FFM lines? The answer, addressed in this section, is that the triarchic model traits are conceptualized in biobehavioral-developmental terms (Patrick et al., 2009), through direct reference to developmental and biobehavioral research findings, and have nomological networks that include variables from behavioral and neurophysiological as well as self-report and clinical-diagnostic modalities. Importantly, as discussed in the concluding "Neurobiological Systems and Processes" part of this section, the triarchic traits are viewed as open constructs, subject to revision based on accumulating knowledge of their nomological networks.

#### Developmental Pathways

Contemporary developmental research on psychopathy has focused on characterizing a distinct subgroup of clinic-referred youth exhibiting conduct problems accompanied by callous-unemotional traits-corresponding to dispositional meanness in the triarchic model. Comparatively little attention has been devoted to externalizing proneness (disinhibition) as a distinct dispositional factor contributing to the emergence and persistence of psychopathic behavior. This is surprising, given the emphasis that has been placed on weak inhibitory (or effortful) control as a risk factor in the developmental psychopathology literature (Kochanska et al., 1997; Rothbart, 2007). Equally surprising is the paucity of work devoted specifically to the study of boldness in the child psychopathy literature, given evidence for a role of fearless temperament in early socialization and conscience development (Kochanska, 1997).

However, recent research on psychopathy in youth has begun to examine how the triarchic traits of disinhibition and boldness contribute to the emergence and expression of conduct problems, relative to and in concert with callous-unemotionality (meanness). An initial study using the TriPM with adolescents aged 16-17 years (Somma et al., 2016) reported similar-level unique associations for all three triarchic traits when entered together as predictors of self-reported engagement in delinquent acts over the preceding year. Another study of 14to 18-year-olds that used a shortened (approximately half-length) version of the TriPM (Sica et al., 2020) reported significant unique effects for disinhibition and meanness, but not boldness, in predicting self-reported conduct problems over the preceding 6 months. Boldness in this study was related, however, to lower reports of negative emotional states and lesser susceptibility to anxious/ depressive symptoms.

An alternative to using established inventories like the TriPM is to construct scale measures of the triarchic traits using construct-relevant items from questionnaires available in already existing datasets. Employing this approach to quantify the triarchic traits in a longitudinal sample, Bertoldi, Perkins et al. (2022) reported comparable unique relations for boldness and disinhibition (but not meanness) assessed at age 14-15 with reported engagement in nonaggressive antisocial acts at age 19-20; meanness at age 14-15, by contrast, emerged as the sole unique predictor of reported aggressive acts at age 19-20. In contrast with their joint positive prediction of later nonaggressive antisociality, boldness and disinhibition at age 14-15 each predicted uniquely, but in opposing directions (- and +, respectively), internalizing symptomatology at age 19-20. These longitudinal study results provide evidence for the triarchic traits as indicators of liability versus immunity to problems of different types and align with findings from cross-sectional work on relations of latent triarchic traits with HiTOP psychopathology dimensions in adults as described in the preceding section.

#### Neurobiological Systems and Processes

Variations along psychological trait dimensions have long been viewed as intertwined with variations in neural function (Allport, 1937; Eysenck, 1967). However, observed relations between trait scores and indicators of neural function tend to be small and inconsistent due to conceptual and measurement mismatch. A systematic approach to interfacing neural systems and processes with clinical symptom scores involving the use of multimodal operationalizations of biobehavioral trait constructs has been described by Patrick, Iacono, and Venables (2019). A detailed illustration of this approach was provided by Venables et al. (2018), who specified a multimethod structural model for the biobehavioral construct of inhibitory control-corresponding to the triarchic trait of disinhibition-using indicators from modalities of self-report, task performance, and brain evoked response potential (ERP) response. Expanding upon this illustration, Figure 30.2 depicts different-modality indicators of biobehavioral traits corresponding to all three triarchic constructs (upper part; see Table 30.3 for specific listing of indicators), within a framework

<b>Table 30.3</b> Physiological and task performance indicators of biobehavioral traits depicted as counterparts totriarchic psychopathy dimensions in Figure 30.2			
Biobehavioral trait/modality of measurement	Trait indicator (direction of association)	Studies reporting trait-indicator associations	Label within Figure 30.2
(Low) Threat Sensiti	<i>i</i> ) Threat Sensitivity

*Note*: Trait indicators listed are ones for which associations have been demonstrated in two or more studies employing different participant samples. Directions of associations for indicators (+ = positive; – = negative) are with biobehavioral traits *in reverse* (such that they correspond to boldness, meanness, and disinhibition), as assessed by informant-rating (Dargis et al., 2018; Jones et al., 2009; Marsh et al., 2008; Petitclerc et al., 2019; White et al., 2012) or self-report (all other studies except Dadds et al., 2006, 2008, 2011, and Young et al., 2009, which used informant-rating and self-report measures combined).

<sup>a</sup> The sample for this study (Palumbo et al., 2020) subsumed that employed by Brislin et al. (2018), but reported new evidence for reduced early brain-ERP reactivity to fearful faces in a different task paradigm.

<sup>b</sup> The task used in this study (Brennan & Baskin-Sommers, 2018) was a "modified oddball" task, characterized by the authors as "similar to a go/no-go task in terms of instructions, stimuli frequency, and behavioral measures" (p. 73).

for interfacing neural systems with HiTOP psychopathology dimensions (lower part).

A more detailed discussion of the framework depicted in Figure 30.2 can be found in other published works (e.g., Patrick & Drislane, 2015; Patrick, Durbin, & Moser, 2012; Patrick, Iacono et al., 2019; Patrick, Venables et al., 2013). However, some specific points warrant mention. One is that multiple scale sets exist for operationalizing biobehavioral traits corresponding to boldness, disinhibition, and meanness in the modality of self-report (see numbered citations in the figure). Some of these consist of items from psychopathy inventories or omnibus personality questionnaires; others are composed of items taken from different questionnaire measures included in specialized existing datasets. These various scale sets have been created using the construct-rating protocol introduced by Hall et al. (2014) and validated against one another and in relation to pertinent criterion variables (including clinical outcomes) to establish consistency of measurement (i.e., harmonization; Hussong et al., 2013). The availability of these alternative scale sets provides a means to extend what we know about neurophysiological and task-behavioral indicators of key biobehavioral constructs and establish formal multimodal measurement models for these constructs through use of existing large-scale datasets—including etiologically informative (e.g., twin, longitudinal) datasets (Patrick, Iacono et al., 2019).

A second point is that self-report indicators of biobehavioral traits are intended to serve only as provisional referents for identifying candidate indicators from other modalities (e.g., lab-task performance, brain physiology), in order to establish multimodal measurement models of these traits (Patrick, Iacono et al., 2019). Self-report measures of traits are convenient and effective as referents because they can be constructed using different item sets to be indicative of specific psychological content, psychometrically reliable, and harmonized in terms of their convergence with one another and their relations with external criterion measures. Brislin et al. (2019) illustrated this by developing a scale measure of disinhibition using items from the European IMAGEN dataset and, employing data for a separate sample, showing that it correlated highly with a previously validated disinhibition scale and comparably well with an established neural indicator of disinhibition (oddball P3 response). The view of self-report scales as provisional indicators connects in turn to the idea of biobehavioral traits as open constructs that can be refined or reshaped based on empirical findings. Venables et al. (2018) illustrated this idea by specifying a structural model in which measures from three modalities (self-report, task performance, brain response) loaded onto lowerorder modality factors, which loaded in turn onto a common higher-order factor reflecting crossmodal inhibitory control. A shift in the construct being measured—away from the modality of selfreport-was evidenced by a smaller loading of the self-report modality factor onto the higher-order factor compared to loadings for the behavioral and brain modality factors.

A further key point is that the framework depicted in Figure 30.2 includes a developmental component, depicted by the downward pointing arrow on the right side. The literature on temperament indicates that traits are moderately stable across time but affected by maturation and ongoing environmental events that impact psychobiological function (Bornstein et al., 2015; Kopala-Sibley et al., 2018). The types of measures that can be used to index traits also vary across time. For example, self-report measures cannot be used with very young children, and tasks suitable for assessing behavioral and brain response often differ across age levels. Also, physiological or behavioral measures that relate concurrently to trait levels or clinical symptoms may not exhibit relations prospectively if they reflect dysfunctional states or persisting consequences of dysfunction, as opposed to dispositional liability (Perkins et al., 2020). We believe these complexities in characterizing the nature of biobehavioral risk for mental health problems, and pathways from risk to symptom expression in differing forms, can ultimately be addressed through systematic collaborative efforts along coordinated lines. Researchers dedicated to the scientific study of psychopathy are encouraged to benefit from and contribute to this broader mission in ways highlighted within this chapter.

#### Conclusion

Despite decades of vigorous research, progress in the field of psychopathy has been hampered by persisting disagreement about how this clinical condition should be defined and measured. Various interview and self-report measures have been developed to index psychopathy in diverse participant samples (e.g., forensic, clinical, community, youth, etc.), each grounded-in differing respects and to varying degrees-in historic descriptions of psychopathy in psychiatric patients (e.g., Cleckley, 1976) and criminal offenders (e.g., McCord & McCord, 1964). Research on the psychological, clinical-diagnostic, and neurobiological correlates of psychopathy as assessed by these measures has revealed contrasting patterns of associations for distinct symptom subdimensions (factors or facets) of each. The triarchic model (Patrick et al., 2009) posits that trait constructs of disinhibition, boldness, and meanness, represented in alternative measures for assessing psychopathy, can account for these contrasting patterns of associations because they reflect distinct biobehavioral constructs of deficient inhibitory control, weak affiliative capacity, and low threat sensitivity, respectively. Importantly, the triarchic traits are viewed as "open constructs" that are not tied to any specific manifest measure and thus can be quantified using different items sets.

A growing body of work has sought to develop scale measures of the triarchic traits using items from preexisting psychopathy inventories, normative and maladaptive personality inventories, and other item sets available in etiologically informative (twin, longitudinal) studies. Following upon these efforts, recent studies have modeled the triarchic trait constructs as latent variables using alternative scale sets as indicators. The triarchic traits are represented in the dimensional model for PDs in the DSM-5, through traits from domains of antagonism and disinhibition, and a "psychopathic features" specifier that indexes boldness. Progress has also been made toward interfacing the triarchic traits with a broader dimensional system for psychopathology as a whole, the HiTOP model. Finally, given that the triarchic traits were explicitly framed in biobehavioral-developmental terms, increasing efforts are being made to examine their relations with clinical outcomes of various types across development and to identify replicable brain and behavioral indicators of each that can be integrated into multimodal measurement models. Growing knowledge of the triarchic traits' nomological networks, combined with recent advances

in latent variable modeling and data harmonization and the availability of triarchic scale measures in etiologically informative datasets, provides rich opportunities for further understanding the etiological bases of psychopathy and refining methods for preventing and treating it.
