#### CONTENTS

Preface vii About the Editors ix Contributors xi

#### Part I • Foundations and Perspectives

- 1. Classification in Traditional Nosologies 3 Jared W. Keeley, Lisa Chung, and Christopher Kleva
- 2. Historical and Philosophical Considerations in Studying Psychopathology 33 Peter Zachar, Konrad Banicki, and Awais Aftab
- 3. The Hierarchical Taxonomy of Psychopathology 54 Christopher C. Conway and Grace N. Anderson
- The Research Domain Criteria Project: Integrative Translation for Psychopathology 78 Bruce N. Cuthbert, Gregory A. Miller, Charles Sanislow, and Uma Vaidyanathan
- 5. Complex Systems Approaches to Psychopathology 103 Laura Bringmann, Marieke Helmich, Markus Eronen, and Manuel Voelkle
- 6. Developmental Psychopathology 123 Dante Cicchetti

#### Part II • Major Clinical Syndromes

- Generalized Anxiety Disorder, Panic Disorder, Social Anxiety Disorder, and Specific Phobia 147 *Richard E. Zinbarg, Alexander L. Williams, Amanda M. Kramer*, and *Madison R. Schmidt*
- 8. Obsessive-Compulsive and Related Disorders 181 Jonathan S. Abramowitz
- 9. Posttraumatic Stress Disorder and Dissociative Disorders 199 *Richard J. McNally*
- Mania and Bipolar Spectrum Disorders 228 June Gruber, Victoria Cosgrove, Alyson Dodd, Sunny J. Dutra, Stephen P. Hinshaw, Stevi G. Ibonie, Piyumi Nimna Kahawage, Thomas D. Meyer, Greg Murray, Robin Nusslock, Kasey Stanton, Cynthia M. Villanueva, and Eric A. Youngstrom
- 11. Depression: Social and Cognitive Aspects 257 Rick E. Ingram, Jessica Balderas, Kendall Khonle, and Joe Fulton

12.	Diagnosis, Comorbidity, and Psychopathology of Substance-Related Disorders 277 <i>Ty Brumback</i> and <i>Sandra A. Brown</i>		
13.	Substance Use and Substance Use Disorders 296 Kenneth J. Sher, W. E. Conlin, and R. O. Pihl		
14.	Schizophrenia: Presentation, Affect and Cognition, Pathophysiology and Etiology 332 Angus MacDonald III and Caroline Demro		
15.	Social Functioning and Schizophrenia 352 Jill M. Hooley and Stephanie N. DeCross		
16.	Paranoia and Paranoid Beliefs 380 <i>Richard P. Bentall</i>		
17.	Sexual Dysfunction 404 Cindy M. Meston, Bridget K. Freihart, and Amelia M. Stanton		
18.	Eating Disorders 424 <i>Howard Steiger, Linda Booij, Annie St-Hilaire</i> , and <i>Lea Thaler</i>		
19.	Life-Span and Multicultural Perspectives 450 <i>Thomas M. Achenbach</i>		
20.	Attention Deficit Hyperactivity Disorder 474 Siri Noordermeer and Jaap Oosterlaan		
21.	Autism Spectrum Disorders 492 Fred R. Volkmar and Kevin Pelphrey		
22.	Functional Somatic Symptoms 510 Peter Henningsen, Theo K. Bouman, and Constanze Hausteiner-Wiehle		
23.	Sleep and Circadian Rhythm Disorders 523 Lampros Bisdounis, Simon D. Kyle, Kate E. A. Saunders, Elizabeth A. Hill, and Colin A. Espie		
24.	Paraphilia, Gender Dysphoria, and Hypersexuality 549 James M. Cantor		
Par	t III • Personality Disorders		
25.	ne DSM-5 Level of Personality Functioning Scale 579 Johannes Zimmermann, Christopher J. Hopwood, and Robert F. Krueger		
26.	The DSM-5 Maladaptive Trait Model for Personality Disorders 604 Colin D. Freilich, Robert F. Krueger, Kelsey A. Hobbs, Christopher J. Hopwood, and Johannes Zimmermann		
27.	Narcissistic Personality Disorder and Pathological Narcissism 628 Aaron L. Pincus		
28.	Borderline Personality Disorder: Contemporary Approaches to Conceptualization and Etiology 650 <i>Timothy J. Trull</i> and <i>Johanna Hepp</i>		

- 29. Schizotypy and Schizotypic Psychopathology: Theory, Evidence, and Future Directions 678 Mark F. Lenzenweger
- 30. Psychopathy and Antisocial Personality Disorder 716 Christopher J. Patrick, Laura E. Drislane, Bridget M. Bertoldi, and Kelsey L. Lowman

Index 749

Although this *Textbook* may also serve active professionals by providing them with reviews and updates, it is aimed primarily at graduate students taking an advanced survey course in abnormal psychology and psychopathology. Among texts that might be used in such courses, it has some distinctive aspects. It provides unusually thorough coverage of novel and emerging approaches to studying psychopathology, including a focus on modern approaches to personality disorders. Throughout the volume, the focus is on what is known about psychopathological constructs; while assessment and intervention are sometimes mentioned, they are not covered systematically. Regarding traditional mental disorder categories, we assume that, when studying this volume, the reader has *DSM-5* at hand and that systematic repetition of *DSM-5* criteria here would be an unwarranted redundancy.

Scholars commonly use abbreviations (usually initializations) in place of their common terms. Because it can be hard for a reader to keep track of their meanings, in this *Textbook* brief glossaries of selected abbreviations have been added at the beginning of most chapters. The reader should be alert with respect to the following abbreviations, as they are defined differently in various chapters: AD, AS, ASPD, CD, ED, PD, PE, and SSD.

We have opted to forgo standard citation practice with respect to DSM and ICD within chapters. The meaning of those abbreviations will likely be obvious to the reader, but, as examples, we here note that DSM-5 refers to the current edition of the Diagnostic and Statistical Manual of Mental Disorder, published in 2013 by the American Psychiatric Association, while ICD-11 refers to the current version of the International Classification of Diseases, effective in 2022 and published in 2019 by the World Health Organization.

As with the prior three editions of this *Textbook*, it is the product of an effort to enlist the best possible array of experts and to charge those individuals with the task of summarizing what future mental health professionals should know. Authors were given considerable latitude; as a result, the reader is exposed to a variety of outlooks and emphases when moving from chapter to chapter. The roster of chapters shows some continuity from prior editions but also important changes and innovations reflecting contemporary developments in the study of psychopathology. Changes reflect recent progress in the field plus (in the case of returning authors) developments in these individuals' thinking.

#### Robert F. Krueger, PhD

Dr. Krueger is Distinguished McKnight University Professor in the Department of Psychology at the University of Minnesota. He completed his undergraduate and graduate work at the University of Wisconsin, Madison, and his clinical internship at Brown University. Professor Krueger's major interests lie at the intersection of research on psychopathology, personality, behavior genetics, health, and aging. He has received several major awards, including the University of Minnesota McKnight Land-Grant Professorship, the American Psychological Association's Award for Early Career Contributions, the Award for Early Career Contributions from the International Society for the Study of Individual Differences, and an American Psychological Foundation Theodore Millon Mid-Career Award. He is a Fellow of the American Psychopathological Association (APPA) and the Association for Psychological Science (APS). He has been named a Clarivate Analytics Highly Cited Researcher, and Research.com ranks him in the top 100 most impactful psychologists in the world. He is also editor of the *Journal of Personality Disorders*.

#### Paul H. Blaney, PhD

Dr. Blaney received his BA degree from Eastern Nazarene College, Quincy, Massachusetts, and his PhD in clinical psychology from the University of Minnesota. He held faculty positions at the University of Texas at Austin, the University of Miami, and Emory & Henry College, from which Dr. Blaney retired at the end of the 2013–2014 academic year. He served on the editorial boards of a number of journals, including the *Journal of Abnormal Psychology* and the *Journal of Personality and Social Psychology*. While at the University of Miami, he was Associate Dean of the College of Arts and Sciences, and, from 2000 to 2005, he was Dean of Faculty of Emory & Henry College.

# PART T

## Foundations and Perspectives

### Classification in Traditional Nosologies

Jared W. Keeley, Lisa Chung, and Christopher Kleva

Diagnosis is simple. The clinician meets with the patient and assesses his or her symptoms in an interview. Given the list of symptoms, the clinician then consults the current version of the *DSM* or *ICD* and decides which diagnoses are relevant. However, like most things that appear to be simple, the topic of classification becomes more complicated upon examination. For example, even the name for this topic is more complicated that many readers might think. In popular usage, terms like *diagnosis, classification, taxonomy,* and *nosology* are often treated as if they either are synonyms or, at least, are largely interchangeable. However, to those who study this topic, these four terms have separable meanings.

Diagnostic systems, generally called classifications, are lists of terms for conventionally accepted concepts that are used to describe psychopathology. *Classification*, when the term is used specifically, refers to the activity of forming groups. *Diagnosis*, as this word is used in medicine and the mental health field, is the process by which individuals are assigned to already existing groups. *Taxonomy* is a term usually reserved for the study of how groups are formed. In effect, taxonomy is a meta-level concept that looks at different theoretical ways in which classifications can be organized, studied, and changed. *Nosology* is the specific application of taxonomy (which can apply to chemistry, zoology, or how to best arrange products in the grocery store) in the context of medical sciences.

The classification of mental disorders has a lengthy history. The first description of a specific syndrome is usually ascribed to an Egyptian account of dementia dating to about 3000 BCE. An early classification of mental disorders was found in the Ayurveda, an ancient Indian system of medicine (Menninger et al., 1963). Ancient Greek and Egyptian writings refer to disorders remarkably similar to concepts of hysteria, paranoia, mania, and melancholia. Since then, numerous classifications have emerged, and enthusiasm for classifying mental disorders has waxed and waned. During the last half of the twentieth century, classification was a prominent theme in the study of psychopathology. Following World War II and the foundation of the United Nations, the World Health Organization (WHO) took over responsibility for managing international health classification systems, resulting in the sixth edition of the International Classification of Diseases and Related Health Conditions (ICD) published in 1948, which including mental disorders for the first time. The release of the ICD-6 corresponded to the development of the first edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM) in the United States, first published in 1952, in recognition of a need for a unified system in the United States (Grob, 1991; Houts, 2000). Currently, DSM is in its fifth edition and the ICD is in its 11th edition.

This productivity has not, however, resolved some of the fundamental problems confronting psychiatric classification. Unresolved issues include the nature of the entities being classified, the definition of what is a mental disorder, the nosological principles for organizing psychiatric classifications,

Abbreviations			
	AD	autistic disorder	
	AMPD	alternative model of personality	
		disorders	
	ASD	autism spectrum disorder	
	CDD	childhood disintegrative disorder	
	FFM	five factor model	
	LAF	low anxiety fearlessness	
	NOS	not otherwise specified	
	PCL-R	Psychopathy Checklist—Revised	
	RDoC	Research Domain Criteria	
	SCID	Structured clinical interview for DSM	

the distinction between normality and pathology, and the validity of many diagnoses. Controversies exist regarding the definition and logical status of some diagnoses and even whether some entities are pathological conditions. For example, heated debates occurred in the 1960s and 1970s over whether homosexuality should be considered a mental disorder. Current debates exist on whether Internet addiction belongs in an official classification. Presently, there is no consensus regarding the taxonomic principles for resolving these controversies (Kamens et al., 2019).

This chapter provides an overview of some issues associated with the classification of psychopathology in traditional nosologies. The next chapter ("Historical and Philosophical Considerations in Studying Psychopathology") will address modern alternatives to the nosological approaches discussed in this chapter. In discussing these issues, the chapter presents an overview of psychiatric classification from a historical perspective so that the reader can understand how these issues have arisen and who have been the central authors involved in discussions of these issues.

#### **Purpose of Classification**

Classification involves creating and defining the boundaries of concepts (Sartorius, 1990). Through this process, diagnostic entities are defined (Kendell, 1975) and the boundaries of the discipline are ultimately established. The reason that psychiatric classification has had such an impact is that it has defined the field of psychopathology. For example, should Alzheimer's disease, alcoholism, or oppositional behavior in a child be considered mental disorders? Should they instead be considered medical disorders or just problems of everyday living? A classification of mental disorders stipulates the range of problems to which mental health professions lay claim.

Classifications serve several purposes with specific goals. The goals of a good classification scheme include (1) providing a *nomenclature* for practitioners, (2) serving as a basis for organizing and *retrieving information*, (3) *describing* the common patterns of symptom presentation, (4) providing the basis for *prediction*, (5) forming the basis for the *development of theories*, and (6) serving *sociopolitical functions*.

The first major function of a classification is the provision of a standard *nomenclature* that facilitates description and communication. A nomenclature is simply a list of names or terms within a classification system. At its most basic level, a classification

of psychopathology allows clinicians to talk to each other about the "things" in their world: the patients and clients who seek the care of mental health professionals. Without a classification system, clinicians would be reduced to talking about clients one after another without any way of grouping these clients into similar types. A classification allows the clinician to have a set of nouns that can be used to provide an overview of the clinician's world when talking to other clinicians, laypeople, insurance companies, or other professionals. Note that this purpose provides a shorthand and does not imply or require any scientific reality to the concepts.

Second, a classification structures *information retrieval.* Information in a science is organized around its major concepts. Knowing a diagnostic concept helps the clinician to retrieve information about such matters as etiology, treatment, and prognosis. A classification shapes the way information is organized thereby influencing all aspects of clinical practice and research. In the current world, in which information is easily retrieved by electronic searches on the Internet, classificatory concepts are useful devices by which professionals, family members, clients, and interested laypeople can obtain information about the prognosis, treatment, and current research related to various mental disorders.

Third, by providing a nomenclature to describe all levels of psychopathology, a classification establishes the *descriptive basis* for a science of psychopathology. Most sciences have their origins in description. Only when phenomena are systematically organized is a science in the position to transform accounts of individual cases into principles and generalizations. Cases that are diagnosed with a particular disorder should be similar in important ways to other cases with that same diagnosis, and these cases should be different in important ways from cases belonging to other diagnoses.

The fourth goal of classification, *prediction*, is the most pragmatic from the perspective of clinicians. What a mental health professional typically wants from a diagnosis is information that is relevant to the most effective treatment and management of his or her patient. A classification that is useful for prediction is a system in which there is strong evidence that patients with different diagnoses respond differentially to a specific treatment or one that informs how to best manage the nature of that person's condition. Classifications are also clinically useful if the categories are associated with different clinical courses even when the disorders are not treated.

Fifth, by providing systematic descriptions of phenomena, a classification establishes the foundations for the development of theories. In the natural sciences, especially biology and chemistry, a satisfactory classification was an important precursor for theoretical progress (Hull, 1988). The systematic classification of species by Linnaeus stimulated important questions about the nature of phenomena or processes that accounted for the systemquestions that ultimately led to the theory of evolution. For these reasons, classification occupies a central role in research. For example, the National Institute of Mental Health (NIMH) in the United States has instituted a large-scale project designed to identify common pathological mechanisms that could guide informed understanding of mental disorders (termed the Research Domain Criteria [RDoC] project; NIMH, 2012). The RDoC will be discussed at greater length in the next chapter as an alternative to traditional classifications.

Finally, no classification system exists in a vacuum. Rather, a classificatory system exists in a context of groups and individuals that stand to benefit from the classification. For example, a classification of mental disorders can serve the social purpose of identifying a subset of the population that society has deemed need treatment. However, the sociopolitical functions of a classification are not always so altruistic. The American Psychiatric Association, through its production of the various editions of the DSM, has developed a lucrative printing business that serves as a major funding source for the organization (Frances, 2014). At a more individual level, some authors have argued that the classification of mental disorders serves the objective of maintaining the social power of the majority by marginalizing and stigmatizing those people who fall under the domain of "mental illness" (e.g., Kirk & Kutchins, 1992; Kutchins & Kirk, 1997).

#### **History of Classification**

Although attempts to classify psychopathology date to ancient times, our intent is to provide only a brief overview of major developments, especially those occurring in the past century, as a context for understanding modern classifications. Examining previous classifications shows that many current issues have a long history. For example, writers in the eighteenth century, like many contemporary authorities, believed that the biological sciences had solved the problems of classification and that biological taxonomies could serve as a model for classifying psychopathology. The Edinburgh physician

William Cullen, for example, applied Linnaeus's principles for classifying species to illnesses. The result, published in 1769, was a complex structure involving classes, orders, genera, and species of illness (cited by Kendell, 1990). One class was neurosis (Cullen introduced the concept as a general term for mental disorders) that was subdivided into 4 orders, 27 genera, and more than 100 species. Contemporaneous critics, who believed that there were far fewer diagnoses, dismissed Cullen as a "botanical nosologist" (Kendell, 1990). Nonetheless, interest in applying the principles of biological classification to abnormal behavior continues today, as does the debate over the number of diagnoses. "Splitters" seek to divide mental disorders into increasingly narrowly defined categories, whereas "lumpers" maintain that a few broadly defined categories are adequate to represent psychopathology (Havens, 1985). One compromise is to create a hierarchical solution (again, similar to biology) in which there are a relatively small number of higher order groups divided into more specific varieties at lower levels of the hierarchy.

The features used to classify mental disorders varied substantially across eighteenth- and nineteenth-century classifications. Some diagnoses were little more than single symptoms, whereas others were broader descriptions resembling syndromes. Yet other diagnoses were based on speculative, early pre-psychology theories about how the mind worked. As a result, many classifications from the nineteenth century relied heavily on traditional philosophical analyses of the faculties or attempted to organize disorders around poorly articulated views of etiology.

#### Kraepelin

With the work of Emil Kraepelin, the structure of modern classification began to take shape. Kraepelin was born in 1856, the same year as Sigmund Freud, an ironic fact considering that they established two very different approaches to conceptualizing psychopathology. Kraepelin was influenced by two traditions (Berrios & Hauser, 1988). The first was the scientific approach to medicine that dominated German medical schools in the late nineteenth century. Many important medical breakthroughs, especially in bacteriology, occurred in Germany during that period. German psychiatrists of the time generally believed that mental disorders were biological and that psychiatry would gradually be replaced by neurology. Kraepelin was also influenced by early work in experimental psychology (Kahn, 1959).

During his medical training, he worked for a year in the laboratory of Wilhelm Wundt (*1832–1920*), one of the first experimental psychologists. In early research, Kraepelin applied Wundt's methods to the study of mental disorders.

Kraepelin's reputation was based on his textbooks of psychiatry. Like most textbook authors, Kraepelin organized his volumes with chapters on each of the major groupings of mental disorders. What has become known as Kraepelin's classifications (Menninger et al., 1963) are little more than the table of contents to the nine published editions of his textbooks. In the sixth edition, Kraepelin included two chapters that attracted considerable international attention. One chapter focused on the concept of dementia praecox (now called schizophrenia) which included hebephrenia, catatonia, and paranoia as subtypes-descriptions that remained intact up through ICD-10 and DSM-IV but were removed in the current editions. The other chapter discussed manic-depressive insanity-a revolutionary idea that combined mania and melancholia, two concepts that had been considered separate entities since the writings of Hippocrates. The two diagnoses, dementia praecox and manicdepressive psychosis, established a fundamental distinction between psychotic and mood disorders that forms a linchpin of contemporary classifications.

#### The Early Editions of the DSM and ICD

In medicine, the official classification of medical disorders is the ICD, published by the WHO. Historically, this classification began at the end of the nineteenth century when a group named the International Statistical Institute commissioned a committee headed by Jacques Bertillon (1851-1922) to generate a classification of causes of death. This classification, initially known as The Bertillon Classification of Causes of Death, was adopted as an official international classification of medical disorders at a meeting of 26 countries in France in 1900. The name of the classification was slightly modified in the early 1900s to The International Classification of Causes of Death. This original version of ICD was revised at subsequent conferences held in 1909, 1920, 1929, and 1938 (Reed et al., 2016).

After World War II, the WHO met to generate a sixth revision of this classification. A decision was made at that point to expand the classification beyond causes of death and to include all diseases regardless of whether those diseases led to death or not (i.e., morbidity as well as mortality). The name of the classification was revised accordingly to the International Statistical Classification of Diseases, Injuries, and Causes of Death, Sixth Revision (ICD-6; World Health Organization, 1948). Because it focused on all diseases, *ICD-6* added a section devoted to mental disorders.

The undertaking and consequent publication of the ICD-6 by the WHO "marked the beginning of a new era in international vital and health statistics" (Reed et al., 2016). The WHO recognized the importance of agreed-upon international rules for mortality and morbidity data. An essential component to ensure success was international cooperation by other countries, recommending that governments establish their own national committees to collect vital and health statistics. The national committees were to communicate with the WHO, which would serve as the central source and governing body for international health statistics.

Shortly after the publication of *ICD-6*, the American Psychiatric Association published its first official classification of mental disorders (*DSM-I*; American Psychiatric Association [APA], 1952). The creation of this classification was justified because there were four different classifications of psychopathology in use in the United States during World War II, a situation that American psychiatry found embarrassing. Thus, the United States created its own nomenclature that blended features of the previous four systems (Grob, 1991).

Generally, other countries in the world were like the United States in that, instead of adopting ICD-6 as the official system, most decided to use locally created classificatory systems whose diagnostic concepts did not have international acceptance. Only five countries adopted the ICD-6 classification of mental disorders: Finland, New Zealand, Peru, Thailand, and the United Kingdom. To understand why, the WHO asked British psychiatrist Erwin Stengel to review the classifications of mental disorders used in various countries. Stengel's review (1959) was very important because he carefully documented the widespread differences that existed in terminology from country to country (and even within countries). Stengel concluded that the variation in classifications from one country to another meant there was a failure for these systems to become useful nomenclatures. In addition, Stengel documented how different subsections of these classifications were organized according to quite variable beliefs about the etiologies of the disorders being classified. Stengel suggested that the solution was to develop a classification that simply provided operational definitions of mental disorders

without reference to etiology. This suggestion led to the eighth revision of the mental disorders section of *ICD* (World Health Organization, 1968), which was to include a glossary defining the various components of psychopathology to go with the list of diagnoses. Unfortunately, the glossary was not ultimately included. However, at the same time, American psychiatrists did publish a second edition of *DSM* (i.e., *DSM-II*; APA, 1968). *DSM-II*, unlike *ICD-8*, contained short prose definitions of the basic categories in this system; however, the diagnostic terms and structure were otherwise almost identical.

#### Criticisms of Classifications Through the 1960s

During the 1950s and 1960s, concern about the reliability of psychiatric diagnoses surfaced. Problems with levels of diagnostic agreement had been noted in the 1930s. Masserman and Carmichael (1938), for example, reported that 40% of diagnoses in a series of patients followed up 1 year later required major revision. Ash (1949) compared the diagnoses of three psychiatrists who jointly interviewed 52 individuals applying to work for the Central Intelligence Agency (CIA). These clinicians agreed on the diagnosis for only 20% of the applicants, and, in 30% of the cases, all three psychiatrists made a different diagnosis. Beck (1962) reviewed a series of reliability studies and reported that the highest level of interclinician agreement was 42% for DSM-I. The problem with reliability was further highlighted by the UK/US Diagnostic Project, which found major differences in diagnostic practice between Britain and the United States (Cooper et al., 1972; Kendell et al., 1971). These studies suggested that Americans had an overinclusive concept of schizophrenia and tended to apply the diagnosis to any psychotic patient. British psychiatrists, in contrast, were more specific in the use of schizophrenia as a diagnosis. These differences probably stemmed from both differences in the definition of schizophrenia as well as its application by individual psychiatrists.

Diagnostic unreliability creates major problems for clinical practice and research. For example, the results of studies on patients with schizophrenia as diagnosed in Britain cannot generalize to patients diagnosed as having schizophrenia in the United States if these results are based on different applications of the concept of schizophrenia. However, the problem was not confined to schizophrenia. The reliability studies of the 1960s and 1970s were interpreted as indicating that clinicians had problems achieving high levels of agreement for any area of psychopathology. More modern commentators on this literature have suggested, however, that the criticisms of diagnostic reliability during this era were overstated (Kirk & Kutchins, 1992).

Concurrent with the empirical studies questioning the reliability of psychiatric diagnosis, psychiatry came under considerable attack from the antipsychiatry movement. Much of this criticism focused on the clinical activities of diagnosis and classification. Szasz (1961) went so far as to argue that mental illness was a myth.

By the late 1960s, three major criticisms of psychiatric classification were popular. First, psychiatric diagnosis was widely thought to be unreliable. Second, classification and diagnosis were considered fundamental components of the medical model that was questioned as the basis for understanding mental disorders. This model clashed with other models, particularly those stemming from behavioral and humanistic perspectives that were influential in clinical and counseling psychology. The medical model of illness was viewed as both speculative and as demeaning of patients. Third, widespread concern was expressed, particularly among many sociologists and psychologists, about the labeling and stigmatizing effects of psychiatric diagnoses (Goffman, 1959, 1963; Scheff, 1966, 1975). Labeling theorists tended to view mental illness and other forms of deviant behavior as largely politically defined and reinforced by social factors and agencies. Psychiatric diagnoses were considered to be self-fulfilling prophecies in which patients adopted the behaviors implied by the label. Their arguments were bolstered by philosophers such as Foucault (1988), who condemned psychiatry as little more than an agent of social control.

A demonstration of these issues was contained in a paper published in Science by Rosenhan (1973), titled "On Being Sane in Insane Places." In this study, 8 normal persons sought admission to 12 different inpatient psychiatry units. All accurately reported information about themselves except that they gave false names to avoid a mental hospital record, and they reported hearing an auditory hallucination in which a voice said "thud," "empty," or "hollow." In all instances, the pseudo-patients were admitted. Eleven of these admissions were diagnosed as schizophrenia, the other as mania. On discharge, which occurred on average 20 days later, all received the diagnosis of schizophrenia in remission. Rosenhan concluded that mental health professionals were unable to distinguish between sanity and

insanity, an observation that was eagerly seized by the antipsychiatry movement. However, the Rosenhan study was not without its critics. Rosenhan's paper resulted in an explosion of responses that challenged his research and claimed that psychiatric diagnosing is a valid and meaningful process. The majority of the criticisms focused on Rosenhan's flawed methodology and his unfounded interpretations that clinicians are unable to distinguish between those who are sane and those who are insane (Farber, 1975; Millon, 1975; Spitzer, 1975; Weiner, 1975).

#### The Neo-Kraepelinians

During the 1970s, a small but effective group of researchers emerged in North American psychiatry (Compton & Guze, 1995). These individuals influenced both academic psychiatry and practice. The movement, usually referred to as the neo-Kraepelinians (Klerman, 1978), sought to reaffirm psychiatry as a branch of medicine. The neo-Kraepelinians emphasized the importance of diagnosis and classification. The movement was a reaction to the antipsychiatrists and the psychoanalytic dominance of North American psychiatry. Klerman's assumptions of the neo-Kraepelinian positions included emphasizing the medical roots of psychiatry, such that psychiatry provides treatment for people who are sick with mental illness. Klerman further highlighted that the biological aspect of mental illness should be the central focus, and any area of psychopathology that might represent a disease process (e.g., schizophrenia) belonged to psychiatry, whereas other areas could be assigned to ancillary professions such as psychology, social work, and nursing. The neo-Kraepelinians, in the attempt to medicalize psychiatric disorders, emphasized qualitative distinctions between normality and illness, a view criticized by writers such as Szasz, who considered mental disorders to be problems of living that are on a continuum with normal behavior. Furthermore, the position of the neo-Kraepelinians suggested different forms of disorders, which laid the basis for the continued use of a categorical approach to classification.

The neo-Kraepelinians believed that psychiatry should be founded on scientific knowledge. This assumption insisted on a solid empirical foundation to ensure psychiatry as a medical specialty. The neo-Kraepelinians placed additional emphasis on diagnosis and classification by proposing that diagnosis is the basis for treatment decisions and clinical care—a view that contrasted with that of psychoanalysts, who believed that descriptive classification focused on superficial behavioral aspects of patients' lives (Havens, 1981). Klerman stressed the importance the neo-Kraepelinians placed on improving the reliability and validity of diagnoses through the use of statistical techniques.

Reading these propositions more than 50 years later reveals the extent to which the neo-Kraepelinians felt the need to reaffirm the medical and biological aspects of psychiatry. They felt embattled and surrounded by powerful influences that advocated a very different approach. These propositions now seem curiously dated, perhaps indicating the extent to which the neo-Kraepelinian movement was successful in achieving its objectives. In many ways these propositions are now widely accepted within the profession, although most would probably express these positions less vehemently. Klerman's statements also indicated the importance that the neo-Kraepelinians placed on diagnosis and classification. The way to ensure that their views were adopted was to develop a new classification system. The antipsychiatry movement's concerns about labeling and other negative reactions to psychiatric diagnosis provided an important context that spawned DSM-III (APA, 1980), but the neo-Kraepelinian movement provided the agenda (Rogler, 1997).

#### DSM-III and Its Successors

*DSM-III* was the culmination of the neo-Kraepelinian efforts to reestablish psychiatry as a branch of medicine with diagnosis and classification as fundamental components. The classification took more than 5 years of extensive committee work and consultation to produce.

DSM-III differed from DSM-II in four major ways. First, DSM-III adopted more specific and detailed diagnostic criteria, as compared to DSM-II, in order to define the various categories of mental disorders. If a patient met the diagnostic criteria, then the patient was said to belong to the category. Before DSM-III, most definitions of specific mental disorders were in prose format and implicitly referred to the "essence" of the disorder. Since the publication of DSM-III, the use of diagnostic criteria has reflected a shift to a prototype model whereby a category is defined not by a list of necessary and sufficient conditions but rather by a list of characteristics that any individual member may or may not have. Thus, two individuals may qualify for the same diagnosis even though they have few symptoms in common as long as each of them has enough of the listed symptoms to attain the specified threshold. The more characteristics

the individual evidences, the better fit that person is to the category (Cantor et al., 1980). The intent of using these diagnostic criteria was to make the diagnostic process more explicit and clear-cut, thus improving reliability. Second, DSM-III proposed a multiaxial system of classification. Thus, instead of assigning one diagnosis per patient, as was typical with DSM-I and DSM-II, clinicians were expected to categorize the patients along five axes: (I) symptom picture, (II) personality style, (III) medical disorder, (IV) environmental stressors, and (V) role impairment. Third, DSM-III substantially reorganized the hierarchical arrangement of mental disorder categories. In DSM-I and DSM-II, the hierarchical system of organization recognized two fundamental dichotomies: (1) organic versus nonorganic disorders and (2) psychotic versus neurotic disorders. DSM-III dropped these dichotomies and instead organized mental disorders under 17 major headings based on the phenomenology of the disorder (e.g., "mood disorder" or "psychotic disorder"). Fourth, DSM-III was a much larger document than its predecessors. DSM-I contained 108 categories and was 130 pages in length. In contrast, DSM-III had 256 categories and was 494 pages long.

By almost any standard, *DSM-III* was an astounding success. Financially, it sold very well. As a result of this success, the American Psychiatric Association developed a publication arm of the organization that began to publish a large number of *DSM*-related books and other psychiatric works. Although explicitly an American classification, *DSM-III* quickly became popular in Europe, overshadowing the *ICD-9* (1977), particularly among academics and researchers.

Another way of measuring the success of DSM-III is in terms of research. DSM-III stimulated a great deal of research, especially regarding the definitions of the categories proposed in this classification. As a result of this research, DSM-III-R (APA, 1987) was published with the explicit goal of revising the diagnostic criteria for the categories stemming from new research findings. However, like most committee products, the changes from DSM-III to DSM-III-R were not limited to diagnostic criteria. A number of new categories were introduced, including a group of diagnoses associated with the general category of "sleep disorders." Additionally, many specific categories were revised (e.g., histrionic personality disorder), dropped (e.g., attention deficit disorder without hyperactivity), or added (e.g., premenstrual syndrome had its name changed and was added to an appendix of DSM-III-R).

Because of the revolutionary impact of *DSM-III*, the mental disorders section of *ICD-10* (World Health Organization, 1992) was substantially changed relative to earlier *ICDs. ICD-9*, published in 1977, had been very similar to *ICD-8*. Hence, *ICD-10* was published in two versions: a clinical version that contained prose descriptions of categories and a research version that contained diagnostic criteria. However, *ICD-10* did not adopt a multi-axial system.

As work was progressing on ICD-10, a decision was made to perform another revision of DSM-III that, it was hoped, would make it more similar to ICD-10. Indeed, a special "harmonization" committee was established and work on the two manuals proceeded, to some degree, in parallel. The result was DSM-IV (APA, 1994). The committee work that went into the creation of DSM-IV was extensive. The American Psychiatric Association even sponsored special research projects that attempted to empirically resolve important debates that had arisen around classificatory issues. One example of such a research project was the 1999 DSM Research Planning Conference sponsored by the American Psychiatric Association and the NIMH. This conference established the research priorities for future DSM editions, which included addressing the continued dissatisfaction with the DSM nomenclature (Kupfer et al., 2002).

DSM-IV was larger than previous DSMs in terms of the sheer size of its publication and the number of categories. Interestingly, different commentators have computed different numbers for the total diagnoses in DSM-IV, ranging from just under 300 to just under 400 (cf. Follette & Houts, 1996; Kutchins & Kirk, 1997; Sarbin, 1997; Stone, 1997). Despite the intent of making DSM-IV more like ICD-10, DSM-IV and ICD-10 are quite different. Of 176 diagnostic categories that shared similar names, there were intentional conceptual differences in 21% (First, 2009). However, there were unintentional nonconceptual differences in 78% of categories; only one disordertransient tic disorder-was identical between the two systems (First, 2009). The most impactful difference between the two systems was the DSM-IV "clinical significance" criterion, which required the presence of distress and/or functional impairment for diagnosis. ICD-10 did not always consider the presence of distress and/or functional impairment a requirement (Reed et al., 2016). Additionally, the ICD-10 used diagnostic guidelines rather than criteria, which provided greater flexibility in their

interpretation and application than the *DSM-IV* descriptions.

In 2000, the American Psychiatric Association published a text revision of *DSM-IV*, titled *DSM-IV-TR*, which updated the prose sections of the manual but left the diagnostic criteria and number of diagnoses mostly the same. Two exceptions included dropping the clinical significance criterion from the tic disorders and adjusting it to account for nonconsenting victims of paraphilic disorders (First & Pincus, 2002).

The current editions of DSM and ICD have undergone yet another revision. DSM-5 was published in May 2013; ICD-11 was approved in 2019. The co-chairs of DSM-5 hoped to make DSM-5 as revolutionary as DSM-III had been. The major changes that they instituted with DSM-5 were to add diagnostic spectra (e.g., the autism spectrum and the schizophrenia spectrum), offer dimensional alternatives or enhancements to categorical diagnosis (e.g., the five dimensions for describing personality disorder in Section III titled "Emerging Measures and Models"), improve the assessment of dysfunction as a result of psychopathology (the adoption of the WHO Disability Assessment Schedule [WHODAS] in place of the Global Assessment of Functioning [GAF], also in Section III), and drop the multiaxial approach to diagnosis that appeared in DSM-III and DSM-IV (all diagnoses are now in a single section of the manual instead of spread across five axes; APA, 2012a; 2013).

Just as DSM-III was partially driven by the attempt to overcome the reliability issues with DSM-I and DSM-II, one goal of DSM-5 was to address meta-structure issues that became prominent with DSM-III-R and DSM-IV (Regier et al., 2012). Specifically, the arrangement of disorders within the manual could be informed by empirical findings rather than based solely on phenomenological similarity or work group arrangement. An example is the dissolution of the childhood disorders grouping of DSM-IV, whereby some disorders were placed under a neurodevelopmental heading (e.g., intellectual disability, attention deficit hyperactivity disorder [ADHD], autism spectrum disorder) and others were placed with similar-appearing "adult" disorders (e.g., reactive attachment disorder in the trauma- and stressor-related disorders group).

In its final form, *DSM-5* contained 584 diagnostic categories (compared to 357, by our count, in *DSM-IV*). The size of *DSM-5* also grew to 947 pages from 886 pages in *DSM-IV* while the purchase cost of the manual more than doubled. In contrast, the number of categories with diagnostic criteria was reduced from 201 in *DSM-IV* to 138 in *DSM-5*.

With respect to the development of the *ICD-11*, the WHO focused on enhancing clinical utility and global applicability (Reed, 2010). They were dedicated to addressing the global mental health gap between those who need services and those who receive them, and they sought to develop the ICD-11 as a mechanism for better identifying individuals with mental health needs. A three-step plan was developed to provide guidance for the structure of the Mental and Behavioral Disorders chapter in the ICD-11. The first step involved evaluating the scientific evidence and information regarding the actual use of the ICD in clinical practice, including two major surveys of psychiatrists and psychologists (Evans et al., 2013; Reed et al., 2011). The second step consisted of two field studies that examined how clinicians from around the world conceptualize mental disorders and their relation to one another (Reed et al., 2013; Roberts et al., 2012). These findings were used to inform the structure (or table of contents) of the manual. The third step involved two sets of field studies designed to evaluate the proposed diagnostic guidelines (Keeley et al., 2016). One evaluated how global mental health clinicians apply the guidelines to a set of case vignettes with the intent of identifying confusions or clarifications. The other examined reliability and feasibility in clinical settings. The development process also involved an attempt to synchronize the ICD-11 and DSM-5. It is important to note that any differences between the two systems were intentional. For example, there are distinct differences in regards to sleep disorders and sexual health and gender identity which ICD-11 justifies as being more consistent with current evidence and clinical practice (Reed et al., 2016).

#### **Taxonomic Issues**

A number of controversies have arisen around the classification of psychopathology. The purpose of the following list is not to provide a comprehensive overview but simply to list the issues and controversies that are frequently raised about psychiatric classification.

### Classification of Syndromes, Disorders, or Diseases

The terms "syndrome," "disorder," and "disease" can (erroneously) be used interchangeably to describe mental health conditions. In fact, these three terms refer to explicitly different assumptions about the nature of the category they describe. At the most basic level of description, a person experiences symptoms (self-reported issues) and evidences signs (observed by others) of a problem. As mentioned before, if mental health professionals were forced to idiosyncratically describe the unique pattern of symptoms and signs for every patient, their work would be hopelessly stymied by trying to account for each patient. However, symptoms and signs often co-occur. When they co-occur with sufficient frequency, that condition is termed a syndrome. Note that the concept of a syndrome does not include any assumptions about the cause of the condition or why those symptoms belong together. It is a purely descriptive notion.

A *disorder*, on the other hand, provides an additional level of description beyond that of a syndrome. A disorder is a pattern of symptoms and signs that includes an implied impact on the functioning of the individual. While some causal factors might be understood for a disorder, its etiology is still unclear or multiply determined. In contrast, a *disease* is a condition where the etiology is known, and the path from the causal agent to the symptoms and signs it causes is more or less clear.

By way of example, a condition known as general paresis was the most common single disorder represented in mental asylums in the mid to late 1800s. Initial investigations found that certain individuals exhibited similar symptoms: grandiose delusions and excitable behavior. At that point, the concept would properly be termed a syndrome. After further investigation, it became clear that these individuals followed a similar course. The problem began with excitable, grandiose behavior but progressed to degenerative muscle movements, paralysis, and eventually death. Once the course and outcome were known, general paresis was more properly termed a disorder. Many theories were posited about the cause of the disorder, varying from overindulgence in alcohol to inflammation of the meninges. However, eventually the discovery came that it was tertiary syphilis, having migrated from a genital infection through a long dormant phase to the central nervous system. When general paresis was understood as a syphilitic infection, the concept became a disease (Blashfield & Keeley, 2010).

The history of general paresis is important in classification because it was a mental disorder that was understood as a disease and eradicated with proper treatment (i.e., penicillin). Paresis was a major victory for the science of psychiatry, as the majority of asylum patients could be successfully (and simply) treated and sent home. Many individuals believed that all other mental health conditions (especially schizophrenia) would follow similar developments, eventually being "cured" once the proper cause was known. Unfortunately, no other conditions to date have enjoyed the scientific success of general paresis. Rather, nearly all mental health categories are more properly termed "disorders," in that their cause and therefore treatment are much more ambiguous.

### Classification of Disorders Versus Classification of Individuals

On the surface, this controversy appears to be a somewhat simple-minded issue of terminology. Individual patients are diagnosed with various mental disorders. A classification system contains the names of mental disorders that have been recognized or are officially sanctioned as diagnoses by some governing body. What difference does it make whether a classification system is said to classify disorders or individuals?

Interestingly, however, the authors of *DSM-IV-TR* did think that this distinction made a difference. They adopted an explicit position relative to this issue.

A common misconception is that a classification of mental disorders classifies people, when actually what are being classified are disorders that people have. For this reason, the text of the *DSM-IV* (as did the text of *DSM-III-R*) avoids the use of expressions such as "a schizophrenic" or "an alcoholic" and instead uses the more accurate, but admittedly more cumbersome, "an individual with Schizophrenia" or "an individual with Alcohol Dependence." (APA, 2000, p. xxxi)

The DSM-IV-TR adopted this position to try to avoid the problem of stigma. Mental disorders largely refer to undesirable aspects of the human condition. Most of us do not want to be diagnosed with a mental disorder. To call someone "schizophrenic" is to imply that that individual is a member of a diagnostic category that is immutable, unchanging, and destructive both to that person and to the significant others in that person's life. The contrasting language of "an individual with schizophrenia" implies that the person is not inherently schizophrenic, but that schizophrenia, being a disease of the brain, is something that happens to people without the occurrence of the disease being their fault. By saying that DSM is a classification of disorders, the authors were trying to emphasize the value of beneficence so that no or minimal harm

was done by assigning psychiatric diagnoses to individual human beings.

On the other hand, as mentioned at the beginning of this chapter, diagnosis is the process of assigning individuals to categories. Individual clinicians are concerned with the process of how best to characterize the individuals they see. The mental disorder groups characterized in a classification would not exist without individuals who instantiated those symptoms. Admittedly, the population of individuals with mental disorders is not permanent, as many mental disorders are time limited (a person initially does not have the disorder, then does, and goes back to not having it). The conditions that define the presence or absence of the disorder state become crucial to understanding if the classification captures individuals, disorders, or both. Thus, the definition of mental disorder has profound consequences for what the classification captures.

#### Definition of Mental Disorder

The definition of the domain to which a classification of mental disorders applies-that is, all mental disorders-is an important aspect of the classification. The early editions of the DSM and ICD did not provide any definition of a mental disorder. An attempt to define this concept was provided with DSM-III by the head of the task force that created this classification. Robert Spitzer's view about how to define a mental disorder became controversial when he claimed "mental disorders are a subset of medical disorders" (Spitzer et al., 1977, p. 4). Many viewed this statement as an attempt to secure exclusive rights to mental disorder treatment for psychiatry, thereby excluding or marginalizing other disciplines such as psychology and social work. However, a psychologist on the DSM-III task force, Millon (1983), stated that this sentiment was never the official perspective of those creating DSM-III.

One year later, Spitzer and Endicott (1978) made an explicit attempt to define both mental disorder and medical disorder, with the former being a subset of the latter. It is worth reproducing their definitions *in toto*.

A medical disorder is a relatively distinct condition resulting from an organismic dysfunction which in its fully developed or extreme form is directly and intrinsically associated with distress, disability, or certain other types of disadvantage. The disadvantage may be of physical, perceptual, sexual, or interpersonal nature. Implicitly there is a call for action on the part of the person who has the condition, the medical or its allied professions, and society.

A mental disorder is a medical disorder whose manifestations are primarily signs or symptoms of a psychological (behavioral) nature, or if physical, can be understood only using psychological concepts. (p. 18)

Wakefield (1993) argued that Spitzer and Endicott's definition of a mental disorder failed on many levels to successfully operationalize the role of dysfunction inherent to mental disorders. Consequently, Wakefield (1992a, 1992b, 1993) provided an alternative definition of mental disorders, in which he placed dysfunction within an evolutionary framework to better distinguish disorders from non-disorders. Wakefield's approach to mental disorders, termed "harmful dysfunction," considered mental disorders as "failures of internal mechanisms to perform naturally selected functions" resulting in impairment (Wakefield, 1999, p. 374). Wakefield appreciated the fact that defining a disorder must incorporate both value-based (the harm element) and scientific-based (the dysfunction element) criteria.

Wakefield and others have argued that both values and science are inherent components to the way in which DSM-III and its successors have defined individual mental disorders (see Sadler, 2005). Distress, or harm, is included either by definition (feelings of depression, anxiety, etc.) or through the criterion of clinical significance. Clinical significance refers to the judgment made by the clinician that the severity of the dysfunction present in the disorder justifies treatment. Spitzer and Wakefield (1999) justified the inclusion of clinical significance in the DSMs as a means of limiting false-positive diagnoses (i.e., individuals who are symptomatic but do not qualify for a full diagnosis of a disorder). Note, however, that clinical significance is not an objectively defined concept but rather requires a subjective decision by a clinician regarding when a set of symptoms warrants clinical attention. For a classification system that has argued its strength is objectivity and freedom from clinical bias, the explicit inclusion of subjectivity in the definition of a mental disorder is a problem.

Wakefield's harmful dysfunction approach has not been without its critics. Lilienfeld and Marino (1995) criticized Wakefield's evolutionary basis of mental disorders, arguing that mental disorders do not have defined properties and are not necessarily evolutionary dysfunctions. To use a medical example, sickle-cell anemia is evolutionarily functional in malaria-prone regions but typically dysfunctional in malaria-free environments. Similar arguments can be made with specific phobias, such as snake phobias, which could be quite functional when an individual human lives near poisonous snakes; however, a snake phobia is of less functional use for the typical person living in a large city in which snakes are uncommon. Other critics (Fulford, 1999; Richters & Cicchetti, 1993; Sadler & Agich, 1995) have provided analyses and substitutes to Wakefield's harmful dysfunction concept. For further discussion on the debate centered on Wakefield's harmful dysfunction approach, we refer the reader to a recent review about how the debate is related to the DSM-5 (Wakefield, 2016).

As mentioned briefly in the beginning of this chapter, lack of a consensual definition of mental disorders has important consequences. Definitions establish boundaries, in this case the boundary regarding what is and what is not a mental disorder and hence the boundaries of the mental health profession. The current definition posed in DSM-5 reflects the logic of Wakefield's harmful dysfunction concept but is more lenient regarding the cause of the dysfunction. Furthermore, the DSM-5 definition included the phrase "clinically significant disturbance," but the definition did not clarify the meaning of this phrase (APA, 2013, p. 20). The WHODAS, in Section III, was included to give clinicians more precision in the measurement of dysfunction.

#### **Dimensions Versus Categories**

Although the term "classification" traditionally applies to a system of classes or categories, a number of contemporary writers have suggested that dimensional approaches to the classification of psychopathology would be preferable (Widiger & Samuel, 2005; Widiger et al., 2005).

The debate about categorical versus dimensional models is an old one. Advocates for each model tended to adopt particular theoretical and statistical approaches. Advocates of a dimensional model were often users of factor analysis, whereby advocates of a categorical model favored cluster analysis. Factor analysis is a multivariate statistical procedure pioneered in the 1930s by L. L. Thurstone (1934) and his colleagues.

The first known application of a dimensional approach to the classification of psychopathology

was performed by a priest and psychiatrist named Thomas Moore. Moore (1930) gathered data on individuals with schizophrenia and subjected his descriptive information to a factor analysis. The result was five factors, which, in retrospect, were quite contemporary in their meaning. Using modern terms, these five factors could be named as follows:

- 1. Positive symptoms of schizophrenia
- 2. Negative symptoms of schizophrenia
- 3. Manic symptoms
- 4. Depressive symptoms
- 5. Symptoms of cognitive decline (dementia)

Shortly after World War II, Eysenck (1947), a psychologist in Great Britain, became a strong advocate for a dimensional approach to all psychopathology. He argued for three basic dimensions (Eysenck & Eysenck, 1976) that could be used to organize all descriptive information about mental disorders, which he called:

- 1. Neuroticism
- 2. Extroversion
- 3. Psychoticism

He used *neuroticism* to refer to individuals who were anxious or prone to negative feelings versus those who were emotionally calm and steady. *Extroversion* referred to an individual's proneness to be outgoing versus introverted. His description of *psychoticism* included a variety of other constructs, including constraint, impulsivity, sensation-seeking, and even creativity. Eysenck believed that high levels of the personality trait psychoticism made one prone to schizophrenia or other psychotic disorders. These three dimensions have resurfaced in one form or another in many later models, although the same names are sometimes applied to slightly different constructs.

Eysenck was a protégé of Aubrey Lewis, a leading British psychiatrist of his time. Later Lewis and Eysenck split over Eysenck's determined advocacy of a dimensional model. Lewis, a physician, believed that a categorical/disease model of psychopathology was more appropriate. Shortly after this split between Eysenck and Lewis in the late 1950s, a related debate appeared in the British literature about whether depression was best viewed from a dimensional perspective or from a categorical model (Kendell, 1968; see Klein, 2010, for a modern discussion of this issue).

After Eysenck, other dimensional models of psychopathology began to appear. Within child psychopathology, Achenbach (1966, 1995) became a proponent of a dimensional model with two constructs: (1) an internalizing dimension and (2) an externalizing dimension. Internalizing referred to children who displayed internally expressed emotional problems, like anxiety or depression, whereas externalizing referred to children who acted out through disruptive behavior. More recently, Krueger (1999; Krueger et al., 2005; Forbes et al., 2016) has shown that this two-dimensional approach can be generalized to account for a subset of common DSM diagnoses. Additionally, Eaton et al. (2012) replicated the internalizing-externalizing structural model which was found to be applicable to both men and women. Under that context, generalized anxiety disorder, major depressive disorder, and other anxiety disorders loaded onto a common factor, while antisocial personality disorder and substance use disorders loaded onto a second factor. However, that organization left many facets of psychopathology unaccounted for (e.g., bipolar disorders, psychotic disorders). Later work investigated a wider range of disorders and found a more complicated structure, but the dimensions of internalizing and externalizing remained (Conway et al., 2020; Kotov et al., 2017). Studies of this kind formed the basis of the meta-structure of the DSM-5 and, to a lesser degree, ICD-11. Note that these structures are often hierarchical in nature, with higher-order factors corresponding to more general domains and lower-order factors referring to more specific manifestations. Similar to our earlier mention of lumpers and splitters, some advocates prefer description at the broader, higher level while others are more focused on the lower, narrower descriptors.

Another subset of psychopathology that has been a focus of dimensional investigation is the personality disorders. A variety of investigators such as James McKeen Cattell (1860–1944), Joy Paul Guilford (1897–1987), and Lewis Goldberg (1932–) developed dimensional approaches to personality traits in normal human beings. McCrae and Costa (1990) expanded this earlier research into what has become known as the Five-Factor Model (FFM) of personality with five dimensions:

- 1. Neuroticism
- 2. Extroversion
- 3. Agreeableness
- 4. Openness

14

5. Conscientiousness

Clark (2007) expressed concern about the application of the FFM to personality disorders because the most commonly used measure of the FFM, known as the NEO-PI-R, was designed to measure normal-range personality. For example, the construct of openness, as measured in normalrange personality, does not seem to be meaningfully related to pathology, but a separate constructoddity-does capture behaviors of interest like magical or obsessive thinking (Watson et al., 2008). Cicero et al. (2019) investigated how symptoms of schizophrenia and schizotypal traits align with the personality taxonomy, finding that positive symptoms were linked to psychoticism while negative symptoms linked to extraversion. Recent work has compared the domain overlap between common personality measures (Crego et al., 2018) and the large degree of overlap between normal and abnormal personality presentations with respect to psychopathology (Widiger & Crego, 2019).

Many models of normal and disordered personality were considered by the *DSM-5* work group concerned with personality disorders. In the end, the work group developed its own distillation of these models that—when empirically tested largely resembled the domains of the FFM (Krueger et al., 2012). Through an iterative process, they refined a list of 37 initial personality facets into a best-fitting model that contains 25 facets loading onto five higher-order domains (negative affect, detachment, antagonism, disinhibition, and psychoticism). While the structure resembles the FFM, it was intended to represent the more extreme and/ or pathological variants of those traits (Krueger et al., 2012).

The *ICD-11* approach to classifying personality disorder also moved toward a dimensional model, although it looks somewhat different from the DSM-5 proposal (Tyrer et al., 2015). First, personality disorder is classified along a severity continuum, moving from severe to moderate to mild personality disorder, with an option to indicate a subthreshold personality difficulty that is not severe or impairing enough to warrant a clinical diagnosis. Next, one may indicate the presence or absence of each of five personality trait domains (negative affectivity, dissocial, disinhibition, anankastic, and detachment). Four of those domains overlap substantially with similar personality concepts in the DSM-5 model (negative affectivity, dissocial, disinhibition, and detachment); however, the ICD-11 does not include a psychoticism domain. In the ICD tradition, schizotypal presentations are conceptualized as

a psychotic disorder and not a personality disorder. Instead, the *ICD-11* includes the domain of anankastic features, which is characterized by rigidity, perfectionism, and overregulation of one's own and other's behavior.

Although statistical work on the categorical approach to the classification of psychopathology has not been as extensive, a number of studies have appeared. The most notable of these efforts were Maurice Lorr's use of cluster analysis to study individuals with schizophrenia (Lorr, 1966) and Paul Meehl's development of taxometrics-a set of techniques aimed at discerning the latent categorical vs. dimensional status of specific psychopathological constructs (Meehl, 1995; cf. Schmidt et al., 2004). Interestingly, the majority of taxometric studies have supported dimensional structures for mental disorders rather than categorical, although some have favored distinct groups of disordered individuals (Haslam et al., 2012, 2020). An analysis that parallels the logic of factor analysis but is used to identify categories is called latent class analysis (for a single indicator variable) or latent profile analysis (for multiple indicator variables). In essence, the analysis helps the investigator identify the number of possible groups that exist in a sample of individuals. A relevant example is the debate surrounding whether posttraumatic stress disorder (PTSD) is best represented by a single group-and single diagnosisdifferentiated only on severity or multiple groups that differ in symptom type. The DSM-5 elected to expand the symptoms of PTSD to incorporate a wider range of presentations within a single diagnosis, whereas the ICD-11 opted to split the diagnosis of PTSD into two: regular PTSD and complex PTSD (Elklit et al., 2013; Wolf et al., 2015).

A new analysis approach termed *factor mixture* analysis (Muthen, 2006; Muthen & Muthen, 2010) creates hybrid dimensional-categorical models, where the taxonicity and dimensionality of a set of measures can be examined simultaneously. This sort of model would represent distinct groups of individuals (taxa) that vary along some latent dimension (i.e., an ordering of the groups). Interestingly, when this sort of hybrid model is employed, some studies find that dimensional structures continue to be favored (Eaton et al., 2011, 2013; Wright et al., 2013), whereas others find taxons meaningfully differentiated by underlying dimensions (Bernstein et al., 2010; Lenzenweger et al., 2008; Picardi et al., 2012).

Most classifications of psychopathology employ categories because they offer certain advantages. In everyday life, categorical concepts are used because they are familiar and easy. Psychiatrists have been trained in a tradition associated with medical and biological classification, and this influence has colored mental health classification. Both biological and medical classificatory systems are categorical; however, in regard to medical classification, certain portions can be viewed as dimensional (e.g., hypertension).

The tendency to think categorically should not be underestimated. Work in anthropology suggests that hierarchically organized categorical systems are the product of universal cognitive mechanisms that have evolved as adaptive ways of managing information (Atran, 1990; Berlin, 1992). In his study of various indigenous cultures, Berlin (1992) found that these societies had hierarchical organizations for the living things they encounter in their environment, and the structure of these "folk taxonomies" tended to be universal-but not concordant with scientific classifications. Evidence from cognitive and developmental psychologists shows that children seem to learn about the natural world through category formation (Hatano & Inagaki, 1994; Hickling & Gelman, 1995; Kalish, 2007; Nguyen, 2008). It is not surprising, therefore, that people, including clinicians, prefer to use concepts that are the products of these cognitive mechanisms that favor categorical concepts (Gelman, 2003; Yoon, 2009).

There are, however, substantial disadvantages to using categories. Categorical diagnoses often result in the loss of some information. Categorical systems also depend on nonarbitrary boundaries or at least on points of rarity between syndromes, as are seen in the valley between the two modes in a bimodal frequency histogram (Kendell, 1975, 1989).

Haslam (2002) outlined a taxonomy of "kinds of kinds," or a model of category types ranging from true categories to true dimensions. The truest form of a category is what various philosophers have termed a "natural kind" (Kripke, 1980; Putnam, 1982). A natural kind represents a group with a unitary etiology that leads to necessary outcomes and a discrete separation from other psychopathologic syndromes. However, true natural kinds are rare or nonexistent in the realm of psychopathology (Zachar, 2000). It could be that certain groups are qualitatively separate from other entities but lack the underlying "essence" of a natural kind, which Haslam termed "discrete kinds." An example would be the qualitative difference between regular and endogenous depression proposed by some (van Loo et al., 2012). Even though depression exists on a

severity dimension, these authors would claim that a qualitative shift occurs at a certain threshold, creating a truly different kind. However, categories of mental disorders are not always well demarcated. When a category does not have a clear boundary, Haslam terms it a "fuzzy kind." A fuzzy kind exists when there is a definable group, but the characteristics of that group blend into other groups. Next, there are phenomena, such as hypertension, that can be thought of existing along a dimension (measured by blood pressure), but for which there are functional reasons to categorically scale the dimension (i.e., a cut point above which the person is seen as needing medical intervention). The choice of the cut point may be debatable, but the presence of a cut point serves a pragmatic purpose. These sorts of groups are termed "practical kinds" (Haslam, 2002; Zachar, 2000). The final entry in Haslam's taxonomy consists of true dimensions, or continua of psychological characteristics that do not justify any cut point.

From this discussion, the selection of the type of theoretical concept to use in classification (i.e., dimensions vs. categories) is fundamental to the development of a classification. Jaspers (1963) suggested that different classificatory models might be required for different forms of psychopathology. This idea has merit. Some conditions, especially those traditionally described as organic disorders, are similar to diagnoses in physical medicine. These could probably best be represented using a categorical model in which diagnoses are specified by diagnostic criteria. Other areas of psychopathology, especially the affective disorders and personality disorders, might be better represented using a dimensional framework. However, the distinction between categories and dimensions is a human convenience that we force on the world. A better approach might be to think about how categories and dimensions can best be used to describe a given psychopathological phenomenon and how they each might be better for individual purposes, such as clinical diagnosis versus research.

Interestingly, the issue of dimensions versus categories became a focus of significant controversy within *DSM-5*. The Personality and Personality Disorders Work Group for *DSM-5* was orchestrated in hopes of offering an alternative model that would address the shortcomings of the *DSM-IV* (Morey et al., 2015; Zachar et al., 2016). The categorical model led to a significant level of co-occurrences and heterogeneity among personality disorders. It is fairly common for an individual to meet the criteria

for multiple personality disorders and for them to present differently than another person diagnosed with the same disorder. In fact, many individuals do not fall neatly into an arranged category, which has led personality disorder-not otherwise specified (PD-NOS) to be the most frequently diagnosed personality disorder. The work group proposed an empirically supported, hybrid model, termed the Alternative Model of Personality Disorders (AMPD), whereby some personality disorder categories would be retained while also including a dimensional model to describe individuals who did not fit neatly into a category (Skodol, 2012). Additionally, the proposed model mirrored the popular FFM of personality by mapping pathological variants of the Big Five personality factors onto personality disorders as well as the lower-order personality facets. The creators of the AMPD conceptualized personality disorders as a result of the interaction of personality functioning impairment and pathological personality traits. Within the work group, there was not unanimous agreement on the best approach involving dimensions and/or categories (Zachar et al., 2016). This hybrid structure was a compromise that could capitalize on the benefits of both categories and dimensions. However, the Board of Trustees of the American Psychiatric Association did not accept the proposal, electing to keep the same 10 categorical personality disorders found in DSM-IV. Instead, the work group proposal was published as a separate chapter in Section III of the manual to foster further research, with the hope of adopting those portions of the model that achieve sufficient empirical support.

#### Atheoretical Approach to Classification

At the times that DSM-I and DSM-II were written, the dominant theory in psychiatry was psychoanalysis (Blashfield et al., 2014; Cooper & Blashfield, 2016). However, as the psychoanalytic perspective began to lose favor, a more biological approach began to emerge as the force behind explaining and conceptualizing mental disorders. The committee members of DSM-III (headed by Spitzer) were sensitive to this division between the psychoanalytic and biological explanations of mental disorders. Consequently, the determination was made that DSM-III would be theory-neutral in order for the classification to be more accessible to all mental health professionals. This approach has been preserved throughout the modern DSMs and mirrored in the ICD but has sparked a number of criticisms on the failure of specifying a theory to guide the classification system (Castiglioni & Laudisa, 2014; Harkness et al., 2014). Most writers who have thought about the recent classification systems agree that the implicit theoretical model associated with these systems is the biological (medical) approach (Harkness et al., 2014; Sedler, 2016). According to Harkness, Reynolds, and Lilienfeld (2014), the refusal by the authors of these classifications to postulate a theory of psychopathology explicitly hinders scientific progress within the field and removes focus from the evolved adaptive systems which underlie pathology.

Though the authors of *DSM-III* denied having a theory, Sadler (2005) argued that certain values or assumptions are nonetheless embedded in the structure of the *DSMs* and *ICDs* that emerge with their application. Because these six values, as discussed by Sadler, do represent the beginning of a theory of psychopathology, each of them will be discussed next.

The first is the value of *empiricism*, which is the belief that the contents of psychiatric classification are based on scientific research, complete with testable hypotheses and controlled clinical trials. This empirical advancement discourages the exclusive use of expert opinions and clinical judgment when making nosological decisions, as was seen in early editions of the *DSM* and *ICD*.

Second, Sadler discussed how the classification is hypo-narrative, a term he coined to describe the manuals' lack of storytelling qualities. Narrativity was especially lost during the transition from DSM-II to DSM-III, when disorder descriptions became symptom listings. Applying this language to diagnosing an individual loses the richness of the "biographical" explanation of the individual. However, Sadler argued that the role of classifications is not to capture necessarily the life story of each patient but to address the signs and symptoms associated with diagnosis. Hypo-narrativity leads the clinician to focus exclusively on the symptoms of a patient, rather than on the interactions between the symptoms and the relationships, priorities, aspirations, and daily functioning of the patient. It is these interactions that provide the plot line for the patient's story.

A third assumption of modern classifications is *individualism* (La Roche et al., 2015; Poland, 2016). As expressed in the *DSM* definition of mental disorder, psychopathology resides within the individual and is not the manifestation of the interactions of the individual with others or with the social forces around that individual (APA, 2013). The *DSM* and

ICD have notoriously ignored pathological processes that exist among individuals, like family systems or romantic partners, and a group of researchers have been petitioning to include diagnoses of relational processes for decades (Wambolt et al., 2015). For example, a married couple might be highly dysfunctional even though neither individual qualifies for an individual mental health disorder. Another example of the effect of focusing on individualism as a value can be seen with the removal of gender identity disorder as a mental disorder. Nonbinary, gender fluid, or non-cisgender identities should not be classified as mental disorders because the struggles associated with such identities are induced by society and not something inherent within the individual (Drescher et al., 2012).

Fourth, psychiatric disorders are assumed to have a natural essence. In other words, disorders follow a natural order whereby etiologies are multifactorial-including biological, psychological, and sociocultural influences. Sadler stated that this assumption is important to understanding the atheoretical approach of these classifications because they stipulate that multiple theories, not just one all-encompassing explanation, are essential to understanding mental disorders. According to Bueter (2019), the inherent pluralism of this approach allows the classifications to fill a multitude of roles expected of them. Because the classifications-which possess influence and a special power over public perception of mental health due to their required use in many contexts, such as healthcare reimbursement or research fundingare often expected to fit a one-size-fits-all purpose, a pluralistic nature allows them to fit a variety of contexts and has many advantages for describing the breadth of psychopathology. With its tenth edition, the ICD attempted to directly address the one-size-fits-all problem by publishing several versions of the classification: one for clinical use, one for research, and one specifically for use in primary care. Regardless, this pluralistic approach impedes monistic beliefs that a single theory (like evolution in biology) could account for the entire landscape, as might be the agenda of biologically oriented researchers (Bueter, 2019).

The fifth value, *pragmatism*, refers to the use of classifications as a means to help individuals with mental disorders. The *DSM* and *ICD* exist for a practical purpose: the desire to improve the condition of individuals who are suffering or impaired. This pragmatism creates a difference from scientific disciplines that are studied for their own sake, like

chemistry. The elements in the periodic table may change as new ones are discovered, but those additions do not vary over time as a function of society's demands. Because psychiatric classifications exist to serve a societal function, they can never be objectively separated from that function, meaning that societal values will always play a role in defining mental disorders. As the needs and priorities of a society changes, so will the conditions that are included in these manuals. For example, both *DSM* and *ICD* considered including a disorder intended to capture problematic (or addicted) Internet usage in their latest edition.

Finally, Sadler described the sixth implicit value of psychiatric classifications as *traditionalism*. The diagnostic concepts in the *DSMs* and *ICDs* have a history. The modern classifications have been built on past classifications. Trying to maintain continuity over time is important both for psychiatry and for the other mental health professions. Sadler suggested that the continuity of a classification system results in this system becoming familiar, being valued, and serving as the basis of a long-standing research and clinical infrastructure.

#### Organization of Recent Classifications by Work Groups

The process used to formulate and revise the *DSMs* and *ICDs* warrants comment. A lengthy consultation process with panels of experts and the profession at large was used to ensure the face or content validity of diagnoses and widespread acceptance of the resulting system. The consultation process was partly a scientific exercise designed to produce a classification based on the best available evidence and expertise and partly a social-political process designed to ensure the acceptability of the resulting product. Because scientific and political objectives often run counter to each other, compromises were necessary.

With *DSM-III*, a task force handled the process and established advisory committees. These committees were composed of experts whose task was to identify and define diagnostic categories in their areas. Each committee also had a panel of consultants to provide additional advice and information. As the process continued, drafts of *DSM-III* were circulated to the profession for review and comment. Finally, field trials were conducted to evaluate the proposals and identify problems.

Although a similar process was used for *DSM-III-R*, *DSM-IV* went a step further. Work groups were established to address specific diagnostic classes, and each group followed a three-stage process. First, comprehensive literature reviews were conducted so that *DSM-IV* reflected current knowledge. Second, existing data sets were reanalyzed to evaluate diagnostic concepts and provide information on the performance of diagnostic criteria. Third, extensive field trials were conducted to address specific issues.

The DSM-5 work group process appeared to be fairly different from the work group process of its predecessors. The work groups often had broader agenda, and their assignments were not just to one family of disorders. For example, the anxiety disorder work group of DSM-5 had responsibility for the categories of separation anxiety disorder, body dysmorphic disorder, social phobia, substance-induced obsessive-compulsive disorder, PTSD, and dissociative amnesia. In addition, from the rationales presented for changes in categories, there appeared to be obvious interaction across the work groups. For example, substance-induced obsessive-compulsive disorder, as mentioned earlier, involved interaction with the work group for substance use disorders. Under the family of schizophrenic disorders, the psychotic disorders work group and the personality disorders work group integrated their efforts.

The *ICDs* have followed a similar organizational structure. However, being an international manual, the selection of individuals also included international politics. The *ICD-10* was criticized for largely being a European product develop by European experts. In response, the *ICD-11* explicitly made attempts to include on every work group individuals from low- and middle-income countries (International Advisory Group, 2011).

There are many laudable features to the process used to revise and develop each edition. Each work group faced a major undertaking that required careful analysis of information as well as consultation with other experts in the field. This division of labor into work groups probably contributed to the acceptance of the resulting classifications. But there were also problems with the process. The initial structure for DSM-III was established when the work groups were identified. Each was given a defined area of psychopathology. The separation into committees along major topic areas led to both personal and conceptual conflicts. Psychopathology is not readily divisible into discrete areas. Overlap occurred between various committees, leading to dispute. Once a committee was established with a given mandate, that committee was reluctant to relinquish domains of psychopathology that might have been better classified elsewhere. The superordinate

task force was responsible for resolving these disputes and ensuring integration. Inevitably, political processes within and between work groups influenced the solutions adopted. Additionally, who is selected to be a member of the work group is not without its own biases and limitations. Typically, those researchers with the most publications or most notable reputations are selected. To date, it is rare for clinicians to be selected, and never has an individual with the diagnoses in question been included, despite these individuals' perspectives potentially being useful regarding the usability and acceptability of the resulting product (Kamens et al., 2019). The people selected to be on work groups tend to publish together, receive grants together, and otherwise have similar viewpoints, creating an ingroup that perpetuates a group-think process (Blashfield & Reynolds, 2012). Furthermore, the process of discussions among the work group is influenced by nonscientific processes. As noted by Frances and Widiger (2012), two of the developers of DSM-IV, experts tend to be very opinionated and assertive in their beliefs, leading to the person with the loudest voice being the most influential.

#### **Measurement and Methodological Issues**

The final section of this chapter addresses more practical concerns about the classification of mental disorders. While it is good to debate the ontological status of the term "mental disorder" and consider the political forces that impact classification schemes, at some point, practical decisions must be made regarding actual patients. Many of these practical concerns embody decisions about measurement, or how one assesses the nature of the condition. We adopt some of the standard terms of psychological measurement theory, including concepts like reliability and validity, to elucidate issues surrounding psychiatric diagnosis.

#### Reliability

The reliability of a classification of mental disorders is the degree of diagnostic agreement among users. Reliability is clearly important; diagnoses have little value for communication or prediction if there are high levels of disagreement among clinicians. As Kendell (1975) pointed out, the accuracy of clinical and prognostic decisions based on a diagnosis cannot be greater than the reliability with which the diagnosis is made, and most writers allege that reliability places an upper limit on the validity of a given diagnosis (Spitzer & Fleiss, 1975; Spitzer & Williams, 1980).

A variety of factors influence reliability estimates. For instance, variations in patient characteristics influence clinicians' diagnostic decisions. Farmer and Chapman (2002) found that clinicians were much more consistent in providing a diagnosis of narcissistic personality disorder to men than to women. Some studies have examined the influence of variables such as race, age, and low socioeconomic status on diagnosis (Abreu, 1999; James & Haley, 1995; Littlewood, 1992). Einfeld and Aman (1995) suggest that reliability in DSM diagnoses appears to deteriorate markedly as patient IQ scores decrease. Furthermore, it is important to note that reliability estimates based on well-controlled research studies are likely inflated relative to reliability in day-to-day practice in clinical settings.

#### HISTORY

As noted earlier in this chapter, reliability became a major focus of empirical criticisms of psychiatric diagnosis during the 1950s and 1960s. Generally, the impression from these studies was that psychiatrists and clinical psychologists, when independently diagnosing the same cases, did not agree on the diagnoses that they were assigning to cases. Interestingly, as the methodology of these studies improved, the estimates of reliability generally appeared more positive than in the early, rather hastily designed studies. One study in this series (Ward et al., 1962) made the additional conclusion that the reason for this relative lack of diagnostic agreement among clinicians (i.e., poor reliability) was that the definitions of the diagnostic categories in DSM-I were too vague. Although the methodology of the Ward et al. study had serious limitations (Blashfield, 1984), this conclusion appealed to the field, and the Ward et al. (1962) paper was often cited prior to the publication of DSM-III, when diagnostic criteria were used to improve the precision of defining diagnostic categories.

Another source of variability in early research on reliability was the statistical procedure used to provide reliability estimates. In earlier years, this was a serious problem (Zubin, 1967). By the mid-1970s, a statistic named *kappa* became the standard technique for estimating diagnostic reliability. Kappa corrects for chance levels of agreement between raters and thus is an improvement on a simple percentage of agreement. However, a limitation of this statistic is its instability when the base rate of a diagnosis within a sample is less than 5% (Spitznagel & Helzer, 1985).

#### ASSESSING RELIABILITY

It is instructive to compare reliability as applied to psychiatric classification with reliability as applied to psychological tests. In test theory, "reliability" refers to the consistency of scores obtained with the same test on different occasions or with different sets of equivalent items (Anastasi, 1982). If a test is reliable, parallel scales constructed from an equivalent pool of items will yield the same measurement values. The extent to which this does not occur indicates the extent to which measurement is influenced by error. Traditionally, the reliability of psychological tests is assessed in three ways: (1) testretest reliability, (2) alternative forms, and (3) internal consistency. A fourth method directly relevant to the clinical enterprise is interrater reliability, or the consistency of different diagnosticians regarding the same patient.

Test-Retest Reliability. The test-retest method assumes that the administration of the same scale at different points in time represents parallel tests. Memory for items is the most common confound with this approach. High test-retest reliability is to be expected only when measuring a variable assumed to be stable; some mental disorders are assumed to follow a relatively stable course (e.g., autism spectrum disorders), but many disorders (e.g., mood disorders) are assumed to fluctuate across time. In a multisite collaborative study of DSM-IV disorders, Zanarini et al. (2000) found that test-retest kappa coefficients ranged from 0.35 to 0.78 for a variety of clinical disorders and from 0.39 to 1.00 for personality disorders. However, more recent research has questioned just how consistent personality disorder diagnoses are across time, finding substantial fluctuation across categorical personality disorder types (Hopwood et al., 2013).

Alternative Forms. The alternative-form method uses equivalent or parallel measures of the same construct. Ideally, different sources of information should converge on the same conclusions. Hilsenroth, Baity, Mooney, and Meyer (2004) examined three sources of information regarding depressive symptoms: in vivo interviews, videotaped interviews, and chart reviews. Clinicians made reliable ratings of depressive symptoms across in vivo interviews and videotaped interviews, but chart reviews were not consistent with either. Similarly, Samuel and colleagues (2013) examined the convergence of clinician-assigned personality disorder diagnoses, self-report questionnaires, and semi-structured interviews. They found that the convergence of these methods was low, but they

equally predicted clients' functioning at a 5-year follow-up, suggesting that the difference in reliability may not have much practical importance. Diagnostic disagreement can occur when clinicians have different kinds and amounts of information on which to base diagnosis. This problem may arise from differences in clinicians' ability to elicit information, the way patients respond to questions, and the availability of information from other sources. Thus, there are important sources of variance that can contribute to unreliability, including differences in clinical skill, patient responsiveness, and diagnostic setting.

Internal Consistency. Internal consistency measures (split-half techniques and coefficient alpha) assume each item on a scale is like a miniature scale. Thus, internal consistency estimates the extent to which the items in a scale are homogeneous. In psychological testing, this estimate of reliability is the most common. Morey (1988) examined the internal consistency of diagnostic criteria for personality disorders and found low correlations among criteria used to diagnose the same disorder. Other studies have found higher estimates of internal consistency, but using logistic regression and calculations of sensitivity and specificity have concluded that some criteria for certain personality disorders could be dropped because they do not form a cohesive diagnosis (Farmer & Chapman, 2002). These criticisms (among others) have led to some of the changes proposed in DSM-5's Section III regarding personality disorder diagnosis. However, care should be taken with such conclusions. It is reasonable to posit heterogeneous symptom groupings for which internal consistency estimates are therefore inappropriate means of measurement, just as test-retest estimates are inappropriate for diagnoses expected to change over time.

Interrater Reliability. The three forms of reliability just discussed focus on the construct underlying the diagnosis. However, discrepancies can also occur in the application of the diagnosis. Two clinicians, for example, may disagree about what diagnosis is best for the same case. In studies of interrater reliability, two or more clinicians interview each patient either conjointly in a single interview or in separate interviews close together in time. In *DSM-II* and *DSM-II*, consistency among clinicians was low, and the advent of diagnostic criteria in *DSM-III* was supposed to increase reliability. However, claims that reliability has increased seem to be overstated; diagnostic reliability does not seem to be substantially different over time (Vanheule et al., 2014).

The field trials for DSM-5 utilized a methodology that gave a realistic estimate of how reliable diagnoses for these conditions are under natural clinical conditions versus the stricter standardization present in research protocols (often through structured interviews). As might be expected, testretest reliabilities were lower, with kappas ranging from 0 to 0.78, with some common diagnoses not faring as well as might be expected (e.g., major depressive disorder = 0.28; Regier et al., 2013). The ICD-11 field trials used a methodology whereby the raters had access to the exact same information; as a result, reliability estimates were higher (Reed et al., 2018). Furthermore, a meta-analysis of diagnostic methods found that concordance between structured diagnostic interviews and standard clinical evaluations varied widely, with some diagnostic areas having relatively good agreement (e.g., eating disorders kappa = .70) and others relatively poor between the two methods (e.g., affective disorders kappa = .14; Rettew et al., 2009). While structured interviews do typically result in higher reliability estimates, correcting for the interviewers accessing the same information versus conducting separate interviews seems to account for much of the discrepancy in reliability (Chmielewski et al., 2015). Generally, the more training and structure provided in the diagnostic assessment, the higher the reliability coefficients will be; however, one must consider whether the procedure used to obtain a high reliability is feasible for implementation in daily clinical use. With DSM-III, obtaining higher reliability was an explicit goal. Now, some have questioned if test-retest reliability should be a goal in and of itself (Kraemer et al., 2012).

#### Validity

The main impetus for the development of *DSM-III* was the perceived crisis surrounding diagnostic reliability. Many clinicians purported that a set of criteria could not be valid if it were not first reliable. Although this assumption is not necessarily true (Carey & Gottesman, 1978; Faust & Miner, 1986), the creators of *DSM-III* saw the production of a reliable diagnostic system as their primary task. After establishing reliability, researchers could turn their attention to issues of validity.

"Validity" in common usage refers to the truthvalue of a statement. However, it is important to note that using *valid* in that sense does not imply that there is only one valid conclusion for a given set of facts; rather, there are many possible valid conclusions based on one's point of view. HISTORY

The concept of validity is often discussed within the context of the classification of psychopathology, but, ironically, like many classificatory concepts themselves, finding a clearly specified, thoughtfully articulated definition of validity has proved elusive. Two major approaches to diagnostic validity have been discussed in the past 50 years. One is a relatively common-sense, medicine-based approach that appeals to psychiatrists. The other, which often is discussed in more abstract, empirical contexts, is the view psychologists have about validity based on their experience with different forms of assessment.

A short paper published by Eli Robins (1921-1994) and Samuel Guze (1923-2000) of Washington University in 1970 contained the major discussion of validity from the medical perspective. Robins and Guze were leaders of the neo-Kraepelinian group whose views led to DSM-III. Robins and Guze discussed validity in the context of five phases of research that would demonstrate that a diagnostic concept represented a disease. These five phases were (1) clinical description (i.e., establishing that the disorder represents a "syndrome" of symptoms that can be empirically shown to co-occur at relatively high rate), (2) laboratory studies (which establish the biological substrate of the disorder), (3) delimitation from other disorders (which would establish that the disorders are relatively, though not perfectly, divided into discrete categories), (4) follow-up studies (which show that the individuals with this disorder have a common course to their symptom patterns), and (5) family studies (which establish the genetic basis of the biological phenomenon associated with the disorder). Robins and Guze believed that their approach to validity stemmed not only from the medical research of Thomas Sydenham (1624-1689) but also was consistent with the views of validity adopted by German medical researchers of the late nineteenth century, when the latter resolved the etiologies of many bacterial diseases (e.g., tuberculosis, smallpox, syphilis).

The other approach to the meaning of validity when applied to psychiatric classification has come from the work of psychologists who have drawn on discussions of validity in the context of psychological tests. Joseph Zubin at Columbia University was one of the first to promote the application of a psychological testing view of validity to psychiatric diagnosis. Zubin (1967) stated that the broad concept of validity should be subdivided into four subsidiary concepts: (1) concurrent validity, (2)
predictive validity, (3) construct validity, and (4) content validity.

In the past few years, a new development has occurred in the approach to diagnostic validity. This approach is represented by a concept titled clinical utility, which, like the views of Robins and Guze, has a pragmatic emphasis. In the words of First et al. (2004), clinical utility "is the extent to which the DSM assists clinical decision makers in fulfilling the various clinical functions of a psychiatric classification system" (p. 947). According to First (2010), the clinical functions of a psychiatric classification are (1) assisting clinicians in communicating clinical information; (2) assisting the selection of effective interventions; (3) predicting course, prognosis, and future management needs; and (4) differentiating disorder from non-disorder for the purpose of determining who might benefit from treatment. Verheul (2005) argued that increased clinical utility (especially regarding communication and clinical decision-making) may provide the rationale for shifting from a categorical to dimensional model of personality disorder. Reed (2010) has argued that clinical utility should be the driving force for making classificatory decisions when more convincing scientific information is equivocal or not available.

#### ISSUES

The psychiatric approach to validity, embodied by the work of Robins and Guze (1970), is based on the medical concept of disease, which has proved elusive in its own right (Aboraya et al., 2005; Jablensky, 2016). Many, but not all, references to the concept of disease are making assumptions about *essentialism*. According to essentialism, a category is defined by some*thing* (an essence) that causes one to be a member of the category. For example, when syphilis was found to be the cause of general paresis, the essence of the disease category became the presence of syphilis in the central nervous system. Thus, a valid category is one that has an identifiable etiological agent. Schizophrenia is valid to the degree that some*thing* causes one to have schizophrenia.

Essentialism has proved problematic even in the realm of physical diseases (Lemoine, 2013). Even in the most archetypal cases of "disease," for example—a bacterial infection—it is impossible to define the disease category in a way that corresponds to the state of nature and is free of human value assumptions (Smith, 2001). The disease is not the presence of bacteria, as perfectly healthy individuals have the bacteria in their system. Rather, the disease is an interaction effect that emerges from the presence of the bacteria and an immunological weakness, among other factors. In short, diseases have multiple causes in even the simplest of cases; therefore, to define them as having simple, reified essences is inappropriate at best. The essentialist view of validity has proved even less effective in the case of psychiatric conditions, the causes of which are complex and multiply determined (Dekkers & Rikkert, 2006; Zachar, 2000). Alzheimer's disease is another example of this phenomenon. While often termed a genetic disease, there is no singular genetic cause of Alzheimer's, and the presence of a gene known to cause Alzheimer's does not guarantee an individual will contract the disease. Instead, a host of genetic and environmental factors are known to influence the likelihood of contracting Alzheimer's, which is only diagnosed when the associated symptomology (i.e., the interaction of the factors within the individual) is present (Dekkers & Rikkert, 2006). In fact, while defining the terms "disease" and "health" may be of philosophical importance to medicine, concrete definitions are still illusive (Lemoine, 2013).

In contrast, the psychological approach to validity has been based on psychometric test theory. A psychological test is considered valid to the extent to which its items and resultant scores reflect the construct of interest. For instance, the items on a test should represent the entire domain of the construct, which is generally termed *content validity*.

For example, a test of depression should have items that sample all the relevant symptoms and expressions generally considered to be a part of depression. In the same fashion, the diagnostic criteria used to define a mental disorder category should represent the range of behaviors associated with that category.

Second, the test may be considered valid if it meets some predetermined criterion, that is, *criterion validity*. To continue with the example of depression, a test of depression would be criterion valid if it consistently classified people in the same manner as a *DSM-5* diagnosis. The criterion is context-dependent. In one context, one might consider a diagnosis from a structured interview (e.g., the Structured Clinical Interview for *DSM* [SCID]) the "gold standard," whereas in another context, an unstructured interview might be the appropriate criterion.

The third and perhaps most important aspect of validity for psychological tests is *construct validity*—the degree to which the scores on the test measure

what they are expected to measure (Cronbach & Meehl, 1955; Smith & Combs, 2010). This definition has several implications. First, raters should respond consistently to items that are meant to tap into the same construct, assuming that the construct is meant to be stable across time and homogenous. In that sense, reliability is an integral part of validity in that a measure's reliability should be consistent with the description of the construct. Second, the items on a test should correlate with each other. In the context of mental disorders, different items, which represent different symptoms, should cooccur (i.e., the construct is a syndrome). The degree to which the items correlate should be consistent with the supposed homogeneity or heterogeneity of the construct. Third, the test score should be related to measures of other constructs in an expected pattern. For example, a test of depression should be negatively correlated with a measure of positive affect. Furthermore, test scores should be related to other measures of the same construct using different measurement methods. This approach is usually evaluated using the classic multitrait-multimethod procedure described by Campbell and Fiske (1959).

A fourth concept of validity-structural validity-defines how closely a set of symptoms defined by the literature match how a disorder actually presents in reality (Jacobs & Krueger, 2015). A statistical procedure termed structural equation modeling (SEM) allows researchers to evaluate structural validity. SEM is a correlational and regressional technique that models complex interrelationships in a multivariate format and allows one to test a variety of hypotheses regarding a construct (Campbell-Sills & Brown, 2006; Bentler & Savalei, 2010). It involves testing reliability and factor structures of measures as well as the relationships between measures. For example, Neumann, Johansson and Hare (2013) examined the interrelationships between clinical anxiety/fearless ratings (LAF) and the factor structure of the Psychopathy Checklist Revised (PCL-R) in a sample of prisoners. Using SEM, Neumann, Johansson and Hare sought to determine to what degree the PCL-R accounted for LAF factors, which may be part of the psychopathy construct and unaccounted for in the PCL-R model. Consistent with previous research, SEM analysis indicated that the PCL-R superordinate factor set was able to account for all LAF factors without changes to the PCL-R model. Put another way, if LAF factors are a part of the psychopathy construct, they are already accounted for by the PCL-R (Neumann et al., 2013).

Despite developments in psychological testing, substantial theoretical limitations to the psychological test approach to validation exist in the context of mental disorders. The construct validation approach used in psychology assumes that the construct is already well-defined. If the concept of a construct changes, as is inherent in any empirical science, any test purporting to measure that construct must be revalidated. In a strange way, the psychological test approach puts the cart before the horse as the structure of the diagnostic construct must be assumed before it can be investigated.

#### Diagnostic Overlap

Another major problem with *DSM* is the degree of diagnostic overlap that occurs throughout the classification. For example, of those in the general population who meet criteria for a disorder, half meet criteria for two or more other mental disorders (Kessler et al., 2005), a phenomenon termed *comorbidity*.

#### HISTORY

In 1984, Boyd and associates published a landmark empirical study that documented a surprisingly high degree of overlap among mental disorders. The sample was taken from a large (nearly 12,000 participants) multisite epidemiological study performed after the publication of DSM-III. DSM-III included specific exclusionary criteria to prevent the overlap of certain diagnoses. However, Boyd et al. found that if the exclusionary criteria were ignored, instances in which an individual received more than one diagnosis were quite common. For instance, the diagnostic overlap between major depressive disorder and agoraphobia was 15 times what might be expected by chance. Boyd et al. also found that the diagnostic overlap among mental disorders for which no exclusionary criteria were given in DSM-III was also quite high (e.g., the co-occurrence of schizophrenia and alcohol abuse/dependence was 10 times greater than expected by chance).

Stimulated by the Boyd et al. (1984) finding, the NIMH sponsored a conference of prominent psychiatrists and psychologists, in the late 1980s, to discuss the implications of this finding, the results of which were later published (Maser & Cloninger, 1990). Later, the NIMH funded a large-scale epidemiological analysis of the occurrence of mental disorders in the United States in two research studies known as the National Comorbidity Survey (Kessler et al., 1994) and the National Comorbidity Survey Replication (Kessler et al., 2005). The results showed that virtually all mental disorders showed a high rate of diagnostic overlap with almost all other mental disorders.

Krueger and Markon (2006) have reviewed the resulting literature on the comorbidity of mental disorders. They noted that this term was rarely used before the mid-1980s when the Boyd et al. study was published, but that, in the next two decades, approximately 8,500 journal articles appeared of relevance to the concept of comorbidity.

#### THE MEANING OF COMORBIDITY

The issue of diagnostic overlap has been termed "comorbidity," although there are those who contend the term is a misnomer (Lilienfeld et al., 1994). Feinstein (1970) introduced the term "comorbidity" in the context of medical epidemiology. Later, Lilienfeld (2003) reported that Feinstein had never intended for the term to refer to all cases of diagnostic overlap, as seems to be its current usage in the literature. In general, one would expect a certain degree of overlap simply by chance. However, when disorders co-occur at greater than chance levels, the overlap begins to have implications for the classification system.

For example, a patient may present with a case of panic disorder and be concurrently depressed. On the other hand, a patient presenting with panic may have a comorbid diagnosis of ADHD. In these cases, it could be that depression and panic are meaningfully correlated; that is, the depression may cause the panic or vice versa, a third variable could cause both, or some alternative complex causal model could account for the relationship. However, when two co-occurring conditions are not meaningfully related but simply overlap by chance, as could be the case with panic and ADHD, that sort of comorbidity is of decidedly less theoretical interest. Given the base rates of disorders in the population, one would expect a certain number of cases to present with overlap just by chance. Hypothetically, if there were a 10% chance of having panic disorder and a 15% chance of having ADHD, one would expect a 1.5%  $(10\% \times 15\%)$  chance of having both conditions in the general population. However, epidemiological work on psychiatric disorders has shown that various mental disorders co-occur at a rate in the population much greater than that expected by chance (Boyd et al., 1984; Kessler et al., 1994, 2005).

When disorders co-occur at greater than chance levels, comorbidity begins to have implications for the classification system. As stated before, the authors of *DSM-III* and beyond have assumed that the categories in the classification are relatively discrete. However, if there is significant covariance between these conditions, that assumption of discreteness is untenable. For example, unipolar affective disorders and anxiety disorders co-occur at a very high rate. This finding has led some authors to contend that these disorders are not discrete conditions but varied expressions of a single disorder (Wilamowska et al., 2010). If that is the case, the current diagnostic system is not accurately "carving nature at the joints."

However, there are also artifactual reasons why disorders could co-occur at greater than chance levels. For instance, Berksonian bias (Berkson, 1946) states that a person with comorbid disorders has twice the chance of seeking treatment as does a person with a single disorder and so has a greater chance of being included in studies. Similarly, comorbidity rates may be overestimated because of clinical selection bias or because individuals with multiple disorders may be more impaired and thus overrepresented in treatment studies. However, significant rates of comorbidity occur even in communitybased samples (e.g., Kessler et al., 2005). Finally, it has been demonstrated that structured interviews generate much higher rates of diagnosis overall, and higher rates of comorbidity specifically, than do unstructured interviews (Verheul & Widiger, 2004; Zimmerman et al., 2005). However, such differences in diagnostic method may not be artifactual because structured interviews ensure that the breadth of psychopathology is assessed, whereas unstructured interviews address only salient points, and legitimate disorders may be overlooked.

Recently, increased attention has been paid to developing statistical models of comorbidity (e.g., Borsboom et al., 2011; Kotov et al., 2017; Krueger & Markon, 2006). Using sophisticated multivariate statistical methods, it is possible to test potential causal models of comorbidity, thereby elucidating the structure of the classification of mental disorders and suggesting changes to the arrangement of the DSM. For example, there is increasing support for organizing both childhood and adult disorders along internalizing and externalizing spectra (Kotov et al., 2017; Krueger et al., 2005). Indeed, this approach led the creators of DSM-5 and ICD-11 to place internalizing groups of disorders (e.g., anxiety, depressive, and somatic disorders) and externalizing disorders (e.g., impulsive, disruptive conduct, and substance use disorders) sequentially next to each other in the organization of the manual (Krueger et al., 2011; Roberts et al., 2012).

A similar approach has argued that all mental health disorders share a common liability. A common finding in the history of psychopathological research is that a factor analysis of symptoms, disorders, or measurement scales will often result in a single factor—sometimes termed a "*p*-factor"—that seems to account for a substantial amount of the overlap in people's presentations (Caspi et al., 2014). There are multiple possible interpretations of this general factor, including but not limited to the distress felt by people with a mental disorder, a common genetic liability, and common social factors like stigma.

One approach to understanding comorbidity is that groups of disorders, diagnostic spectra, are more accurately classified together than as discrete disorders. Criticisms of the structure and organization of previous versions led DSM-5 and ICD-11 work groups to reconceptualize many sections of the manual. One area of controversy in the literature regards the distinctions among pervasive developmental disorders (i.e., Kamp-Becker et al., 2010; Klin & Volkmar, 2003). Pervasive developmental disorders have included diagnoses such as autistic disorder (AD), Asperger's disorder (AS), childhood disintegrative disorder (CDD), Rhett's syndrome, and miscellaneous categories. Since AD was first included in DSM-III-R (APA, 1987) and AS was first included in DSM-IV (APA, 1994), researchers have questioned the uniqueness of these diagnoses. The distinction between AD and AS was popularized by Wing (1981) when she coined the phrase "Asperger's disorder" to discuss symptoms first described by Hans Asperger (1944). Ironically, Wing (2000) later wrote that she did not intend to imply that AS and AD were distinct disorders. Regardless, varying conceptualizations of these diagnoses have been present since Asperger's 1944 description of what is now called Asperger's disorder and Kanner's 1943 description of autism.

Many researchers have since examined AS and AD to garner additional understanding of the etiology, symptoms, and potential differences in presentation between these diagnoses. Although some studies have proclaimed differences between AD and AS (i.e., Ghaziuddan & Gerstein, 1996; Paul et al., 2009; Szatmari et al., 2009), many researchers have concluded that there are no distinguishable or useful differences beyond variations in severity (i.e., Ozonoff et al., 2000; Rogers & Ozonoff, 2005; Szatmari et al., 1989). Subsequently, arguments for the combination of AD and AS into one spectrum diagnosis are prevalent (i.e., Miller & Ozonoff, 2000; Via et al., 2011). The *DSM-5* neurodevelopmental disorders work group created a new autism spectrum disorder (ASD) diagnosis that incorporates all individuals who previously held a pervasive developmental disorder diagnosis. Under this "umbrella" there will be a great deal of individualization in symptom presentation and functioning level. The *DSM-5* work group anticipated these variations and stated that individuals who meet criteria for ASD should additionally be described based on intellectual level and language ability.

The variation present in this example reflects many areas of psychopathological classification. When differences between two disorders are difficult to identify, it is possible that the disorders may actually be variable presentations of the same, broader diagnosis. Other spectra included in DSM-5 and ICD-11 include a disruptive behavior spectrum of impulse control disorders, conduct disorder, and oppositional defiant disorder; a spectrum of obsessive-compulsive disorders including things like body dysmorphic disorder and trichotillomania; and a psychotic spectrum including schizophrenia, schizoaffective disorder, delusional disorder, and schizotypal personality disorder. When the meta-structure of these disorders has been examined, externalizing and psychotic dimensions seem to emerge, supporting the notion of grouping these disorders (Wright et al., 2013). The relatedness within each of these potential spectra also represents the dimensionality of mental health disorders in general. Ultimately, the criteria for a clinical diagnosis are met at a cutoff that splits the dimension between normal functioning and each of the graded severities of the respective disorders (Bernstein et al., 2010). The next chapter, on diagnostic alternatives, will go into greater detail about the background, rationale, and research support for large-scale models that attempt to represent this overlap.

#### Conclusion

This chapter starts with the sentence "Diagnosis is simple." Approximately 17,000 words and 190 references later, diagnosis does not seem so simple. This chapter has focused on a taxonomic view of modern psychiatric classification. The organization of this chapter, just by itself, was a complex act of classification into topics, history, discussion of controversies, terminology, and reviews of the writings of others. We could have used quite different organizational principles to structure our chapter. For instance, we could have written the chapter with a chronological structure moving from one *ICD* and DSM edition to another. We could have organized the chapter by professions—what psychiatrists have written about classification, what psychologists have said, what philosophers have written, etc. We could have focused on the prominent individuals in the classification literature: Kraepelin, Menninger, Spitzer, Zubin, Lorr, Frances, Robins, etc. We could have emphasized diagnostic concepts that have been controversial and why: dementia praecox, neurosis, homosexuality, premenstrual syndrome, narcissistic personality disorder, masochistic personality disorder, online gaming addiction, etc.

Like most "simple" topics, when thought about carefully, diagnosis becomes complex. Our organization of this chapter represented our view of a controversial but important area of concern regarding how knowledge about psychopathology is organized. It is important for the reader of this chapter to note that the problems and dilemmas enumerated here have no easy resolution, if a resolution is even possible. No "perfect" approach to classification exists. Each attempt has its own flaws and limitations. The task of the mental health field is to determine which classificatory scheme best matches the values and goals of the discipline and would be the most useful for their purpose. But perhaps it is even more important to recognize the limitations of the system because it is all too easy to accept a classification system as "given." We hope this chapter will not only inspire a healthy skepticism regarding the traditional nosological systems but also help the reader to appreciate the necessity and importance of classification within the mental health field.

#### Acknowledgments

We would like to thank Danny Burgess, Hannah Morton, and Roger Blashfield for their work on previous versions of this chapter.

# Historical and Philosophical Considerations in Studying Psychopathology

Peter Zachar, Konrad Banicki, and Awais Aftab

#### Introduction

In this chapter, our account of historical and philosophical considerations in studying psychopathology emphasizes how, across the ages, psychopathologists have grappled with whether a descriptive or hypothetical-conjectural approach best promotes the advancement of knowledge. To explain what we mean by this, let us explore a related but distinct contrast—that between syndromic versus causal/ etiological approaches.

The syndromic approach has typically relied on descriptions of surface-level phenomena (i.e., signs and symptoms) and is referred to as "descriptive" for that reason. Because the causes of psychiatric disorders have been poorly understood (and continue to remain so due to the complex nature of these conditions), the causal approach has been dominated by conjectural hypotheses for the most part. The contrast between syndromic and etiological approaches has therefore played out as a contrast between descriptive and conjectural approaches, but this is not always the case. Syndromic approaches can be conjectural (e.g., the syndromic entity of "hysteria" is widely contested), and etiological approaches can be descriptive (e.g., reporting that syphilis is the cause of general paresis).

In fact, whether we consider something a description or a conjecture is a theoretical issue that depends on background assumptions. Consider Galileo Galilei's (1564–1642) description of the four moons of Jupiter. What Galileo saw through his telescope were points of light near the planet Jupiter, which he initially considered to be distant stars. He soon realized, however, that the movements of these points of light did not match the movements of the stars. In his model of

the galaxy, the stars do not move relative to each other because they are all very far away. Jupiter does move relative to the stars because it is a planet within our solar system and relatively close to us. These four points of light were also moving relative to the stars and remaining within proximity of Jupiter. In Galileo's model of the solar system, as one planet orbiting the Sun—the Earth—has a moon, other planets could have moons as well. Galileo concluded that the four points of light are moons of Jupiter.

Some of Galileo's contemporaries were not persuaded that these points of light could be described as moons-in part because they had doubts about using telescopes to view far distant events. Whether claims about the moons of Jupiter are considered more descriptive or more conjectural depend on various background theories about optics and the organization of the solar system and the galaxy. If you accept these theories, reports of moons orbiting Jupiter will be considered descriptions. The more agreement there is on the background theoretical assumptions, the less disagreement there is on "what" is being described. This suggests that what are considered "descriptive" approaches to psychopathology are approaches where there has been comparative agreement among multiple parties regarding the background assumptions.

One can also look to history to see how the lines have shifted. In the 1950s, the Freudian theory of the Oedipus complex was widely accepted and reporting that a patient has Oedipal conflicts would have been treated as a description. In one version of the Oedipal situation, a young boy has a strong attachment to his mother and may see his father as a rival. According to the Oedipus complex theory, this tension is resolved if the boy forgoes a special relationship with his mother as something unobtainable and identifies with his father. Today, there are still men who desire a seemingly unobtainable relationship and lose interest in it if they ever do obtain it in favor of a new hard-to-obtain relationship, but this is rarely described as an unresolved Oedipal conflict. The Freudian theoretical framework is no longer a taken-for-granted background.

New descriptions can also make previously unnoticed things apparent if their background assumptions are also accepted. For example, in the late 1970s, the conditions of being a Holocaust survivor who isolates himself from interpersonal attachments, a rape victim having flashbacks, and a combat veteran who has panic attacks when exposed to sudden loud sounds were all classified as posttraumatic stress disorder (PTSD) (Scott, 1990; Zachar & McNally, 2017). Once a conjecture that there are chronic, trauma-produced disorders became a background assumption, it became apparent that these different conditions were all variations of the same phenomenon.

Others, however, believe that describing trauma as the cause of "PTSD" symptoms is an implausible conjecture. Instead, they argue that temperaments, personality traits, family history, and previous experiences with psychiatric distress can produce a range of disorders such as depression, addiction, and personality disorders. In their view, these disorders can all be associated with nonspecific symptoms such as feeling estranged from others, diminished interest in pleasure, and sleep problems, which in many cases are incorrectly being described as PTSD and "explained" by a faddish assumption of how the mind deals with trauma (McHugh & Treisman, 2007).

Conjecture, importantly, can take us beyond what is readily apparent—with the goal being that the conjectures of today articulate the descriptions of tomorrow. Throughout the history of psychopathology, however, when conjecture was seen as taking us too far beyond anything apparent in an agreed upon sense, there were calls to limit claims to what are more readily considered to be descriptions. When someone believes a conjecture is too tenuous, they may say "don't speculate, just describe."

In this chapter we will follow a tug of war between description and conjecture from the seventeenth to the early twenty-first century. More recently, some opposition has arisen to the descriptive psychopathology model of the *DSM-III* and its successors—with a renewed focus on discovering the hidden causes of disorders. This raises questions about the nature of causality and the relationship between mind and body, which we will briefly explore. We conclude the chapter by looking at how more descriptive versus more conjectural commitments continue to assert themselves in the study of psychopathology in the contrast between scientific realism and scientific anti-realism.

# A Tug of War Between Description and Conjecture

Our account begins with what historians such as Porter (1987) call the "long eighteenth century," which encompasses developments in the seventeenth century associated with the beginning of modern philosophy and the culmination of the Scientific Revolution. In England, the Scientific Revolution's center of gravity was the Royal Society of London.

Medical knowledge was an important focus of the Royal Society (Porter, 1989). One of the most revered physicians of the day, Thomas Sydenham (1624–1689), was never invited to join the Royal Society due to his cantankerous personality. He was, however, close to two Royal Society luminaries, the chemist Robert Boyle (1627–1691) and the philosopher John Locke (1632–1704). Locke was also a physician, and both he and Boyle joined Sydenham at the bedside of Sydenham's patients (Anstey, 2011; Cunningham, 1989). These three thinkers mutually influenced each other and, as conveyed through the writings of Locke, introduced the philosophy of empiricism.

*Empiricism* is often defined as the view that all knowledge begins with experience and therefore there are no innate ideas, but this definition does not fully capture empiricism in the philosopher's sense. Prior to making claims about the role of experience and observation, the empiricists were skeptical about hypothetical notions such as the Divine Right of Kings and Papal Infallibility. In the seventeenth century, people were killing each other over such notions. By emphasizing the importance of being verified in experience, the empiricists could relegate these conjectures to the domain of an unverifiable "metaphysics."

Empiricism as a philosophy has evolved over the centuries (Quine, 1951; Sellars, 1956; van Fraassen, 2002). This includes abandoning the view that our knowledge of the world is grounded in observation alone. Contemporary empiricism acknowledges that observation occurs in cooperation with background assumptions. Two features, however, are shared by empiricists across the ages, and these features should be kept in mind when we refer to empiricism throughout the rest of the chapter. These are:

- a. Experience is partial, so our knowledge about the world is provisional and potentially revisable.
- b. Our proclivity for making conjectures can result in the adoption of strong commitments to abstract concepts, such as immortal souls, special life forces, and Oedipal conflicts, that are remote from any consideration of fact.

# From Speculative to Descriptive Medicine (Seventeenth Century)

The Scientific Revolution dismantled the dominance of Aristotelian philosophy in the scholarly community. Its target was not only Aristotle's (*384– 322 BCE*) theories of motion used in astronomy and elsewhere but the speculative Aristotelian essentialism. For Aristotle, the essence (or nature) of a thing is what makes something be what it is. Aristotelians believed that human beings possess a specific intellectual faculty for knowing essences.

In seventeenth-century medicine, the dominant perspective was called the *Galenist tradition*. The Galenists explained health and disease with respect to the theory of the four humors, specifically blood, phlegm, yellow bile, and black bile. According to this theory, having the right balance of humors was the essence of health, imbalance the essence of disease. For instance, excessive black bile was associated with melancholia, excessive blood and yellow bile with mania. Treatments such as bloodletting, purgatives, and emetics aimed at restoring balance.

The theory that diseases are due to humoral imbalances has been rejected by medical science. Furthermore, nothing in modern physiology corresponds to black bile. The notion that these conjectures about the essences of disease were mistaken and therefore not about anything real raises the question about the relation between scientific conjectures and reality in general. We return to this issue in the final section of the chapter.

In contrast to the conjectural approach of the Galenists, Sydenham favored using trial and error to discover which treatments work (Bynum, 1993;

Cunningham, 1989). Much of Sydenham's practice involved working with epidemics, such as smallpox. This gave him an opportunity to see large numbers of cases during outbreaks and describe what is called the *natural history of diseases.*<sup>1</sup> In addition to symptom presentation, these natural history descriptions included identifying precipitants and time courses. They also included noting the effects of interventions and experiments.

The Galenist physicians of the day criticized Sydenham for adopting this nontheoretical, practical approach, accusing him of being aligned with the quack doctors who relied on their own experience to treat symptoms rather selecting treatments to counteract theoretically inferred humoral imbalances (Wear, 1989). A common pejorative for these quack doctors was "empirics."

Working closely with Sydenham, Locke (1689/ 1997) famously introduced a distinction between real essences (hidden natures) and nominal essences (observable features we use to identify kinds) and argued that, for things like diseases, we do not know real essences, only nominal essences. For Locke, natural history descriptions did not eschew causes, only conjectures about ultimate causes and essences. Sydenham, for example, emphasized less speculative proximate causes. This is illustrated in Sydenham's (1682) essay on hysteria, which he believed to be a family of different symptom presentations shared by women and men.

It would take up too much time to enumerate all the symptoms belonging to hysteric diseases; so much do they vary, and differ from each other. . . . Nor do they only differ so greatly, but are so irregular likewise, that they cannot be comprehended under any uniform appearance, as is usual in other diseases; but are a kind of disorderly train of symptoms, so that 'tis a difficult task to write the history of this disease. The *Procatarctic* [i.e., predisposing], or *external causes* thereof are either violent motions of the body, or, more frequently some great commotion of mind . . . either of anger, grief, terror, or the like passions. (p. 223)

In addition to describing the relevant proximate causes of hysteria, this quote from Sydenham illustrates another important feature of seventeenthcentury medicine: its awareness of what Porter (1987) called the *protean* nature of psychiatric

<sup>&</sup>lt;sup>1</sup> As with most thinkers in this period, innovations were gradual and Sydenham held a mix of older and new ideas, including humoral notions.

problems. By "protean" Porter meant that, for any one person, what symptoms he or she experiences can be continually changing and fluid. Melancholia, mania, hysteria, and hypochondriasis could merge into each other as the symptom picture shifted. Complicating the job of the historian, the concepts of the seventeenth century had only passing resemblances to our current concepts. For example, hypochondriasis was the male version of hysteria. Jointly, hysteria and hypochondriasis encompassed many internalizing symptoms: depressions, anxieties, phobias, traumas, and somatic concerns.

## From Immortal Souls and Disturbed Bodies to Disturbed Minds (Eighteenth Century)

The first half of the eighteenth century was not much different than the last half of the seventeenth. In these years, many new descriptions of diseases were articulated, but reliance on conjecture continued unabated in medicine (Ackerknecht, 1982). During this time period there were genuine advances in the natural sciences, but attempts to apply them to medicine, called *iatro-physics* and *iatro-chemistry*, consisted in conjectures about nerve vibrations and intestinal fermentations—shifting from humors to anatomy, but still mostly conjectural.

The eighteenth century also saw the rise of fashionable nervous diseases in works like George Cheyne's (1672–1743) monograph of 1733, *The English Malady*, the focus of which was hysteria, hypochondriasis, and melancholia. Cheyne did not work in a mental asylum; rather, he was a society physician or "spa doctor," tending to the affluent (Shorter, 1997). These difficulties became fashionable in part because they were more likely to manifest in those who were prosperous.

We cannot assume that the people living in past centuries shared the same background assumptions about the mind and its disorders that we do. Suzuki (1995) argued that the concept of mind that was dominant during the seventeenth and early eighteenth century was intimately associated with the soul, which was considered to be immortal and therefore not subject to decay and disease. The body, however, as a window to the soul, was not immortal and could become diseased. This meant that mental faculties considered essential to human nature, such as reason and judgment, remained intact but could be indirectly affected by illusory sensory images produced by lower faculties such as imagination and memory which were directly affected by alterations in the body.

For hysterical complaints in women, one popular conjecture was that the womb gave off toxic vapors—indeed suffering from "the vapors" became a common diagnosis. Likewise, melancholic and hypochondriacal men were said to be suffering from "the spleen." Various notions about the gastrointestinal nature of hysteria and hypochondriasis persisted even into the next century. In Charles Dicken's (1812–1870) novella A Christmas Carol, published in 1843, when Marley's ghost asked Scrooge why he doubted his sense experience, which clearly indicated that Marely was sitting there before him, Scrooge replied,

Because . . . a little thing affects them. A slight disorder of the stomach makes them cheats. You may be an undigested bit of beef, a blot of mustard, a crumb of cheese, a fragment of an underdone potato. There's more of gravy than of grave about you, whatever you are! (pp. 20–21)

#### And later, Scrooge says,

You see this toothpick?"... I have but to swallow this, and be for the rest of my days persecuted by a legion of goblins, all of my own creation. Humbug, I tell you! Humbug! (p. 21)

The Enlightenment movement in the eighteenth century was a cultural phenomenon too diverse to be adequately described here. Besides spawning both the American and French Revolutions, the Enlightenment advocated for a thoroughgoing naturalism. By *naturalism*, we mean Enlightenment thinkers began banishing theological and supernatural assumptions from science in a way that would have been shocking to seventeenth-century Christian thinkers such as Boyle and Locke.

During the Enlightenment, references to the soul became optional, even questionable, and an important change occurred in which the mind was no longer co-extensive with an incorruptible soul. The mind became naturalized. After this separation, it became theoretically possible for the mind itself to be directly diseased (i.e., a concept of actual *psychopathology* was introduced). Suzuki (1995) has suggested that in this new psychological model, rather than illusory sensory images being presented to an intact faculty of reason, a directly disturbed faculty of reason actively misperceived intact sensory images.

With this new concept of mental disorder came the potential for specialization. As Porter (1987) argued, throughout eighteenth century, private asylums were established with care varying from poor to quite good and humane. Many physicians used their own homes to supplement their incomes and, over time, came to think of managing mental disorder as their area of expertise. As early as 1758, William Battie's (1703–1776) Treatise on Madness argued that hospitals for the insane should be asylums that promote recovery, not warehouses where patients are locked away and chained up. This approach came to be known as "moral treatment," where moral treatment primarily in this context meant humane and psychological.

Histories of psychopathology usually describe moral treatment as a revolutionary development introduced in the 1790s at the York Retreat in England and by Phillipe Pinel (1745–1826) in Paris. Porter (1987), however, claimed that the York Retreat and Pinel's reforms are better seen as banging the drum about an important change in outlook that had already been occurring for some time. Within the medical profession, this change was likely irreversible when, in 1788, the physicians of King George III of England (1738–1820) admitted that they had failed to cure his debilitating mental problems and turned his treatment over to private asylum physicians who specialized in mental disorder.

# The Development of a Descriptive Clinical Science (Nineteenth Century)

In the first part of the nineteenth century, optimism about the therapeutic value of the asylum resulted in new institutions being founded throughout Europe. With the opportunity to observe large numbers of cases, many new descriptions of disorders were articulated. These included descriptions of "partial insanity" conditions such as paranoia and obsessiveness that were not as severe as the cases of mania and dementia treated by the asylum doctors but were more serious than the hysteria and hypochondriasis treated by the spa doctors. By midcentury, the asylums were asked to accommodate more patients than they could handle-especially patients with severe problems. As chronic cases increased, the asylums ceased to be therapeutic environments, and became warehouses.

The growth of asylums occurred at the same time that German and Austrian countries invented what we would recognize as the modern research university. By *modern research university* we mean one that trains graduate students and postdoctoral students to be producers of knowledge. Prior to the Franco-Prussian war which resulted in the unification of Germany in 1871, the German Confederation was made up of more than 40 independent states, many of them with their own flagship university. Professorships were prestigious appointments, and the competition for them was stiff. To even teach as an adjunct (or *privatdocent*), one had to complete a habilitation thesis (i.e., sustained postdoctoral scholarship demonstrating one's ability to make an independent contribution to the knowledge base). Due to this institutional structure, the German research universities became hotbeds of scholarly activity.

Several new departments of psychiatry were created at this time and, after mid-century, began establishing their own clinics—a trend initiated in 1865 by the Berlin psychiatrist Wilhelm Griesinger (1817–1868). After the unification of Germany, the leading research psychiatrist of his day was Theodor Meynert (1833–1892) at the University of Vienna (and one of Sigmund Freud's most admired mentors). University psychiatrists such as Meynert viewed asylum patients as incurable and had no interest in clinical practice or promulgating psychological descriptions (Shorter, 1997). They were academics searching for the anatomical causes of diseases. As Meynert wrote,

The study of human anatomy in its current form has passed from a solely descriptive science to something higher, to a form of knowledge that attempts to explain. (quoted in Shorter, 1997, p. 77)

Asylum doctors opined that the researchers were interested in brain tissues, not people. The academics, an elite group, disparaged the scientific/medical qualifications of the asylum doctors and saw them as standing in the way of progress (Harrington, 2019).

Meynert and his students' search for the pathological anatomy of mental disorders did not succeed. Thus, beginning in 1896, Emile Kraepelin (1856-1926) reemphasized natural history descriptions in contrast with what he considered the conjectural brain mythology of the Meynert school. Kraepelin studied with Wilhelm Wundt (1832-1920), who is widely considered the founder of scientific psychology (Engstrom & Kendler, 2015). The reason most of the credit for founding the discipline of psychology is attributed to Wundt is that he started a journal, founded a lab to train doctoral students, and wrote textbooks. Kraepelin argued that Wundt's new experimental psychology was natural science. Psychiatry, Kraepelin believed, was a clinical science—a science of psychopathology. It should draw on the biological sciences but its descriptions

should also be consistent with the new science of psychology.

As noted above, during these years, hysteria and hypochondriasis referred to broad collections of depressions, fears, somatic concerns, emotional lability, and so on. In the asylum setting, the category of mania, encompassing delusions, agitations, paranoia, obsessions, and impulsivity, was also broader than it is today. In the 1860s, the private asylum doctor Karl Kahlbaum (*1828–1899*) claimed that these broad categories were merely symptom clusters—transient combinations of symptoms that are nonspecific and cut across different diseases (Kendler & Engstrom, 2017). The goal of psychiatrists, argued Kahlbaum, should be to delineate the natural disease forms in which symptoms manifest.

In this notion of natural disease forms we see conjecture, but conjecture that is grounded in a clinical description, specifically the description of general paresis of the insane. General paresis was the most prevalent mental disorder in late nineteenthcentury asylums. Its symptoms included personality changes, mood disturbances, and delusions. Ninety-one years before general paresis was confirmed to be the result of untreated syphilis, it was demarcated as a distinct disease entity using natural history descriptions alone. Epilepsy, tuberculosis, and smallpox were also demarcated by natural history descriptions, not conjectures about causes.

Unlike other university psychiatrists, Kraepelin was not hostile to the asylum doctors, and his career-spanning goal was to describe natural disease entities (Heckers & Kendler, 2020). He also argued that symptoms are nonspecific but can be grouped with respect to shared course, treatment, and outcome. This natural history approach resulted in the famous Kraepelinian dichotomy of dementia praecox (i.e., schizophrenia) featuring a deteriorating course, and manic depressive illness featuring a recurrent course (Kraepelin, 1907).

In Kraepelin's view, natural disease entities continually manifest heterogeneity and lack of specificity at the symptom level, in part due to the randomizing influence of individuals' reactions to distress (i.e., personality) (Hoff, 2003). To accurately identify the disease entities, Kraepelin proposed that clinical description needs to converge with etiology (e.g., head injury or extreme stress) and an underlying pathology (e.g., degenerating nerve cells).

Bentall (2003) called this Kraepelin's "big idea." Kraepelin believed that an accurate descriptive classification would lead the way to etiology and pathology, and vice versa. Each is like one part of the Rosetta Stone, upon which the very same message was written in three different but still mutually translatable languages.

# The Unity of Science Project and the Methodenstreit

Kraepelin's notion of a convergence between description, etiology, and pathogenesis expresses another development in nineteenth-century philosophy, called the *unity of science project*. The unity of science project is typically traced back to the *Positivist* movement as elaborated by its founder August Comte (1798–1857) in the mid-nineteenth century (Comte, 1856; Kolakowski, 1969).

Comte proposed a hierarchy of scientific disciplines, ordered by decreasing generality and increasing complexity. He began with mathematics at the base of the hierarchy, which deals with quantities only and is thus the most general and least complex of the sciences. Second are disciplines focused on the inorganic world, such as astronomy, physics, and chemistry. Next are all the sciences investigating the living domain, such as biology and ecology. Finally, Comte placed sociology at the top of the hierarchy. Neither psychology nor psychopathology was included in Comte's list. We can speculate that both would have a foot in biology but, from this grounding, also have a hand raising up to grasp sociology.

Kolakowski (1969) called attention to the historical dimension of Comte's hierarchy in which it takes longer for more complex sciences to reach a mature, or "positive" stage of development, especially since they must depend on results achieved by their simpler predecessors. From this perspective, to describe psychiatry, psychology, or psychopathology as immature sciences implies that their subject matter is more complex than the subject matter of more mature sciences.

At roughly the same time that Comte developed his positive philosophy, John Stuart Mill (1806– 1873) published A System of Logic (Mill, 1843/ 2015). Firmly rooted in the tradition of British empiricism, Mill claimed that any genuinely scientific claim must be based on the content provided by observation, which is extended by the method of induction. With induction, observations of particular events form the basis for inferring general maxims and laws. For instance, one can observe that a copper penny conducts electricity, that a copper coil conducts electricity, and that a copper wire conducts electricity and infer the law-like statement that all copper conducts electricity. Mill considered induction to be a universal method common to all genuine sciences.

According to Mill, the "moral sciences" could also become genuine inductive sciences even though what kinds of laws might explain such complex domains remained hidden. Similar to how moral treatment in the late eighteenth century meant "psychological" treatment, for Mill moral sciences meant "sciences of the mind."

### The European Methodenstreit

As noted above, one of the contributions of the Enlightenment was deemphasizing the importance of an incorruptible soul, thus making the notion of a diseased mind potentially less controversial. This, however, was not a sudden transition. Particularly in Germanic countries, in the early part of the nineteenth century the importance of soul, spirit, and a special life force persisted. In part, this persistence of the spirit was defended by a romanticist movement that resisted the notion of an all-encompassing scientific method that brought everything under its scope. This led to a reaction in the middle part of the century in which the romanticist approach was criticized as too conjectural. A purely physical, natural science approach was promoted in its place.

In the latter part of the nineteenth century, some thinkers came to believe that the natural scientists who rejected romanticist attachments to the notion of spirit had thrown a baby out with the bath water. This led to yet another reaction, known as the *Methodenstreit* (methodological dispute). The goal of the *Methodenstreit* thinkers was not to preserve and defend romanticist notions of spirit and life forces but to justify some autonomy for the human sciences while still attributing to them a genuinely scientific form of rationality. For them, the human sciences included history but also cultural studies and psychology.

One important thinker in this tradition was the historian Wilhelm Dilthey (1833–1911) who distinguished between the Naturwissenschaften (natural sciences) and Geisteswissenschaften (human sciences). These two distinct sciences, he believed, differed in terms of their subject matter, respectively, the physical versus the mental (subjective, lived experience). They also differed in terms of their proper methods, respectively, explanation (Erklären) based on causal, deterministic, and law-like connections for the natural sciences versus understanding (Verstehen) based on meanings, goals, and values for the human sciences.

We will say more about this latter distinction shortly when we describe the work of Karl Jaspers.

A different approach was taken by Wilhelm Windelband (1848–1915) who distinguished between *nomothetic* and the *idiographic* methods which can be used to study the same phenomena. To oversimplify, this distinction is mirrored in the contrast between a research study in which different samples (of persons) are compared to each other and a case study of one person.

In adopting a nomothetic approach, one seeks to discover generalizations that apply to entire classes. For example, one factor that makes people in general more vulnerable to alcoholism is a tendency to discount future rewards such as a promotion at work in favor of short-term rewards such a night of drinking with friends (Petry, 2006). Another general theory of alcoholism is that the brain circuitry that mediates "liking" is different from the circuitry that mediates "wanting." This explains why alcoholics continue to drink, wanting and craving ever more, even when the drink no longer affords them pleasure (Berridge & Robinson, 2016).

In contrast, with an idiographic approach one studies particular entities in time and space. Idiographic accounts can be thought of as descriptions in a natural history sense, but they are also potentially interpretive. An example of an idiographic approach would be a case study of how someone named Walker developed alcoholism. It might include a natural history description of his family history, his history of increasing alcohol use, and the consequences his drinking has for him and his family. More interpretively, it could also assert that the men in the Walker family have been heavy drinkers going back to the 1800s, and our Walker has incorporated this into his identity, believing that drinking is what real Walker men do.

By the latter part of the nineteenth century, as John Stuart Mill foresaw, it had become indisputable that psychology and related disciplines should aspire to the status of sciences, but it was less clear which methodological approach should be adopted. The *Methodenstreit* constituted a background against which the new disciplines of psychology, psychiatry, and psychoanalysis attempted to justify their status as genuine sciences.

With respect to the influence of the *Methodenstreit* on the philosophy of psychopathology, Karl Jaspers (1883–1969), through his book *General Psychopathology*, remains a dominant reference, especially in Europe. Let us briefly look at what Japsers had to say.

## Karl Jaspers: Methodological Pluralism for Psychopathology (Twentieth Century)

Jaspers (1968/1997a, 1968/1997b) hoped to integrate a scientific approach to psychiatry with the traditional humanities. Rather than limit psychopathology to one methodological approach alone, he sought to make room for different perspectives (i.e., both the nomothetic and idiographic). Studying things from more than one perspective is called *pluralism*. Jasper's precondition for being pluralistic about methodological perspectives is that the employment of any method should be accompanied by a recognition of its background assumptions, justification, and proper domain.

The framework of methodological pluralism is important for thinking about Jaspers' two most frequently discussed contributions to psychopathology: the application of Dilthey's *Erklären* (explanation) versus *Verstehen* (understanding) distinction and the employment of the sociologist Max Weber's notion of *ideal types* (Hoerl, 2013; Schwartz et al., 1989; Wiggins & Schwartz, 1991).

The *explanation versus understanding* contrast calls attention to different kinds of connections that can manifest in clinical phenomena. The first are causal and ideally law-like connections. One example would be the connection between tangles and plaques in the brain and the manifestation of Alzheimer's type dementia. Jaspers believed that these connections are revealed through an inductive method founded on repeated experience with many cases. What is expressed by such connections is *explanation*.

The second kind of connections are meaningful ones. Understanding meaningful connections depend on "empathy," consisting of a reenactment in one's imagination of the other person's mental life. "We sink ourselves into the psychic situation," as Jaspers (1968/1997a) said, "and understand genetically by empathy how one psychic event emerges from another" (p. 301). For example, returning to the example of Walker, we might understand how his failed business and the meaning of that failure for him, related to his father's business failures many years earlier, are part of the context for his most recent episode of depression. Understanding refers to seeing connections that are more individualist than the general connections of law-like causal explanations. For Jaspers, both ways of comprehending clinical phenomena are important.

Jaspers also thought that thinking in terms of *ideal types* could expand and enrich the conceptual repertoire of psychopathology. The ideal-type

framework had been originally developed within sociology and was intended to express a kind of blended nomothetic-idiographic perspective, serving as a conceptual vehicle "for the scrutiny and systematic characterization of *individual concrete patterns* which are *significant in their uniqueness.*" (Weber, 1949, p. 100, emphases added).

An ideal type, be it historical, sociological, or psychopathological, is always rooted in observation of a particular phenomenon, which is then made abstract by leaving out some of the details. For Jaspers, the ideal type is different from the average or the general type in a statistical sense (Fulford, Thornton, & Graham, 2006). The ideal type consists of those aspects of a particular phenomenon "that are *the most striking* . . . *the most unique* or *interesting*" (Ghaemi, 2003, p. 179, emphases added).

To illustrate, if borderline personality disorder (BPD) is thought of as an ideal type, it becomes a tool for thinking about a particular person that calls your attention to features of the case that are important for your goals and purposes. In the *DSM*, borderline personality disorder is a general diagnostic concept, but used as an ideal type it would also be an understanding of how a single person is borderline without reducing that person to the diagnosis. An important feature of the ideal type framework is that even the most optimally chosen ideal type will never exhaust the infinite complexity and richness of the individual phenomenon (i.e., the person).

According to Jaspers, ideal types have a relatively limited application, being relevant for psychiatric disorders that cannot be conceptualized as disease entities or general clinical syndromes. This claim can be best understood in the context of Jasper's notion that psychiatric conditions can be divided into three groups:

- 1. *Somatic entities*, such as brain tumors and Alzheimer's disease, that display mental symptoms
- 2. *Psychological and developmental syndromes* covering easily recognizable major psychoses like bipolar disorder and schizophrenia
- 3. *Psychopathies (Psychopatien)*, referring more or less to personality disorders and neuroses (i.e., anxiety, depression, somatic concerns, etc.)

Jaspers (1968/1997b) conceived of these three classes as "essentially different from each other" without prospects for a "single unifying and

comprehensive viewpoint from which any systematic ordering . . . could emerge" (p. 610).

In Jaspers's view, somatic entities did not pose methodological challenges because their etiology and underlying pathology had been identified and they seemed to form classes in which membership is clear. He considered the psychoses to be syndromes that, like general paresis before them, look like disease forms even though etiology and underlying pathology have not been adequately identified. With respect to personality disorders and neuroses, Jaspers thought that it was better not to conceptualize them as disease forms. Indeed, they may be so entwined with a person's individuality that to label them as diseases might even be insulting. Instead, Jaspers recommended employing the framework of ideal types.

# Freud and Psychoanalysis: A Different Reaction to the Methodenstreit

As noted above, thinkers such as Meynert believed that psychiatry should be an explanatory, natural science. Before he decided to take a degree in medicine, Sigmund Freud (1856–1939) was a scientist in the physiological lab of Ernst Brucke (1819–1892), who was one of the leading anti-romantic scientists of the mid-nineteenth century. During his medical training, Freud worked with Meynert. This pedigree was important to Freud, and he always contended that psychoanalysis was one of the natural sciences.

A few years before he introduced psychoanalysis in his famous book the *Interpretation of Dreams* (1900/1953), Freud (1895/1965) wrote a manuscript (published posthumously under the title of *Project for a Scientific Psychology*) in which he proposed a clinical science founded in study of neurology. However, as his actual clinical work evolved into psychoanalysis proper, he employed a more narrative-based, conjectural approach. For Freud and his followers, many of these conjectures became taken-for-granted background assumptions (e.g., the Oedipus complex and repressed unconscious mental processes).

Freud himself failed to acknowledge this transition and continued to describe psychoanalysis as an explanatory, natural science. This led to the criticism that psychoanalysis did not substantiate its claim to being genuine science and instead rested on case studies and unsupported conjectures. The critics included Kraepelin and scholars in both psychology and the philosophy of science (Dalzell, 2018; Gellner, 2008; Popper, 1963). Also a critic, Jaspers claimed that Freud mistook his understanding of meaningful connection in his patients' lives as general casual connections in the nomothetic sense (Kräupl Taylor, 1987).

An important feature of the early history of psychoanalysis was Freud's belief that sexuality from infancy and beyond is the primary source of human motivation. By infantile sexuality, Freud meant pleasure based on the experience of the body in the first few years of life (Sulloway, 1979). For Freud the most important causes of behavior were desires for pleasure that were not accessible to consciousness but operated nevertheless. Freud saw sexuality as a biological phenomenon and believed that by rooting motivation in biology, psychoanalysis could maintain its link with the medical sciences. Throughout his career, he resisted any attempts to deemphasize the importance of sexuality. After Freud died 1939, however, psychoanalysis evolved, especially in Britain and the United States. Two of the most important developments were ego psychology and object relations theory.

Ego psychology incorporated a model of healthy personality functioning, placing increased emphasis on conscious adaptation to reality but staying committed to the importance of biologically based drives for human motivation (Blanck & Blanck, 1974; Erikson, 1950; Hartmann, 1958). Psychoanalytic ideas about defense mechanisms such as projection and repression were elaborated on by ego psychologists. Object relations theorists, in contrast, rooted human motivation in the psychological need to establish relationships and emphasized how representations of self and other develop (Fairbairn, 1952; Klein, 1964; Winnicott, 1965). Attachment theory in developmental psychology originated in the object relations tradition (Ainsworth & Bowlby, 1991; Bowlby, 1969).

Despite a shared willingness to extend Freudian ideas, ego psychological and object relation theorists were also keen to trace their ideas back to Freud himself, and the two camps battled over which of them were the more legitimate Freudians (Greenberg & Mitchell, 1983). Partly due to the ego psychological and object relations theorists continued commitments to various Freudian background assumptions, critics continued to evaluate their clinical descriptions as too conjectural.

In the 1950s, psychoanalysis became the dominant force in American psychiatry, with most major university psychiatry departments being led by psychoanalysts and training models being psychoanalytically oriented. Rather than the profession operating under a shared psychoanalytic paradigm, however, theoretical disputes between warring camps continued.

In the next section we will see the beginning of a transition that occurred in US departments of psychiatry in which biologically oriented psychiatrists assumed control of the institutional reins (Harrington, 2019; Luhrmann, 2000). Although the shift in institutional control happened suddenly, it would be a mistake to conclude that the psychoanalysts' influence disappeared.

For example, both borderline and narcissistic disorders as disturbances in the structure of the self were described as part of a détente between ego psychological and object relations theories in the late 1960s and early 1970s (Kernberg, 1969, 1975; Kohut, 1971). Borderline disturbances involve a failure to modulate strong positive and negative views of self and others. Narcissistic disturbances involve modulating negative emotions by adopting a grandiose view of the self.

Borderline and narcissistic disturbances were incorporated into the *DSM-III* in 1980 as specific personality disorders and have been included in each subsequent manual. In general, psychoanalytic perspectives tend to view all kinds of psychopathology (including depression and schizophrenia) as expression of personality. In 2013, the Alternative *DSM-5* Model for Personality Disorders included disturbances in self and interpersonal functioning as one of the essential features of any personality disorder, drawing on research conducted from object relations perspectives (Bender et al., 2011).

Over time, as borderline and narcissist disturbances have become more detached from psychoanalytic conjectures, they are increasingly viewed as descriptively valid (Beck et al., 2004; Linehan, 1993; Millon et al., 2009). They have also been important targets of scientific research, especially borderline disturbances (McGlashan et al., 2005; Pincus & Roche, 2011; Skodol et al., 2005; Zanarini et al., 2003).

## **Rethinking Causation in Psychopathology**

Beginning in the early 1970s, a group of psychiatrists at Washington University in St. Louis sought to replace the conjectures of the psychoanalytic model with a more research-oriented and biomedical model. The challenge was that previous iterations of the biomedical approach to psychiatry were mostly conjectural. Led by Eli Robins (1921–1994) and Samuel Guze (1924–2000), they argued that the reason psychiatry had not made progress in developing a biologically grounded nosology was because its psychoanalytically based descriptions were too conjectural and inadequate to the task. They began, therefore, with redescribing clinical syndromes based on observable signs and self-reported symptoms only, without making inferences about unconscious processes (Feighner et al., 1972; Robins & Guze, 1970).

Just as Kraepelin explicitly emphasized both the symptomatic/descriptive level and the importance of etiology and underlying pathology, Robins and Guze (1970), labeled as *neo-Kraepelinians*, supplemented natural history descriptions with laboratory findings (endophenotypes and biomarkers) and family studies (i.e., genetics) with the hope that they could eventually explain disorders. Like Kraepelin, Robins, and Guze thought that description, etiology, and underlying pathology should ultimately converge.

At about this same time, Robins began working with the psychiatrist Robert Spitzer (*1932–2015*) and the psychologist Jean Endicott (b. 1936) to develop a set of diagnostic criteria for use in research (Spitzer et al., 1978). Spitzer was trained as a psychoanalyst, but his interest lay in developing ratings scales, and he worked closely with Endicott, who was trained in psychometrics (Decker, 2013).

Spitzer is best known for revolutionizing psychiatric diagnosis when, as leader of the *DSM-III* revision, he oversaw the implementation of an operational definition approach to psychopathology which used observable signs and self-reported symptoms as diagnostic criteria. This operational approach, which describes recognizable clinical features and minimizes the need to make theoretical inferences, is often called *descriptive psychopathology*.

Despite an initial alliance with Spitzer, the Washington University psychiatrists thought that Spitzer paid too much attention to making the *DSM-III* useful for practicing clinicians by including diagnoses such as borderline personality disorder (Decker, 2013). In their view, natural history descriptions could identify only 14 valid syndromes, and they believed that cases that could not be classified into one of these 14 categories should be coded as undiagnosed psychiatric illness (Feighner et al., 1972).

The diagnostic criteria and the list of disorders in the *DSM* were revised two more times before the end of the twentieth century (i.e., the *DSM*-*III-R* and the *DSM-IV*). By the beginning of the twenty-first century, doubts were building over the *DSM's* usefulness for promoting the advancement of knowledge.

The historian of psychiatry Berrios (2003) argued that the science of psychopathology is suffering because there is a mismatch between descriptive psychopathology and recent advances in neuroscience, with the descriptive landscape being much the same as it was 100 years ago. There are, he argued, many more potentially relevant symptoms than those contained in the current classification, but the descriptive project has been foreclosed and largely limited to accounts offered in the nineteenth century. He also noted that, despite the age-old importance of natural *history*, the current descriptive landscape is often cross-sectional, considering a single point and time rather than how symptoms develop, waxing and waning, over time.

Indeed, some psychiatrists argue that the *DSM* classifications have become barriers to progress. For example, Hyman (2010) reported that when he was director of the National Institute of Mental Health (NIMH), grant applications for studying the treatment of cognitive symptoms of schizophrenia had a difficult time winning approval because those symptoms were not listed in the *DSM* and had not been given an indication for treatment by the US Food and Drug Administration. Hyman claimed that the *DSM* criteria have been inappropriately reified, by which he means that, rather than seeing diagnostic criteria as provisional indicators of revisable concepts, they are treated like true identifying features of fixed entities.

Likewise, when he was the director of the NIMH, Insel (2013) argued that psychiatry cannot succeed in developing a classification based on biomarkers and cognitive deficits if the symptom-based diagnoses of the *DSM* remain the gold standard. According to Insel, scientists need to study not just how *DSM* symptoms cluster together, but also how genetic, imaging, physiological, and cognitive data cluster with symptoms as well. Insel here was responding to the premature closure of the symptom space on the part of grant reviewers after learning that grant applications for his new research domain criteria (RDoC) initiative had received low scores because they did not use *DSM* symptoms and/or categories (Zachar et al., 2019).

RDoC is a framework that seeks to focus research efforts not on discrete disorders, such as major depression (present vs. absent) but on dimensions of psychological functioning, such as negative emotionality, that span the normal and abnormal (from low to high). One criterion for a dimension to be included in RDoC is that it must have been shown to be implemented in a neural circuit. In fact, Insel specifically stated that mental disorders are biological disorders involving brain circuits. This conjecture, that mental disorders are brain disorders whose causes are to be discovered by neuroscientists, raises interesting philosophical issue about the nature of causation in psychopathology.

### Two Approaches to Causation in Psychopathology

The philosophical literature on causality is extensive and beyond the scope of our chapter. Pernu (2019) helpfully simplified the conceptualization of causality for psychopathology by distinguishing two broad clusters of philosophical views, which we will call production accounts and regularity accounts.

### PRODUCTION ACCOUNTS

Production accounts understand causation in terms of specific physical processes. These processes are continuous, unbroken chains of events connecting cause and effect, in which interactions between cause and effect involve energy transfer. The interaction of billiard balls is a common example of energy transfer. When one ball hits another ball and causes it to move, kinetic energy from the first ball is transferred to the second.

In medicine, production accounts take the form of *mechanistic models*. According to Craver and Darden (2013), mechanisms are "entities and activities with spatial and temporal properties organized to produce, underlie, or maintain a phenomenon" (p. 11). Mechanistic models take a process, decompose it into components, and then describe how those components interact to produce the process.

How an action potential is produced in a neuron is a common example of a mechanistic model. The components include sodium and potassium ions, gated protein channels, and a lipid membrane. These components interact to produce the action potential. This model is also an abstraction that ignores many particular features of neurons. For instance, although blood oxygen levels and membrane turnover are important features of neurons, they can be ignored when our goal is to describe the actional potential (Craver, 2009).

In mechanistic neuroscientific models, the task is to show how different parts of the brain interact to produce or maintain the disorder. For example, if we want to understand how the death of a child caused someone to grieve, with cause involving some kind of energy transfer, the grief reaction has to be decomposed into physical-neural parts that involve a transfer of energy.

#### REGULARITY ACCOUNTS

Regularity accounts are derived from empiricist suspicions of conjectures about things not observed. According to the empiricist philosopher David Hume (1711–1776), we observe that causes occur before effects, that causes and effects are conjoined in space and time, and that when the cause occurs, the effect follows (Hume, 1739/2000, 1748/2007). What we observe, says Hume, are regularities or dependencies between events—but we do not observe "causality" in terms of the cause *making* the effect happen.

One example of advocating for the Humean approach to causality in psychology can be seen in the work the behaviorist B. F. Skinner (1904–1990). As a commited philosophical empiricist, Skinner was suspicious about causation. He thus claimed that his work on operant conditioning only described the regularities that occur between behaviors and patterns of reinforcement (Skinner, 1953).

A more recent regularity account in the philosophy of science is Woodward's (2003, 2008) interventionist model. According to this view, if you make an intervention on X, and it is reliably followed by a change in Y, then X is the cause of Y. In this account, the reliability of the change often depends on the appropriate background conditions being present. For example, tackling someone to the ground will reliably be followed by a sudden increase in negative emotion if it occurs in the office, but not if it occurs on the football field.

For X to be the cause of Y, there also must be a contrast where an intervention on X changes Y, but, if the intervention had not occurred, and everything else stayed the same, then Y would not have changed. For example, let's say that someone on average needs 4 or more weeks of exposure habituation therapy to achieve long-term reduction of obsessive-compulsive symptoms. In contrast, 1–3 weeks of therapy on average will not lead to longterm reductions of symptom.

If the person had 1 year of therapy, they would experience a reduction of symptoms as well, but it is not the case that, in contrast, less than 1 year of therapy would not lead to a reduction in symptoms. Three months of therapy on average would also lead to a reduction of symptoms. The 1 year of therapy is a cause, but not the kind of cause sought for in the interventionist model. It is too fine-grained and has no noncausal contrast. Although broader (or more coarse-grained), 4 or more weeks of therapy more accurately describes the cause.

This model has several attractive features with respect to the study of psychopathology. For one, it connects causation with the practical issue of interventions, making it relevant for thinking about causality in treatment settings. In fact, the practice of making an intervention and describing the results was an important part of the natural history approach.

Another attractive feature of the interventionist account is that it places no a priori restrictions on which level of analysis can have genuine causal power. If intervening on X reliably leads to a change in Y, then X is a cause of Y.

For instance, in reductionist models, the causal power of psychosocial variables like social status is ultimately explained by how social status is implemented in the brain. The causality is reduced to brain activity. In the interventionist account, however, top-down causation can also occur in which manipulation of upper-level psychosocial events can cause changes in lower-level brain events. For example, Raleigh and colleagues (1984) have shown that you can intervene to raise a male monkey's position in a social dominance hierarchy (X) by removing higher status monkeys from the troupe. When a lower ranking monkey gains higher social status, that change in status is reliably followed by a rise in serotonin levels in that monkey's brain (Y). The intervention, however, was on social status so the change in social status was the cause of the change in serotonin levels.

A third attractive feature of the interventionist account is that a relatively coarse-grained event, such as giving an unemployed person a meaningful job, might be a more preferable explanation for something like the remission of a depressive episode than would be theories about fine-grained events such as alterations in the connections between neurons in the person's brain. Although alterations in connections between neurons are reasonable causes of things like the remission of depressive episodes, on the interventionist account, the causal contrast is between giving the person a job versus the person remaining unemployed.

As noted above, if production accounts (mechanistic models) incorporate an energy transfer notion of causation, then they are likely to promote understanding the mind as expressing physical brain functions. One feature of the interventionist model that people find attractive is that it does not push all the causal work down to the level of the brain. Put side by side, these alternative approaches raise important issues about the nature of the relationship between the mental and the physical. We briefly explore this relationship in the next section.

# Psychopathology and the Mental: Nonreductive Approaches

The realm of psychopathology is complicated by the thorny questions of the relationship between the "mental" and the "physical." Historically, two important solutions have been dualism and reductionism. In *dualism*, mind and brain are considered distinct. Traditionally dualists see mind and brain as separable entities. Others dualists believe that that minds do not exist apart from brains but the *properties* of the mind such as the feeling of distress are mental not physical properties. <sup>2</sup>

*Reductionism* implies that if we knew everything there was to know about the biology of the brain, psychological explanations would be rendered superfluous because any explanation that utilizes psychological constructs could instead be reduced to an explanation that utilizes neurobiological constructs. This has also been termed "greedy reductionism" because the lower level of explanation is seen as capable of "eating up" the higher level of explanation (Dennett, 1995).

On the surface, the RDoC project would seem to be in the reductionist camp given its emphasis on brain circuits, but the story is more complex. RDoC does give priority to psychological constructs whose implementation in the brain has at least been tentatively described, but RDoC is not seeking to replace descriptions of psychological functions with description of brain states (Cuthbert & Kozak, 2013; Miller & Bartholomew, 2020). RDoC seeks to use information from neuroscience to redescribe the psychological functions (or symptoms) that are important in psychopathology and may even identify symptoms not yet recognized.

In this respect, RDoC is potentially consistent with philosophical work in recent decades that has developed accounts that rely on neither dualism nor greedy reductionism. The philosophical term of art is "nonreductionism." To briefly illustrate the nonreductionist notion that mind and brain are not separate entities, but the mind is not fully reducible to the brain, let us look at what philosophers of mind refer to as the *4E framework*.

# The Embodied, Embedded, Enacted, and Extended Mind (4E Perspectives in Psychopathology)

Traditional approaches to cognitive science view cognition in terms of information processing and manipulation of abstract internal representations mediating between sensory input and motor outputs. The 4E framework refers to a family of disparate perspectives that were grouped together beginning around 2006 because of their shared opposition to viewing cognition as something that occurs completely within the confines of the brain (Drayson, 2009; Newen et al., 2018).

Although the 4E framework is primarily about cognitive science, it has also been applied to psychopathology. As in the cognitive sciences, 4E philosophy of psychopathology is best seen as an alliance of perspectives with some shared, overlapping features. Those who advocate for the 4E framework oppose the reduction of mental disorders to brain disorders (de Haan, 2020a; Glackin et al., 2021; Maiese, 2016; Nielsen & Ward, 2018). In their view, mental disorders cannot be localized to specific brain circuits and isolated from an individual's social and cultural context. For example, Fuchs (2018) articulates his perspective as follows:

[P]sychic processes may not be reduced to the brain or to localized neural activities; they are embodied, inherently intentional, and context related; and they are inseparable from the intersubjective world of shared meanings and interactions. . . . this applies to dysfunctional or disordered mental processes as well. (Fuchs, 2018, p. 253)

This may sound to readers like the return of the *Geisteswissenschaften*, and certainly some of the philosophical perspectives included in the 4E framework are historically rooted in the European human sciences tradition, but the 4E framework also draws on dynamical systems theory, which is historically rooted in mathematics and the natural sciences (Varela et al., 1991). Dynamical systems theory studies how complex systems develop over time and seeks to make complex sciences more mature in Comte's sense.

<sup>&</sup>lt;sup>2</sup> A similar view that the concepts/terms of psychology cannot not be replaced with the concepts of neuroscience is not called property dualism but *nonreductive materialism*. The latter view holds that the experience of distress cannot be fully explained by neuroscience, but it is not a special mental property.

4E's nonreductionist emphasis also calls to mind the biopsychosocial model of psychopathology, which for many years has been an important framework for thinking about psychopathology in both psychiatry and psychology (Bolton & Gillett, 2019; Engel, 1977). Introduced as an extension of the medical model, the biopsychosocial model claims that although diseases and disorders are implemented in biology, in many cases, understanding how they develop, are maintained, and resolved requires taking psychological and sociocultural factors into consideration.

The biopsychosocial model is so ingrained in the study of psychopathology that some features of the 4E framework which are novel for cognitive science are already taken for granted in psychopathology. The 4E framework does, however, articulate some ideas that are left too vague in the biopsychosocial model. More specifically, the 4E framework views the mind as *embodied*, *embedded*, *enacted*, and *extended*. Let us briefly explain each of these notions.

To say the mind is *embodied* emphasizes that mental functioning is entangled with biological functioning and cannot exist apart from it. One way to think about this is to see the entire nervous system as a single organ that inhabits the whole body—all of which is the substrate of the mind.

Lakoff and Johnson (1980) argued that our subjective experience is entwined with our experience of having bodies. For example, we describe happiness as "up" and sadness as "down" (i.e., "I'm feeling up" and "My spirits rose" vs. "I'm feeling down" and "My spirits sank"; Lakoff & Johnson, 1980, p. 15). According to the embodiment perspective, many taken-for-granted givens in our mental lives have bodily bases. Human bodies are vertically oriented, and positive and negative emotions alter our posture, so describing the experience of happiness with the physical metaphor being up and sadness with being down makes sense to us. In fact, "depression" is a description of bodily posture. In contrast, were a linguistically competent mammal to have a body oriented horizontally more like that of a dog, perhaps an experience of happiness would be described as being "forward."

To say that the mind is *embedded* stresses that the mind is not isolated from the world but dependent on the physical, social, and cultural environments we inhabit. In psychopathology, embeddedness is seen in the emphasis placed on stress and trauma in the etiology of some disorders. Embeddedness also emphasizes the importance of context. For example, Horwitz and Wakefield (2007) argued that experiencing symptoms of depression in the context of the loss of a loved one indicates normal grief, not a disorder. If, instead, those same symptoms appear out of the blue without any precipitants, they more like indicate a depressive disorder.

The *enactive mind* is best understood in contrast to a model in which the mind reacts to stimuli in reflex-like ways, often due to the triggering of brain circuits (Ellis, 2000). The enactive mind is consistent with William James's (1842–1910) notion of the mind as an organ of adaptation that is shaped by the world and actively shapes the world (James, 1890). This can be seen in a process called *circular causality*. In circular causality, changes in the environment can influence the individual in ways that change brain activity. These changes in brain activity can result in changes in the individual's interactions with the environment, which in turn can change the environment (thus completing the circle).

A more specific example of circular causality is the active gene-environment correlation (Scarr & McCartney, 1983). People with a vulnerability to alcoholism may actively seek out and shape environments in which drinking occurs. Fellow drinkers jointly create an environment, encouraging each other to drink excessively and excluding nondrinkers from the group. Rather than a genetic inheritance directly causing alcoholism, an inherited disposition leads some people to occupy and actively shape environments that in turn enable heavy drinking. According to the enactive perspective, the explanation of alcoholism should not be limited to the brain and the individual's internal psychological functioning but also include the individual's dynamic interaction with the world.

Psychopathology may also reflect deficient enactivism. De Haan (2020b) and Nielsen (2021) suggest this possibility by writing about psychopathology as inflexible. For instance, one of the best predictors of a depressive episode is experiencing stress in the previous 6 months (Kendler, Karkowski, & Prescott, 1998, 1999). In a depressive disorder though, this depressive reaction can settle into a stable state in which the depression symptoms are locked in and persist long after the stress that precipitated the episode has been resolved. In dynamic systems theory this is called *hysteresis*, referring to a change of state lagging behind changes in causation. It is a failure to adapt to changing conditions.

The *extended mind*, as Hoffman (2016) notes, is a stronger and more novel view for psychopathology. According to this view, parts of the world are parts of the mind: that is, the mind extends out into the world, such that it is not confined to the physical body of the organism and is partly constituted in world. To illustrate, for people with some kinds of brain injuries, their beliefs about how to navigate around their home city may be stored in notebooks, and recall is a process of checking the notebook. In this case, internal processes (such as the intention to visit the museum) and an external resource (transcribed beliefs about where the museum is located) are coupled together to form an integrated cognitive system (Clark & Chalmers, 1998).

Consider, for instance, the process of selfregulating emotion. Some clinicians claim that, for young children, emotional regulation is normally accomplished externally through interactions with parents (Bowlby, 1969). For example, when children are upset, their parents can soothe them. Over time, positive interactions with parents are internalized and become an inner resource. As they mature, children can draw on such internalized resources to regulate emotion on their own (Mahler et al., 1975; Zachar, 2000).

Psychodynamic models of some personality disorders view the internalization process as having been disrupted (Mahler, 1971). For example, part of the pathology of borderline personality disorder is an inability to regulate emotion internally, which manifests as intense and fluctuating positive and negative emotions. For some patients, analogous to the notebooks of patients with brain injury, drawing on external sources of regulation can promote emotional stability. It may also be the case that regulating emotion externally is not in itself a problem; rather, the external resources (relationships) that are available to the person are unreliable (Linehan, 1993; Potter, 2009). Indeed, Bray (2008) suggests that the lack of interpersonal boundaries and concerns about abandonment that are characteristic of patients with borderline personality disorder could be seen as a consequence of other people being an extended part of the borderline mind.

## Conjecture, Scientific Realism, and Scientific Anti-Realism

Throughout this chapter we have explored a tug of war that has occurred between more descriptive and more conjectural approaches to psychopathology. The chapter began with a brief description of the Galenist model of medicine and its reference to things that do not actually exist—such as black bile. We also saw Kraepelin referring to Meynert's neuromythology. This referred, among other things, to a conjecture on Meynert's part that mania is caused by an increased supply of blood in the cortex and depression by a decrease. The extent to which scientific conjectures about things not directly observed refer to something real is the problem of scientific realism and anti-realism. It has been lurking in the background throughout our discussion, and, in this last section, we bring it into the foreground. This section includes some of the more difficult philosophical ideas presented in the chapter.

Over the centuries, there have been many debates about scientific authority within society and culture. These cultural debates include

- Galileo versus the Catholic Church on the Copernican theory
- Evolutionists versus creationists on the origins of species
- The scientific community versus the antivaccination movement

According to scientific realism, the proposition *planets in our solar system revolve around the sun* is true no matter what we happen to believe because reality is mind-independent. Successful science describes this mind-independent reality.

Some philosophers assert that because the opponents of the Copernican theory claimed that the Copernican model is useful for making predictions about the movements of planets but is not literally true, they were analogous to contemporary scientific anti-realists (Massimi, 2008). Within the philosophy of science, however, both scientific realists and anti-realists strongly support the authority of Galileo, evolutionists, and vaccine science in the cultural debates. Comparing the debate between scientific realists and anti-realist with the debates about scientific authority is deceptive.

What then is *scientific anti-realism?* More closely associated with the philosophy of empiricism, scientific anti-realism is a doctrine of epistemic fallibilism, especially doubt that one can know with certainty about things that are at least partially beyond their appearances. According to scientific anti-realism, knowledge of such things is dependent on concepts and hence not mind-independent in a way that scientific realism demands. It is a descendant of the more descriptive and anti-conjectural perspective described at the beginning of this chapter.

Throughout history, previously accepted scientific theories such as the sun-centered model of the solar system and the theory that autism is caused by emotionally distant parenting have turned out to be mistaken conjectures. According to *the pessimistic induction*, it is likely that some currently accepted scientific theories will also turn out to be mistaken conjectures as well (Laudan, 1981). Anti-realists are sympathetic to the pessimistic induction.

The disciplines in which scientific realism and anti-realism debates have most thrived are physics, psychology, and psychopathology. For instance, the idea of a hypothetical construct as set forth by MacCorquodale and Meehl (1948) and Cronbach and Meehl (1955) has a scientific realist tone. An example of a hypothetical construct is the personality trait of neuroticism. People who score high on the trait of neuroticism are more likely to experience negative emotions such as anger, fear, and sadness. According to realism about psychological constructs, neuroticism is a hidden attribute of a person that is causally reflected in behavior.

Another example of a hidden cause of behavior is major depressive disorder. According to the scientific realist view, self-reported symptoms such as fatigue and concentration problems are correlated because they reflect an underlying depressive disorder. In developing diagnostic criteria for depression and/or items on a depression scale, psychiatrists and psychologists seek to identify behaviors and selfreports of experiences that are observable indicators of this hidden construct.

There is common ground between by this realist view and the mathematical model used in factor analysis (Borsboom et al., 2003). In factor analysis, the hidden, common causes of the observable indicators are called *latent variables*. When adopting scientific realism, practitioners of factor analysis see the mathematical properties of their technique as having the power to detect hidden realities (latent variables), similar to how astrophysicists see their complex mathematic tools as enabling them to detect hidden realities (i.e., black holes and subatomic particles).

One can also adopt a more anti-realist stance about causally important latent variables "discovered" with factor analysis (van der Maas et al., 2014). In a striking hypothesis, van der Maas et al. (2006) argued that as long as the observable indicators are positively correlated, factor analysis will extract latent variables even if the positive correlations are not the result of hidden, common causes but the result of direct causal connections between the observable indicators themselves. That is to say, rather than level of fatigue and concentration problems being correlated because they are both caused by the same underlying mood disturbance, they may instead have direct causal connections with each other; that is, being fatigued causes concentration problems. In this view, a depressive disorder occurs if depression symptoms enter into causal relationship with each other, and, once established, this *causal network* maintains itself over time even after precipitating causes are no longer operating (i.e., hysteresis, as defined above). For these kind of conditions, latent variables discovered by factor analysis are not real.

Other mathematical models are inherently aligned with a more anti-realist view. One example is principal components analysis (Borsboom et al., 2003). In principal components analysis, the latent variable is a composite constructed out of the observable indicators. For example, the variable of socioeconomic status (SES) is constructed out of correlations between variables such as income, education, and occupation. Variations in income, education, and occupation are not caused by SES: they are parts of SES.

Let's look at what scientific anti-realism would say about the hypothetical personality trait of neuroticism. According to the anti-realist, there is no hidden entity in the mind-brain called neuroticism that causes a person to experience fear, anger, and sadness. Various temperamental, affective, cognitive, and perceptual processes in the context of one's personal history combine to raise the probability of having these negative emotions, but the particular menu of processes that play causal roles for occurrences of these emotions is constantly changing. Behavioral consistency emerges, but it is not caused by a hidden trait called neuroticism any more than a person's income and educational level are caused by his SES.

# A Conditional and Partial Scientific Realism in the Philosophy of Science

Some philosophers of science have adopted a position that is harder to classify as scientific realism or anti-realism (Fine, 1986; Schaffner, 1993; Zachar, 2014). One example of this view is the empiricist philosopher Rudolf Carnap's (1956/ 1991) distinction between questions internal to a linguistic framework and those external to it.

Let us use the example of schizophrenia. Carnap argued that, internal to a linguistic (or scientific) framework, there are norms for deciding if a hypothetical construct such as schizophrenia can be considered real. These norms are stipulations such as (a) there are disorders of psychopathology, (b) schizophrenia is a psychotic disorder, (c) schizophrenia has a genetic component, and (d) schizophrenia requires 6 or more months of continuous symptoms. For complex sciences such as psychopathology, many different norms have been proposed, and it is hard to keep them all straight or consistent that is part of their complexity.

According to Carnap, discussions about what norms to accept are practical matters, focused on consequences.<sup>3</sup> For example, those who reject the view that there are disorders of psychopathology often do so because they believe that the concept of psychopathology is harmful, contributing to stigmatization and blaming the person (Chapman, 2019; Johnstone & Boyle, 2018; Rashed, 2019). Those who advocate for the study of psychopathology tend to believe that rejecting the concept of psychopathology would lead to other negative consequences such as the minimizing of suffering (Frances, 2013; Roth & Kroll, 1986).

Carnap said that once there is agreement on various stipulations and methodological and statistical norms, they become background assumptions, and, internal to the agreed-on framework, one can do the research and potentially learn if schizophrenia is real according to the norms one has adopted. For Carnap, however, no one can absolutely decide whether schizophrenia is real external to all possible frameworks whatsoever.

Independently of Carnap, the psychiatrist Kenneth Kendler (1990, 2020) came to similar conclusions. Kendler was involved in the DSM-III-R and DSM-IV revisions. During the early days of the DSM-IV revision he realized that which diagnostic criteria are best will partly be contingent on our concept for that disorder. Consider schizophrenia. Assume that one set of criteria does better at predicting that the disorder runs in families and another set does better at predicting long-term outcome. Each criterion set also demarcates different groups: a broad group that includes paranoid and schizotypal personality types for the first set and a narrow group of early-onset psychosis for the second. Which criterion set is better? Are these different groups subtypes of one disorder or two disorders? Answering such questions, Kendler realized, is not just a matter of doing more and better studies but contingent on prior assumptions about the nature of a valid schizophrenic disorder. For example, if we assume that a real schizophrenic disorder

would show improvement with antipsychotic medicine, the second set of criteria would likely be better.

Another version of this view is the *internal realism* of the philosopher Hillary Putnam (1988, 1990). By internal realism Putnam meant that we can describe a situation in different ways by using alternative conceptual frameworks. Once we adopt a framework with its own set of background assumptions, however, within that framework, there are facts that are independent of our preferences, statements that can be objectively true and false, and so on.

For example, if you adopt the DSM definition of schizophrenia as your framework and then hypothesize that schizophrenia has a deteriorating course, you can empirically test that hypothesis. In fact, DSM-defined schizophrenia does not always have a deteriorating course. The most common outcome is remitting-improving (Morgan et al., 2021). Other common outcomes are persistent symptoms, late decline, and late improvement. Those outcomes are matters of fact, but such facts do not preclude potentially embracing an alternative concept of schizophrenia in which a deteriorating course is the most common outcome and labeling other outcomes as something different from schizophrenia (such as schizophreniform disorder, attenuated psychosis, and so on). As to which of these concepts we should embrace, there are no determinate framework-free answers.

When someone asks if schizophrenia is real, they are typically looking for a settled, absolute answer. It either is or is not real independent of how we happen to think about it. For Carnap and Putnam, making claims about the reality of schizophrenia independent from a set of background concepts that we embrace would require being able to adopt a god's-eye view. For philosophical empiricists, such an absolute view is beyond the reach of human understanding. In fact, agreeing that something is real internal to a framework but not absolutely real independent of our conceptions/assumptions could be considered an anti-realist position—which is why we noted above that these perspectives can be hard to definitively classify as realist or anti-realist.

#### Conclusion

Looking back through the history of psychopathology, we have emphasized a long-standing tug of

<sup>&</sup>lt;sup>3</sup> Contemporary empiricists would allow that previous scientific findings can always potentially inform decisions about what norms/concepts to accept.

war between descriptions and conjectures. Although we began this story in the seventeenth century, the contrast likely reaches back into prehistory. Ages ago humans started to notice that some members of their clan experienced declines from previous levels of functioning with respect to adaptive skills that involve perception, cognition, emotion, and behavior, although it is unlikely our ancestors articulated such insights using those specific psychological concepts. Many of them would have noted that these changes were accompanied by increased levels of suffering. Quite likely, they also attended to what Sydenham, as quoted above, called the irregularity of the changes—and how the menu of problems shifted over time.

Given humans' inherent predilection for explaining "why," from the very beginning they surely formulated conjectures about what was happening. Conjectures seen as too speculative or as conflicting would eventually initiate attempts to articulate descriptions that people could agree on. Indeed, once the process commenced, asking what came first, the conjecture or the description, would be a chicken-or-egg problem.

The distinction between what is considered more descriptive versus more conjectural could be seen as part of the conceptual history of psychosis, anxiety, depression, conduct problems, substance abuse, developmental disorders, and so on. One could even potentially distinguish psychodynamic, biological, cognitive-behavioral, and psychometricquantitative conceptualizations with reference to what they consider descriptions, acceptable conjectures, and unacceptable conjectures.

As we have suggested, the distinction between description and conjecture is fluid. Claims that are in conformity with accepted background assumptions tend to be considered descriptions, whereas claims that extend beyond current assumptions tend to be considered conjectures. As background assumptions are added and removed, what was seen as conjectural can be considered descriptive, and older descriptions start looking like conjectures.

Articulating background assumptions is a challenging task. These assumptions may be so taken for granted that they are not seen as assumptions or as having a theoretical character. One practical reason for attempting to articulate such assumptions is that when they are taken for granted, they may be seen as necessary and inevitable, but when seen as assumptions having a theoretical character, they may gain some contingency. A perception of contingency supports the empiricist belief that our knowledge of psychopathology is provisional and potentially revisable—which we believe is a historically entrenched, philosophical assumption of any scientific approach to the study of psychopathology.

# The Hierarchical Taxonomy of Psychopathology

Christopher C. Conway and Grace N. Anderson

It is difficult to overstate how important a valid diagnostic system is to understanding psychopathology. It structures research agendas, clinical visits, and all manner of professional training. It is the lexicon professionals use to communicate with one another and to interface with other entities, such as insurance and legal systems.

Official nomenclatures are under continuous revision. Scholars are always searching for a more accurate map of mental health problems. This evolution is evident in the periodic re-releases of official diagnostic manuals (e.g., DSM-I, -II, -III, -IV, and, currently, -5). Those updates tend to be conservative, akin to adding a handful of new chemical elements to the periodic table every decade or so. The purpose of this chapter is to describe a qualitatively different approach to diagnosis that accomplishes something more like systematically reshuffling the familiar layout of the periodic table. The new approach is called the Hierarchical Taxonomy of Psychopathology (HiTOP), and it differs from prevailing systems in that it was formulated on the basis of findings from systematic research. We argue that it overcomes many of the conceptual problems associated with categorical diagnosis that have frustrated researchers and clinicians. We begin the chapter by reviewing the structure and limitations of categorical taxonomies, and we then describe the origins, format, and implications of empirically based diagnosis.

## **Categorical Classification Systems**

The DSM and ICD are the dominant classification systems, also called *nosologies*, in the United States and abroad, respectively. Their history, organization, and utility are described in detail elsewhere in this volume. In this section, we focus on the parts of these systems that motivated investigators to explore alternative classifications. For simplicity, we refer to the particulars of *DSM*, but the same considerations generally apply to *ICD*.

For our purposes, the key thing to know about *DSM* is that it was originally constructed on the basis of expert opinion. Specialists (mostly psychiatrists) met to trade clinical observations and speculate about the mental dysfunctions causing their patients' problems. These sorts of formulations were deduced primarily from clinical experiences rather than systematic research. In other words, expert consensus—or occasionally just the loudest voice in the room—shaped the diagnoses printed in early editions of *DSM* (Spiegel, 2005). Because of the conservative revision process, many of those same constructs persist in *DSM-5* today.

DSM portrays mental disorders as categorical entities. Generally, a person is either a member or nonmember of each category, although some finer gradations of pathology are possible for select diagnoses. Patients are sorted into these categories

Abbreviations	
DBT	dialectical behavior therapy
fMRI	functional magnetic resonance imaging
GWAS	genome-wide association study
Hitop	Hierarchical Taxonomy of
	Psychopathology
MDD	major depressive disorder
NESARC	National Epidemiologic Survey on
	Alcohol and Related Conditions
PD	personality disorder
PID-5	Personality Inventory for DSM-5
SAD	social anxiety disorder
SSRI	selective serotonin reuptake
	inhibitors

if they express enough of the diagnostic criteria, which represent our hypotheses about how mental disorders manifest. A cutoff point, separating cases from noncases, is designated for each condition. Patients qualify for *DSM-5* major depressive disorder (MDD), for example, when they satisfy at least five of the nine total diagnostic criteria. Any fewer criteria, regardless of the severity of a patient's depressed mood, and MDD is ruled out.

### **Problems with Categories**

*DSM*'s categorical structure is the status quo. *DSM* diagnoses have been the basic units of mental health disciplines for many decades. As mentioned, quite a few have been conserved through iterations of *DSM* with little or no modification, despite years of research.

There have been complaints throughout *DSM*'s history regarding the validity of categorical diagnoses and their utility in clinical practice. The list of criticisms, recorded in detail elsewhere (e.g., Widiger & Samuel, 2005), is long and compelling. They became the catalyst for new systems, such as HiTOP, that are more closely based on scientific data collected over the past 40 years or so since the publication of *DSM-III*. We catalog some of the main problems with categorical rubrics here to clarify, by comparison, the benefits of a system that does not assume mental disorders are binary categories.

#### Comorbidity

If mental disorders are in fact discrete entities, each with a distinctive etiology, pathophysiology, illness course, and so on, then disorders should not overlap substantially. However, large-scale studies document that disorders co-occur at rates well above what would be predicted by chance (e.g., Kessler et al., 2005). Indeed, in the community, a small percentage of the population is responsible for over half of the total number of diagnoses recorded (Caspi et al., 2020). In outpatient care, if a patient is diagnosed with a mental disorder, the odds are better than 50/50 that they will be diagnosed with two or more conditions (Brown et al., 2001). This effect is even more pronounced in inpatient hospital settings.

Comorbidity muddles the design and interpretation of research projects. Imagine an investigator who is studying attentional bias in panic disorder. They hypothesize that people with panic disorder more readily direct attention to danger cues. They recruit a clinical sample and estimate the correlation between panic and this information-processing outcome. After wrapping up the study, they realize there could be a potential confound: almost all panic disorder cases were also diagnosed with agoraphobia, so perhaps the observed correlation between panic and attentional bias was attributable to agoraphobia instead.

A possible solution is to recruit a "pure" sample of panic disorder cases—people diagnosed with panic disorder but no other conditions. This method would certainly minimize the chances of a spurious correlation. The only problem is that this sample is unrepresentative of the population of people with panic disorder. Panic is correlated with diverse other mental health problems, especially agoraphobia, so the observed effect in this "pure" group would be unlikely to generalize to populations of interest.

Clinicians face the same kind of dilemma. In ordinary practice, most patients qualify for multiple categorical diagnoses. Consider a patient who presents with attention deficit hyperactivity disorder, drug use disorder, and antisocial personality disorder (PD). A psychotherapist is confronted with a tough choice: Address the problems simultaneously or treat them sequentially? If simultaneously, what shared phenomenon or process among these conditions should be in the foreground? If sequentially, in what order? There is virtually no empirical guidance for this type of decision.

### Heterogeneity

Two patients with the same diagnostic label may look very different from one another. This is called within-category variability, and it characterizes most DSM conditions. It occurs because (1) a diverse constellation of signs and symptoms can contribute to any diagnosis, and (2) only a subset of symptoms is needed to cross the diagnostic threshold. Recall the case of MDD, where any five of nine symptoms could qualify a patient for the diagnosis. This implies that two patients could share a diagnosis but have only one depressive symptom in common. Investigators have used simple mathematics to quantify this problem, finding close to 1,000 different possible symptom presentations that fit the DSM-5 MDD criteria (Fried & Nesse, 2015). The situation is worse for posttraumatic stress disorder (PTSD): there are more than 600,000 ways to qualify PTSD (Galatzer-Levy & Bryant, 2013).

In research projects based on categorical diagnoses, it is impossible to tell what disorder components are responsible for a correlation with some outcome variable. *DSM-5* PTSD, for instance, is characterized by several loosely related symptom domains: intrusions (e.g., flashbacks), avoidance (e.g., steering clear of trauma-related places), negative cognitions and moods (e.g., self-blame), and altered arousal and reactivity (e.g., hypervigilance). If a study finds that the PTSD syndrome is correlated with some outcome, it is not obvious which symptom domains are responsible for the observed effect. Conceptualizing PTSD as a categorical entity—collapsing across the subunits—misses the opportunity to explore these nuances.

Diagnostic heterogeneity is problematic in treatment arenas, too. Psychotherapies are typically geared toward categorical diagnoses. There is no guarantee, however, that they target all symptom components equally. If cognitive therapy for PTSD addresses, say, traumatic intrusions and negative cognitions, then people diagnosed with PTSD primarily by virtue of other problems (e.g., avoidance and hyperarousal) would not be expected to benefit substantially from treatment.

#### Unreliability

The interpretability of diagnoses depends on some reasonable degree of consistency across raters and time. Disagreement among raters suggests that the constructs mean different things to different people. This type of inconsistency makes it difficult to be sure whether a sample of people with, say, conduct disorder in one clinic or study is really equivalent to a sample of people with conduct disorder in another. Observations of limited consistency across time would contradict assumptions about the temporal stability of most forms of psychopathology (e.g., PDs).

Findings in large-scale studies point to problematic reliability for categorical conditions. In field trials for *DSM-5*, about 40% of the diagnoses studied did not reach acceptable levels of interrater agreement in real-world practice settings (Regier et al., 2013). Longitudinal studies that track patients over time also document instability in diagnostic status over time. For instance, one prospective study of 160 patients diagnosed with borderline PD an intractable condition, according to received wisdom—discovered that more than 10% of diagnoses remitted within 6 months (Gunderson et al., 2003).

#### Fuzzy Boundary with Normality

Breaking a natural continuum into parts throws away information. For example, collapsing ambient temperature into two categories called "hot" and "cold" sacrifices precision. Say the cutpoint is 60°F. Now a 59°F day is considered categorically different from a 61°F day, whereas 61°F and 100°F are considered equivalently hot. The same practical problem occurs when investigators dichotomize a dimension of, say, depression severity into cases versus noncases of MDD.

There is no empirical evidence to justify this practice for mental disorder. To the contrary, quantitative research shows that people differ by degree, not by kind, on virtually all mental health constructs studied so far (Haslam et al., 2020). According to the extensive literature on this topic (Haslam et al., 2020; Krueger et al., 2018, Markon et al., 2011), the best way to summarize how people differ from one another with respect to any mental health condition is to assume a dimension of severity—marked by nearly infinite gradations—rather than mutually exclusive classes.

#### Blind Spots in Coverage

There are well over 300 diagnoses codified in DSM-5. It is ironic, then, that categorical nosologies are sometimes criticized for poor coverage, meaning they do not adequately capture the range of conditions that clinicians encounter in ordinary practice. A common scenario is that patients will present with symptoms representing an amalgam of features from various "official" disorders. This combination of problems, also called a syndrome, creates significant distress and impairment, leading the patient to seek out professional help. Nevertheless, it does not align with the profile of any single DSM diagnosis. These cases can fall through the cracks in the healthcare system, failing to qualify for services reserved for people whose complaints fit neatly into a particular diagnostic category. In several mental health domains (e.g., eating disorders, PDs), this has led to "other specified"-called "not otherwise specified" in DSM-IV-to be the most common diagnosis (e.g., Verheul, Bartak, & Widiger, 2007).

#### Multifinality

In medicine, a diagnosis implies a particular pathogenesis. Each illness can be traced to its own distinct causal mechanisms. This is decidedly not the case for psychopathology. Despite immense resources devoted to discovering *the* cause for various *DSM* diagnoses, none has been established or appear forthcoming. With few exceptions, there is no one-to-one correspondence between a risk factor and any categorical mental health outcome. Instead, potent risk factors are virtually always related to multiple categorical disorders. This phenomenon has been termed *multifinality* by developmentalists, who observed that adverse events early on in life conferred risk for an array of mental health outcomes (Cicchetti & Rogosch, 1996). It implies that when the architects of official nosologies divided mental health problems into mutually exclusive categories, they did not delineate disorders with meaningfully separate etiologies and correlates.

### A Quantitative Nosology

This report card raises serious questions about the utility of categorical diagnoses for mental health research and practice. No matter how advanced the research technology, how large and representative the sample, how insightful the investigator, the findings built around *DSM* will be, to some extent, difficult to interpret. Perhaps we should not continue to anchor all of the field's knowledge to these suboptimal representations of psychopathology.

Overhauling the diagnostic system would not necessarily mean starting over. Decades of clinical observation and empirical research into the basic features of mental disorder provide a palette to work with. The key proposed change is to bring systematic data analysis, *and not just expert committees*, to the foreground to find out how those building blocks tend to assort into meaningful clinical problems. This quantitative approach moves as far away as possible from the clinical opinion and political processes that have played such a major role in the development of categorical systems (see, e.g., Zachar et al., 2016).

Quantitative nosology's mandate is to summarize mental health problems according to observed patterns of covariation. This means that researchers use quantitative analysis to determine how psychopathology signs and symptoms cluster together. These empirically derived clusters are the constructs (i.e., clinical phenomena) that comprise the new taxonomy.

We can loosely define quantitative analysis as examining correlations among mental health problems. Correlations reflect co-occurrence or clustering. We can identify diagnostic constructs by finding clinical phenomena that tend to cluster together. For instance, if sadness, insomnia, weight loss, and thoughts of dying co-occur, we might posit depression as a common thread through all of these experiences. We can infer constructs unobservable characteristics (e.g., depression, extraversion, intelligence, humor)—that explain why the building blocks of psychopathology assort in systematic ways.

The principal method of quantitative analysis in this area is called *factor analysis*. To oversimplify, factor analysis establishes continuously distributed, unobserved traits (i.e., factors) that explain correlations among a set of observed behaviors (for more information, see Brown, 2015). It was formulated at the turn of the twentieth century to test the hypothesis that a general cognitive ability factor accounted for similarity in performance across several more specific cognitive tasks (e.g., working memory, processing speed, vocabulary). The factors are considered *latent* variables, meaning they are not observable; we infer their existence from patterns of correlation among manifest, or observable, outcomes. To understand the difference between latent and manifest concepts, consider that a clinician might directly observe tearfulness, tiredness, and weight loss (i.e., manifest phenomena), whereas the hypothesis "this patient is depressed"-where depression is a latent phenomenon-is inferred from those observations.

We will refer to the application of factor analysis and related methods as *structural research*, because they describe the way different components of psychopathology fit together. Structural research has a long history in clinical psychology and psychiatry. Early studies examined the relations among symptoms reported by psychiatric patients in an attempt to discern patterns in their presenting problems (e.g., Moore, 1930). There were similar investigations into the coherence of affective experiences in community and clinical populations that spawned a robust line of work into the composition of anxiety and depression (Mineka et al., 1998), which was perhaps the clearest forerunner of contemporary quantitative nosology.

Structural research caught on most quickly in the developmental psychopathology literature; this field has been conceptualizing mental health problems in terms of empirically derived dimensions for decades. Achenbach's (1966) factor analytic research into youth mental health complaints was the main catalyst. He found that recognizable mental health problems like anxiety, depression, and somatic complaints could be conceptualized as aspects of a broad internalizing dimension and delinquency, conduct problems, and aggression could be conceptualized as aspects of an externalizing dimension (Achenbach et al., 1991).

Subsequent research in adult populations detected similar patterns. Kreuger, Caspi, Moffitt,
and Silva (1998) found that internalizing and externalizing factors summarized the interrelations among anxiety and depressive diagnoses, on the one hand, and substance use and antisocial behavior diagnoses, on the other, in a New Zealand community sample. Krueger (1999) then analyzed US epidemiological data and found that the same two dimensions explained comorbidity among DSM-III-R diagnoses. This latter study made the case for a more elaborated, hierarchical structure in which the internalizing factor broke apart into two subordinate factors, which he labeled distress and fear. Distress accounted for especially high comorbidity among depression and generalized anxiety disorder (GAD), whereas fear represented the clustering between panic disorder and the phobias.

The investigations by Krueger and colleagues were a turning point for structural research and, more broadly, the quantitative nosology endeavor. They have inspired a tremendous amount of empirical work over the past 20 years. These structural studies formed the evidence base for HiTOP, which we turn to in the next section.

Much of the ensuing research was oriented around comorbidity patterns among categorical diagnoses. Many large-scale datasets from epidemiological and community-based research included a diverse roster of interviewer-rated diagnoses, and this was the perfect environment for making sense of comorbidity. A meta-analysis, now more than 15 years old, of these efforts supported a model of diagnostic correlations that was anchored by factors that closely paralleled the internalizing and externalizing factors that had originally appeared in developmental research (Krueger & Markon, 2006). Moreover, it again raised the possibility that there were discernable subdimensions within the internalizing spectrum; the internalizing factor in this meta-analytic model bifurcated into distress and fear subfactors, mirroring the factor analysis reported by Krueger (1999).

Later studies with even broader diagnostic coverage revealed other factors adjoining the internalizing and externalizing dimensions. Kotov et al. (2011) searched for clusters of diagnoses in a sample of about 3,000 outpatients who completed a comprehensive interview for *DSM-IV* clinical disorder and PD diagnoses. They described three other factors in this dataset: thought disorder (psychosis, mania, and cluster A PDs), somatoform (hypochondriasis, pain disorder, undifferentiated somatoform disorder), and antagonism (cluster B and paranoid PDs). Results in other samples converged with these new findings (e.g., Forbes et al., 2017; Sellbom, 2017).

We acknowledge that at first glance a research agenda based on DSM diagnoses does not seem likely to move us meaningfully beyond diagnostic categories. After all, the whole purpose of a quantitative nosology is to transcend the traditional categorical system. However, this line of research is valuable because it illustrates that structural research can uncover unobserved dimensions that in theory predispose to clinically recognizable mental health problems. These dimensions offer another way to conceptualize mental disorders. Nevertheless, there are certain constraints. DSM diagnoses may not be the optimal way to sort symptoms. As mentioned, categorical diagnoses most often reflect a heterogeneous symptom set. This means that structural research based on diagnoses cannot speak to the organization of fine-grained signs, symptoms, and maladaptive personality traits.

Structural research therefore increasingly has bypassed diagnoses to focus on more basic units of psychopathology. Markon's (2010) analysis of more than 100 interviewer-rated symptoms in a British epidemiological study extended the evolving structural model "downward" in the sense of zooming in on the homogeneous components that compose psychological disorders. Factor analysis showed that the symptoms in this study clustered into 20 tight-knit subordinate, or lower-order, dimensions. For instance, hazardous alcohol use, physiological withdrawal, and social role failures secondary to alcohol use cohered into an "alcohol problems" dimension. In turn, Markon (2010) examined how these 20 lower-order dimensions assembled into higher-order factors. This process revealed the familiar internalizing and externalizing factors alongside thought disorder-marked by hallucinations, paranoia, and eccentricity—and pathological introversion-marked by social anxiety, unassertiveness, and dependence.

Other research teams followed Markon's (2010) lead. Symptom-based investigations generated insights into the intermediate factors that function as the connective tissue between manifest symptoms and higher-order factors like internalizing and externalizing. A study by Waszczuk, Kotov, Ruggero, Gamez, and Watson (2017) involving two treatment-seeking samples illustrates this point. They administered an interview measure of *every* symptom of *DSM-IV* anxiety and depressive disorders and found that these manifest variables reflected 31 fairly homogeneous latent factors, such as irritability, dissociation, and anhedonia. These subordinate factors cohered into 8 intermediate factors called syndromes (e.g., vegetative symptoms, cognitive depression, mania); these were subsumed by even broader factors called distress, fear, and obsessive compulsive disorder (OCD)/mania; and surmounting them all was a unifying internalizing factor.

Wazczuk et al.'s (2017) approach demonstrates that clinical phenomena can be organized hierarchically, with several tiers of recognizable constructs arrayed across very high levels of resolution (e.g., trouble eating in front of others) to very low levels (e.g., internalizing). Other research confirmed that this principle extended beyond the internalizing domain (e.g., Kotov et al., 2017).

As quantitative nosologists reviewed this literature, a picture of the higher-order dimensions of psychopathology began to emerge. The internalizing factor was defined by anxiety, depression, and sexual and eating problems; thought disorder by mania and psychotic experiences; detachment by emotional and social disengagement; and somatoform by preoccupation with medically unexplained somatic problems (Krueger et al., 2018). The broad externalizing dimension was differentiated into disinhibited externalizing, identified by antisocial behavior and substance misuse, and antagonistic externalizing, marked by antisocial behavior and maladaptive personality traits like narcissism, attention-seeking, and manipulativeness. The evidence base was stronger for some of these dimensions than others, partly because some of them were only evident in research with comprehensive psychopathology assessment. For example, it was clear that antagonistic externalizing and detachment factors were rooted primarily in characteristics normally associated with PD (e.g., Wright & Simms, 2015).

This research program gained more traction as the main structural elements were replicated across diverse contexts. The hierarchical model of psychopathological symptoms and diagnoses appeared fairly uniform across developmental stage, gender, nation, and clinical setting (Krueger et al., 2003). This generalizability supported the hypothesis that these empirically derived groupings of clinical phenomena might have broad utility as diagnostic tools.

## The Hierarchical Taxonomy of Psychopathology

Investigators recognized that this theoretical framework had the potential to improve on categorical diagnostic systems. In 2015, a group of quantitative nosologists founded the HiTOP consortium to synthesize the work that had been done already into a consensus quantitative model of psychopathology, mobilize continued structural research, and explore its applications (Kotov et al., 2017). As an organization open to all sorts of professionals interested in advancing mental disorder diagnosis, it has expanded steadily in recent years.

### The HiTOP Model

One of the consortium's first acts was to integrate the available evidence to sketch a model of the major dimensions of psychopathology (Figure 3.1; reprinted from Conway et al., 2019). The HiTOP model is a proposal; it is a work in progress intended to evolve with new data. Figure 3.1 is a conceptual diagram, as opposed to a representation of results from a single empirical study. It pieces together evidence from independent studies that have surveyed different sections of this landscape.

The diagram's vertical axis represents breadth. Constructs higher up in the figure reflect characteristics that explain the coherence of constructs situated at lower levels. We will start at the base at work our way up. The *symptom components* are tight-knit clusters of symptomatic behaviors. For instance, a tendency to scan the environment for threats and an exaggerated startle response are part of a symptom component called hyperarousal. *Maladaptive personality traits* occupy the same tier of the hierarchy as symptom components. These are homogeneous individual differences discovered in research on the building blocks of PD.

The symptom components and maladaptive traits assort into dimensional syndromes at the next level of the hierarchy. For example, we tend to summarize the co-occurrence of sadness, anhedonia, insomnia, fatigue, and suicidality by referring to a depression syndrome. By definition, constructs at this level are more complex than symptom components and maladaptive traits. Note that the term "syndrome" generally denotes a disease category, and, indeed, many of the syndromes listed in Figure 3.1 are named after DSM diagnoses. However, here a syndrome is a continuous index of severity of a constellation of homogeneous symptoms and traits. The naming scheme is meant to illustrate the link with DSM symptoms; people can see that the familiar categorical constructs are represented, albeit with some reformatting, in the HiTOP framework.

The syndrome concepts presented in Figure 3.1 are provisional pieces of the HiTOP system. To

distress), syndrome (e.g., depression), and symptom components (e.g., anhedonia) and maladaptive traits (e.g., anxiousness). Dashed lines denote provisional elements requiring further study. At the lowest level of the hierarchy, symptom components are listed in the upper half of the box, and maladaptive traits in the lower half. for heuristic purposes, conceptually related signs and disorder; HiTOP, Hierarchical Taxonomy of Psychopathology; IED, intermittent explosive disorder; MDD, major depressive disorder; OCD, obsessive-compulsive disorder; ODD, oppositional defiant disorder; SAD, symptoms (e.g., Phobia) are indicated in bold, with specific manifestations indicated in parentheses. ADHD, attention-deficiv/hyperactivity disorder; BPD, bipolar disorder; GAD, generalized anxiety the figure are narrower and more specific. Starting at the top and working down, the levels are: superspectrum (i.e., general psychopathology), spectrum (e.g., internalizing), subfactor (e.g., Figure 3.1 Hierarchical Taxonomy of Psychopathology (HiTOP) consortium working model. Constructs higher in the figure are broader and more general, whereas constructs lower in separation anxiety disorder; PD, personality disorder; PTSD, posttraumatic stress disorder. date, there is limited research on how fine-grain symptom components and maladaptive traits tend to co-occur (cf. Forbes et al., in press; Waszczuk et al., 2017). This is reflected in the fact that symptom components and maladaptive traits are matched to groups of syndromes, rather than particular syndromes, in Figure 3.1. Much more is known about the ways syndromes assemble into subfactors and spectra, in large part because of the availability of large community and epidemiologic studies that involve diagnosis-based assessments.

Features shared across syndromes are represented by *subfactors*. Recall the fear and distress constructs that summarized distinct patterns of internalizing problems. The fear dimension embodies the processes that trigger pronounced defensive reactions (similar to the "fight or flight" response) to real or perceived immediate threats. This sort of psychological and physiological overreaction is evident in panic, for instance, where uncomfortable internal sensations are interpreted as signs of an imminent medical problem like a heart attack. At a similar level of breadth to fear and distress are substance use, antisocial behavior, eating problems, and sexual problem subfactors.

Spectrum constructs are at the next level up. These are often the focus of structural research, especially factor analyses of categorical diagnoses (e.g., Krueger & Markon, 2006). As mentioned earlier, there is solid evidence for thought disorder, internalizing, and externalizing—especially the latter two as dimensions that explain patterns in manifest psychopathology. Based primarily on PD research distinguishing disinhibition and antagonism as separate personality dimensions that underpin fairly different sets of clinical phenomena, the HiTOP model splits externalizing into two spectra: disinhibited and antagonistic (e.g., Krueger et al., 2012).

The somatoform spectrum is provisional. It is clear that *DSM-5* somatic symptom disorder and illness anxiety disorder often co-occur with anxiety disorders and that anxiety is the predominant reaction to somatic issues in these conditions (APA, 2013). Nevertheless, the available structural research suggests that somatoform and internalizing problems are meaningfully distinct (Kotov et al., 2011; Sellbom, 2017). The detachment spectrum has also attracted less attention, although structural analyses of PD data over the past couple decades consistently identify this dimension, which represents avoidance of social and emotional engagement. Traces of detachment are evident in autism, as well as in PDs associated with suspiciousness, aloofness, and withdrawal (e.g., avoidant, schizoid).

Surmounting all the spectra is a superspectrum called the general factor of psychopathology (Lahey et al., 2012). It is also known as the pfactor due to its conceptual similarity to intelligence's g-factor that is theorized to encompass all mental abilities (Caspi et al., 2014). It accounts for the correlations among the six spectra. For example, internalizing and externalizing dimensions often are correlated around .50 (Krueger & Markon, 2006), hinting at a common substrate. There are many theories as to what this general factor might represent, but none has been seriously tested (Caspi & Moffitt, 2018). The leading hypothesis is that it reflects general distress, demoralization, and/or impairment that pervade all types of mental health conditions.

#### Implications of a Quantitative Approach

As mentioned, HiTOP involves the same basic units that make up the *DSM*, but it reshuffles them according to how they tend to cluster together empirically. We can think of HiTOP as a diagnostic tool—an alternative to *DSM*—that is distinguished by its emphasis on *hierarchy* and *dimensions*.

#### HIERARCHY

Figure 3.1 clearly reflects HiTOP's hierarchical view of clinical phenomena. From this perspective, there is no single, "optimal" level of resolution for mental health problems. Any condition can be conceptualized at varying levels of resolution. Clark and Watson (2019) provide an example involving insomnia. They start with sleep difficulties reported as "I woke up much earlier than usual." This symptom could be conceptualized as part of a tight-knit symptom cluster representing problems with terminal insomnia (i.e., difficulty with early morning awakenings). Alternatively, it could also be considered a reflection of a broader insomnia construct, which encompasses trouble sleeping at early, middle, and late points of the sleep cycle. At an even broader level, there is evidence that it is part of a *depression* syndrome that involves sleep, weight, mood, and cognitive problems. Finally, a pattern of early awakenings also can be thought of as an internalizing problem; terminal insomnia and other sleep disruptions permeate various expressions of anxiety and depression.

To repeat, there is no optimal level of resolution, or frame of reference, for any mental health problem. One can zoom in as far as possible to consider a manifest symptom in terms of its specific ecology or context. What biological processes regulate difficulty returning to sleep after an unexpected awakening? How can the patient limit sunlight exposure during the early morning hours when they would like to be asleep? Alternately, one can just as easily zoom out and address the more general context in which the symptom is embedded. What biological factors predispose people to internalizing problems? What behavioral treatments are known to alleviate internalizing distress?

The researcher or clinician can choose the level of abstraction that is best suited for their particular objective. If the question concerns a process that mental health problems have in common, they can focus on a higher-order dimension. This is how the HiTOP model copes with comorbidity among categorical diagnoses. Professionals can work directly with the construct(s) hypothesized to reflect psychopathological processes that shape multiple conditions.

On the other hand, if the research or clinical question has to do with a very specific problem, such as anxiety in performance situations (e.g., public speaking), one can bypass categorical diagnoses and zero in on the particular symptom component or trait of interest. This flexibility allows a bit more control over the problem of heterogeneity that is baked into diagnostic categories. Some people with DSM-5 social anxiety disorder qualify for the diagnosis on the basis of significant performance anxiety, but others struggle primarily with other forms of social interaction anxiety (e.g., difficulty talking to coworkers and authority figures). The syndrome (in DSM's case, a categorical syndrome) collapses across these more specific features. HiTOP allows case conceptualization, diagnosis, research, and treatment to focus on these detailed, lower-order elements if need be.

HiTOP's hierarchical format mirrors other individual difference domains. Cognitive ability and personality are structured in much the same way. We alluded to the general intelligence factor (g) that purportedly explains why people who perform well on one IQ "subtest" (e.g., putting blocks together to make a pattern, remembering who wrote "Hamlet," recalling a string of numbers) tend to do well on the others. There is also a range of intermediate abilities, akin to HiTOP spectra and subfactors, such as verbal memory, visuospatial reasoning, and processing speed. Others are narrower still (e.g., vocabulary, matrix reasoning), mirroring symptom components and maladaptive traits.

#### DIMENSIONS

Using dimensions, it is much easier to consistently rate people in terms of severity. There is much more room on a dimension to decide that person X has much more of a quality than person Y, but slightly less than person Z. This subtlety is impossible with binary diagnoses. A categorical depression diagnosis does not discriminate between the person who seemingly has never had a gloomy day in their life and the person who for the past 2 years has been actively suicidal, sad, sleeping poorly, and feeling worthless but is missing a fifth criterion that would cross the threshold for an MDD diagnosis.

This extra information in the dimensional system fosters reliability. People's relative position on a psychopathology dimension is stable over brief intervals. Clinicians have better agreement regarding the severity of clinical phenomena (Markon et al., 2011). This is in large part because dimensions avoid the tricky business of deciding whether a patient falls just above or below a categorical threshold. In other words, dimensions largely sidestep the problem of fuzzy boundaries between psychopathology and normality. The dimensional hypothesis embraces that fuzziness; it assumes a continuum of clinical problems that applies to everyone from the most healthy to the most sick. Everyone is "on the spectrum" according to this model.

## **Research Utility**

HiTOP is a descriptive system—another way of cataloging psychopathology—but it can do more than describe. In this section, we cover how HiTOP dimensions are applied to advance realworld research into the causes and consequences of psychopathology. That is, we examine associations between dimensional psychopathology constructs and variables outside the HiTOP system. These associations reflect the model's *research utility*. Whereas the structural research underpinning Figure 3.1 tells us what HiTOP "is," studies focused on research utility tell us what the model "does."

## Siloed Research Literatures

The misconception that *DSM* diagnoses have distinctive ecosystems (e.g., separate causes) has generated a very decentralized literature. It makes sense, from that perspective, for investigators to study one disorder at a time. As a result, knowledge has accumulated in a piecemeal fashion. This applies not just to individual research projects but also to entire careers. Today it is still common for investigators to build a research program around one condition (e.g., "I am a borderline PD expert"), and this trend was even stronger in earlier generations. Researchers sometimes even screen out people with other diagnoses from data collection to minimize "noise." Perhaps at the most extreme, training environments can be explicitly structured around a single *DSM* condition, as is the case with some US Veterans Affairs sites that specialize in PTSD.

This norm creates information silos. Each study or each research program tells only part of the story relevant to a particular cause, correlate, or outcome. These often have a much more complex web of associations with psychopathology than we assume. Connecting the dots is rarely easy because there tends to be very little cross-talk among research teams that are working on different diagnoses.

The field is gradually coming to terms with this inefficiency. It helps when high-profile research findings raise awareness of the problem. The most prominent one in recent memory involves molecular genetics. When the human genome was sequenced, many investigators proclaimed that it was only a matter of time until the gene(s) that determined every DSM diagnosis were identified. After years of research and millions of funding dollars, it became apparent that there was no gene "for" any single diagnosis (Kendler, 2005). Quite the opposite was true: each disorder was related to many different genes, and relevant genes were linked to many disorders. Genetic effects were crossing diagnostic boundaries. This observation has fundamentally changed the way psychiatric geneticists define the phenotypes they study, and they more rarely target DSM diagnoses (Waszczuk et al., 2020).

In sum, huge bodies of information have amassed around *DSM* diagnoses. This makes for a fractured, incomplete picture of how psychopathology relates to important risks and outcomes. This is probably not the optimal way to set up a research agenda. HiTOP provides an outlet by offering an alternative research heuristic that proposes to completely restructure the design and interpretation of empirical studies.

#### An Integrative Approach

We introduce this heuristic with an example. Consider a study on psychophysiological responses to a social stressor. The investigator hypothesizes that people diagnosed with social anxiety disorder (SAD) will overreact—in terms of heart rate, sweat, and respiration—to a standard "evaluative" stressor. The research participants, a mix of people with and without SAD, undergo a common test in stress research: they are asked to deliver an impromptu speech in front of a small audience. Electrodes record physiological activity throughout the task.

The study design and conceptual hypothesis (SAD  $\rightarrow$  hyperarousal) seem sound; they are what we are used to finding in journal articles. Consider how they might be reframed from a HiTOP perspective. First, social anxiety is conceived of as a dimension, as opposed to a dichotomy. A dimensional operationalization makes it easier to identify the individual differences in anxiety among the research participants. Second, as illustrated in Figure 3.1, social anxiety can be conceptualized at multiple levels of analysis. It has both coarse and fine components, just as we mentioned that insomnia is reflected in higher- and lower-level constructs in the internalizing domain.

What this means practically is that a researcher can empirically test, *not just assume*, which social anxiety constructs contribute to the outcome. This flexibility is not possible with categorical rubrics, where the syndrome is the preordained level of analysis. This obscures which part(s) of the clinical picture are "driving" the associations with the outcome. A *DSM* diagnosis is therefore a little bit like a black box—a mix of unknowable components that HiTOP can unpack.

Returning to the example, one can envision a number of different ways that social anxietyconceptualized hierarchically-relates to physiological arousal in the face of evaluative stress. (1) It might be that a very specific symptom component, such as performance anxiety, predicts hyperarousal. Or (2) hyperarousal could depend primarily on the broader constellation of symptom components that make up the SAD syndrome. Alternately (3) it could be that hyperarousal is a common feature of all fear-related disorders, shared by any condition marked by a very sensitive "fight or flight" response. Finally, (4) the key ingredient might be the general propensity to experience negative affect, represented by the internalizing spectrum. Still other scenarios are possible. The take-home message is that we need not assume categorical syndromes are "where the action is"; we can empirically test out all of the possible pathways.

This methodology can be applied to any substantive research area—neuroscience, personality, social relationships, development, and so on. Indeed, this heuristic has generated new insights into how mental disorders onset, develop, and shape important life outcomes (reviewed in Conway et al., 2019). To give a sense of HiTOP's possible research applications, we selectively review this expanding body of evidence in the remainder of this section. For convenience, we group the literature into four topics: personality, genetics, neurobiology, and social environment. We concentrate on two principal themes that cut across this work. First, thinking hierarchically can change the questions we ask about psychopathology. Instead of hypothesizing about the correlation between one syndrome and one outcome, we can inquire about the levels of analysis (e.g., maladaptive trait, syndrome, spectrum) in a particular psychopathology domain that are most relevant to the outcome.

Second, examining HiTOP's criterion validity tells us a lot about its research utility. If empirically derived psychopathology dimensions relate in expected ways to external variables, then they have predictive and explanatory power. Therefore, the effects observed in these studies indicate how useful the heuristic might be going forward. If all effects are very small, or if syndrome constructs tend to have the most explanatory power, then it might make sense to continue to use (dimensionalized) *DSM* operational definitions of mental disorder to test substantive theories. But if meaningful effects are evident across multiple levels of analysis, then there is some evidence to support this model's utility.

#### Personality

Just as is the case with psychopathology within the HiTOP framework, the most influential framework for understanding personality traits is hierarchical. Thus most students learn that personality traits are often characterized in terms of five dimensions—neuroticism, extraversion, conscientiousness, agreeableness, and openness—each of which can be broken down into more specific facets and even smaller "nuances" (Mõttus et al., 2017).

There is more than just architectural resemblance between the domains. Personality is thought to lay the foundation for mental disorder (Clark, 2005). Indeed, this overlap is reflected in the HiTOP model, which rests in part on maladaptive personality traits at the base of the hierarchy. Moreover, several of HiTOP's broader constructs, such as the detachment and antagonistic externalizing spectra, derive almost entirely from research on personality and PD (e.g., Wright & Simms, 2015).

We are beginning to learn about the empirical connections between the two hierarchical domains (Widiger et al., 2019). One early effort involved more than 1,000 middle-age participants in the Minnesota Twin and Family Study who completed diagnostic interviews and personality questionnaires (Krueger et al., 2001). Krueger et al. (2001) used factor analysis to model internalizing as the commonality among anxiety and depressive disorders and externalizing as the commonality among antisocial behavior and substance use disorders. Individual differences on internalizing were significantly correlated with neuroticism (mean r across gender = .25), but not constraint (a near-neighbor of conscientiousness; mean r = .03), which is the ability to keep impulses in check. Externalizing had the opposite pattern of associations (neuroticism r =.02, constraint r = .24). Meanwhile, neither internalizing nor externalizing was linked substantially to extraversion (mean r = -.04).

Among the traits Krueger et al. (2001) examined, neuroticism has perhaps attracted the most research attention. High neuroticism is associated with all manner of physical and mental health problems, especially anxiety and depression (Kotov et al., 2010). Psychologists have designated it as a serious public health problem (Lahey, 2009). More recent personality research has found an even closer correspondence between neuroticism and internalizing than what was reported in the Minnesota Twin and Family Study. In a large cohort of high schoolers enriched for risk of anxiety and depression, Griffith et al. (2010) asked teens to make personality ratings, which included several self- and peer-rated neuroticism scales, and administered standard diagnostic interviews to assess mental disorder. In this study, there was a near-perfect correlation between neuroticism and internalizing (r = .98), whereas neuroticism was much more modestly related to externalizing (r = .29).

Most applied work has involved the HiTOP spectrum-level constructs. To represent lowerlevel dimensions, factor analysis tends to require a wide variety of manifest symptom or disorder variables, and there are relatively few research projects with that sort of comprehensive psychopathology coverage. One such study involved a thorough diagnostic workup and personality assessment in an epidemiological sample of 6,000 adults who responded to the National Comorbidity Survey (Levin-Aspenson et al., 2019). Analysis of the correlations among diagnoses yielded a four-tiered structural model: the *p*-factor was at the summit, and, at a second level, it bifurcated into internalizing and externalizing. At the third level, internalizing divided into fear and distress, and, at the fourth, a thought disorder factor broke off of distress. The *p*-factor had medium ( $r \approx .40$ ) and small ( $r \approx .10$ ) correlations with neuroticism and extraversion, respectively. By examining effects of lower-level dimensions, the authors were able to determine that the *p*-factor's correlation with neuroticism was driven by internalizing dimensions and that its (inverse) correlation with extraversion was attributable to the fear dimension in particular.

Sellbom and colleagues (2020) extended this approach (i.e., studying broad and specific psychopathology phenotypes in relation to personality) to a wider set of personality domains. They recruited 3,000 adults to respond to 29 self-report measures of psychopathology and one measure of maladaptive personality traits. These maladaptive traits came from a leading dimensional model of PD that includes negative affectivity, detachment, antagonism, disinhibition, and psychoticism. These five broad domains have close ties to the primary dimensions of the Five Factor Model of personality. Factor analysis reduced the psychopathology data to 10 factors, which represented syndromes like depression, panic, and psychosis. The interrelationships of these 10 factors were themselves factor analyzed to produce even broader latent dimensions. The factors representing anxiety and depression symptoms cohered into higher-order distress and fear subfactors, which, in turn, coalesced into an even broader internalizing spectrum. Alongside internalizing were thought disorder (encompassing obsessive-compulsive and psychosis factors) and externalizing (inattention, alcohol, and drug problems) spectra. Finally, all three of these spectrum constructs were modeled as representations of a superordinate *p*-factor.

With the complex model of mental disorder symptoms set, Sellbom et al. (2020) tested the dimensional constructs' associations with personality traits. Nearly all of these effects were about as large as was expected, attesting to the robust, predictable relations between the personality and psychopathology domains. Noteworthy results included strong associations of negative affectivity with internalizing (r = .84); psychoticism—a trait capturing eccentricity, unusual beliefs, and perceptual aberrations—with thought disorder (r = .74); and disinhibition—an amalgam of impulsivity and irresponsibility, similar to (low) constraint with externalizing (r = .75). Also, negative affectivity (r = .90), detachment (r = .74), and psychoticism (r = .78) were all intimately related to the general factor of psychopathology.

Together, these results demonstrate that many broad psychopathology dimensions have close analogs in the personality literature, consistent with prominent theories of temperament and personality as core factors in the development of mental disorder (Clark, 2005). Future research will focus on the best ways to overlay these two domains in evolving structural models of psychopathology (Widiger et al., 2019).

#### Genetics

Findings from the quantitative genetics literature strongly suggest that conditions that tend to cluster together phenotypically also tend to have a shared genetic substrate (Waszczuk et al., 2020). That is, the separable individual difference factors emerging from structural research on phenotypes (e.g., fear, distress, thought disorder) appear to line up with distinct genetic factors. This is evidence that the phenotypic dimensions compiled in HiTOP summarize meaningfully distinct etiological pathways to mental illness (Lahey et al., 2017).

In an investigation of 2,000 Norwegian twins, the genetic correlations (i.e., indices of overlap among genes that predispose to different phenotypes) among 22 clinical disorder and PD diagnoses pointed to four underlying genetic factors, interpretable as internalizing, disinhibited externalizing, antagonistic externalizing, and detachment (Kendler et al., 2011). Several other projects confirm the genetic coherence of individual spectra. For example, in the Minnesota Twin and Family Study  $(N \approx 2,000)$ , antisocial behavior, conduct disorder, and various forms of substance dependence were evaluated in a sample of biological and adoptive families (Hicks et al., 2013). The phenotypic correlations among these antisocial behavior and substance misuse conditions supported a unifying externalizing factor, which turned out to be highly heritable, such that 61% of the individual differences on the factor were attributable to genetic differences among participants.

There is evidence for distinct genetic factors at lower levels of the HiTOP model, too, although the data are more limited. Studies find that more homogeneous clusters of conditions, such as symptom components, have unique genetic causes. However, these sources of variation tend to be smaller than those for higher-order dimensions (e.g., Kendler et al., 2013).

A constraint of quantitative genetic research is that it cannot pinpoint the parts of the genome that confer risk. It is based entirely on differences in relatedness among individuals, not direct measurement of genetic variation. This is where molecular genetic methods come in. As genomic technology grows increasingly easy to use, there has been an explosion of research into the specific genetic sequences that contribute to psychopathology. Genome-wide association studies (GWASs) simultaneously examine thousands of genetic polymorphisms in relation to psychopathology phenotypes.

Despite the promise of new technologies, the yield in terms of credible breakthroughs has been limited. The signal associated with particular variants tends to be fairly weak and inconsistent across studies (Sullivan et al., 2018). Part of the problem appears to be the phenotyping, which has not kept pace with technological advancement on the genetic side of the equation. There is concern that categorical disorders—some of which, as described at the outset, were formulated a century ago on the basis of clinical intuition—might not systematically map onto human genetic differences.

There is growing interest in alternate phenotypic approaches that can advance molecular genetic research in psychopathology. HiTOP is a promising solution. It minimizes the problem of heterogeneous diagnostic categories, which attenuate the connection between genes and psychopathology when a variant is associated with part, but not all, of the diagnostic picture (e.g., cognitive, but not vegetative, components of depression). It also accommodates the significant multifinality-called "pleiotropy" in genetics-evident in the psychiatric genetics literature. GWASs show that the genes implicated in one diagnostic category are typically related to various other conditions; a one-gene-tomany-conditions pattern rather than one-geneto-one-condition relationship (e.g., Sullivan et al., 2018). This makes it virtually impossible to create a distinctive etiological model for any categorical disorder.

To be more precise, HiTOP addresses the problems of heterogeneity and pleiotropy by explicitly disentangling the broad and specific phenotypes that compose a particular psychopathology domain. With a hierarchical structure, it should be possible to discover what genetic variants confer widespread vulnerability to mental illness (e.g., at the superspectrum or spectrum level), as compared to variants that have a more specific influence at, say, the symptom component level (e.g., Waldman et al., 2020).

A number of large-scale investigations have now published linkages between genetic polymorphisms and broad psychopathology phenotypes, such as the *p*-factor, internalizing, and fear (reviewed in Waszczuk et al., 2020). These studies adopt the same structural research methods that illuminate the HiTOP constructs and use the resulting, continuously distributed factors, as opposed to categories, as targets in gene finding studies. This approach appears to be accelerating the hunt for replicable genetic risk factors, but research in this area is just beginning.

## Neurobiology

Much like specific collections of genes are known to contribute to diverse mental health conditions, the same neural circuitry is implicated in vulnerability to various categorical disorders. Psychiatry has long lamented this state of affairs. The refrain is that "there is no biological test for any mental disorder," at least as portrayed in *DSM*. This desideratum is called a "pathognomonic" marker, a risk factor that has a one-to-one relationship with a disorder. This is a common feature of modern medical diagnoses that has not materialized for psychopathology; it is impossible to discern one category from another on the basis of some neurobiological signature. Multifinality is the rule, not the exception, in this area (Latzman et al., 2020).

Amygdala responsivity in the face of threat is a well-known example. When people are presented with threatening cues in the functional magnetic resonance imaging (fMRI) scanner, limbic regions such as the amygdala come online (Hariri et al., 2003). Amygdala reactivity is stronger for some people than others, though. This variation is related to risk for depression, anxiety, posttraumatic distress, and substance misuse, among other clinical problems (for a meta-analysis, see McTeague et al., 2020). Elevated activity in this region is a nonspecific risk marker. This type of multifinality in fact characterizes many other indices of brain structure and function that show up in popular etiological accounts of psychopathology, especially anxiety and depression (Zald & Lahey, 2017).

HiTOP provides neurobiologists with a framework that can help to make sense of these findings. One early study used factor analysis to create a hierarchical model of externalizing problems in a group of almost 2,000 European 14-year-olds recruited through their high schools (Castellanos-Ryan et al., 2014). (This is a massive sample size by the standards of neuroimaging research, which is expensive.) Their model consisted of substance abuse and antisocial behavior subfactors, plus a broader externalizing spectrum. Adolescents performed tasks in the fMRI scanner related to inhibition and reward sensitivity. For example, neural activity was monitored as adolescents anticipated the receipt of a monetary reward. The research team reported that the model's three dimensions were associated with different patterns of task-related neural activity. Whereas the externalizing factor had its strongest connection with activity in the substantia nigra and subthalamic nucleus, individual differences in the antisocial behavior factor were linked with frontal cortex activation.

This result indicates that a hierarchical description of externalizing problems can identify new connections between brain function and externalizing problems. They also found effects for these latent factors on behavioral and subjective report variables assessed during the brain scans. That is, the three psychopathology dimensions were differentially related to self-reported and task-based tendencies to make impulsive decisions and inhibit inappropriate responses (Castellanos-Ryan et al., 2014).

There has been substantial interest in the neural correlates of the *p*-factor. Several teams have found that brain activation patterns during popular neuroimaging tasks, such as when participants complete working memory tasks, show meaningful relationships to *p* (e.g., Kaczkurkin et al., 2019). Studies have also examined *structural* brain differences as a function of *p*. For example, in one sample of children (ages 6–10), the *p*-factor was inversely associated with gray matter volume in prefrontal regions (Snyder, Hankin et al., 2017). In this same sample, the internalizing factor, but not *p*-factor, was related to gray matter reductions in limbic areas like the amygdala.

#### Social Environment

Psychopathology does not occur in a vacuum. The environmental context, and social milieu in particular, are intimately intertwined with the onset, severity, and time course of common mental health problems. Countless presentations, articles, and books have delved into the nature of this complex association. Yet, from a HiTOP perspective, most of this investigation has been incomplete, unnecessarily focused on *DSM* constructs that may not best represent how psychopathology manifests as a function of environmental exposures.

Childhood maltreatment is an especially powerful vulnerability factor; its effects endure long after the abuse or neglect stops. Moreover, it confers risk for virtually every known mental health condition. HiTOP is well-suited to handle this nonspecificity. The framework recognizes all possible pathways from early adversity to psychopathology, ranging from the most general (e.g., impact on the *p*-factor) to the highly specific (e.g., impact on maladaptive personality traits).

Keyes et al. (2012) started a line of inquiry into this topic. They analyzed data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), a general population sample of more than 43,000 US adults who completed face-to-face diagnostic interviews. Keyes et al. (2012) found that various retrospectively reported maltreatment events, such as physical abuse and neglect, were robustly related with the full gamut of DSM-IV diagnoses. This result echoed those from many other studies. The advancement was that Keyes et al. discovered that maltreatment was not consistently associated with the parts of diagnoses that were unshared with related conditions. They observed that maltreatment predicted higher standing on the internalizing and externalizing factors, which represented the common elements among their constituent diagnoses, and that effects on individual diagnoses were all mediated through these spectrum-level constructs.

A number of other longitudinal studies corroborated the NESARC result (Caspi et al., 2014; Conway et al., 2018). Another study, which was technically cross-sectional, monitored 2,000 lowincome children, half of whom had verified histories of maltreatment (e.g., confirmed by review of health department records) (Vachon et al., 2015). Structural analysis of symptom scales indicated that the various observed mental health problems (e.g., withdrawal, somatic complaints, rule-breaking) could be effectively summarized with the familiar internalizing and externalizing dimensions. As in Keyes et al. (2012), maltreatment was linked to these spectrum-level constructs but not to the unique parts of each of the more homogeneous symptom dimensions.

None of these studies modeled the *p*-factor, but they hinted that stressor effects might transcend the spectra. This would explain why maltreatment seems have fairly uniform effects on all types of mental health problems. Other research on social stressors in adolescence and adulthood has explicitly examined the p-factor (e.g., Snyder, Young, & Hankin, 2017). One investigation studied the impact of peer victimization, a strong predictor of academic and social success in adolescence and beyond. The dataset included 3,000 14- and 15-year-olds who reported on victimization experiences (e.g., verbal abuse, relational aggression) and psychological symptoms (Forbes et al., 2020). The authors represented the adolescents' symptom scores with a hierarchical model capped by the pfactor. Peer victimization was reliably linked to all psychopathology dimensions in the model; a history of victimization corresponded to about a 1 to 1.5 standard deviation increase in internalizing, externalizing, and p. Mediation analyses showed that almost all of victimization's effects on internalizing and externalizing were attributable to its effect on p. The authors concluded that victimization confers vulnerability to such a broad range of problems because of its relationship to the *p*-factor.

#### Summary

We can take away at least two lessons from the growing literature on HiTOP's research utility. First, the data generally support psychopathology dimensions' criterion validity (i.e., prediction of external variables). Not only do HiTOP constructs systematically relate to other variables *within* the model—as when an internalizing dimension accounts for the pattern of correlations among anxiety, depression, and somatic problems—but they also reliably predict variables *outside* the model, such as individual differences in brain function and personality. This type of information builds confidence in the interpretability and validity of the HiTOP constructs.

Second, HiTOP can unify literatures that until now have been developed in quasi-independent silos. For any given risk factor, enormous bodies of research have sprung up around the many individual diagnostic categories. These data say nothing, though, about whether risk is conveyed at the level of diagnoses (i.e., syndromes) or through higher- or lower-level pathways. HiTOP lifts this constraint. Many of the findings so far indicate that risk factors operate primarily at the level of broader psychopathology dimensions. However, this need not be the case for every risk factor or in every population. The point is that HiTOP allows an empirical test of how risk factors act on psychopathology instead of assuming it occurs at the syndrome level. This flexibility should improve the

precision and power of etiological theories of mental disorder.

## **Clinical Utility**

Categorical diagnoses can be a headache for practitioners. Problems like rampant comorbidity and marked heterogeneity complicate clinical judgments like what primary diagnosis to assign and what treatment is indicated. Surveys of clinicians suggest that more detailed characterization of patients—beyond a binary label—would improve their ability to make valid decisions about diagnosis, prognosis, and treatment (e.g., Maj, 2020). In this section, we describe how HiTOP can foster sound decision making in several aspects of ordinary practice.

### Assessment

#### DIMENSIONAL ASSESSMENT

In a dimensional system like HiTOP, assessment focuses on quantitative indices of severity. This perspective presumes that people differ in mental health as a matter of degree, not as a matter of kind. It implies that every patient can be scored on a psychopathology variable, whereas in traditional evaluations a clinician might "skip out" of a particular domain when a patient does not satisfy one or more cardinal requirements for the *DSM* diagnosis. Even if the assessor is focused on syndromes, these can be measured quantitatively (e.g., as a composite score), as when clinicians disregard "skip-out rules" to evaluate the severity of all disorder symptoms (e.g., Watson et al., 2012).

To be interpretable, dimensional scores require norms. *Norms* are summaries of scale scores drawn from a population of interest. A patient's performance is compared to the norms to figure out where they fall in relation to an appropriate comparison group. If a normative sample of prisoners scores on average a 50 (standard deviation = 5) on a measure of aggression, then when a primary care patient scores 62 on that same measure the physician can be assured that the examinee is highly aggressive. These norms allow more precision, relative to a binary diagnosis, in determining the amount or severity of psychopathological constructs (e.g., Stasik-O'Brien et al., 2019).

Although dimensions convey more information than dichotomies, it could be argued that binary diagnoses, at first glance, lend themselves better to clinical decision-making. So many practical decisions are categorical: whether to treat, what treatment to administer, whether to hospitalize, and so on. Often when patients cross the threshold of a binary diagnosis, these other decisions follow closely on their heels without weighing much extra clinical data. After all, categorical diagnoses in medicine are intended to connote prognosis and treatment, not to mention etiology, pathophysiology, and time course.

When assessing dimensional HiTOP constructs, there are no such obvious thresholds. There has been increasing attention, therefore, to the idea of empirically based cutoffs to guide categorical decisions. For a given dimension, it is possible to determine a range of scores that imply different actions. One can imagine different spans of a continuum that indicate different treatment intensities, such as "none," "watchful waiting," "outpatient care," and "inpatient care." This graded approach is consistent with the logic behind *stepped care* (also called *staged care*) that, in an effort to economically allocate scarce intervention resources, matches patients with the treatment intensity appropriate to their current status (e.g., Davison, 2000).

Dimensional assessment is not an entirely foreign concept. In medicine, characteristics like blood pressure, cholesterol, and weight are all natural continua, but cutoffs have been artificially imposed to help with decision-making. These cutoffs are usually based on empirical findings regarding ranges of the continuum that are associated with morbidity or mortality. For example, the designations "overweight" and "obese" are two successive categories that have been superimposed on a continuum to identify people who might benefit from lifestyle change and/or medical intervention.

In psychology, intelligence is the poster child for dimensional assessment. IQ is a natural gradient, but it is useful for clinical purposes to delimit regions of the continuum that imply a need for services, such as an individualized education plan for school children. A cutoff based on empirical norms is incorporated into the *DSM-5* diagnosis of intellectual disability, such that an IQ score that falls 2 standard deviations below the population mean is necessary (albeit not sufficient) for a diagnosis. This integration of continuous psychometric information with categorical decisions is an instructive model for dimensional assessment based on HiTOP constructs.

#### HIERARCHICAL ASSESSMENT

A HiTOP-oriented assessment routine is highly flexible with respect to breadth. It allows clinical description at the various levels of resolution demarcated in Figure 3.1, as opposed to the syndromeonly approach implicit in *DSM*. The assessment protocol can "telescope" or unfold across different HiTOP strata depending on the task at hand.

The desired degree of specificity could depend on a number of factors. Most generally, it depends on the goal of the assessment. If a patient is referred for OCD, the assessor may choose to concentrate on the symptom components and maladaptive traits most strongly associated with this syndrome, such as checking, compulsions, and rituals. If instead the objective is to screen for risk of any mental disorder, the assessor may target broader dimensions like the *p*-factor.

Available assessment time might also constrain the areas of the HiTOP model an evaluator can reasonably cover. When time is short, it may make sense to briefly screen the severity of the six spectra (Ruggero et al., 2019). If more time is allowed, an assessor may choose to probe a larger number of lower-order dimensions. In this same vein, interviewers might take advantage of follow-up visits to drill down into a spectrum that was flagged during an intake evaluation. This more detailed coverage can help to develop a nuanced clinical picture that might be used to guide ongoing treatment or predict salient life outcomes.

The general idea is that scores on narrow symptom dimensions (e.g., insomnia, appetite loss) represent the variation on broader dimensions (e.g., distress) in greater depth (Clark & Watson, 2019). Conversely, broader dimensions summarize the information conveyed by narrower ones at a higher level of abstraction and are, as a result, comparatively heterogeneous. The hierarchical perspective on psychopathology allows assessors to adjust their focus as a function of the clinical setting and purpose of the evaluation.

#### CASE ILLUSTRATION

What would HiTOP-informed assessment look like in the clinic? Imagine that a 30-year-old woman is referred to you complaining of depression, worry, and obsessive thoughts about contamination. As mentioned, the first step might be to screen for elevations across the higher-order aspects of the HiTOP model. The Personality Inventory for *DSM-5* (PID-5; Krueger et al., 2012), which has a 25-item brief version, might be a fairly quick way to document clinical problems at the spectrum level. That is, the PID-5 has scales that map on to the internalizing (PID-5 Negative Affectivity), disinhibited externalizing (Disinhibition), antagonistic externalizing (Antagonism), detachment (Detachment), and thought disorder (Psychoticism) spectra.

The next step would be to conduct further assessment of the most pressing problem areas, as identified by comparing the patient's PID-5 scores to normative data (see, e.g., Miller et al., 2022). In our case, the PID-5 profile signaled a spike in internalizing problems and, to a much lesser extent, detachment. Thus, you might choose to next administer the Inventory of Depression and Anxiety Symptoms (IDAS-II; Watson et al., 2012), an empirically derived measure of the general and specific components of the internalizing spectrum. The specific dimensions, mapping on to the symptom component level of the HiTOP model, include traumatic intrusions, insomnia, appetite loss, mania, suicidality, and more. Based on the presenting problems, we would expect elevations on Dysphoria, which is a broad scale that encompasses the general features of emotional disorders, such as depressed mood and worry; Well-being, a specific scale that taps into (the opposite pole of) anhedonia, a common feature in depression; and Cleaning, a specific scale that measures contamination fears and compulsive cleaning behavior.

There are many other measures that capture the higher- and lower-order features of internalizing, detachment, and other domains of the HiTOP framework. Kotov et al. (2017) presented a thorough but nonexhaustive list, and more are cataloged on a website maintained by the HiTOP consortium (https://psychology.unt.edu/hitop). More information on approaching clinical assessment through a HiTOP lens is available from Ruggero et al. (2019). Finally, it is worth mentioning that, as of this writing, an omnibus self-report questionnaire to survey the entirety of the psychopathology landscape, as mapped by the HiTOP consortium so far, is under development but not yet published (Simms et al., 2022). Once this measure is available, it will represent a comprehensive tool for assessing dimensional psychopathology phenotypes. There are plans for interview forms and computerized adaptive tests, which should enable huge savings in administration time, to supplement the questionnaire version.

#### Prognosis

Patients are often interested in knowing about the natural course of an illness and the burden that they can expect it to impose over time. Practitioners are interested in monitoring naturalistic and treatment-mediated improvements in psychopathology over time. Categorical diagnoses are not ideally suited for these tasks. They tend to be fairly unstable, and they provide the coarsest possible index of status change (i.e., a binary no vs. yes). In theory, then, dimensions are a superior way to conceptualize clinical change and render prognostic judgments.

A growing evidence base attests to HiTOP's ability to predict clinical outcomes. A consistent finding is that HiTOP spectra show high temporal stability over short and long intervals. In a Dutch general population study, Vollebergh et al. (2001) found impressive continuity in distress, fear, and externalizing factors over a 1-year span (autocorrelation range = .85 to .96). Continuity does not decline much in studies with longer retest intervals (e.g., Krueger et al., 1998). These data suggest that empirically derived dimensions are better reflections, compared to categorical disorders, of the stable individual differences that contribute to mental disorder and shape clinical outcomes.

All mental health systems are concerned with risk of harm to self and others that can accompany psychopathology. There are some data that indicate psychopathology dimensions might be a superior way to forecast risk of suicide than are categorical diagnoses. In the NESARC study, Eaton et al. (2013) found that the distress subfactor was a potent predictor of suicide attempts across a 3-year interval separating assessment waves. Individual differences in distress explained roughly one-third of the variation in suicidality. In contrast, each categorical mental disorder—including some of the usual suspects, such as major depression—in the study explained no more than 1% of outcome variance after adjusting for distress.

Other research in large samples has since reinforced this finding. For example, in a longitudinal study of more than 30,000 children around 10 years old, a *p*-factor reliably predicted suicide attempt history at age 18 (standardized effect = .25), whereas lower-order factors representing inattention, impulsivity, opposition, and anxiety/emotion domains had comparatively small effects (O'Reilly et al., 2020).

Often psychosocial functioning is as much a target of intervention as are mental disorder symptoms. Psychologists are eager to predict breakdowns in normative function that might derail symptom improvement or signal the need for more intensive care. Psychopathology dimensions generally seem to do a better job at predicting such impairment over time. A decade-long study in a large cohort of PD patients showed that quantitative representations of mental disorders were more reliable markers of impairment across various intervals than categorical indices of the same constructs (Morey et al., 2012). Kotov et al. (2016) found that, in a group of 628 first-admission psychosis patients, dimensions in the thought disorder spectrum predicted sizable proportions of variance in social functioning measures (e.g., residential independence) 20 years after their first clinical contact.

#### Treatment

Psychologists tend to design treatments that target one *DSM* diagnosis. Again, this makes perfect sense if those diagnoses truly represent natural kinds with distinct underlying psychological malfunctions. In this case, each diagnosis would seem to require its own unique intervention. The best-practice treatment guidelines published by professional bodies reflect this way of thinking (e.g., American Psychiatric Association, 2019; US Department of Veterans Affairs, 2019).

Earlier we reviewed many of the conceptual and practical problems with addressing each categorical disorder as a discrete problem in healthcare settings. But psychology training programs and professional organizations rarely acknowledge these dilemmas, so it is perhaps unsurprising that mental health professionals rarely follow categorically oriented treatment guidelines in ordinary practice. Instead of matching a categorical disorder to its indicated treatment, psychologists are apt to address the most salient patient characteristics, which inevitably cut across DSM entities (e.g., anger, worry) (e.g., Rodriguez-Seijas et al., 2017). Indeed, there is some empirical evidence that psychiatrists prescribe medications more as a function of outstanding symptom characteristics (e.g., suicidality, psychomotor retardation) than diagnoses (e.g., MDD) per se (Waszczuk et al., 2017). Thus, practitioners seem to be overriding practice guidelines to focus their energies on clinically recognizable symptom clusters, rather than DSM labels.

There is an alternative way to coordinate treatment that is more compatible with the HiTOP approach. Just as an assessment routine can "telescope" to address broader or narrower clinical problems depending on the context, so, too, can treatment expand or contract to address phenomena that transcend *DSM* diagnoses. We spend the remainder of this section describing one such treatment that has gained a strong foothold in the literature over the past decade and has developed hand in hand with the HiTOP framework.

## UNIFIED PROTOCOL FOR THE TRANSDIAGNOSTIC TREATMENT OF EMOTIONAL DISORDERS

The Unified Protocol for the Transdiagnostic Treatment of Emotional Disorders (UP) is a psychological treatment intended to address the full array of emotional disorders (Barlow et al., 2017). The term "emotional disorder" is a bit difficult to pin down, but it refers loosely to mental disorders marked primarily by emotion dysregulation. In the literature this typically means anxiety and depression, but maladaptive reactions to negative emotion are implicated in numerous other *DSM* disorders, ranging from somatic symptom disorder to alcohol use disorder.

The UP targets ineffective reactions to negative emotion that end up prolonging emotional problems. Again, this process is not unique to any *DSM* diagnosis; one could argue it is part and parcel of countless mental health problems (Barlow et al., 2014). Despite reason to believe this is a shared underlying mechanism for an array of emotional disorders, at least 50 separate psychological treatments have been developed and accredited (as evidence-based) for anxiety and depression (Cassiello-Robbins et al., 2020). Virtually all of these are geared toward a single disorder entity.

A comprehensive intervention that goes straight to the source of these different expressions of emotion dysregulation could kill two (or more) birds with one stone. In theory, it would be effective regardless of the exact variety of emotion dysregulation a patient manifests (e.g., illness anxiety, social withdrawal, panic) because the underlying problem is more or less the same. Moreover, its effects might be expected to percolate to any comorbid emotional disorders that are not the primary treatment target. Thus, while a patient's nominal goal for a course of UP might be to overcome obsessions and compulsions, the information and skills they acquire might indirectly resolve co-occurring issues with depression and worry.

The UP is a cognitive-behavioral therapy (CBT), meaning that it concentrates on how people think about (e.g., forecast, interpret) emotions and what they do (e.g., avoid, lash out) in response to them. It differs from traditional CBT protocols, which tend to be tied to a specific disorder (e.g., CBT for panic disorder) in that it tackles defensive reactions to a broad range of emotional experiences. That is, most CBTs limit themselves to the primary emotional processes implicated in a particular DSM diagnosis (e.g., sadness and anhedonia in depression). Also, the UP is modular. Its components can be deployed in an order tailor-made to address a particular presenting problem. Paraphrasing Payne et al. (2014), its modules include (1) promoting emotional awareness, (2) cognitive flexibility, (3) alternative ways to cope with emotion, (4) tolerating physical distress, and (5) deliberate exposure to intense emotion. The combination of all this instruction and experience is meant to change a patient's relationship with their emotions. It intends to build greater awareness and flexibility in thinking about emotion and a belief that emotions-even intense ones-can be tolerated without sacrificing current goals.

The UP appears to work. In the largest trial so far, 223 patients with anxiety disorder diagnoses were randomly assigned to undergo either the UP or a single-disorder protocol (SDP) (Barlow et al., 2017). There were four SDPs, one to match each of the primary anxiety disorder categories selected into the study (i.e., panic disorder, GAD, OCD, and SAD), and each was a gold-standard CBT for that condition. (Three of the four SDPs were developed by the same team responsible for the UP.) The point of the trial was to determine whether the UP, which can be applied to all emotional disorders, might be just as effective as the various SDPs, which each target only one emotional disorder. This is known as a *non-inferiority trial*.

Patients in the UP condition were engaged in treatment for 16 weeks, whereas the SDPs lasted 16 to 21 weeks, depending on the primary diagnosis. Evaluators who were blind to patients' treatment assignment rated the severity of anxiety problems at the end of treatment and at a 6-month follow-up appointment. The impact of the UP on clinical severity was almost indistinguishable from that of the SDPs. The Hedges g value—a statistic that, much like Cohen's d, represents a group difference in terms of standard deviation units—was -0.03 immediately posttreatment and 0.036 months later.

Other empirical studies corroborate this result, although none has matched the size and rigor of Barlow et al.'s (2017) investigation. A meta-analysis of 15 trials indicated generally large gains in anxiety, depression, and quality-of-life domains after UP treatment (Sakiris & Berle, 2019). Recent reviews also highlight the UP's "portability," which is one of its main assets. Researchers are applying the UP to treat the full gamut of emotional disorders and neighboring diagnoses (Cassiello-Robbins et al., 2020). Over 70 studies—a mix of case studies, open trials, and randomized trials—report examinations of the UP in the context of insomnia, eating disorders, bipolar disorders, borderline PD, and more. It has even been modified to address conditions that are not formal *DSM* diagnoses, such as non-suicidal self-injury and minority stress. This reflects an incredible degree of flexibility for a psychological treatment.

To tie this literature back to HiTOP, the lesson is that *DSM* entities need not be the focus of psychological treatment. It is possible, even advantageous, to orient intervention around empirically derived constructs that transcend *DSM* categories. Indeed, this is how recent presentations of the UP have framed it (e.g., Barlow et al., 2020). The UP explicitly targets the common features of emotional disorders, such as maladaptive responses to negative emotion, that are represented by HiTOP's internalizing spectrum. By chipping away at this broad vulnerability, it may end up having an observable effect on *many* emotional problems that belong to the internalizing domain (Figure 3.1).

Some data from Barlow et al.'s (2017) study bear directly on this hypothesis. Sauer-Zavala et al. (2020) analyzed the effect of treatment condition on neuroticism, which, as reviewed earlier, is conceptually and empirically a close match to the internalizing spectrum. The authors found that, although there were no differences in neuroticism at treatment baseline (as would be expected if random assignment went according to plan), patients in the UP condition reported lower neuroticism levels at the posttreatment assessment than those in the SDP condition (a standardized mean difference of 0.32). Thus, the UP, formulated to operate on the shared mechanisms of emotional disorders, seems to have an impact on neuroticism, a broad individual difference factor theorized to set the stage for, and maintain, a variety of emotional problems.

#### THE FUTURE OF TRANSDIAGNOSTIC TREATMENTS

The UP might be a template for other treatment protocols that target cross-cutting characteristics like those portrayed in Figure 3.1. Indeed, scholars have speculated that this tactic has utility beyond the internalizing spectrum (Hopwood et al., 2019; Mullins-Sweatt et al., 2020; Ruggero et al., 2019). Much of the theorizing has concerned ways that treatment could address broad, spectrum-level constructs to achieve far-reaching impacts on clinically recognizable problems (including syndromes), just as the UP seems to have an effect on a variety of categorical anxiety and depressive disorders.

Most of these proposals are just untested recommendations at this point, but they seem to be a worthwhile area for research investment. Plus, there is evidence beyond the UP literature that treatments are able to confer transdiagnostic benefits, putting this enterprise on reasonably strong conceptual footing. The evolution of dialectical behavior therapy (DBT) is a good case in point (Linehan, 1993). Originally developed to treat recurrent suicidality, it was first tested on people with borderline PD. It was perceived to be so effective with complex cases that clinicians successfully applied it to other oftenintractable problems, such as eating disorders, substance dependence, and chronic depression (e.g., Lynch, Morse, Mendelson, & Robins, 2003). This wide range of effects hints that DBT may be altering processes at the source of multiple mental disorders, perhaps those reflected in the internalizing and disinhibited externalizing spectra (e.g., Neacsiu et al., 2014).

A similar observation has been made about certain psychiatric medications that exert an influence on multiple diagnostic categories. Selective serotonin reuptake inhibitors (SSRIs) clearly fit the bill. Psychiatrists prescribe SSRIs for any number of conditions, ranging from depression to smoking cessation to sexual dysfunction (Bostic & Rho, 2006). The precise mechanisms of action of SSRIs remain uncertain despite their widespread use. However, there is some evidence that, to the extent that SSRIs work, they intervene on broad characteristics like neuroticism. For example, in a study of patients randomized to take an SSRI called paroxetine or an inert placebo, those in the SSRI condition experienced almost a 7fold larger drop in neuroticism compared to those taking placebo (Tang et al., 2009).

These case examples (the UP, DBT, and SSRIs) arguably are "proof of concept" for a transdiagnostic approach to mental health treatment. Broad, often modular, treatments that address a cluster of related problems theorized to share common psychopathological processes appear to be feasible and effective. If others like the UP can be developed and empirically vetted, then mental healthcare delivery might become far more efficient and reach more of the people who need it. In principle, they overcome (or at least mitigate) practical barriers surrounding training and dissemination that today limit access to evidence-based care on a broad scale.

#### Summary

HiTOP has clinical value in a number of ways. For one thing, dimensional assessment provides a more detailed characterization of patient problems. Even a dimensional representation of *DSM* categories (e.g., a symptom count) is more informative than a binary label. This extra information is hypothesized to translate into a more nuanced clinical picture and more prognostic power.

The hierarchical structure expands the possible targets for intervention beyond syndromes (see the vertical axis of Figure 3.1). Interventions can focus on processes, whether broad or narrow, that transcend traditional disorder boundaries. Regarding broad constructs, there is reason to believe that targeting mechanisms common to many disorders (e.g., cognitive styles, behavioral patterns) can have far-reaching therapeutic benefits. The HiTOP model can guide interventionists to these areas where they can get the most traction.

#### Conclusion

The problems with categorical diagnoses are as frustrating as ever, and now there is a viable alternative. HiTOP is based on objective data, enabling a more accurate representation of psychopathology than diagnoses rooted, to some degree, in clinical intuition. Its utility extends far beyond description, though. The model unlocks new research avenues and paves the way for more precise theory. It also promises to streamline clinical services, which could conserve scarce resources and extend mental healthcare to more people who desperately need it. Whereas the structural model is what HiTOP "is," these research and clinical applications represent what HiTOP can "do."

Work on this model is just now shifting into a high gear. The HiTOP consortium was founded in 2015, and a new wave of empirical studies is testing the boundaries of how we can use the model. As the database grows, we will gain a better sense of if, when, and how HiTOP might reasonably supplement, and perhaps supplant, categorical models on a broad scale.

CHAPTER

## The Research Domain Criteria Project: Integrative Translation for Psychopathology

Bruce N. Cuthbert, Gregory A. Miller, Charles Sanislow, *and* Uma Vaidyanathan

#### Introduction

This is an exciting period in psychopathology. New methodologies such as magnetic resonance imaging (MRI) and computational modeling are maturing rapidly, conceptual ideas about the nature and structure of mental disorders continue to evolve, and the field is exploring new strategies for research in order to improve diagnosis and treatment. At the same time, traditional methods continue to prevail in research and clinical practice. Current approaches to classification and diagnosis follow patterns that are well over a century old, relying almost entirely upon clinical interviews to assess presenting symptoms and signs. The persistent reliance on these practices is striking given marked progress in many areas of science. The situation is understandable given the ingrained status of current diagnostic classes in all spheres of mental disorders. However, debates about these traditional attitudes are increasing as scientific advances permeate the field. This chapter about the Research Domain Criteria (RDoC) is one of several entries in this edition that feature novel ideas for conceptualizing and studying psychopathology. RDoC represents an example of a strategy for translational research, which can be defined as the attempt to "seek fundamental knowledge about the nature and behavior of living systems and the application of that knowledge to enhance health, lengthen life, and reduce illness and disability" (Lauer, 2016, p. 1).

The RDoC initiative is distinct from other novel approaches in this volume in three ways. First, the project was initiated by a governmental funding

agency, the US National Institute of Mental Health (NIMH, part of the National Institutes of Health [NIH]) in 2009 as a research framework for psychopathology. Second, the RDoC framework is distinguished by the nature of its organization, attempting formally to meld into one schema disparate aspects of measurement classes and influences on mental health. Finally, RDoC is not intended to supplant current diagnostic manuals but rather to provide novel approaches for research. All three of these aspects revolve around a central aim: to promote studies that embody new ways of thinking about and studying psychopathology in terms of disruptions in basic functions, as manifested and analyzed by measurements in multiple response systems. The longterm goal is to provide a literature that will facilitate changes in all aspects of mental health practiceassessment, treatment, and prevention.

Why implement a novel framework for translational research? The rationale is that while morbidity

and mortality have been reduced markedly for many conditions (e.g., cancer, heart disease) over the past several decades, the severe burden of mental disorders persists unmitigated (Insel, 2009). A strong case can be made that the prevailing diagnostic system is a significant part of the problem, particularly with respect to research and its translation into clinical practice. While it is difficult to change a system so entrenched in health systems, insurance billing, and government policies, a marked shift is necessary for progress to be made.

In this chapter, we discuss the rationale for RDoC, summarize its major elements, consider the philosophy of science issues that permeate it (and our field), and review examples of research designs and results that illustrate the framework for both adult and child/adolescent disorders. Several articles have described in detail the original RDoC development process and the components of the framework (e.g., Kozak & Cuthbert, 2016; Morris et al., 2021; Sanislow et al., 2010); this chapter is dedicated to explicating in more depth the principles and concepts of the initiative.

#### Rationale

#### Beginnings of Psychiatric Nosology

A brief account of views about mental illness over the past two centuries provides context for why and how RDoC came about (see Kendler, 2020; Miller, 2020; Chapter 2, this volume). The nineteenth century was a time of marked advances in the field of medicine. Physicians continued to follow the ageold practice of describing and diagnosing illnesses in terms of their symptoms, with the assumption that underlying pathologies existed and that their causes would eventually be discovered. These hopes were gradually realized as scientific technologies and investigations progressed toward an understanding of physical etiology. For instance, edema was recognized in ancient civilizations and known as "dropsy" (a contraction of "hydropsy," i.e., water) due to its primary symptom as the accumulation of fluid in various parts of the body, but differentiation of the multiple causes of edema only began in the early 1800s, when two English physicians reported distinct cardiac versus renal etiologies.

Early students of mental illness followed a similar approach to diagnosis. Individuals generally came to clinical attention when their condition necessitated admission to insane asylums. Their symptoms, typically psychosis or severe depression, were so extreme that early psychiatrists became known as "alienists" (from *aliéné*, French for "insane"). It is little wonder that these debilitating conditions were regarded unquestionably as diseases that were not only qualitatively different from normal behavior, but from other mental diseases as well.

The care of mentally ill patients gradually improved during the nineteenth century. The patchwork system of private hospitals and religious institutions gave way to government-supported asylums in Europe and the United States, which in turn fostered a growing cadre of psychiatrists with formal training and a systematic approach to diagnosis. Those pioneers grappled with a number of fundamental issues regarding mental illnesses that still resonate today. These included the question as to whether mental disorders are better regarded as diseases of the "mind" (following the tradition of mental states established by Enlightenment philosophers) or diseases of the brain (in line with other areas of contemporary medicine), and, if the latter, whether brain pathophysiology should be regarded as disorders of specific locations or of neural circuits (Stoyanov et al., 2019). Notably, psychiatrists such as Emil Kraepelin and Eugen Bleuler regarded mental disorders as involving both mental and physiological aspects (Bleuler, 1911/1950) and attempted to define and differentiate diseases through careful clinical observations of symptoms, severity, and course of illness. Kraepelin, in particular, saw mental illnesses as "natural disease units" (natuerliche Krankheitseinheit; Heckers, 2008) even though he never conclusively decided whether dementia praecox and manic-depressive illness (now schizophrenia and bipolar disorder, respectively) were separate diseases or not. Such viewpoints continue to resonate in modern deliberations, not only about the list of mental disorders but about assumptions (often implicit) regarding the nature of psychopathology.

The failure to establish definitive findings regarding the nature and causes of mental illness (with rare exceptions such as neurosyphilis) resulted in an impasse that was partly responsible for the rise of psychoanalytic psychiatry in the late nineteenth century and its dominance throughout most of the twentieth century, led by such legendary figures as Freud, Jung, and Horney. Initial hopes that psychoanalytic theories could lay the basis for scientific progress were dashed as the various schools of thought failed to develop consensus about the nature of clinical phenomena. Etiological theories and diagnostic practices depended more on the particular school in which therapists were trained than on scientific rigor, resulting in a lack of a coherent set of diagnostic and clinical practices (Lieberman & Ogas, 2015).

In response to the diagnostic quandary, an initial psychodynamic nomenclature issued by the US War Department in 1943 was adapted in the early1950s to generate early versions of the *DSM* that provided lists of specific disorders and brief diagnostic descriptions and criteria (i.e., *DSM-I* in 1952 and *DSM-II* in 1968); however, these largely retained psychodynamic theories not based on scientific data. As a result, the early manuals made little progress to address the issues of interclinician reliability and scientific validity (Spitzer & Fleiss, 1974).

## The Modern Era of Nosology with the DSM: Successes and Problems

Small cadres of research psychiatrists, notably including a group at Washington University in Saint Louis, began working on more systematic descriptions of disorders in hopes of overcoming the reliability and validity problems that were so severe that they threatened psychiatry as a medical discipline (Lieberman & Ogas, 2015). The first widely noted manuscript to address this concern became a foundational document for modern psychiatry, listing five criteria for validating mental disorders: clinical description, laboratory studies (largely aspirational at that time), delimitation from other disorders, course and outcome, and familial incidence (Robins & Guze, 1970). This paper was followed by another landmark article that outlined observational studies of patients to demonstrate for a small number of putative disorders the potential use of descriptive criteria for diagnosis (Feighner et al., 1972).

These seminal papers were formative for the Research Diagnostic Criteria (RDC), intended explicitly to "enable research investigators to apply a consistent set of criteria for the description or selection of samples of subjects with functional psychiatric illnesses" that would "enable investigators to select relatively homogeneous groups of subjects who meet specific diagnostic criteria." (Spitzer et al., 1978, pp. 773 and 774, respectively). The RDC provided an extensive list of disorders, each with detailed diagnostic criteria, but did not attempt to cover all psychiatric phenomena. It was designed to foster research where it seemed ripe for pursuit rather than to serve as a handbook for routine clinical use: "The choice of which diagnostic categories to include in the RDC . . . was based on our judgment of the major problems of current psychiatric research" (Spitzer et al., 1978, p. 775).

The climax of the effort to rescue the problematic diagnostic standards of the DSM-I and DSM-II manuals ensued shortly thereafter with the publication of the third edition of the DSM, adhering closely to the ideas and criteria (and often the exact language) of the RDC. The DSM-III was a paradigm shift, fundamental to the development of modern psychiatric nosology and affecting not only clinical practice but also research grant applications, scientific journals, and regulatory agencies such as the US Food and Drug Administration (FDA). Its polythetic diagnostic system (requiring a certain number of symptoms from a longer list; e.g., five of nine symptoms for a major depressive episode) provided quasi-quantitative criteria for making a diagnosis, and its atheoretical stance enabled investigators of all clinical perspectives to employ the manual. (The other prominent diagnostic manual in recent decades is the mental and behavioral section of the ICD, the international standard published by the World Health Organization. The ICD employs brief descriptions of disorders rather than polythetic criteria, but the listing of disorders is generally quite similar to that of the DSM.)

This summary of the history that eventuated in the current diagnostic system is intended to help the reader appreciate two essential points in the DSM-III architecture that, for all its influence, had particular reverberations for the future. First, the framers of the DSM-III, in no small part due to the welter of competing theories and schools with divergent etiological hypotheses, continued to depend on the nineteenth-century practice of defining disorders by descriptive signs and symptoms (Engstrom & Kendler, 2015; see also Scull, 2021, p. 5: "To attempt to diagnose illness using patient symptoms resembles the approach of the eighteenth, not twenty-first century medicine."). Furthermore, they continued the practice of earlier psychiatrists in assuming that careful clinical descriptions would define specific diseases (earning the sobriquet of "neo-Kraepelinians").

Second, the disorder definitions were developed to promote reliability rather than validity (Hyman, 2010). As explained in the *DSM-III* regarding the pre-release field trials, "Perhaps the most important part of the study was the evaluation of diagnostic reliability" (American Psychiatric Association [APA], 1980, p. 5); and a few pages later, ". . . for most of the categories the diagnostic criteria are based on clinical judgment, and have not yet been fully validated by data about such important correlates as clinical course, outcome, family history, and treatment response" (APA, 1980, p. 8): that is, the *Robins and Guze criteria* (1970). In other words, validity was explicitly deferred in favor of reliability, with the aspirational assumption that the former could eventually be addressed once the latter was sufficiently improved.

Although revisions have occurred periodically (the current version is DSM-5, released in 2013), the basic DSM/ICD architecture has persisted across the 40-plus years since DSM-III's publication. Despite its pervasive influence, scientific reservations about the system began relatively early (e.g., "the existence of an official taxonomy also has become an unintended straitiacket, as more researchers have limited themselves to the DSM criteria rather than investigating different sets of criteria" (Clark et al., 1995, p. 123). Unfortunately, "the focus on reliability came at a time when the scientific understanding of mental disorders was embryonic and could not yield valid disease definitions" (Hyman, 2010, p. 155). As methodologies in areas such as genetics, psychophysiology (including neuroimaging, largearray evoked response potentials [ERPs], and other techniques), and psychometrically sound behavioral measures have evolved from experimental demonstrations to commonplace methods, the practice of studying disorders defined in the absence of any etiological factors has become increasingly untenable.

#### New Directions for Research

The keen awareness of the need to move in new directions is exemplified by a comment from one of the groups considering revisions for the *DSM-5* revision process: "Although a move to an etiologically and pathophysiologically based diagnostic system for psychiatry will be extraordinarily difficult, it is nevertheless essential, based on the increasing belief that many, and perhaps most, of the current symptom clusters of *DSM* will ultimately not map onto distinct disease states" (Charney et al., 2002, p. 34).

Investigators also had suggestions about some of the specific directions that new research should take, as expressed by the well-respected genetics group at Cardiff, Wales.

[S]tudies would benefit from a focus on specific symptoms as well as cognitive and neurocognitive endophenotypes with the confounding effects of diagnostic practices removed. . . . This work will need to take a developmental perspective since it is likely that the manifestations of these phenotypes will vary with age, and longitudinal studies will certainly be required. Aetiological research . . . should now end its exclusive love affair with DSM and ICD categories. The goal must now be to relate research on aetiology and pathogenesis to specific psychopathological syndromes and phenotypes defined by studies of cognition and neuroimaging. (Owen et al., 2011, p. 174)

As these viewpoints indicate, the problem was not that scientists were unaware of the issues with the diagnostic system, nor lacking in new ideas for conducting research. Rather, a significant impediment concerned the custom that study sections (National Institutes of Health peer review committees convened to evaluate and score grant applications) for mental disorders research traditionally prioritized study designs limited to single DSM disorders, typically as compared to healthy controls. This was due in no small part to the fact that the various disorders listed in the DSM-III became reified relatively quickly after its release (and persisted in subsequent editions). A former NIMH director noted that "The problematic effects of diagnostic reification were revealed repeatedly in genetic studies, imaging studies, clinical trials, and types of studies where the rigid, operationalized criteria of the DSM-IV defined the goals of the investigation despite the fact that they appeared to be poor mirrors of nature" (Hyman, 2010, p. 158). It is reasonable to infer that such a situation was facilitated by the bequeathed concept of "natural disease units" stemming from the strong Kraepelinian core of the DSM-III and its successors; the neo-Kraepelinian view promoted adherence to an essentialist view of disorders (i.e., the notion that there must be some essence that categorically defined and distinguished a disease; Astle & Fletcher-Watson, 2020). It was thereby understandable that study sections would regard the DSM diagnostic classes as a high priority for both diagnosis and treatment despite the growing evidence of poor discriminability of such classes.

Another related problem affected the grant review process. Science generally depends on a consensus paradigm for its deliberations to provide a common basis for discussion, a core element at the heart of study section evaluations. Reified *DSM* disorders constituted a hegemonic architecture for consensus in grant reviews (dubbed an "epistemic prison" by Hyman, 2010) that was difficult to transcend. Investigators (as well as the authors of *DSM* editions) were generally aware that disorders as listed in the manuals were heuristic rather than natural kinds, and individual scientists might well have diverse alternative hypotheses, but, in the forum of a review committee, there was little basis for deciding on the merits of alternative research approaches.

NIMH experienced this phenomenon directly with a 2001 funding set-aside (a Request for Applications [RFA]) termed "Modular Phenotyping for Major Mental Disorders," a sort of RDoC prototype. Citing heterogeneity and mechanisms that cut across disorders, the aim of the announcement was to support research that would "dissect currently defined mental disorder syndromes into component symptom clusters or dimensions" and "select a specific symptom cluster or dimension (i.e., an illness module) for intensive analysis." The announcement further called for "hypothesis-driven, experimental methods to discern and map the biobehavioral mechanisms and neurobiological systems that account for disturbed behavior" (NIMH, 2001, p. 3). Although the announcement was well received by the field (as evidenced by an ample number of applications), not one received a fundable score; there was simply insufficient consensus among applicants and reviewers regarding criteria for such aspects as the specific topics of study, the number and types of measures to include, or the kinds of analyses to be employed.

As one might imagine, this issue occurs across many areas of science. For instance, as of this writing, there is spirited debate regarding the longstanding focus on beta-amyloid and tau proteins as primary etiological factors in Alzheimer's disease (Hascup & Hascup, 2020). As one researcher commented,

Despite billions of dollars spent, there are still no effective pharmacotherapies for Alzheimer's Disease (AD). The problem plaguing AD research may well lie at the level of study design/data collection. Because we depend on a peer-reviewed system for funding, in order to get a fundable grant in AD, we all have to meet pre-conceived criteria for appropriate methodology, which has led us all to essentially propose similar study designs and collect essentially the same data. So not shockingly, we are all finding the same thing. And our evidence based approach for determining treatments is leading to the same path of failed clinical trial studies. . . . When we start studying dementia/AD outside the boundaries of what is presumed to be known about the disease is when we will fully start to characterize it. (Au, 2019, pp. 1-2)

These comments aptly relate to the situation that existed for peer reviews of mental disorder grant applications. The challenge for NIMH was not so much to exhort investigators to devise innovative ideas regarding mental disorders. Rather, the imperative was to devise a set of criteria that are mutually understood by applicants and reviewers and thus could enable study designs and research methodologies that diverge from traditional *DSM* approaches to be peer-reviewed in consistent fashion. In essence, the problem was how to implement an ecosystem for grant review that allows applications from diverse perspectives and areas of psychopathology to be considered on an equal footing and for the best to emerge with strong scores.

In short, the need was to craft a research architecture for diagnostic approaches which transcend symptom-based syndromes by incorporating data that include behavioral/psychological functions, implementing biological systems, developmental trajectories, and environmental effects. Movement in this direction required that these aspects were well established and contributing steadily to cumulative literatures on measurement and classification; however, such literatures could not be created as long as clinical research was conducted solely within the current diagnostic system. This paradox provided the rationale for a new framework for experimental psychopathology research.

## The RDoC Project

The NIMH released a major update of its Strategic Plan in 2008. As part of this plan, two of the four major Strategic Objectives contained language referring to new initiatives that would link behavioral and physiological measures in order study dimensions of functioning related to mental disorders.

The key statement was contained in Strategy 1.4 of the plan: "Develop, for research purposes, new ways of classifying mental disorders based on dimensions of observable behavior and neurobiological measures" (NIMH, 2008). The phrase "new ways of classifying mental disorders" denotes the intent to devise novel criteria for forming groups or dimensions to serve as independent variables in experimental studies (e.g., on the basis of behavioral and/or biological measures rather than traditional disorder categories). (Some observers mistakenly construed the phrase as implying an attempt to propose an alternative to the DSM-5, but that was not the purpose). RDoC is formally agnostic regarding DSM/ICD categories, based on the stance that any potential changes to DSM categories (or its overall

architecture) can only be evaluated on the basis of data from various alternative scientific approaches.

The elaboration of this strategy directly addressed the two salient obstacles to research progress summarized above: viz., the reliance on symptoms in defining disorders and the lack of validity in current diagnostic classes.

[T]he way that mental disorders are defined in the present diagnostic system does not incorporate current information from integrative neuroscience research, and thus is not optimal for making scientific gains through neuroscience approaches. . . . Many mental disorders may be considered as falling along multiple dimensions (e.g., cognition, mood, social interactions), with traits that exist on a continuum ranging from normal to extreme. . . . To clarify the underlying causes of mental disorders, it will be necessary to define, measure, and link basic biological and behavioral components of normal and abnormal functioning. . . . By linking basic biological and behavioral components, it will become possible to construct valid, reliable phenotypes (measurable traits or characteristics) for mental disorders. (NIMH, 2008, p. 10)

The language in the second Strategic Objective specifically acknowledged the importance of developmental and environmental influences. This objective included a directive to "define the developmental trajectories of mental disorders," with a related aim to "Link studies of brain development with behavioral development to understand how brain regions critical for mental disorders are associated with typical and atypical behavioral functioning" (NIMH, 2008, p. 13). The importance of environmental factors was recognized in both objectives, as these interact with developmental trajectories and genetic variation.

These ideas fall under the purview of psychophysiology, a discipline that is central to this undertaking given its long-standing status as a field that focuses (both philosophically and empirically) on the relationships between behavioral/cognitive constructs and physiological phenomena (Miller et al., 2016). An editorial in the initial issue of the field's eponymous journal succinctly expresses the relevance for RDoC: "Psychophysiology provides a method for bringing both physiological and psychological aspects of behavior into a single field of discourse by which truly organismic constructs may be created" (Ax, 1964, p. 1). The principle expressed in that statement is notable in that advances from new technologies such as neuroimaging or computational modeling of behavior fit readily under the aegis of "organismic constructs."

## The RDoC Framework

The RDoC framework represents the organizing principles of the project and includes four major elements (Figure 4.1; see Cuthbert & Insel, 2013, for a concise summary). First, the various "dimensions of observable behavior and neurobiological measures" noted above are grouped in superordinate domains of functioning, such as Cognitive and Social Processes domains, each with multiple dimensions (e.g., dimensions of Attention and Working Memory in the Cognitive Domain). Second, the dimensions can be measured by multiple classes of variables (such as brain activity recordings, behaviors, and self-report instruments), which are referred to in the framework as "Units of Analysis." Third, developmental trajectories as studied across the lifespan have a high priority in examining normative development and the transitions to psychopathology. Fourth, environmental influences of all types, both negative and positive, are critically important factors in studying the etiology of psychopathology. These principles are detailed below. Strategy 1.4 (the defining statement of the new goal) included four specific aims that add further provisos regarding the domains and units of analysis; these are accordingly addressed first, followed by a discussion of the development and environmental factors.

## Aim I

"Initiate a process for bringing together experts in clinical and basic sciences to jointly identify the fundamental behavioral components that may span multiple disorders (e.g., executive functioning . . .) and that are more amenable to neuroscience approaches" (NIMH, 2008).

A working group of NIMH staff convened in early 2009 to determine the various aspects of the framework and devise a process for generating the set of "fundamental components" that comprise the central core of the RDoC concept. The components are conceived in terms of psychological constructs as used in the traditional sense (e.g., MacCorquodale & Meehl, 1948; Kozak & Miller, 1982) but with a psychophysiological orientation. RDoC constructs are jointly defined by (1) evidence for a basic psychological or behavioral function and (2) evidence for a neural circuit or system that plays a major role in implementing the given function (along with guidance that the

**Figure 4.1** Major elements of the Research Domain Criteria (RDoC) framework. Domains are superordinate groupings that contain the various dimensional RDoC constructs, with each domain containing three to six related constructs. The Units of Analysis depict examples of the various classes of measurement that could be used to study constructs, such as genetics, molecular/cellular recordings, brain circuit activity, self-report instruments, and behavior. Developmental trajectories are viewed from a life span perspective. The Environment represents the wide range of potentially relevant aspects, such as the built environment, cultural factors, neighborhoods, and social factors (often referred to collectively as the *exposome*). Inclusion of the Development and/or Environment elements is encouraged in experimental designs in order to study the effects of the contexts in which domains and constructs are studied. The overlaps among the four circles are intended to connote the importance of studying interactions among the four elements.

construct should have relevance to mental disorders). Basically, RDoC calls for studies that explore various aspects of psychopathology in terms of these constructs, which will in most cases be narrower and more focused than current diagnostic classes and yet will often be transdiagnostic.

At present, the constructs included in RDoC are grouped into six broad domains as determined by the working group: Negative Valence Systems (responses to aversive situations), Positive Valence Systems (responses to appetitive situations), Cognitive Systems, Social Processes, Arousal/ Regulatory Systems, and Sensorimotor Systems (NIMH, 2020). The constructs were defined in a series of workshops beginning in 2011 by groups of scientists with specialized expertise in the respective domains (one meeting for each domain; see Kozak & Cuthbert, 2016, for procedural details and the RDoC website for the proceedings, NIMH, 2020).

Starting with a set of candidate constructs based on the working group's literature review and preworkshop survey responses from the field, the experts evaluated the strength of data for both psychological functions and implementing neural systems. The participants accepted some candidate constructs (often with varying degrees of modification), declined others, and created new constructs in keeping with the guidelines; a definition was written for each approved construct. As an example of the workshop process, the mirror neuron system (initially nominated) was not included because the experts at the workshop reported that it was as yet not clear what the function of the system was, and so it did not meet the criterion for "evidence for a basic psychological or behavioral function." Note that this decision only reflects the stringency of the criteria for vetting constructs that can serve as exemplars of the RDoC framework, rather than

signifying that the mirror neuron system is considered unworthy for further studies; in fact, this would suggest continuing the research to understand such a potentially important construct for social interactions.

The constructs that emerged from the workshops were regarded as strong examples of a main principle: to study psychopathology via psychophysiological constructs that are more specific in nature than are broad diagnostic syndromes. Some constructs and domains were given relatively new names to avoid carry-over implications from related terms that could be misleading; for instance, the term "fear" has a long history with many different shades of meaning (and science), so the term "acute threat" was adopted to represent a more specific meaning. (See the workshop proceedings for insight into the various perspectives and considerations that had to be discussed; NIMH, 2020.)

As these points imply, the intention from the beginning was that the set of constructs should not be a fixed grouping. As befits a research framework, constructs were anticipated to undergo continual change on the basis of new data-whether new, revised, merged with others, or deleted. Moreover, the initial constructs were seen as exemplars that could guide investigators in proposing and validating new constructs through research. In this manner, the framework could grow with the progress of psychological science and neuroscience. Changes that have occurred since the project's inception include a revision of constructs in the Positive Valence domain, the addition of the Sensorimotor Systems domain, and ongoing discussions of revisions to Negative Valence constructs.

These alterations highlight one of the most important (and often misunderstood) points to be emphasized: the central purpose of RDoC is not to curate a list of domains and constructs per se (important as they are for actual research). Rather, the core is a set of principles by which the constructs and hypotheses are derived in order to foster research that diverges from studies of traditional disorder categories. Ongoing research progress depends on a flexible framework that can accommodate the pace of scientific advances over time.

## Aim 2

"Integrate the fundamental genetic, neurobiological, behavioral, environmental, and experiential components that comprise these disorders."

One of the major complications in our field concerns the various ways of construing and assessing

mental illness. These include various data sources; for example, behavior (in structured behavioral tasks or observations of behavior in various contexts), measurements of brain structure and/or activity, and phenomenology (the patient's reports or other manifestations of his or her subjective experiences). Although opinions differ as to which of these kinds of data are most informative, it may be most fruitful not to choose one to the exclusion of others or even to privilege one over the others. As per the classic "blind men and the elephant" metaphor, what is important is to figure out how these various classes of measurement relate in order to reach a comprehensive understanding. From a scientific perspective, a difficult methodological challenge concerns the frequent modest-to-low relations among various measurement classes in studies of mental disorders or indeed normal behavioral/psychological concepts (Kozak & Miller, 1982; Lang, 2010; Miller & Bartholomew, 2020). This is a long-standing problem in many areas of psychological science, not only in psychopathology (Campbell & Fiske, 1959). In the mental disorders arena, one obvious example is the low correspondence between symptom-based diagnostic classes and biological measures.

It is sometimes assumed that these issues simply reflect measurement error and that improved methodologies will solve the problem, but this premise greatly underestimates the complexity of the various systems involved in functional behavior. As a pioneering group of psychophysiologists noted, "Somatic responses are often discussed and sometimes experimented on because they are thought to be the flesh-and-blood embodiments of certain immaterial realities which psychological analysis seems to discover: psychological concepts such as emotion, anxiety, stress, inner tension, [etc.] . . . . [But] rather than being hopeful of homologies between the somatic responses and psychological concepts built from other materials, we should be surprised by their discovery and rather astonished at the simplicity of the universe" (Davis et al., 1955, p. 1). This is an explicit reason that RDoC constructs are unlikely to be considered as direct equivalents of those stemming from psychological concepts derived mostly from self-reports or common words (e.g., "enjoyment" or "negative affect").

Accordingly, a significant aim of RDoC is to foster studies that examine the complex relations among different classes of measurement (i.e., the units of analysis). Investigators are encouraged (but not required) to include multiple units of analysis in their studies, choosing a subset appropriate to the research question. As one way to assist investigators in understanding and applying RDoC principles to their research, a two-dimensional RDoC matrix was cumulated as the workshops progressed. The rows of the matrix contain the domains and constructs, and the columns denote the units of analysis. The latter currently include genes, molecules, cells, measures of circuit activity (e.g., functional MRI [fMRI] or large-array ERPs), peripheral physiology (e.g., cortisol or heart rate), behavior (e.g., performance on psychological tasks or quantitative assessments of behavior in various contexts), and self-reports (including paper/pencil instruments or quantified interviews) (see Kozak & Cuthbert, 2016, for details). For each cell representing the intersection of a construct and a unit of analysis, workshop participants generated a provisional list of variables reported in the literature as measures of the construct (see the online matrix for further information; NIMH, 2019).

Like domains and constructs, the units of analysis and variable lists are intended as a heuristic set of exemplars for investigators to become familiar with the RDoC organization and principles rather than as an exhaustive and static compendium. It should be noted that the units of analysis pertain to data acquired from individuals, whereas developmental time periods and/or environmental influences represent important contexts that affect individuals; in other words, it is important to study the effects of development and the environment on individuals, as assessed by selected units of analysis.

#### Aim 3

"Determine the full range of variation, for normal to abnormal, among the fundamental components to improve understanding of what is typical versus pathological."

As mentioned earlier, the beginnings of organized psychiatric practice originated with patients who were so impaired that alienists understandably concluded that they were observing a severe disease that was distinct from normality, a position particularly associated with Kraepelin and other early nosologists. Although outside the scope of this chapter, it should be noted that dimensional theories also date back to the beginnings of psychopathology (e.g., Bleuler, 1911/1950) and have been extensively studied since that time (e.g., Clark et al., 1995). However, the neo-Kraepelinian renaissance, starting with the Feighner criteria in 1972 and culminating in the *DSM-III* in 1980, established the contemporary precedent for considering psychiatric disorders as specific disease entities. Well over a century after Kraepelin's time, this assumption—having generalized to almost all other disorders—continues to drive research as well as clinical services: both the DSM and ICD manuals depend on dichotomous, ill/not ill diagnostic practices.

The continued reliance on binary categories remains one of the most constraining aspects that nineteenth-century psychiatric perspectives bequeathed to contemporary research. Modern medicine matured when scientists were gradually able to discover basic mechanisms and functions and then determine the malfunctions in those systems that eventuated in disorders. To the extent possible, such mechanisms, rather than just their downstream symptoms, became the target of intervention or prevention. These developments were followed by the acquisition of population-level distributions of relevant measurements, and it became feasible to gauge increasing levels of risk (or early pathology) over time with dimensional quantitative measures (such as glucose tolerance for diabetes risk). Furthermore, clinical researchers could establish cut points on dimensional distributions to demarcate different ranges of risk or disorder, which may be revised periodically on the basis of new data (e.g., American Heart Association News, 2018). From this perspective, it is not surprising that attempts to apply continuous biological or behavioral measures to symptom-based dichotomies of mental illness versus health have been unsuccessful (Kapur et al., 2012).

Organizing the framework around fundamental dimensions of behavior, as viewed in terms of population-level distributions, enables RDoC to foster a research perspective aligned with other contemporary areas of health research. RDoC inverts the usual paradigm for conceptualizing psychopathology: Rather than defining illnesses on the basis of presenting signs and symptoms and then searching for a disease-related problem, RDoC treats psychopathology in terms of varying degrees of dysregulation in normal-range functioning, considered from a relatively specific, construct-oriented focus. This approach has important ramifications for translational research in that studies of basic processes (in humans and nonhuman animals) can be applied much more directly to clinically significant issues (Anderzhanova, Kirmeier, & Wotiak, 2017). Moreover, following the course of basic functions across developmental trajectories may provide advantages for research projects that examine risk factors over time or implement prevention strategies

employing dimensionally oriented research designs (Zalta & Shankman, 2016).

### Aim 4

"Develop reliable and valid measures of these fundamental components of mental disorders for use in basic studies and in more clinical settings."

Measurement represents a critical component of the RDoC program and particularly for the development of behavioral tasks or self-report instruments specifically conceived in terms of RDoC or similar constructs. Although evidence for a psychological function is a necessary criterion for any RDoC construct, the particular tasks or measures generating that evidence may vary in strength and specificity. For instance, a number of tasks align closely with the cognitive control construct (Braver et al., 2021); on the other hand, tasks across the Social Domain are generally less well-developed and there are fewer, and less well-validated, measures (although progress is under way; e.g., Gur & Gur, 2016; Hawco et al., 2019). This situation is related to the history of various constructs and particularly the progress made in studying relevant neural systems and in developing tasks that were generated for testing theoretical models. For example, brain structures involved with working memory were first identified in the 1930s, and the development of generative models in the early 1970s (Baddeley, 2003) contributed to the localization of relevant neural systems (D'Esposito & Postle, 2015). Developing and clarifying functional constructs from both psychological and neurophysiological perspectives accordingly represents a high priority (a challenge that confronts the field as a whole, not confined to RDoC).

The binary, disease/no-disease legacy of the DSM/ICD system represents another issue. Many instruments have been devised to assess either psychopathology (ranging from mild to severe) or normal behavior (e.g., personality and other traits). Such dichotomized distinctions often occur for self-report instruments but can also be a concern for behavioral tasks not designed to accommodate psychometric characteristics observed across the span from high-performing healthy individuals to severely impaired patients (e.g., Chapman & Chapman, 1978). Accordingly, another priority concerns the creation of tasks that span the entire range of functioning both for behavioral tasks and self-report instruments (e.g., a self-report scale for aggression, Krueger et al., 2007).

Priorities for developing behavioral tasks are changing rapidly due to the accelerating pace of computational models for studying behavior-brain relationships (Ferrante et al., 2019; Sanislow et al., 2019), an area whose varied origins crystallized as computational neuroscience in a seminal volume in 1990 (Schwartz, 1990). These methods have been increasingly applied to mental disorders, inspired in part by the nascent RDoC framework that called for psychophysiological constructs rather than symptom-based syndromes as the fundamental unit of analysis (Adams et al., 2016). Broadly speaking, there are two main computational approaches relevant to psychopathology (Huys, 2018). The first concerns the use of machine learning tools (also referred to as data-driven approaches) to "utilize large data sets and sophisticated mathematical techniques to characterize either the latent organization of the data (i.e., unsupervised learning), or multivariate relationships between specified groups of variables (i.e., supervised learning)" (Ferrante et al., 2018, p. 480). As one example, Kernbach et al. (2018) applied a sophisticated machine-learning algorithm to resting-state brain connectivity data gathered from a large sample of three groups of youth aged 7-21 (attention deficit hyperactivity disorder [ADHD], autism spectrum disorder [ASD], or typically developing), which returned three factors of network connections whose combined effects were related dimensionally to both ADHD and ASD.

The second approach involves the testing of mathematical models of brain-behavior relationships, and it is this aspect that most pertains to task development. The essence of the strategy is to specify models involving multiple parameters relevant to particular tasks and then test how closely sets of specific parameter values match observed data; this enables quantitative tests of the model and revisions as needed to the parameter set. (Often, multiple models are compared to determine which most closely accounts for real-world results.) For instance, a working memory task might involve both behavioral and neurophysiological parameters such as the number of items to store, the extent of decay in memory across time, ERPs, and fMRI (Lemaire & Portrat, 2018). This approach is well-suited for evaluating the kinds of brain-behavior relationships involved with RDoC constructs and has prompted considerable attention regarding both the advantages and the cautions as the field proceeds (Teufel & Fletcher, 2016). A detailed discussion of this growing area is beyond the scope of this chapter (e.g., see Mujica-Parodi & Strey, 2020).

#### Development and Environment

The field of developmental psychopathology has a well-established history, and research on developmental trajectories is a critical area for understanding the processes that occur during transitions from normal-range functioning to dysregulation (Chapter 6, this volume; Rutter & Sroufe, 2000). For some time, child-onset and adult-onset behaviors generally were regarded as mostly distinct. However, developmental psychopathology's emphasis on a life span approach helped move the field toward a continuous perspective on trajectories. Even for disorders that typically have onsets in adulthood, many symptoms of mental disorders are evident by adolescence (Casey et al., 2014). The relationship between the risk for childhood-onset and adult-onset disorders has long been established for mental disorders such as depression and anxiety (Rutter & Sroufe, 2000). Data from genetics and other fields indicate that similar patterns hold for psychotic-spectrum conditions: "There is now a need to focus upon the relationships among the neurodevelopmental syndromes that typically present in childhood and between these and the disorders that typically present in adulthood" (Owen et al., 2011, p. 174).

RDoC aligns with many of the components of developmental psychopathology, such as full-range dimensional aspects and the use of multiple measurement classes. The framework adds such aspects as constructs jointly defined by behavior and biology and an emphasis on functional dimensions rather than symptom-based disorders (Astle & Fletcher-Watson, 2020). While the field has shown considerable interest in RDoC research (e.g., Beauchaine & Hinshaw, 2020; Mittal & Wakschlag, 2017), it is clear that growth trajectories bring additional complexities: functional constructs emerge at varying points across development, their characteristics change over time (Posner & Rothbart, 2000), and the neural systems that implement various functions can shift as the brain develops (Sullivan, 2005). The result has been an ongoing outreach to communicate with the field in various ways to provide more guidance for investigators in elucidating these important developmental aspects (e.g., Garvey et al., 2016; Pacheco et al., 2022; NIMH, 2020). Overall, it is important to bear in mind that the framework is a set of principles intended to enable maximum flexibility in creating research designs that address the investigator's theories and hypotheses. As recently pointed out, "Interpreting the RDoC matrix as a starting point rather than

definitive, future research may reveal developmental variations that are not currently captured" (Casey et al., 2014, p. 351).

The influence of the environment (encompassing, for these purposes, all social and physical aspects) is an equally important etiological factor (and also included in Strategic Objective 2). Such influences have often been perceived as situations that begin when babies begin to acquire behavioral repertoires and interact with family members (e.g., attachment, Rutter & Sroufe, 2000). However, research has more recently reported that prenatal effects, such as maternal stress or diet, can result in epigenetic modifications that result in lifelong susceptibility to mental and physical disorders (Bale et al., 2010). Clearly, the number and scope of environmental factors are not only vast, but also depend on the particular stage of the life span being studied. The pervasiveness of environmental effects is daunting yet, at the same time, indicates the need for new measurement and analytic methods (Smith & Pollak, 2021).

In sum, developmental and environmental factors (and their interactions) represent critical components of the RDoC framework. They exert significant effects on the various dimensional constructs described above and, as such, are overarching concepts that are infused throughout all aspects of RDoC.

# Philosophy of Science Fundamentals in RDoC

The nature of the relationship between mind and body is a topic that has occupied philosophers and scientists since the time of Descartes and continues to pose difficult challenges both for conceptualizations of disorder and for practical issues of study design and interpretation. RDoC adopts a novel stance toward this issue in several respects, which are summarized in this section. The mostly implicit perspective of current nosologies serves as a jumping-off point for discussing the various aspects of RDoC's philosophy.

#### Mind-Body Considerations

A number of observers have recently discussed the paradoxical relationship that has developed between the essentialist, categorical approach of the *DSM/ICD* tradition discussed above and the growing expectation (as accentuated by such efforts as the "Decade of the Brain" in the 1990s) that biological explanations of mental illness were nearly within reach and that they would resolve the aforementioned scientific and clinical problems. *DSM* and *ICD* diagnostic criteria are almost exclusively psychological in that they cite selfreports and behavioral symptoms with little or no biological measures, yet those diagnostic categories were used to drive research priorities that were increasingly focused on biological phenomena (Scull, 2021). As *DSM/ICD* criteria are generally remote at best from biological mechanisms, they have proved an unproductive guide to research intended to identify those mechanisms (Kapur et al., 2012).

From a contemporary perspective, such a clinical research strategy was almost certain to be unsuccessful with respect to progress on mental illness. This is due to issues discussed above: first, that diagnostic practice continues to follow a nineteenth-century model in which symptoms and signs are necessary and sufficient to define particular "natural disease units" and, second, that each disease will be associated on a one-to-one basis with a specific pathophysiology. However, these assumptions have been shown to be unworkable due to the nature of mental illness and its characteristically divergent manifestations in expressive language, overt functional behavior, and central and peripheral physiology (Lang, 1968; Miller, 2010; Miller & Bartholomew, 2020; Miller & Keller, 2000).

## Toward Alternative Paradigms to Reconcile Mind and Body

Given that overt impairments in mental illnesses are fundamentally problems of functioning and mental states, the field is increasingly realizing that an approach to accounting for mental disorders that treats them as primarily biological is not likely to succeed (Belluck & Carey, 2013). Miller (2010) provided numerous examples of the widespread adoption of, and faith in, the premise that a focus on biology will suffice and discussed its logical and public policy shortcomings. Conversely, given that biological phenomena instantiate and support psychological phenomena, and given that there is no question that biologically framed interventions can alter psychological function (and vice versa; Miller, 2010; Yee et al., 2015), neglect of biological phenomena (genes, cellular mechanisms, neural systems) in a diagnostic system attending almost exclusively to psychological signs and symptoms also surely has to fail as a path toward discovering the relevant biology. This realization is a major reason for the emphasis on studies that include measures from multiple response systems.

However, it is not sufficient to declare, diplomatically, that we must incorporate all of the possible types of data that are available simply because they exist as aspects of psychopathology. Merely adding social and environmental phenomena does not suffice either. The oft-cited "biopsychosocial model" (Engel, 1977) is not a formal model; it is just a list of three realms of phenomena (biology, psychology in the sense of phenomena about a single person, and social processes), typically handled distinctly and originally proposed simply as a guide for clinicians in interactions with patients. In contrast, a model specifies mechanisms connecting the elements of such a list. We must develop an approach that feasibly connects various domains of observable phenomena and also connects the unobserved and the observed. The RDoC framework is not a specific model per se, but instead calls for formal analyses of relationships between the elements of the RDoC framework (Adams et al., 2016). Crucially, a way is needed to relate the biological and the psychological, not just as enumerated neighbors but as coherently linked features of the research enterprise and of the very concept of mental health and mental illness.

## The Role of Public Data in Psychopathology Research and Theory

From its inception, the RDoC initiative has been especially attentive to philosophy of science issues that are central to conceptualizations of mental health and mental illness. The very term "mental," referring to private events that only an individual can access, challenges the desire of modern Western science to rely as much as possible on public phenomena-events that, in principle, any observer can detect and measure. It is not that science cannot accommodate unobserved events or laws about which one makes inferences from observed events; that is in fact routine in the sciences. MacCorquodale & Meehl (1948) provided guidelines for psychological science to make inferences from one or more public events to hypothetical constructs (Kozak & Miller, 1982): public data are aggregated into intervening variables, and bridge principles "indicate how the processes envisaged by the theory are related to empirical [i.e., observed] phenomena" (Hempel, 1966, p. 72). Hempel (1966, p. 74) went on to explain that "Without bridge principles . . . a theory would have no explanatory power [and] would be incapable of test." But there has been no consensus about the constructs to use in understanding mental illness

and about the bridge principles to use in making inferences from public data to mental health and mental illness constructs.

It helps to clarify the nature of scientific data by considering how the concept has evolved. In historical perspective, the common modern term "empirical science" is incoherent. A central contribution of the British Empiricist school to modern Western philosophy was an emphasis on distinguishing between public events and an individual's experience of those events (that which is "empirical" in the traditional sense, going back to ancient Greek philosophy). "Empirical" knowledge came to be understood as fundamentally unscientific, even contrary to science, for which only public data are data. But, by the twentieth century, the common meaning of "empirical" had evolved to refer to the portion of one's private experience that is directly driven by the public events one observes. Modern science relies on the assumption that any typical observer will see the water level in a glass rising as the ice melts. Each observer has direct access only to their own perception of that phenomenon, but we assume that any attentive observer will have the same perception.

The role of subjective experience (conscious or unconscious) in modern science thus must be considered carefully (Lang, 1984). What one feels is not scientific, empirical data, in the modern sense of publicly observable phenomena, though for many in our field and most laypeople such feelings are assumed to be what is most important in mental health and mental illness. Early behaviorists sought to leave subjective experience out of science entirely, though this attempt failed along with their larger effort to avoid hypothetical constructs altogether. At present it is widely recognized that we can make inferences about subjective experience from public data (self-report, overt behavior, biological measures), but the question of what role subjective experience should have in studying, understanding, preventing, and treating psychopathology and how to include it in rigorous science is not settled.

#### An Integrative Approach

The 2008 NIMH Strategic Plan that gave birth to the RDoC initiative shifted from a primary reliance on biological reductionism and instead emphasized an integrative approach in which psychological phenomena and biological phenomena have equal status (Kozak & Cuthbert, 2016; Lake et al., 2017). RDoC did not turn away from heavy reliance on biological constructs and observations, but it restored equally heavy reliance on psychological constructs and observations—not those derived from the Freudian tradition, as the pre-1980 *DSMs* did, but those that have emerged in modern psychological science. It consistently champions the inclusion of psychological and biological constructs and observations on an equal footing.

As discussed earlier, the RDoC framework provides guidelines for inclusion of psychophysiological constructs (the rows of the evolving RDoC matrix). The initial selection of those constructs and their ongoing evolution relied primarily on how strong a basis the human and nonhuman animal literatures provide for characterizing the construct and grounding it in available psychological and biological data. The current set of constructs does not attempt to cover all of mental health and mental illness because not everything that is of interest to clinicians and clinical researchers is well studied nor is there good evidence of relevant neural circuits or other biological mechanisms. As a research framework intended to demonstrate how functions defined by brain-behavior relationships can be applied to psychopathology, it has been acknowledged that some clinical phenomena may not (for the foreseeable future, at least) be represented as RDoC constructs.

Some have found the RDoC initiative still too biologically oriented (e.g., Lilienfeld, 2014). While it is true that some presentations of RDoC posed the ideas in reductionistic terms, there was a concomitant emphasis on psychological and behavioral aspects. For example, although an early RDoC paper contained the statement "mental disorders can be addressed as disorders of brain circuits," an ensuing elaboration pointed out the importance of integrative connections between functional behavior and brain: "Examples where clinically relevant models of circuitry-behavior relationships augur future clinical use include fear/extinction, reward, executive function, and impulse control" (Insel et al., 2010, p. 749). Others have cast RDoC as not sufficiently biological (e.g., Ross & Margolis, 2019). Criticisms of RDoC as too biological or too psychological reflect assumptions about the primacy of one or the other that have not been productive, as well as a misreading of RDoC as foregrounding one over the other.

#### Causation in Biology-Psychology Relationships

The degree of biological reductionism implicit and sometimes explicit in psychopathology research in recent decades embodies premises that such reduction is desirable and feasible (Miller, 2010; Miller & Bartholomew, 2020). The notion is often that biology is the level of analysis where the real action is—the point at which the true causes of mental illness lie and where the most effective measures to prevent and treat it should be directed; thus, that reducing psychological constructs and understanding psychological interventions entirely in terms of their biological effects are appropriate steps as a matter of both good science and effective public health.

However, the philosophy of science literature has repeatedly shown those premises to be untenable even in principle across decades of evaluation. As is often the case for relationships among various areas of science, important aspects of psychological science cannot be represented adequately in biological science. For instance, with respect to various levels of psychological and biological mechanisms, "macro findings are indispensable to explanations of phenomena of interest by (a) providing information regarding higher levels of organization in mechanisms, (b) including information not contained within certain micro explanations and (c) providing more general and stable causal explanations relative to micro explanations in certain situations" (Sharp & Miller, 2019, p. 18; see also Miller, 2010, for extended critique, and Miller & Bartholomew, 2020, for suggestions of further reading on this point).

A relatively recent approach in that literature has been developed by a group of philosophers of science known as the "new mechanists," who are developing fundamental changes in the way we understand relationships among different types of phenomena, including causal relationships. For instance, Bechtel (2020) distinguished production mechanisms from control mechanisms. To simplify, one can imagine production mechanisms arranged in linear order: we feed materials into a machine that heats them, blends them, bends them, and produces a new material. In contrast, control mechanisms typically involve both local feedback and a hierarchical relationship among a larger set of control mechanisms. The relationships among them may be what Bechtel called "heterarchical," meaning not just top-down control but a mix of top-down and bottom-up control mechanisms that can even make the "up" and "down" metaphors inadequate. For instance, the control mechanisms by which we maintain blood pressure (and in fact quite different pressures in

different arteries) are many and complex in their interrelationships.

Thomas and Sharp (2019) interpreted and extended the new mechanist approach for psychologists and neuroscientists with a proposal for integrating biological and psychological constructs and phenomena. They discussed a strategy for developing a nonreductionist understanding of the ways in which psychological functions are implemented in biological structures. In turn, this strategy draws on a construal of the relationship between biology and psychology developed by earlier philosophers (e.g., Fodor, 1968, 1974). "The biological monism that has dominated American psychiatry for 40 years and more has been unable to solve questions of causation. That should not come as a surprise. There is mounting evidence for the importance of social factors in the genesis of major mental disturbance" (Scull, 2021, p. 4). Those social factors are not readily reducible to biology. Bolton (2013) similarly argued that some aspects of mental illness can be understood in biological terms, while other aspects will be better understood (and treated) using psychological constructs, phenomena, and methods.

The state of the art with respect to causation between biological and psychological events is such that there is not a single instance in which we have worked out the full causal chain. Furthermore, for logical as well as practical reasons, it is not at all apparent that we will ever be able to do so. Claims such as that mental illness is a brain disease, and goals such as the pursuit of the genes or circuits that explain mental illness, are not only untenable but misleading with respect to causation. It is at best premature to view biological mechanisms as "underlying" psychological phenomena or psychological mechanisms "underlying" biological phenomena. We do not know how biology/psychology causation works, and we should not pretend that we do in designing or revising a diagnostic system, developing research funding priorities, or talking with our patients. The hope offered some years ago that casting mental illness as merely physical illness would destigmatize mental illness has proved unsuccessful (Miller, 2010) and has fostered overreliance on pharmaceutical interventions.

## Levels Versus Units of Analysis

A feature of RDoC that is very intentional is its use of the term "units" rather than "levels" of analysis. Woodward (2020) provided a critique of the many ways that the "levels" metaphor has been used. As discussed by Borsboom and Cramer (2013), Kendler (2012), Miller (2010), and Miller and Bartholomew (2020), the "levels" metaphor carries undesirable baggage.

Traditionally, researchers tend to think of these levels as being intrinsically ordered, in the sense that genes cause brains and brains cause behaviors. However, in our view it is extremely likely that once researchers start taking the dynamics of symptomatology seriously, they will find feedback loops that cross the borders of traditional thinking. Naturally, genetic differences may predispose to the development of disorders, but persistent symptomatology (e.g., insomnia or loss of appetite) may cause differential gene expression just as well; in turn, such changes may affect a person's brain state and ultimately feed back into the environment [in] extended feedback loops. (Borsboom & Cramer, 2013, pp. 116–117)

Given such an understanding of the relationships among different facets of and mechanisms in mental illness, the implication of some reductive or causal ordering of "levels" is inappropriate, and the reductionism that the "levels of analysis" metaphor encourages is counterproductive. The RDoC initiative chose to characterize the columns of its initial matrix as "units of analysis" rather than "levels of analysis" specifically to avoid implying any causal ordering among those elements. RDoC is explicitly agnostic about what may be optimal ways of thinking about the relationships among them. This is an inherently nonreductionist stance while remaining open to scientific (and philosophical) advances that may point to reductionist or other relationships among them.

## Designing and Conducting RDoC Research

The background discussed above provides a basis for addressing how RDoC principles can be applied for research. The criteria emphasize psychophysiological constructs, dimensional approaches to functions, research designs that integrate multiple units of analysis, and inclusion of developmental aspects and environmental influences. There have been many misperceptions of the framework and how it is to be used, so it may be helpful at the outset to clarify some important aspects.

## Context: Scientific Funding Policies

The unique status of a psychopathology framework generated by a funding agency necessitates some explanation as to why its architecture is designed as it is and how that relates to devising research designs. Although this section may be of particular interest to readers in the United States, the application of RDoC principles concerns all investigators interested in utilizing the matrix for RDoC-oriented studies.

The goal of most grant-funding solicitations emanating from governmental agencies is to encourage applications in a specified scientific area or methodology, minimizing constraints on the "what" or "how" in order to encourage innovative ideas. As the experience with the NIMH "modular phenotyping" RFA showed, some guidance is necessary to communicate the high-level strategic goals for a particular area of research; however, it is always a desideratum for applicants to be as free as possible in choosing the particular research question, specific aims, and methods. Accordingly, while the current RDoC domains and constructs are considered as promising subjects for exploring psychopathology, an equally (or more) important role concerns their status as exemplars that illustrate the principles of dimensional functions for investigators interested in developing other aspects of dysregulated behavior.

There have been at least two kinds of misunderstandings about these policies (see Lake et al., 2017, for discussion of other common misunderstandings of RDoC). First are misapprehensions of NIH funding policies. Grant applications for RFAs can be returned by an Institute if the application is judged to be nonresponsive to the RFA criteria, while almost all other applications submitted by scientists ("investigator-initiated applications" in NIH-speak) are accepted for review in order to promote new ideas. Also, funding decisions are based heavily on scores in peer review, such that reviewers' perspectives play a major role in receiving a grant award (cf. the Alzheimer example mentioned earlier; Au, 2019).

In this context, the early RDoC RFAs (NIMH, 2012) prompted complaints that investigators could not use RDoC for their research because the particular construct that they wished to study was not listed in the matrix. This was not so. Although the RFAs specified that only constructs emerging from the original workshops could be included in research designs (in order to evaluate the grant application/peer review process for the new approach), they also stated that researchers were encouraged to submit ideas for new constructs via the investigator-initiated process. Others objected that NIMH no longer accepted applications focused on *DSM* disorders, which was also not true. The RFAs stated that applications focusing on *DSM* disorders per se

would not be accepted given the intent to solicit RDoC-oriented studies. However, *DSM*-based applications have always been accepted through the investigator-initiated process and continue to represent a majority of the clinical research grants at NIMH. At present, as planned from the beginning, RDoC- and *DSM*-oriented grant submissions are all reviewed as investigator-initiated applications. In fact, because of the *DSM* hegemony that had existed in peer review, RDoC has likely provided an example to open the way for other types of non-*DSM* applications to be given equal consideration in study sections.

The second misunderstanding has come about due to the distinction between the aims of funding agencies, as described above, and the practices of academic research for formal theory construction. Some critiques have asserted that RDoC omits various important specifications and hypotheses. For instance, a recent review commented that "RDoC does not explicitly promote theory building or the generation of falsifiable mechanistic explanations" (Haeffel et al., 2021, p. 12). However, developing and testing theories is a task for investigators to propose in grant applications. In contrast, the role of RDoC is to specify a new set of criteria for translational research (i.e., relationships among multiple measures of dimensional constructs relevant to psychopathology); these standards apply to all RDoC-oriented research, whether they involve tests of theories, data-driven studies of new phenotypes, or other aims.

## RDoC-Oriented Constructs and Experimental Designs

We consider in this section some of the considerations involved in devising RDoC-oriented research designs. The focus here is particularly on new or revised constructs, which are at the heart of progress for RDoC's translational goals. In keeping with the emphasis on particular constructs and specific aspects of psychopathology, RDoC studies typically have a narrower purview compared to the broad syndromes represented by DSM disorders. This approach facilitates transdiagnostic explorations of specific functions and basic-to-abnormal dimensional studies. For instance, in carrying out a transdiagnostic study of mood and anxiety disorders, the focus might be on reward valuation or reward learning rather than clinical instruments used to diagnose a particular disorder.

The initial set of considerations outlines three aspects regarding RDoC-like constructs in research

designs. One issue concerns the appropriate level of granularity for studying new constructs, a common problem in studying brain-behavior relationships (Poeppel & Adolfi, 2020). Broad constructs may be too ambiguous and vague for the RDoC context, as in concepts such as positive affect or internalizing, and may well subsume multiple circuits or functions (Sanislow, 2016). On the other hand, overly detailed constructs (e.g., proposing a construct for each nucleus related to threat in the amygdala) are likely to be too numerous and complex to be useful. Subconstructs were included in several instances where clearly appropriate, such as the RDoC concept of perception (with subconstructs of vision, audition, etc.), which provides examples of appropriately finer granularity.

A second, related consideration concerns the variety of psychological concepts and constructs that are similar, but not identical, to RDoC constructs. For instance, the RDoC construct of Cognitive Control has a substantial history in the literature, but there are many related psychological constructs (e.g., effortful control, self-regulation, and impulse control, to name but a few). While these concepts overlap to varying degrees, there are also multiple distinctions that are further complicated by differing levels of granularity (Nigg, 2017). Adding to the complexity, data suggest that self-report and behavioral measures may not entirely possess the same conceptual factor structures (Enkavi & Poldrack, 2020; Sharma et al., 2013). RDoC aligns with the cognitive neuroscience field in supporting ongoing research that continues to unravel and clarify the nature of concepts that share such knotty relationships and thus welcomes related constructs that are compatible with the RDoC approach.

A third design consideration concerns the examination of complex behavior in an RDoC context. Adaptive behavior requires effective interactions among multiple brain/behavior systems (motivational, perceptual, motoric, etc.), the precise combinations depending on environmental circumstances and the current state of the organism. While it is reasonable to conduct studies of particular functional systems (e.g., RDoC constructs) in relative isolation, ultimately there is a pressing need to examine interactions among systems-both for a fundamental understanding of basic behavior based on human and animal experiments (Anderzhanova et al., 2017) and for the unpacking of complex psychopathological phenomena such as hallucinations (Ford, 2016). Accordingly, studies examining research questions that involve multiple constructs
are strongly encouraged (e.g., Cohen et al., 2017; Gibb et al., 2016).

To summarize, the preceding considerations highlight various aspects of the need for a flexible approach to implementing RDoC-oriented research questions. Classifications have been defined as "cognitive structures imposed on data to make them more intelligible and useful for specific human purposes" (Hyman, 2021, p. 24). This comment applies to RDoC constructs (as with traditional psychological constructs) even though they do not comprise a formal system like the DSM. They represent well-replicated findings about the current state of the science with respect to various functions; however, there is no claim that RDoC constructs are definitive or "correct" in any way or an exhaustive list of functions. In fact, a major goal is for RDoC constructs to be refined by new data, often resulting in revised perspectives or multiple novel constructs that clarify our knowledge. For instance, the concept of a straightforward brain "reward circuit" was exciting news nearly 70 years ago (Olds & Milner, 1954); since then, science has revealed multiple aspects of mammalian reward systems (Berridge & Kringelbach, 2015)-including unexpected relationships between appetitive and aversive functions in what were traditionally regarded as "reward" circuits (Kutlu et al., 2021).

Accordingly, in considering research questions for an RDoC-oriented application, it is important to create study designs that incorporate RDoC principles rather than utilize a construct from the extant RDoC matrix simply because it is one of the listed entries. The essential point is to consider carefully the posited relationship between the function embodied in the research question and its implementing neural system, and to develop a programmatic line of research that explores the hypothesized relationships and their import for psychopathology.

A different set of ideas for research designs concerns how RDoC constructs are related to *DSM* categories because the latter have been involved in the majority of RDoC-themed studies to date. There are two broad themes in this respect. First, an increasing number of studies examine relations among various measures (e.g., genetics, functioning, neural systems, symptoms) across different disorder classes, such as schizophrenia and bipolar disorder or mood and anxiety disorders, that can contribute to an understanding of the prevalent comorbidity of disorders. The growing realization that such overlaps are common contributed to the inception of the RDoC project, and, in turn, transdiagnostic studies have increased over the past decade since RDoC began (Dalgleish et al., 2020).

Transdiagnostic studies implement a variety of research designs. One approach is to form transdiagnostic groups (i.e., the independent variable) on the basis of particular measures. For example, one ongoing research program explored effects in large samples that included patients with a variety of primary diagnoses from various mood, anxiety, and posttraumatic stress disorders (Lang et al., 2016). In a representative study, psychophysiological measures were recorded while patients imagined short narrative scripts depicting their own personally threatening material (e.g., encountering a large spider, being trapped during a car accident) and other standard scripts describing neutral situations. Patients were grouped into five quintiles (i.e., the independent variable), independent of diagnosis, according to a composite physiological reactivity measure-heart rate response and the startle blink magnitude elicited by an intense noise burst during imagery-calculated by the differences in magnitude between threatening and neutral scenes (both measures typically larger for emotionally evocative scenes). The dependent variables, a composite negative affectivity score (self-report measures of anxiety and depression) and a functional impairment scale, might be expected to be positively related to physiological responsiveness under the usual assumption that higher reactions to threat are associated with greater avoidance and distress. However, the results showed an inverse linear relationship across quintiles: higher reactivity was associated with less negative affectivity and lower functional impairment.

The investigators noted that the proportion of patients with a principal diagnosis of anxiousmisery disorders (e.g., generalized anxiety disorders or depression) was progressively larger across the highest to lowest quintile of physiological reactivity; in contrast, the opposite trend occurred for patients with circumscribed fear (e.g., specific phobia or circumscribed social phobia). Still, approximately 30% of the most reactive quintile were patients with anxious-misery disorders, with a similar percentage for patients with circumscribed fear disorders in the least reactive quintile. These data are consistent with prior DSM-oriented studies from the same group. For instance, patients with PTSD showed widely varying physiological responsivity to personal anxiogenic images, with high reactivity for singletrauma patients and blunted responsiveness with a multiple or chronic traumatic history (McTeague et al., 2010). Similarly, McTeague et al. (2009) reported that patients with specific social phobia responded most strongly to their personal fear scenes, while those with generalized social phobia showed attenuated physiological reactivity. Overall, these results indicate that it may be useful to focus on response mechanisms rather than diagnoses in order to consider treatments that could be targeted to the individual patient's particular dysfunction.

Somewhat more common designs involve analyses that group participants into clusters based on combinations of variables, often in data-driven computational analyses. An excellent example of this type is the Bipolar-Schizophrenia Network for Intermediate Phenotypes (B-SNIP) study, which involved two large cohorts-one initial sample and a replication sample, each with more than 700 patients and 200 or more controls-enrolling patients with either schizophrenia, schizoaffective disorder, or bipolar disorder (Clementz et al., 2021). A large number of behavioral and psychophysiological measures were obtained, with principal components analyses used to reduce 44 individual variables into nine factors comprising cognitive and stop-signal tasks, anti-saccade measures, and ERPs related to auditory stimuli. In turn, a cluster analysis of these factors was used to derive three "biotypes" (clusters) from the total patient sample. The DSM diagnostic categories were distributed across the three biotypes in both the original and replication samples. Schizophrenia probands were somewhat more numerous in Biotype 1 and bipolar probands more numerous in Biotype 3; however, all three biotypes included at least 20% of each DSM category. Two clusters were comprised of participants with very impaired cognitive performance, one cluster with blunted ERP reactivity, and the other with hyperreactive ERPs, while the third cluster scored close to control subjects on both cognitive performance and ERP reactivity. The second sample replicated the initial cohort closely. Importantly, in both studies a number of external validators were differentiated more precisely by the biotypes than by DSM diagnoses, including cortical thinning as measured by structural MRI, social functioning, and similar but less marked patterns of response in close relatives (Clementz et al., 2016). Once again, these data suggest that measures combining behavior and psychophysiological responses may provide more distinction in terms of pathological mechanisms and potential treatment targets than traditional disorder classes (Clementz et al., 2021).

A second theme involves explorations of the dimensional aspects of RDoC constructs, whether

a severity range within diagnosed patients or the broader normal-to-abnormal spectrum. These often relate to the usual inclusion of DSM diagnoses in research designs, but with analyses of a single large sample including both patient and control groups in order to study the dimensionality of various response measures that extend from normal-range to variably abnormal. As one example from a recent RDoC-oriented study, fMRI data were acquired from participants in two groups (schizophrenia spectrum disorder [SSD] and healthy controls) while they observed facial expressions (fearful, happy, etc.) in one session and imitated the expressions in a separate session (Hawco et al., 2019). A cluster analysis of fMRI reactivity scores (defined by the difference in fMRI activation between the "imitate" and "observe" conditions in a canonical "simulation circuit" of frontoparietal areas) was used to divide the sample into three groups of high, medium, and low reactivity. Notably, membership in the three groups was not related to diagnosis, nor to education or clinical ratings in the SSD group. Analyses relating reactivity to a principal component representing social cognition and neurocognitive scores showed that reactivity was inversely related to functional measures in both patients and controls, although functional scores for controls were much higher than that of SSD patients. High reactivity participants showed increased activation not only in the canonical simulation circuit but also in more diffuse patterns that extended to other cortical areas, prompting the inference that these individuals activated a more extensive network to compensate for local deficiencies. In contrast, lowreactivity participants inferentially suppressed activity in task-irrelevant areas to optimize performance.

Data for a replication sample that included euthymic bipolar patients in addition to SSD patients and controls demonstrated the same three patterns across groups (cf. similar distributions of patients across the three clusters in the B-SNIP study; Clementz et al., 2021). The investigators concluded by emphasizing the importance of examining dimensional measures across controls and patients: "participants showed greater similarity to members of their own cluster than to other members of their diagnostic group. This result calls into question the implicit assumption in case-control designs that groups are homogeneous but distinct from each other. Our results are more consistent with the RDoC framework, as we have demonstrated a gradient of neural efficiency to inefficiency mirroring better to poorer cognitive performance,

respectively" (Hawco et al., 2019, p. 529). The results also provide another instance of the divergence between different response measures: there was no difference in average neural efficiency during social processing tasks between patients and controls but functional differences in performance were highly significant, highlighting the need to relate dimensional aspects of data across measures to understand the nature of impaired functioning and neural circuit activity.

## Development and Environment in RDoC Designs

Work that is aligned with RDoC principles in studying developmental processes in youth and their relationship to psychopathology generally exemplifies one of two modes. The first examines cross-sectional similarities and distinctions within and across various disorders. Similar to findings in adult participants, such studies have found far more overlap among various forms of psychopathology with respect to both biology and behavior as compared to results that align with specific disorders. For example, in a transdiagnostic sample of youth diagnosed with various disorders such as bipolar spectrum disorder, ADHD, and disruptive behavior disorders, Bebko et al. (2014) found that, across diagnostic groups, scores on a measure of behavioral and emotional dysregulation were positively associated with left middle prefrontal activity to the "win" condition of a reward paradigm. The authors concluded that "elevated left prefrontal activity may reflect heightened sensitivity to reward-related cues and may be a biomarker of pathophysiologic processes associated with behavioral and emotional dysregulation and heightened reward sensitivity across different diagnoses in youth" (Bebko et al., 2014, p. 78).

As a second example, Kaczkurkin et al. (2020) examined structural brain similarities and differences in a large sample of youth who met criteria for an anxiety/depressive disorder or those with no psychiatric diagnoses. Analyses of structural brain measures in the internalizing sample, using a semisupervised machine learning tool, returned two transdiagnostic subtypes. Subtype 1 had smaller brain volumes as well as reduced cortical thickness, resting state activity, and white matter integrity; furthermore, cognitive tests were associated with poorer functioning across multiple domains including executive function, social cognition, and episodic memory. Subtype 2, on the other hand, showed intact cognitive functioning, brain structure, and brain function while still demonstrating clinically significant levels of psychopathology. Both of these studies represent the increasing trend toward transdiagnostic analyses in developmental samples (Astle & Fletcher-Watson, 2020).

The second line of studies focuses on examining trajectories of development and inferring what processes potentially go awry in psychopathology. For example, Cropley et al. (2021) used a normative model of brain morphology from structural MRI data to predict symptom ratings for seven independent dimensions from more than 1,000 participants in the Philadelphia Neurodevelopmental Cohort (PNC); they found that deviation of brain-predicted age from true chronological age was associated with psychosis, obsessive compulsive symptoms, and general psychopathology. Older than predicted brain morphology was associated with greater symptom severity along these dimensions, especially in frontal cortical and subcortical nuclei.

The transdiagnostic and developmental trajectory threads are complementary and provide the warp and weft of the tapestry of mental disorders. They depict the normative development of brain structure and function; assess when, how, and where potential deviations occur; and explore how such discrepancies are related to dimensions of clinical phenomena beyond diagnostic categories. Layered on top of this complex picture of development and its trajectories is the crucial factor of environment. Environment, as defined in the RDoC framework, is used in the broadest sense of the word and can include varying factors such as neighborhoods, schools, family, and events that occur to an individual (e.g., traumatic incidents). Every type of environment can also interact with the point in development at which it occurs and influence various aspects of behavior and biology.

For example, in a meta-analysis of 109 studies, McLaughlin and colleagues (2019) examined the impact of exposure to threat or violence in children and found that reductions in amygdala volume, increased amygdala reactivity to threat cues, and greater threat-related activation in the anterior insula were observed across studies. In contrast, children exposed to deprivation showed reduced volume and thickness of the dorsolateral prefrontal cortex and superior parietal cortex. These results suggest that different types of developmental and environmental insults are associated with distinct patterns of altered brain measures. As another example from an ongoing longitudinal study, resting-state functional connectivity (rsFC) measures were acquired from youth who had experienced maltreatment at two points

in late adolescence (ages 16 and 19). Maltreatment was associated with increases in rsFC from age 16 to 19 among default mode, dorsal attention, and frontoparietal systems; furthermore, the increases in rsFC mediated the relationship among maltreatment and depressive symptoms at age 19 (Rakesh et al., 2021). Similar to the McLaughlin et al. (2019) results, the investigators noted the importance of attending to the potential differences resulting from different types of maltreatment—a problem that is noted in many studies and has received increasing attention with respect to concepts and methodologies (e.g., Smith & Pollak, 2021).

An individual's temperament and predisposition represent another factor in the Rubik's cube of interactions regarding development and environment. The significance of temperament for both normalrange and disordered behavior of many kinds has been recognized for some time (Clark, 2005). Studies of temperament trajectories that include an RDoC perspective have increasingly highlighted their role for risk across all areas of psychopathology (e.g., Wakschlag et al., 2018), and systematic ideas about integrating temperament and development with the RDoC framework have been proposed (Ostlund et al., 2021).

The few studies reviewed here are representative of the larger literature indicating that development is equally important for disorders traditionally distinguished as "childhood-onset" and "adult-onset" conditions. The gradual onset of aberrant functioning suggests opportunities for early intervention, and many strategies for prevention research in mental disorders have been developed (Arango et al., 2018). However, the current diagnostic system is not well-designed for prevention studies. The use of a symptom-based diagnostic nosology means that psychopathological processes are, by definition, already well-established by the time of diagnosis (Insel, 2009); the binary diagnostic system also hampers the use of dimensional outcome measures. Furthermore, the heterogeneity and comorbidity of disorders, related to issues of multifinality and equifinality (Cicchetti & Rogosch, 1996), make it difficult to decide on the particular intervention or groups to be included in any given trial. As prevention experts have noted, "Risk or protective factors do not seem to be specific for particular mental disorders. . . . Although some interventions could be more specific, . . . public health interventions, whether population-wide or in a high-risk subgroup, might have low specificity and reduce incidence or improve outcomes across disorders" (Arango et al., 2018, p. 596).

The RDoC framework fosters research designs that contribute to mitigating these problems. Studies can be focused on particular constructs (e.g., fearful behavior, self-regulation) that are defined in terms of both psychological and biological aspects, and dimensional approaches enable quantitative dependent variables in both respects. Due to methodological advances in various areas, it is also increasingly possible to identify dimensions of early problems before they are clinically overt (Gur et al., 2014; Wakschlag et al., 2018). Experimental designs to implement RDoC prevention studies of various types have already been delineated in detail (Zalta & Shankman, 2016), notably including a "prevention-mechanism" trial paradigm designed to focus on proximal mechanisms related to RDoC constructs that are free of the constraints and heterogeneity of categorial diagnostic systems (Goldstein & Morris, 2016).

## **Conclusion and Future Directions**

The RDoC initiative is an experimental psychopathology program that provides a framework for research intended to foster alternative approaches to conceptualizing and studying mental illness. Prefaced by a review outlining the historical trends in psychiatric nosology that eventuated in the need for such a project, this chapter has summarized the major elements of the RDoC framework, important ideas in the philosophy of science that permeate its concepts, and issues and considerations involved in designing RDoC-oriented studies.

Seen in retrospect, psychiatric diagnosis is in many respects a case of history repeating itself, and an understanding of the factors that have contributed to this pattern is important for considering future research. Modern psychiatric nosology had its roots in the nineteenth century, following other areas of medical research in attempting to define diseases on the basis of symptom patterns that were expected over time to reveal underlying pathologies. The inability to establish definitive diagnostic classes due to multiple difficulties of science and philosophy were partly responsible for the rise of psychoanalytic theories that also were unable to reach consensus regarding etiology or diagnosis (Lang, 1984). The imperative to provide a comprehensive diagnostic manual as medicine became more systematized in the mid-twentieth century resulted in a reversion to the use of symptoms and signs for diagnosis ("neo-Kraepelinians"), albeit with more precise criteria; unfortunately, despite caveats in the DSM-III manual, its disorders quickly

became reified and thus viewed by many as natural disease entities.

The consequence was that the listed disorders rapidly became the sine qua non for various purposes such as research grant applications, journal articles, regulatory approvals, and insurance coverage. Ironically, just as twenty-first-century scientific methodologies (e.g., fMRI, psychometrically sophisticated behavioral tasks) matured sufficiently to resume the paradigms and practices of nineteenth-century medical research-that is, seeking to understand disorders in terms of departures from normal functioning in such aspects as behavioral performance or brain structure and activitythe diagnostic system had become so entrenched as to daunt any efforts at fundamental revisions to scientific and clinical approaches. Furthermore, various disciplines in the mental illness arena differentially focused on psychology, biology, or phenomenology, often to the exclusion of other data sources. Clearly, no one class of information offers the sole answer, and ignoring mind-body challenges hampers efforts at integration.

Given this context, RDoC is necessarily a research program-one intended to provide components that emphasize systematic and long-term change rather than promoting a shift to a prematurely developed compendium of psychopathology or clinical nosology. A key aspect of the RDoC framework is concisely expressed in a recent commentary (as contrasted to categorical approaches): "Clinical description, laboratory studies, and family (now genetic) studies do not converge at all on distinct categories. Rather, modern studies are consistent with psychiatric disorders as heterogeneous quantitative deviations from health" (Hyman, 2021, p. 6). These various "quantitative deviations" are implemented in RDoC as psychophysiological constructs, and multisystem measurement and analysis are encouraged to address directly the knotty problems of mind-body issues and modest covariation among measures that have impeded progress in understanding mental illness. A strong emphasis is placed on the study of constructs and measures within the context of developmental trajectories and their interactions with all manner of environmental effects. Finally, a high priority is given to devising age-appropriate measures that span the range from normal functioning to varying degrees of abnormality.

With respect to the next steps for RDoC, one important direction is to continue the rapidly expanding application of computational analyses, both for more precise definition of model-based constructs and for new clinical phenotypes (e.g., B-SNIP biotypes; Clementz et al., 2021) based on data-driven analyses (Huys, 2018). New technologies also have promise for providing novel information, such as digital measurements that acquire data from mobile devices regarding various aspects of behavior and cognitive processes (Torous et al., 2017) and natural-language analyses that provide RDoC-oriented dimensional phenotypes from electronic health records (McCoy et al., 2018). One important topic, related ultimately to granularity, is the oft-asked question of whether observed similarities across diagnostic groups in transdiagnostic studies are due to the same mechanisms or involve differences at other levels of analysis that would suggest divergent mechanisms. A related topic concerns the differing patterns of abnormality among various types of measurement that are found across distinct groups (e.g., Lang et al., 2016; Hawco et al., 2019). These kinds of challenges reflect the difficult scientific terrain that will be encountered as investigators engage with the complexity of trying to understand normal processes and their relationships to psychopathology.

At the outset, we referred to the current period as an exciting time for psychopathology, and RDoC has been a salient part of the ongoing scientific ferment. It is important to acknowledge that RDoC is one of a number of projects pursuing innovative approaches to diagnosis and clinical practice, including three examples noted here. The Hierarchical Taxonomy of Psychopathology (HiTOP) project includes dimensional and hierarchical components (as does RDoC) (see Chapter 3, this volume). A second research program explores disorders in terms of symptom networks that are causally connected and interact in multiple ways; formal modeling techniques are applied to construct the networks and analyze the complex relationships among the nodes (Borsboom & Cramer, 2013). Finally, clinical staging is a transdiagnostic approach that employs quasi-dimensional measurements to follow the evolution of psychopathology over time, delineating successive illness stages in terms of symptom domains such as psychosis or mood rather than traditional disorders (McGorry & Hickie, 2019).

While these other projects are more oriented toward nosological and clinical use in the relatively proximal future as compared to RDoC, they share a transdiagnostic approach and research flexibility. It augurs well for the future that after so many decades constrained to a single diagnostic paradigm,

multiple innovative efforts toward change are simultaneously under way. It can be hoped that all of these projects will share some central concepts while at the same time contributing divergent methodologies and data that continually stimulate progress. To this end, RDoC will continue its role with a perspective on viewing psychopathology in terms of quantitative deviations from normal functioning and the importance of integrative analyses across multiple measures. In the near term, advances in all of these areas are likely to be incremental and largely oriented around current DSM/ICD diagnostic classes-whether considered singly or in transdiagnostic cohorts. However, the first steps of a long journey are under way. Those in the early stages of their careers can anticipate many promising opportunities in the coming decades to reduce the burden of suffering from mental disorders through improved understanding, assessment, treatment, and prevention of psychopathology.

# Complex Systems Approaches to Psychopathology

Laura Bringmann, Marieke Helmich, Markus Eronen, and Manuel Voelkle

## Introduction

Science is permeated by complexity. In biology, systems such as insect colonies, flocks of birds, or ecosystems exhibit extremely complex behavior. For example, ant colonies construct large and elaborately structured nests, without any central control or leader ant, but rather through the intricate interactions of thousands of individual ants (Mitchell, 2009; Richardson et al., 2014). The human brain is a paradigmatic complex system, consisting of a vast number of interconnected neurons that are constantly interacting with each other. The Internet is a complex human-made system of interconnected servers, computers, and other elements. As well, social systems, such as economies or the stock market, are complex systems (Newman, 2018). Complexity thus occurs in (nearly) all scientific disciplines.

Clinical psychologists and psychiatrists also encounter complexity in their research and daily practice. Mental disorders, such as major depressive disorder, are the result of complex interactions at multiple levels, from the genes to maladaptive behavior and social influences (Freeman, 1992; Orsucci, 2006). In recent years, we have witnessed a sharp increase in studies that approach psychopathology from the perspective of complex systems. However, the idea that psychological and social processes are dynamical and complex is far from new; it goes back at least to the 1930s (Lewin, 1936; Richardson et al., 2014). Elaborate models of mental disorders based on complex systems theory were introduced already in the 1970s (Zeeman, 1976; see also von Bertalanffy, 1967) and further developed especially in the 1990s (Tschacher et al., 1992; van der Maas & Molenaar, 1992). One of the key challenges has been, and continues to be, how to translate these theoretical models into practical applications.

In this chapter, we provide an introduction to those complex systems approaches that have received the most attention in psychopathology. We start by discussing the general idea of complexity and complex systems and what those terms entail. We then turn to the framework of complex dynamic system models and how they have been applied to psychopathology. After this, we discuss early warning signals (EWSs), which hold the promise of providing a clinically useful application of the theoretical ideas of complex dynamic systems models. Finally, we go through the recent popular network approach to psychopathology and how it is related to the broader framework of complex systems. In all of these sections, we discuss both the promises and possible applications as well as the challenges and limitations of these approaches.

# **Complex Dynamic Systems**

Although complex systems studied in different disciplines are highly diverse (e.g., ant colonies, the Internet, or the human brain), it is thought that they share some common features and can therefore be studied with similar techniques. For this reason, the study of complex systems has emerged as a meta-paradigm or interdisciplinary field of its own (Orsucci, 2006). However, even among complexity

Abbreviations

obsessive-compulsive disorder	
vector autoregressive	

researchers, there is no agreement on what complexity or a complex system is precisely. The different definitions in the literature strongly diverge. For example, Orsucci writes, "Complexity science can be regarded as a scientific toolbox, containing some tools to deal, empirically and theoretically, with complex dynamical systems (i.e., many variables [in] systems changing in time)" (Orsucci, 2006, p. 390). On the other hand, Weng and colleagues characterize complexity based on our capabilities to understand a system.

In a general sense, the adjective "complex" describes a system or component that by design or function or both is difficult to understand and verify. . . . In physical systems, complexity is determined by such factors as the number of components and the intricacy of the interfaces between them, the number and intricacy of conditional branches, the degree of nesting, and the types of data structures. (Weng et al., 1999, p. 92)

Foote (2007), in contrast, lists several key features of complex systems.

In recent years the scientific community has coined the rubric "complex system" to describe phenomena, structures, aggregates, organisms, or problems that share some common themes: (i) They are inherently complicated or intricate, in that they have factors such as the number of parameters affecting the system or the rules governing interactions of components of the system; (ii) they are rarely completely deterministic, and state parameters or measurement data may only be known in terms of probabilities; (iii) mathematical models of the system are usually complex and involve nonlinear, ill-posed, or chaotic behavior; and (iv) the systems are predisposed to unexpected outcomes (so-called "emergent behavior"). (Foote, 2007, p. 410)

In sum, researchers define complexity or complex systems in wildly different ways.

One key and oft-noted characteristic of complex systems is *nonlinearity*. In nonlinear systems, changes in the input do not result in proportional changes in the output. Mathematically, a linear function can be plotted as a straight line, whereas a nonlinear function will have a more complex shape, such as a u- or s-shape (Salvatore & Tschacher, 2012), which can be described, for instance, with higher-order polynomial functions. For example, when gradually reducing the medication of individuals suffering from depression, the effect on mood is usually not linear but often results in sudden shifts in mood (Helmich et al., 2020). In general, nonlinearity "comes closer than does a straight line to therapists' and clients' clinical experience" (Barkham et al., 1993, p. 676). However, it is important to note that nonlinearity is a very general and common feature. In nature, nonlinearity is the rule rather than the exception: "calling a science 'nonlinear' is like calling zoology the 'study of non-human animals'" Stanislaw Ulam, quoted in (Orsucci, 2006, p. 390). However, modeling the behavior of nonlinear systems does not always require nonlinear functions because complex nonlinear behavior can also arise from linear interactions of simple components. For example, in an ant colony, even if the behavior of individual ants is linear and based on simple rules, the result is complex nonlinear overall behavior (Bonabeau et al., 1997).

In addition to nonlinearity, a typical feature of a complex system is that its behavior is the result of self-organization: there is no central controller or external designer, just many individual components interacting (Richardson et al., 2014; van Geert, 2019). For example, in a flock of starlings, there is no leading bird that decides where the flock goes, but rather individual birds whose interactions with their neighbors result in the behavior of the flock. Often, this behavior of a complex system, where the system-level behavior is difficult to anticipate or predict based on the individual components, is called emergence (Richardson et al., 2014). Such interacting components can also be seen as a network, an approach recently introduced into psychopathology research and something we will come back to in later sections. Sometimes complex systems can result in unpredictable emergent behavior, even when they consist of relatively simple components, which is referred to as chaotic behavior. In chaotic systems, tiny variations in the initial conditions can result in vastly different overall outcomes, making prediction difficult or impossible (Richardson et al., 2014). For example, tiny differences in the locations of individual birds can completely change the direction in which the flock is flying.

An essential feature of complex systems is that they are *dynamic*, which is why they are often referred to as *complex dynamic(al) systems* (Thelen & Smith, 1994). That is, the behavior of the system changes or evolves and unfolds over time in such a way that the current state of the system is dependent on its past states (van Geert, 2019). Thus, in order to study and model the system, *time* must be taken into account (Voelkle et al., 2018). The dynamic behavior of psychological processes becomes clear from examples such as emotions. Feelings of positive affect generally fluctuate throughout the day, from hour to hour or even minute to minute (Kuppens et al., 2010).

The importance of such changes is also apparent in symptoms of mental disorders. Mental disorders are usually not trait-like phenomena but dynamical processes, in which during some weeks one has more symptoms while at other times the symptoms seem to wane. This is clearly illustrated by Caspi et al.'s (2020) study of more than 1,000 individuals from New Zealand, followed from ages of 11 to 45. They found that mental disorders not only ebb and flow over years and decades, but that individuals also often experience several different mental disorders in their lifetimes. Finally, it is important to emphasize that change is also central to clinical practice, as one of the main aims of therapy is to instigate change (e.g., from an episode of major depression to no longer having a depression).

Traditionally, researchers have studied psychopathology as a trait-like phenomenon (Hamaker, 2012; see also Chapter 6, this volume). Following this paradigm, it is natural to just measure individuals once, for example with questionnaires concerning their symptoms, at a single time point. Such questionnaires mostly include retrospective items referring to a period of several weeks or even a whole life span (Kruijshaar et al., 2005). These measures and the statistical methods associated with them are meaningful and useful in their own right, such as when the goal is to compare two groups to find out which form of medication works better, information that is important for therapists and policymakers (Lichtwarck-Aschoff et al., 2008).

In contrast, when researchers want to study psychopathology as a process, the dynamic approach becomes important. The first step is to capture the process over time, for which time series or (intensive) longitudinal data are needed. Such data consist of many measurements, for example over days, weeks, or months, sometimes also multiple times per day, typically gathered using methods known as the experience sampling method (ESM), ecological momentary assessment (EMA), or ambulatory assessment (aan het Rot et al., 2012; Csikszentmihalyi & Larson, 1987; Ebner-Priemer et al., 2009). Although these methods have different historical backgrounds, they are overlapping, and the terms are increasingly used interchangeably. These methods are focused on the individual and describe the individual in context, taking the dynamics of and variability in emotions, cognition, and behavior into account (Devries, 1987; Myin-Germeys et al., 2009). In this way, biases of more traditional methods are reduced, such as retrospective recall bias. Take as an example a study by Mokros (1993), in which patients were asked to report their symptoms during the week and also to recall the symptoms they had experienced at the end of the week. This study vividly showed that the symptoms that were reported in the moment during the week were strikingly different from the symptoms that were recalled at the end of the week (see also aan het Rot et al., 2012).

The change processes in complex dynamic systems can also occur at several different time scales, even within one system. For example, changes in affect may take place over several minutes or even hours, whereas changes in the underlying neural circuits of the brain occur much faster, at the time scale of 10–100 ms, and the firing of a neuron takes only around 1 ms (Bertenthal, 2007).

These differences in time scale can make it difficult to determine whether a process should be studied with state- or trait-like measures: sometimes a process seems to be trait-like until it is examined on a different time scale, when one can see that it is actually a succession of different states. For example, an individual with obsessive-compulsive disorder (OCD; see also Chapter 6) may be characterized by repetitive behaviors such as hand washing according to specific rules. When OCD is thus fully developed, it may seem like a stable trait-like characteristic of an individual that can be captured with a retrospective questionnaire at a single time point. However, taking a different perspective and measuring the symptoms of OCD at a more fine-grained timescale, one could actually capture the process in which such rituals develop and become established. In the latter case, a mental disorder such as OCD can be seen as a process that needs to be studied dynamically in order to understand and perhaps even prevent it. Thus, depending on the time scale, one can perceive a phenomenon, such as a mental disorder, as either trait-like or state-like.

Notably, these different time scales in complex dynamic systems are typically not distinct but hierarchically related (Bertenthal, 2007; Eronen, 2021). For example, an episode of depression unfolds over a time scale of weeks or months. However, the episode of depression itself consists of symptoms, such as insomnia, pessimistic thoughts, or rumination, which take place at a faster time scale of weeks or days. These symptoms, in turn, can be seen as consisting of moment-to-moment changes and interactions among affect states (Wichers, 2014). Specifically, experiences of negative affect may not be disabling if they occur every now and then, but become problematic and disabling when they occur repeatedly or are constantly present, turning into a symptom of depression. Thus, studying mood in daily life at the time scale of minutes or hours can give a more fine-grained picture of the development of symptoms related to depression (Wichers, Wigman, & Myin-Germeys, 2015).

In this way, complex dynamic systems can be seen as having a hierarchical structure, forming multiple levels at different time scales (see also Jeronimus, 2019). Moreover, whether a level is (higher) macrolevel or (lower) micro-level depends on the context: if the starting point is disorders or diagnostic categories, individual symptoms can be seen as forming a micro-level from which disorders arise, but from the perspective of daily life at the time scale of minutes or hours, symptoms themselves can be seen as a higher macro-level. In general, none of these levels should be seen as a priori good or bad; instead, their suitability and importance should depend on the question at hand (Bertenthal, 2007; Eronen, 2021; Lichtwarck-Aschoff et al., 2008).

## **Complex Dynamic System Models**

Dynamic system models can be understood very broadly as mathematical descriptions of how a system changes or evolves over time and how the state of a system depends on its past states (Laurenceau et al., 2007; Richardson et al., 2014). Formally, the state of a system is defined as the current value of the variable(s) that describes the system (Richardson et al., 2014). A dynamic system model is then a set of mathematical equations (e.g., differential equations, see below) that specify how the state of the system changes from one moment to the next as a function of the past (Granic, 2005). In contrast, static models, such as mixed-effect or multilevel models (Snijders & Bosker, 2011) or (latent) growth curve models (McArdle, 2009), are far more dominant in clinical psychology, especially in longitudinal research (Voelkle & Oud, 2015). However, unlike dynamic models, static models do not capture how the state of a system depends on its state at a previous moment (Laurenceau et al., 2007). In other words, static models often resort to explaining changes by the mere passage of time, whereas dynamic models use past behavior to explain future behavior (Voelkle et al., 2018).

Commonly used static models also have further limitations when applied to mental disorders. For

example, a standard linear growth function assumes that there is unbounded increase or decrease ad infinitum when extrapolating into the future or past. This is not realistic when studying an individual with, for example, major depressive disorder. The symptoms of depression do not just increase indefinitely, but rather fluctuate around an equilibrium, also known as an attractor in the dynamic systems literature (Johnson & Nowak, 2002). One can have more symptoms one day and fewer symptoms on another day as the system is influenced by (external) factors such as stressful (e.g., a fight with one's partner) or positive (e.g., getting a promotion) events (Laurenceau et al., 2007). These fluctuations can then occur either around a nondepressed attractor, when the person tends to return to a nondepressed state after perturbations, or an attractor corresponding to depressed state, when the person tends to return to a depressed state after perturbations. The goal of treatment can be seen as helping the individual to shift from one attractor (a depressed state) to another (a nondepressed state).

In the dynamical systems literature, a common approach has been to use sets of differential equations, which have a long tradition in physics where they were originally used to model the dynamics in systems such as pendulums or planetary systems (Richardson et al., 2014). Today, differential equations are also increasingly used in psychological research (Boker & Wenger, 2007; van Montfort et al., 2018; Ryan et al., 2018). As they specify the amount of change occurring in a variable at a specific moment (i.e., over an infinitesimally small time interval), they are particularly well suited for modeling change processes in psychology (Boker et al., 2016).

Importantly, differential equation models can indicate that there are specific attractors toward which the system tends to move over time (Wood et al., 2018). Thus, internal factors or external stressors can "push" the system away from its stable state, and it will take a certain amount of time for the system to return to a stable state, depending on how strong the attractor is. By observing the variables of the system for a period of time, these fluctuations around a stable state can be mapped in such a way that they visually describe the "landscape" of the system (Richardson et al., 2014). One central aim in dynamic systems modeling is to capture and study this *stability landscape* and its attractors in the system of interest.

Figure 5.1 provides a simplified visualization of such a stability landscape, which represents the

Figure 5.1 Visual representation of alternative stability landscapes. The stability landscape represents a person's psychological system, where the shape of the system reflects how resilient a person is to external shocks (e.g., psychologically impactful events). The ball represents the current state of the system (e.g., current emotion) and the attractors the possible stable states that the system can be in (e.g., depressed state). A. The system shows a strong ("deep") attractor. B. The system is destabilizing and the attractor has weakened. C. The ball has "tipped over" into the new attractor, and the old attractor disappears. Adapted from Helmich, M. A. (2021). Early warning signals and critical transitions in psychology: challenges and recommendations. *Current Opinion in Psychology, 41*, 51–58. Copyright 2021 by Marieke Helmich. Adapted with permission.

person as a psychological system. The basins represent attractors in the system (e.g., a depressed and nondepressed state) and the ball symbolizes the individual's psychological state at a given time (e.g., current emotions). The shape of the landscape and the depth of the basins, in particular, reveal how resilient a person is to external shocks or stressors (e.g., psychologically influential events): they are likely to recover more quickly when the basin is "deep" and the ball is less likely to move far away from the bottom of the basin.

For example, in a landscape with one deep attractor, shown in Figure 5.1c, the system has a single stable resting point around which it varies and to which it returns over time. However, a system may also be *bistable*, having two attractors in the stability landscape (e.g., a depressed and nondepressed state), as in Figure 5.1a and 5.1b, or have multiple attractors between which it can switch. Not only can there be several attractors in a dynamic system, but the number and type of attractors in the system can also *change* in response to internal or external factors (Richardson et al., 2014). For instance, a bistable landscape with two attractors (depressed and nondepressed state; Figure 5.1b) may develop into a landscape with just one attractor (depressed state; Figure 5.1c).

A particular focus of interest has been cases where gradual change in external variables results in a sudden dramatic change in the stability landscape and thus the behavior of the system (Chow et al., 2015; Richardson et al., 2014). These are called *catastrophes*, and a mathematical framework to describe them is provided by *catastrophe theory* (Chow et al., 2015; van der Maas & Molenaar, 1992; Zeeman, 1977).<sup>1</sup> There are several different types of catastrophe models in the literature, of which a specific model called the *cusp catastrophe model* has been the most popular one, also in psychology (Chow, 2019; Richardson et al., 2014). The cusp model is one of

<sup>&</sup>lt;sup>1</sup> A similar approach coming from a different theoretical background is the synergetics approach building on the theory of Hermann Haken (Tschacher et al., 1992).

the simplest catastrophe models, and it describes how the interplay of just two independent variables (called *control parameters*) results in sudden changes in the behavior of the system (represented by one dependent variable).

One of the earliest applications of catastrophe theory to clinical psychology was Zeeman's model of anorexia nervosa (Scott, 1985; Zeeman, 1976). According to this model (which comes from Zeeman and does not necessarily reflect current knowledge about anorexia nervosa), sudden changes in eating behavior occur even though the underlying factors, namely hunger and abnormal attitude toward food, change only gradually (Nelson et al., 2017; Zeeman, 1976). As abnormal attitude toward food increases and diets become more restrictive, hunger also steadily increases. At some point, behavior may then switch abruptly from fasting to the other extreme, binge eating.

In dynamic systems terms, the control parameters in this catastrophe model are abnormal attitude toward food and hunger, and the dependent variable is eating behavior. Initially, there is only one attractor in the system-namely, fasting-meaning that the person tends to return to fasting behavior after perturbations, such as attempts to normalize eating behavior. However, as the control parameters (abnormal attitude toward food and hunger) steadily increase, the stability landscape of the system changes in a sudden and catastrophic way. A new landscape emerges, now with two attractors: fasting and binging. Eating behavior will then jump between these two extremes, fasting and binging. Thus, with the catastrophe model, these interactions between the abnormal attitudes toward food and hunger (the control parameters) and eating behavior (the attractors; fasting and binging) can be mathematically described.

Although catastrophe theory provides an elegant mathematical framework, in practice it is often very difficult to fit a catastrophe model to (clinical) data (Chow, 2019; Chow et al., 2015). Therefore, in psychology, the focus has been on so-called *catastrophe flags*, which are specific features that can indicate that the system exhibits catastrophic behavior (Gilmore, 1981; Kunnen & van Geert, 2012). Of most interest for clinical psychology have been flags that can be observed right before or during a sudden change or transition: anomalous variance, divergence of response, and critical slowing down (van der Maas & Hopkins, 1998). First, *anomalous variance* refers to the phenomenon that the variance of the key variable (e.g., eating behavior in the anorexia example) increases markedly before a transition occurs, meaning that the spread of the values of the variable becomes wider. Second, *divergence of response* means that, before a transition occurs, even small external stressors result in large fluctuations in the behavior of the system. Finally, a closely related flag is *critical slowing down*, meaning that when it is close to a transition, the system takes more time to recover and returns more slowly to its stable state when perturbed.

These flags can be detected from time series data (e.g., ESM/EMA data). As fitting a (cusp) catastrophe model can be very challenging, a common solution is to, for example, detect anomalous variance by checking if there is a sudden change in the data (e.g., with change point analysis; Wichers, Schreuder, Goekoop, & Groen, 2019). These flags are not only indicators of catastrophic behavior of the system in general, but also central candidates for EWSs, which we will discuss in more detail in the next section. Importantly, while a given flag may suggest that the system exhibits catastrophic behavior, taken alone it cannot sustain the conclusion that a (cusp) catastrophe model applies (van der Maas & Molenaar, 1992). Furthermore, there is a large translational step from the dynamic (catastrophe) models to time series models, and many assumptions and choices have to be made regarding, for example, time scale, number of measurements, and relevant variables measured, which can all influence the outcomes (Haslbeck & Ryan, 2021). These issues will be also touched upon in the next section.

# **Early Warning Signals**

EWSs are the part of complex dynamic systems modeling that has drawn the most attention in psychopathological research. EWSs occur when the stability landscape is slowly changing as the system approaches a tipping point, it becomes less resilient to shocks, and a sudden "critical transition" to a new state may be imminent (Scheffer et al., 2009). To explain this, we return to Figure 5.1. In Figure 5.1a, the system appears relatively stable, the basin is "deep"—the attractor is strong—and even though the ball will move around in response to external stressors, with time, the ball will be pulled back to the bottom of the basin. Note that, while a potential alternative attractor appears on the right side of Figure 5.1a, only a very strong impulse would cause the ball to be pushed into that basin.

Translated to psychology: if we view the left side of the figure as an individual's mental state, which is currently relatively stable and healthy, it would require a strong trigger—like losing a loved one—for the system to switch to the right side, which can be understood as a more negative, possibly depressed, stable state. In Figure 5.1b, the system has lost resilience and the current attractor has become weaker and the basin shallower. As a result of this change in the stability landscape, the system in Figure 5.1b is more vulnerable to "tip over" with a sudden shift to the alternative attractor on the right side of the figure: no longer does the ball need a large impulse to be pushed over the edge of the left-hand basin; even a small push could effectively cause a critical transition to a depressed state or another psychopathological state.

As complex dynamical systems are composed of interacting variables that can change at different rates, zooming in on the moment-to-moment changes in one variable can be informative of an upcoming change in another, slower changing variable. In the context of psychopathology, this had led to the hypothesis that EWSs may be detectable in momentary affective states before a sudden shift in symptoms, such as a depressive relapse (Wichers et al., 2016, 2020) or sudden improvements in the context of therapy (Olthof et al., 2020).

The clinical promise of EWSs is that clinically important symptom changes could be anticipated by monitoring individuals' moment-to-moment (affective) experiences in the course of daily life (e.g., based on ESM/EMA data). The idea that EWSs could be used as "generic" indicators of future symptoms shifts has led researchers to speculate about the potential of monitoring individual patients or at-risk individuals and using EWSs to make personalized prediction and timely intervention possible. For instance, if EWSs are found to be consistently effective at predicting impending changes in individuals, their application in clinical practice could include early detection of episodes of mental illness (Kuppens et al., 2012; Wichers et al., 2019), thus identifying sensitive periods in which psychological treatment may be more likely to effectuate positive symptom change (Hayes & Yasinski, 2015; Schiepek, 2003), as well as improving timely intervention in cases of depressive relapse and suicide attempts (Bryan & Rudd, 2018; Wichers et al., 2016, 2020).

# Examples of Early Warning Signals

Many different possible EWSs have been discussed in the literature; here we focus on those that have received the most attention in psychology: critical slowing down, flickering, and critical fluctuations (similar to anomalous variance). The latter is a notion developed in recent years in ecology, a field in which many other EWSs also have been described (e.g., spatial variance and spatial skewness; Scheffer et al., 2009). Further EWSs have also been explored in simulations studies (e.g., dominant eigenvalue of the covariance matrix; Chen et al., 2019). However, these have not been tested in clinical data yet.

The first one, *critical slowing down*, was already briefly mentioned as a catastrophe flag in the previous section. In the context of EWSs, critical slowing down can be inferred from changes in the temporal dynamics of the system's variables, which then serve as an EWS. This "critical slowing" of the system means that the current attractor becomes weaker (the basin in Figure 5.1a changes to that in Figure 5.1b), and this changing landscape can be inferred from how the system recovers (returns to its stable state) from perturbations. Thus, in the landscape in Figure 5.1b, the ball tends to go farther away from the stable state and takes longer to return than in the landscape in Figure 5.1a. In other words, it takes longer for the system to recover after perturbations.

In statistical terms, this has been taken to imply an increase in autocorrelation. In brief, autocorrelation indicates how well the value of a variable (e.g., an emotion) at a given point in time predicts the value of the same variable at the next point in time (e.g., the same emotion at the next time point). Thus, as the ball spends more time away from its stable position (the mean), consecutive states are more similar and more highly correlated with previous states, which results in higher autocorrelation. Moreover, as the distance from the stable position also increases, critical slowing down is expected to correspond to a higher variance (i.e., more spread in the values of the variable) over time. Translated to the individual's psychological viewpoint, and specifically to momentary affect, the effect of critical slowing down would show as emotions that become increasingly volatile as the system is destabilizing (increased variance), and, once something triggers an emotional reaction, this feeling is likely to linger longer over time (increased autocorrelation).

A second possible EWS that has been studied in psychology is a phenomenon known as *flickering*, where the system moves back and forth between two alternative attractors (Scheffer et al., 2009). This can happen when the landscape changes in a way that makes it easier for the ball to roll from one basin (attractor) to another, as in Figure 5.1b. This, too, can be considered an EWS because the system

109

may end up being shifted permanently to the alternative state and restabilize into a new (single) stable state. When statistically analyzing the changes in the system based on time series (ESM/EMA) data, flickering can be observed as bimodality or skewness in the distribution of the variables measured and can also be indicated by increases in variance (Scheffer et al., 2009). In psychopathology, bimodality has been observed in the (frequency) distribution of symptoms of major depressive disorder (Hosenfeld et al., 2015) and has been hypothesized to be of particular interest for patients with bipolar disorder, where the manic and depressed state may represent alternative stable states of the system (Goldbeter, 2011; Johnson & Nowak, 2002).

Finally, as the system is destabilizing, but has not yet settled into a new attractor, EWSs in the form of critical fluctuations may occur (Hayes et al., 2007; Olthof et al., 2020). With the stability landscape losing resilience and the current attractor losing strength-or even disappearing-the system starts moving between many different alternative states. These critical fluctuations occur over more dimensions than can be shown in Figure 5.1, and, in contrast to flickering, where the ball is rolling back and forth between two basins (i.e., attractors), in critical fluctuations the ball is rolling wildly around a destabilized landscape until it settles into a new stable attractor (Hayes et al., 2007). This behavior of jumping around in the destabilized landscape appears as large fluctuations and can be statistically observed as increases in indicators such as variance (or entropy; Olthof et al., 2020).

In general, what holds for all these EWSs is that if the "normal," dynamically stable state of the system is known, for example through studying the system over a long period of time, the EWSs can be identified as deviations from what would be expected if the system was stable. For instance, if the autocorrelation or variance of the system no longer fluctuates around the expected stable value but starts to increase, these increasing trends can function as EWSs.

# Early Warning Signals in Psychopathological Research

EWSs have been studied in psychopathology at both the group (nomothetic) and individual (idiographic) levels, mostly focusing on major depressive disorder. Group-level studies have examined, based on time series (ESM/EMA) data, whether indications of instability and destabilization on average relate to stronger concurrent symptoms (Koval et al., 2013; Sperry et al., 2020) or later symptom change (Curtiss et al., 2019; Kuppens et al., 2012; Kuranova et al., 2020; Olthof et al., 2020; Schreuder, Hartman, et al., 2020; van de Leemput et al., 2014). These studies show that, on average, persons with higher levels of autocorrelation and variance in their daily affective experiences are more likely to have a psychopathological diagnosis or experience a change in symptoms later in time. While this provides some evidence for the hypothesis that (developing) psychopathology is related to the temporal dynamics associated with EWSs, this group-level evidence is indirect, and a true test of this hypothesis requires studies at the individual level (see also Bos & de Jonge, 2014).

Indeed, because EWSs hold the promise of informing person-specific predictions, they should also be studied and tested at the individual level. This requires examining the temporal dynamics in time series of individual subjects as they experience changes in symptoms. Because such an intensive longitudinal design is not (yet) common in psychopathology research, only a few studies have been able to test empirically whether sudden symptom transitions were indeed preceded by EWSs in individual time series data (Olthof et al., 2020; Wichers et al., 2016, 2020).

For instance, Wichers and colleagues (2016) monitored one individual with a history of major depressive episodes while he was tapering his antidepressant medication. The participant completed 10 ESM questionnaires each day, which were sent at semi-randomly determined times across the day, and his depressive symptoms were assessed every week, over a period of about 8 months (239 days).<sup>2</sup> While the participant's symptoms were stable at the start of the study period, reducing medication dosage increased the risk of a depressive relapse, and the participant did relapse after 18 weeks. Upon examination of the temporal dynamics in the data, the researchers found that EWSs in the form of autocorrelation and variance rose significantly in the weeks preceding the symptom transition. This study was the first to show empirical evidence of EWSs for a specific individual in the context of psychopathology. Since then, the same researchers have replicated this result in one more participant, finding

<sup>&</sup>lt;sup>2</sup> The data are openly available here: https://openpsychologydata.metajnl.com/articles/10.5334/jopd.29/

that autocorrelation and variance started rising a month before a transition in symptoms—again, a depressive relapse—occurred (Wichers et al., 2020).

Moreover, F. M. Bos and colleagues (2021) conducted an exploratory study of whether EWSs (again, rises in autocorrelation and variance) in EMA-measured affective time series preceded transitions to depression and mania in a sample of 20 bipolar I/II patients. Eleven patients experienced one or more transitions to depression or mania during the 4-month observation period, but the results regarding the added predictive value of EWSs were mixed both between and within persons.

In sum, these first empirical studies provide tentative evidence that a rise in autocorrelation and variance preceded a transition in depressive symptoms and could therefore function as an EWS. However, much more research and consistent evidence is required to substantiate the utility of these EWSs for personalized predictions.

#### Promises and Problems

Although the focus in studies of EWSs in psychopathology has been on rises in autocorrelation and variance, there is no consensus on how to best search for EWSs in clinical research and practice. Here we discuss some important challenges and open questions, as well as possible solutions.

The first challenge is in collecting data that are suited for detecting EWSs and testing the hypothesis that EWSs serve as indicators for symptom changes (Helmich, Snippe et al., 2021; Schreuder, Groen, Wigman, Hartman, & Wichers, 2020). For optimal chances of detecting EWSs, individual time series of several patients, consisting of many (several hundred) observations per patient, are needed to ensure that the EWSs can be calculated reliably. A key question is deciding which variables are the most suitable for detecting EWSs (e.g., mood, affect, or symptom variables) and therefore should be measured. It has also been suggested that it may be worthwhile to consider combining several variables, or combining different EWSs (Dablander et al., 2020), to improve the power to detect an effect.

An additional challenge is that, in order to test the hypothesis that EWSs precede transitions, the data also have to include such a transition. Therefore, the data collection should cover a period in which transitions are more likely to occur (e.g., during psychological therapy, while tapering antidepressant medication, or in a group of patients who are prone to showing sudden symptom shifts, such as bipolar patients). Relatedly, the data should include a baseline period to be able to determine if the potential EWSs (e.g., autocorrelation or variance) are really changing relative to what is "normal" for that person.

Regarding transitions, because psychopathology is notoriously heterogeneous in how it is expressed in different individuals, it is important to consider what constitutes a "transition" for a specific individual (Helmich, Olthof et al., 2021). The relative speed, magnitude, and frequency at which symptom shifts occur may strongly vary between persons, disorders, and direction of change (i.e., symptom improvement vs. deterioration). Thus, for one individual a certain increase in depressive symptoms might be an exceptional change, whereas for another individual the same increase may be just usual day-to-day fluctuation. Currently, there is insufficient knowledge of how to generally or specifically identify "critical transitions" in psychopathology, and it is an important and challenging task to explore which change patterns EWSs can actually warn us about.

Finally, an important limitation when focusing on autocorrelation and variance is that increases in them can occur for many different reasons. Therefore, although an increase in autocorrelation or variance can be an indicator of critical slowing down, it can also precede more gradual transitions, or autocorrelation or variance can go up and then down without any transition occurring. It is also possible that critical transitions sometimes occur in a system without being preceded by an EWS (Dablander et al., 2020). Furthermore, an issue that has been recently raised is that it is not clear how much predictive value autocorrelation has over and above the mean (Dejonckheere et al., 2019), as the mean is a function of the intercept and the autocorrelation (see Bringmann et al., 2017, for more details).

In conclusion, although EWSs provide a promising opportunity to apply complexity and dynamical systems theory to improve clinical predictions of changes, many challenges and open questions remain. Several studies are expected to be completed in the coming years that will provide further indications of whether EWSs will deliver on their promise.

#### **Psychopathological Networks**

In the past decade, the network approach to psychopathology has become increasingly popular in clinical research and is also finding its way to clinical practice (Robinaugh et al., 2020; von Klipstein et al., 2020). In this section, we describe this approach and also explain how it is related to the other complex systems approaches discussed above.

The network approach focuses on psychological symptoms and their interrelations, the central idea being that these symptoms causally influence each other in a way that eventually results in a mental disorder (Borsboom & Cramer, 2013). For example, sleeping problems can lead to fatigue, which in turn leads to concentration problems and feelings of sadness, and these latter two then lead to even more sleeping problems (Cramer et al., 2016). As symptoms keep causing and sustaining other symptoms in this way, the result is an episode of depression. Thus, mental disorders are conceptualized as networks of interacting symptoms.

A network can be understood, in the most general terms, as a representation that describes how elements in a system are connected (Bringmann & Eronen, 2018). In network terminology, the elements are called *nodes* and the connections between them are called *edges* (Newman, 2018). For example, if we look at a railway network, the nodes are cities or stations, and the edges are the railways connecting them. Other examples of networks are the Internet, networks connecting brain regions, or social networks (e.g., representing the friendship relations between people). In psychopathological networks, the nodes are symptoms, and the edges are (causal) connections between the symptoms.

By placing the focus on symptoms and their interactions, the network approach provides an alternative to the medical disease model (Cramer et al., 2010). According to this model, the symptoms of mental disorders have a clear (biological) root cause, analogous to how viruses cause flu symptoms or tumors cause cancer symptoms (Borsboom et al., 2019). The proponents of the network approach argue that no such root causes have been found for mental disorders and that they are likely not to exist: instead, mental disorders simply are networks of interacting symptoms. Therefore, they should also be treated and studied at the level of psychological symptoms. This also fits well with traditional ideas in cognitive behavioral therapy, where interactions between mental states (e.g., Beck's negative triad; Beck, 1979) are seen as central for treating mental disorders (Bringmann et al., 2022).

#### Constructing a Psychological Network

Networks such as railway networks or social networks can be constructed by simply observing the nodes and connections (e.g., by looking whether there is a railway between two cities or asking whether individuals are friends with each other). These raw data can then be immediately visualized as a network, such as a friendship network that illustrates which children in a school class are friends with each other. However, in psychopathological networks, the edges (i.e., the connections between the symptoms, such as causal relationships) are not visible in the raw data but have to be inferred (Bringmann et al. 2019). Therefore, several existing modeling techniques have been applied to infer psychopathological networks. We focus here on two modeling approaches that have been the most widely used so far.

In the first approach, the edges (or connections) between symptoms are inferred from correlational analyses of data obtained from large groups of persons (Borsboom & Cramer, 2013). In such networks, the nodes are symptoms that are measured once per individual, and the edges are (partial) correlations between symptoms. This results in a symptom network with undirected edges, meaning that the edges do not give information on the direction of the causal influence between the nodes over time (see also the networks in Figure 5.2). Estimating direct (causal) relationships between symptoms is in principle possible but requires strong assumptions (Malinsky & Danks, 2018) and is, in practice, rarely done for psychopathological networks. One shortcoming of cross-sectional networks is that because they are based on aggregating data from many individuals, it is unclear to what extent they reflect within-person processes and thus whether they give information on the network of any specific individual (Hamaker, 2012). Moreover, as cross-sectional networks are based on one measurement occasion, they cannot give information about how psychopathological processes evolve over time (see the earlier section on "Complex Dynamic Systems").

The second modeling approach is based on time series or intensive longitudinal (ESM/EMA) data. As described in the section "Complex Dynamic Systems", these data consist of repeated measurements over time, where, for example, often measurements at 60 time points or more per person are collected. The most widely used method at the moment to infer networks from such data is the vector autoregressive (VAR) model, in which an individual network for each person is inferred (Bringmann et al., 2013). A VAR-based network is a directed network where an edge between symptoms A and B reflects the extent to which variance in symptom B can be predicted based on variance

**Figure 5.2** Symptom network structure and vulnerability for psychopathological change in a complex dynamical system. This figure shows how the network structure and stability landscape of an individual are expected to differ depending on how vulnerable the system is. The left panel (A) represents a symptom network in a system with low vulnerability: the six symptom nodes (S1–6) are sparsely connected, and the connections are weak, as represented by thinner lines. The right side of A reflects the stability landscape in which such a network may be observed: stressors (the lightning bolt) may push the ball away from its stable point, but the basin is deep and the system will recover rapidly. Moreover, if any of the symptoms are triggered, the other symptoms are not likely to be triggered as well. In B, the left panel displays a more densely connected symptom network in a system with high vulnerability. The stability landscape in the right panel shows that the system is currently still resting in a healthy state but the basin of attraction is weaker (shallower). Here, a stressor is more likely to cause the system to tip over into the "disordered" attractor, and, furthermore, the densely connected symptom network makes it more likely that the individual will remain in this state, as the connections between symptoms reinforce each other.

in symptom A while controlling for all other nodes in the network (Bringmann et al., 2022). Therefore, in contrast to cross-sectional networks, VAR-based networks are person-specific, directional, and explicitly represent relationships over time. VARbased networks can also include self-loops (i.e., an edge from a symptom to itself, reflecting the extent to which variance in the symptom at one point predicts variance in the same symptom at the next time point) and can also be used to infer contemporaneous effects (e.g., the concurrent [partial] correlations between symptoms within an individual; Epskamp, van Borkulo, et al., 2018).

Importantly, however, VAR-based networks represent just predictive relationships over time, which do not automatically translate to causal relationships (Bringmann, 2021). Indeed, in a recent simulation study, Haslbeck and Ryan (2021) tested how well current VAR-methods recover the causal relationships of a relatively simple system. They concluded that, due to problems such as insufficient frequency of measurements, VAR-based models in most circumstances cannot be used to reliably infer the causal structure of symptom interactions (Haslbeck & Ryan, 2021).

In addition to these modeling techniques, psychopathological networks have also been constructed based on perceived causal relationships (Frewen et al., 2013). The idea behind this approach is that clinicians (or patients) are asked about how they think that symptoms are related to each other, and then networks are constructed based on these expert judgments (Deserno et al., 2020). Thus, the edges in the networks still represent the strength of the (causal) relationship between two symptoms, but instead of being derived from data, they are now based on the estimates of clinical experts or patients. These networks can be person-specific, describing the network of one individual, or general expert estimates on how the symptoms of a disorder are expected to relate to one another. For example, Deserno and colleagues (2020) asked experienced clinicians to rate the relationships between pairs of symptoms of autism spectrum disorder, and then

constructed a network based on the average of these ratings. Such perceived causal networks can be seen as hypotheses about the causal symptom structure of patients and can provide a good starting point for further research.

Another possibility is to construct networks based on diagnostic manuals such as the DSM or ICD, for example by looking at how symptoms of different disorders overlap. Borsboom and colleagues (2011) used this approach to study the symptoms structure of the DSM-IV by taking the symptoms as nodes and drawing an edge between two symptoms whenever they appear in the same disorder. This resulted in a network illustrating the symptom overlap in the DSM-IV, showing, for example, that there is considerable overlap among the symptoms of mood, anxiety, and substance abuse disorders. Tio and colleagues (2016) used the same approach to compare the symptom structure of DSM-IV and ICD-10 and found clear structural differences between the two diagnostic systems (e.g., that there was more symptom overlap in ICD-10 than in DSM-IV).

Perceived causal networks and diagnostic manual networks are promising approaches but have received relatively little attention in the psychological network literature so far. Note that although the ways that these networks are constructed are very different from cross-sectional or VAR-based networks, they have nevertheless been analyzed using the same network techniques (described in the next section).

#### Density and Centrality

Once a network has been constructed, it can be further analyzed with a whole toolbox of techniques stemming from network science. We focus here on *density* and *centrality*, which have been the most commonly used network measures in psychopathology. The density (also known as connectivity in the psychopathological network literature) of a network refers to the relative number of edges in the network: a network with many edges and therefore many connections between the nodes is said to be *dense*, whereas a network with few edges is said to be sparse (Newman, 2018). In the psychological network literature, density is also used to refer to the mean strength of the edges: a network with stronger connections is denser than a network with weaker connections, even if they have the same number of edges (Pe et al., 2015).

One hypothesis is that individuals suffering from depression have a denser symptom or emotion network than do nondepressed people and are therefore more resistant to change (Pe et al., 2015). In a dense network, the symptoms or negative emotions can easily strengthen each other, making it more difficult to get out of a state of depression or a spiral of negative mood. This hypothesis has been studied in cross-sectional setups, but the results are inconclusive (Robinaugh et al., 2020), and it is also unclear to what extent cross-sectional studies can give information about the density of individual networks (Bos & Wanders, 2016). Time series analyses based on the VAR-model have found some evidence for denser networks in depressed individuals but have focused more on emotion or affect networks than on symptom networks.

For instance, Pe and colleagues (2015) conducted an ESM study comparing a healthy control group (n = 53) with participants diagnosed with major depression (n = 53). Over the course of 7 days, participants were prompted eight times per day to assess their negative (seven items) and positive (four items) affect using a 4-point scale. Networks were then inferred using a multilevel version of the VAR model. Density was calculated based on the absolute values of the connection strengths between the affect variables (i.e., the slope coefficients of the multilevel VAR model). When comparing the networks of the depressed and healthy individuals, the results indicated that depressed individuals had a denser network of (negative) emotions than did healthy individuals. Using the same method, Wigman and colleagues (2015) also found evidence for a more strongly connected network of thoughts and affect states in individuals with a diagnosis of depression than in healthy individuals.

However, results of density studies may be sensitive to specific methodological or modeling choices, such as whether the estimated parameters are penalized to limit the complexity of the model (de Vos et al., 2017). Ideally, the density hypothesis should also be studied within an individual. For example, in the study described in section "Early Warning Signals in Psychopathological Research," Wichers and colleagues (2016) also followed the network density in a person who first was in a healthy state and then transitioned abruptly to an episode of depression. Indeed, results seem to indicate that the network density of affect states increased over time for this specific individual, but replication studies are still needed before any conclusions can be drawn (see also Wichers et al., 2020).

Perhaps the most widely used network measures in psychopathology are *centrality measures*. These measures are intended to indicate which nodes in the network are important. The underlying idea is that nodes with a high centrality have strong connections to other symptoms and therefore play an important role in the network (Newman, 2018). In psychopathological network theory, an important hypothesis has been that the highly central symptoms can spread the activation of symptoms in the network and therefore intervening on such symptoms would be an important goal for clinical practice (Borsboom & Cramer, 2013). In this way, the focus is shifted from the state of the overall network to individual symptoms (Robinaugh et al., 2020). Following these theoretical ideas, many empirical studies have aimed at finding the most central symptoms in psychopathological networks (Boschloo et al., 2016; Rodebaugh et al., 2018).

There are many centrality measures, but those most widely used in this field have been *degree* and *betweenness* centrality (Bringmann et al., 2019). Degree centrality is calculated simply by taking the sum of the edges that a node has. Therefore, nodes that are connected to many other nodes have a higher degree centrality than nodes that are connected to only a few other nodes. For example, in a network representing the friendship relationships in a school class, the child with the most friends would have the highest number of edges and therefore the highest degree centrality. If the network is weighted—that is, the edges can have different weights—the sum of the (absolute) weights is taken, and the measure is called *strength* centrality.

Betweenness centrality is a more complex measure and is calculated based on the shortest paths between nodes (Freeman, 1977). A node that lies on many shortest paths between other nodes has a higher betweenness centrality than a node that lies on only a few shortest paths. For example, if a city in a railroad network lies on many shortest paths between other pairs of cities, then that city has a high betweenness centrality.

Translating these measures to psychopathological symptom networks is not always straightforward (Dablander & Hinne, 2019; Hallquist et al., 2021). It may at first blush seem intuitively plausible that a symptom with many connections to other symptoms (i.e., degree centrality) or a symptom that is on many shortest paths between other symptoms (i.e., betweenness centrality) plays an important role in the symptom network. However, the centrality measures were originally developed with social networks in mind, and, as we have mentioned earlier, there are important differences between social networks and psychopathological networks (Bringmann et al., 2019). For instance, in psychopathological networks the edges are often negative (representing, e.g., a negative partial correlation), whereas in the kind of networks for which the measures were developed, there are only positive edges (e.g., there cannot be a negative railroad path: there is either a path or there is not). Researchers using psychological networks deal with this generally by using absolute values of the edges when calculating centrality measures, making the negative edges positive. The result is that crucial information (e.g., that the partial correlation was negative) is lost. Due to this and many other issues (Bringmann et al., 2019), some experts on psychological networks have refrained from using centrality measures in their network analyses (e.g., Epskamp, van Borkulo, et al., 2018).

#### Networks and Complex Systems

In its early days, the network approach was not connected to complex systems theory (Borsboom, 2008), or the nature of the connection between the two was not explicitly spelled out (Cramer et al., 2010). However, there is considerable overlap between the two approaches, and, in recent years, the connection between them has also been clarified and discussed (Borsboom, 2017).

A starting point for connecting the complex dynamic systems and network approaches is network density (see section "Density and Centrality" above). Following Borsboom (2017), a network of symptoms can be seen as a complex dynamic system that can be in different stable states. These different stable states correspond to attractors in the system: for instance, a depressed and a healthy state. The idea is then that the density of the network partly determines how many attractors there are and whether a system transitions easily from one attractor (e.g., healthy state) to another (e.g., depressed state).

First, let us consider a network with low density, illustrated in the left panel of Figure 5.2a. Because the connections between symptoms are weak (indicated by thinner lines), external stressors do not easily result in symptoms activating each other. The stability landscape associated with this network is shown in the right panel of Figure 5.2a: there is just one attractor (the deep basin) in the system, corresponding to the stable healthy state, and the system tends to return to this attractor after perturbations (Borsboom, 2017).

However, in a dense symptom network, illustrated in the left panel of Figure 5.2b, the edges between symptoms are strong, and the activation of a symptom after an external stressor easily leads to symptom spread throughout the network. In complex systems terms, there are two attractors in the stability landscape of the system: one corresponding to a stable healthy state and one to a stable depressed state (Borsboom, 2017). The stability landscape in the right panel of Figure 5.2b illustrates how the system is currently still resting in a healthy state, but the attractor (the basin) is weaker (shallower) than the attractor corresponding to the depressed state (the deeper basin on the right). Between these attractors is a tipping point (the ridge), and, when this tipping point is reached (through perturbation and symptom activation), the system transitions from a healthy to a depressed state (Borsboom, 2017). Thus, stressors may cause the system to tip over into the "depressed" attractor, and furthermore, the densely connected symptom network makes it more likely that the individual will remain in this state (the deeper basin) because the connections between symptoms reinforce each other. Based on this conceptual framework, Borsboom (2017) defines mental health as "the stable state of a weakly connected symptom network" and mental disorders as "alternative stable states of highly connected (sub)networks of symptoms."

This theoretical framework has direct connections to the EWS literature discussed in the previous section. In addition to measures such as autocorrelation, network density also can be interpreted as an EWS, the idea being that the density of the network increases before the transition is reached. In other words, close to a transition, the variables of the system start to behave more similarly and are thus more highly correlated. In fact, these two measures, autocorrelation and density, are closely linked: autocorrelation is represented as self-loops in the VAR-based network, and therefore network density also partly reflects the strength of the autocorrelation of symptoms (Pe et al., 2015). Indeed, as discussed above in section "Density and Centrality," preliminary research suggests that the density of the network also is increasing before a transition into a depressed state (Wichers et al., 2016, 2020).

#### Challenges and Future Outlooks

Although these theoretical ideas are promising, there are still important unresolved issues. To start with, in the current network literature we often observe networks that not only contain symptoms and negative affect states, but also positive affect states as "happy" or "excited" (Pe et al., 2015). However, the original network theory as described above is based on symptom networks, and the idea that a dense network is associated with psychopathology crucially relies on the assumption that the nodes are symptoms or negative variables, which then keep easily activating each other. In a network with nodes representing positive affect states included (i.e., positive nodes), the reasoning does not work in the same way. In a dense network, these positive nodes also are more easily activated, which can lead toward a more positive overall state as positive nodes keep activating each other. Therefore, the link between density and psychopathology is conceptually unclear in networks where positive nodes are included.

The same holds for autocorrelation or self-loops: with positive nodes such as "happy," a high autocorrelation is unlikely to function as an EWS for depression. Moreover, not only the strength of the autocorrelation (and whether the node is positive or negative) but also the mean level of the node is crucial. If the mean level is low, a high autocorrelation actually implies that the node will tend to stay at a low mean level. Thus, even in symptom or negative affect networks, a high autocorrelation is unlikely to be an EWS if the mean symptom levels are very low. This highlights that although the edges are often the focus of interest in networks and complex dynamic systems, the simple mean should not be forgotten when studying psychopathology (Bringmann & Eronen, 2018).

Another way to connect network theory and complex systems theory is via formal theories using differential equations, which have recently received much attention (Burger et al., 2020; Robinaugh et al., 2021; see also Goldbeter, 2011). In the formal theory approach, a model is constructed where the nodes and the relationships between them are specified in a mathematically precise way, typically with differential equations that describe how each variable changes over time as a function of the other variables. Thus, in contrast to a data-driven model such as the VAR model, where the edges are purely determined by the data, the formal approach starts from theory, from which testable models are then derived.

Robinaugh and colleagues (2019), for example, used this approach to develop a model of panic disorder, including variables such as arousal, perceived threat, and escape behavior. Based on theoretical considerations, they formulated a set of differential equations that represent the presumed relationships between these variables. At the core of this model is a bidirectional causal relationship between perceived threat and arousal, which is moderated by a context variable (representing the presence or absence of an anxiety-inducing context) and arousal schema (representing beliefs and learned associations regarding arousal).

By means of computational modeling (simulations), Robinaugh and colleagues (2019) studied the behavior of their proposed model and evaluated its ability to produce common features of panic attacks and panic disorders. According to the authors, the model successfully reproduces some key features of panic disorder, such as the rapid onset of panic attacks. It also makes predictions that can be tested: for example, the model initially did not reproduce the phenomenon of nonclinical panic attacks because, in the simulations, occurrence of panic attacks always resulted in developing a full-blown panic disorder. This led the authors to add an "escape schema" variable to the model, representing beliefs concerning the effectiveness of escape behavior as a way to respond to perceived threat. However, a shortcoming of the model is that it remains highly theoretical: the parameter values and functions are not based on empirical data, but on their theoretical plausibility and ability to produce the relevant behavior (Robinaugh et al., 2019).

More generally, Burger and colleagues (2020) propose to use these kinds of theory-driven models based on differential equations to model mental disorders and also argue that they can be useful to inform case conceptualization in clinical practice. Overall, there seem to be relevant links between networks and complex dynamic systems models and ways in which they can be fruitfully combined to model and understand psychopathology.

# Conclusion

In this chapter, we have shown that there are many different approaches to studying psychopathology in terms of complex systems. We started out by discussing what complexity means and what complex systems are. After this, we turned to complex dynamic models that appear in the psychological literature and how these models are currently used in the field of psychopathology in the form of EWSs and psychological networks.

An important point to emphasize is that there are many different definitions of complexity or complex systems and that, even focusing just on the psychological literature, there is no exact definition for these terms that would be currently agreed upon. Even more so, the translation of the theoretical concepts and ideas associated with complex systems to actual models and applications is challenging and has taken place in very heterogeneous ways. For instance, nonlinearity and self-organization are central to theories of complex dynamic systems, the idea being that complex nonlinear behavior emerges from the interactions of many components. However, in practice, when applying a complex systems approach in clinical psychology, researchers are often just looking at increases in autocorrelation or variance in one variable (e.g., negative affect), which does not reflect the idea of complex behavior emerging from the interactions of many components.

Similarly, approaches that focus on individual symptoms, such as centrality measures, may not capture or reflect the complexity of mental disorders (Bringmann et al., 2019). It is hard to understand the behavior of a complex system by studying individual components (Cramer et al., 2010); instead, a more promising approach is to focus on the dynamics of the system as a whole (Bringmann et al., 2019). Furthermore, standard network models such as partial correlations or VAR models are linear models, and, even more so, partial correlation models are static, not dynamic, models. A promising approach that can help in translating the ideas of complex dynamic systems theory to psychological models is the recent turn in the network approach to formal models based on differential equations.

A further open question that needs to be emphasized is: What is the "system" when we talk about complex dynamic systems in psychopathology? Depending on the context and the author, it can be the person (as in most examples in this chapter), the mental disorder (Kossakowski et al., 2019), a network of symptoms (Nuijten et al., 2016), or many other things. This question is important, not only because it determines the focus of research, but also because variables that belong to the internal dynamics of the system are treated differently than external influences when modeling the behavior of the system.

In conclusion, complex systems approaches have become an integral part of psychopathological research, and many different pathways of implementing these approaches have evolved in the past decades. It is up to future research to disentangle the conceptual landscape of complexity and develop further ways of applying the theoretical ideas to the field of psychopathology.

#### Acknowledgments

We are very grateful to Timon Elmer and Freek Oude Maatman for helpful comments on an earlier draft of this manuscript, as well as the editors for their extensive and extremely helpful feedback. The research that resulted in this chapter was partly funded by the Netherlands Organization for Scientific Research, Veni Grant (NWO-Veni 191G.037; Laura Bringmann).

# Developmental Psychopathology

Dante Cicchetti

Etiological and teleological questions have been two of the primary issues that have captured the attention of developmentalists. The term "developmental" is not merely a synonym for the study of youngsters or the field of developmental science (Werner, 1948; Werner & Kaplan, 1963). Instead, a developmental orientation is best depicted as a "world view" (Pepper, 1942). Thus, it follows that one can take an adevelopmental approach to the study of children, or a developmental approach to any unit of behavior, discipline, culture, or person across the life span, either "normal" or atypical in some capacity or capacities. Developmental contributions to virtually every scientific discipline have been with us since the inception of Western thought (Kaplan, 1967). Eisenberg (1977) urged his psychiatric brethren to adopt a developmental framework, presenting it as a unifying perspective that would enable clinical investigators to frame the difficulties they encounter in studying and treating psychopathology. Eisenberg believed that the concept of development could serve as "the crucial link between genetic determinants and environmental variables, between . . . psychology and sociology, and between physiogenic and psychogenic causes" (p. 225). Furthermore, he proposed that the term development should be used in a broad sense and felt that it should include "not only the roots of behavior in prior maturation as well as the residual of earlier stimulation, both internal and external, but also the modulation of that behavior by the social fields of the experienced present" (p. 225).

#### What Is Developmental Psychopathology?

Developmental psychopathology is an integrative scientific discipline that is focused on individual biological and psychological adaptation and maladaption in the context of developmental change (Cicchetti, 1984b; Cicchetti & Cohen, 1995b; Rutter & Garmezy, 1983; Sroufe & Rutter, 1984). Before developmental psychopathology could emerge as a discipline with its own integrity, the efforts of those in related fields (e.g., embryology, philosophy, clinical and developmental psychology, and psychobiology) had been separate and distinct (Cicchetti, 1984b; Santostefano & Baker, 1972). The lack of integration across disciplines stemmed, in part, from long-standing tensions between the philosophical traditions underlying academic training and clinical practice and between basic and applied research (Santostefano, 1978).

Since its inception, developmental psychopathology has strived to unify contributions from multiple fields of inquiry, including epidemiology, developmental and clinical psychology, psychiatry, behavioral and molecular genetics, neuroscience, immunology, pediatrics, and sociology. Instead of espousing a singular unitary theory that could account for all developmental phenomena, a major goal of developmental psychopathology is to integrate knowledge across disciplines at multiple levels of analysis and in multiple domains (Cicchetti & Cohen, 1995b; Cicchetti & Dawson, 2002; Cicchetti & Valentino, 2007; Gottlieb, 1992;

Abbreviations	
5-HTT	serotonin transporter gene
CPP	child–parent psychotherapy
CRP	C-reactive protein
GWAS	genome-wide association study
G×E	gene–environment interaction
IPT	interpersonal psychotherapy
PFC	prefrontal cortex
RCT	randomized controlled trial
SNP	single nucleotide polymorphism

Rutter & Sroufe, 2000). The main goal of developmental psychopathology is to understand the origins and course of disordered behavior. The focus is on comprehending the processes underlying both continuity and change in patterns of adaptation. Major questions include: How does prior adaptation leave the individual vulnerable to, or buffered against, certain types of stresses? And, how do particular patterns of adaptation, at different developmental periods, interact with a changing internal or external environment or physiology to produce subsequent adaptation (Cicchetti, 1993; Sroufe & Rutter, 1984)?

Historically, a number of eminent theorists from diverse disciplines have asserted that we can understand more about normal developmental functioning by investigating its pathology and, likewise, more about pathology by examining its normal condition (Cicchetti, 1990). Indeed, for many theorists, the distinctiveness and uniqueness of a developmental psychopathology approach lie in its focus on both the normal and abnormal, adaptive and maladaptive, developmental processes (Cicchetti, 1984b; Rutter, 1986; Sroufe, 1990). Although traditional perspectives conceptualize maladaption and disorder as inherent to the individual, the developmental psychopathology framework places them in a dynamic relation between the individual and external contexts (Sameroff, 2000).

#### What Is a Developmental Analysis?

Because psychopathology unfolds over time in a dynamically developing organism, it is critical to adapt a developmental viewpoint in order to understand the processes underlying individual pathways to adaptive and maladaptive outcomes (Rutter, 1986; Sroufe, 2007). The undergirding developmental orientation impels researchers to pose new questions about the phenomena they study. For example, with regard to bipolar disorder, it becomes necessary to move beyond identifying features that differentiate children, adolescents, and adults who have and who do not have bipolar disorder (e.g., emotion dysregulation; attributional distortions) to articulating how such differences have evolved developmentally. Likewise, rather than being concerned with merely describing the symptoms of bipolar disorder in children, adolescents, and adults (as is the focus of DSM-V), the emphasis shifts to ascertaining how similar and different biological and psychological organizations contribute to the expression of depressive, hypomanic, or manic outcomes at each specific developmental level.

A developmental analysis presupposes change and novelty, highlights the important role of timing in the organization of behavior, underscores multiple determinants, and cautions against expecting invariant relations between causes and outcomes. Moreover, a developmental analysis is as applicable to the study of the gene or cell as it is to the individual, family, or society. Moreover, a developmental analysis is important for tracing the roots, etiology, and nature of maladaptation so that interventions may be timed and guided, as well as developmentally and culturally appropriate (Causadias, 2013; Toth et al., 2013). Furthermore, a developmental analysis is useful for discovering the compensatory mechanisms-biological, psychological, and socialcontextual-that may promote resilient functioning despite the experience of significant adversity (Denckla et al., 2020; Masten, 2014).

A developmental analysis also seeks to examine the prior sequences of adaptation or maladaptation that have contributed to a given outcome. Because developmental psychopathology adheres to a life span view of developmental processes and strives to delineate how early development influences later development, a major issue in the discipline is how to determine continuity in the quality of adaptation across developmental time. The same behaviors in different developmental periods may represent quite different levels of adaptation. For example, behaviors that indicate competence within a developmental level may indicate incompetence within subsequent developmental periods. Normative behaviors manifested early in development may denote maladaptation when exhibited at a later time. The manifestation of competence in different developmental periods is rarely indicated by isomorphism in behavior presentation.

# Historical Roots of Developmental Psychopathology

Developmental psychopathology owes the emergence and coalescence of its framework to many historically based endeavors (see Cicchetti, 1990). The publication of Achenbach's textbook (1974/ 1982); Rutter and Garmezy's (1983) chapter in the *Handbook of Child Psychology* (Mussen, 1983); the Special Issue of *Child Development* devoted to developmental psychopathology (Cicchetti 1984a); the *Rochester Symposium on Development and Psychopathology* (Cicchetti, 1989); a journal devoted exclusively to the discipline, *Development and*  *Psychopathology* (1989); and the three large volumes entitled *Developmental Psychopathology* (Cicchetti, 2016a; Cicchetti & Cohen, 1995a; Cicchetti & Cohen, 2006) are among its landmark works; however, the field of developmental psychopathology has historical roots within a variety of disciplines (Cicchetti, 1990).

One of the basic themes in the writings of the earlier thinkers was that if one aims to comprehend pathology more fully, then one must understand the normal functioning against which psychopathology is compared. Without a sophisticated understanding of the range of diversity in normal development, we would be severely hampered in our attempts to elucidate the pathways to adaptation and maladaptation in high-risk and disordered individuals of varying backgrounds. Although some definitional divergence exists, it is generally agreed that developmental psychopathologists should investigate functioning through the examination of multiple biological and psychological domains and levels of analysis (Cicchetti & Dawson, 2002; Cicchetti & Valentino, 2007, Masten, 2007).

The eminent psychiatrist Adolf Meyer put forth a psychobiological orientation. For Meyer, the psychobiological approach depicted humans as integrated organisms such that their thoughts and emotions could affect the functioning all the way down to the cellular and biochemical level, and, conversely, that occurrences at these lower biological levels could influence thinking and feeling (Meyer, 1950-1952; Rutter, 1988). Gilbert Gottlieb (1991) depicted individual normal development as characterized by "an increase of complexity of organization at all levels of analysis as a consequence of horizontal and vertical coactions, including organism-environment coactions" (p. 7). For Gottlieb (1992), horizontal coactions were thought to take place at the same level of analysis (e.g., gene-gene, cell-cell, person-person), whereas vertical coactions occurred at a different level of analysis (e.g., cell-tissue, organism-environment, behavioral activity-nervous system) and are reciprocal in nature. Consequently, vertical coactions are capable of influencing developmental organization from either lower to higher or higher to lower levels of the developing system. Accordingly, epigenesis is viewed as probabilistic rather than predetermined, with the bidirectional nature of genetic, neural, behavioral, and environmental influence over the course of individual development capturing the essence of Gottlieb's (1992) conception of probabilistic epigenesis (Gottlieb, 2007).

# The Organizational Perspective

Developmental psychopathology is not characterized by the acceptance of any theoretical approach; however, the organizational perspective on development has proved to be a powerful theoretical framework for conceptualizing the intricacies of the life span perspective on risk and psychopathology, as well as on normal development (Cicchetti, 1993; Cicchetti & Sroufe, 1978; Sroufe & Rutter, 1984). The organizational perspective focuses on the quality of integration both within and among the behavioral and biological systems of the individual. Furthermore, the organizational perspective specifies how development proceeds. Development occurs as a progression of qualitative reorganization within and among the biological, socioemotional, cognitive, representational and linguistic systems proceeding through differentiation and subsequent hierarchic integration and organization. The orthogenic principle (Werner, 1948; Werner & Kaplan, 1963) specifies that the developing individual moves from a state of relatively diffuse, undifferentiated organization to states of greater articulation and complexity by differentiation and consolidation of the separate systems, followed by hierarchic integration within and between systems

At each juncture of reorganization in development, the concept of *hierarchic motility* specifies that prior developmental structures are incorporated into later ones by means of hierarchic integration. In this way, early experience and its effects on the organization of the individual are carried forward within the individual's organization of systems rather than having reorganizations override previous organizations. Accordingly, hierarchic motility suggests that previous areas of vulnerability or strength within the organizational structure may remain present although not prominent in the current organizational structure. Nonetheless, the presence of prior structures within the current organization allows for possible future access by way of regressive activation of those previous structures in times of stress or crisis. Thus, for example, a behavioral or symptomatic presentation of a depressed individual may appear discrepant with recently evidenced adaptations but, in effect, indicates the activation of prior maladaptive structures that were retained in the organizational structure through hierarchic integration.

Organizational theorists contend that each stage of development confronts individuals with new challenges to which they must adapt. At each period of reorganization, successful adaptation or competence is signified by an adaptive integration within and among the emotional, social, cognitive, representational, and biological domains as the individual masters current biological and psychological developmental challenges. Because earlier structures of the individual's organization are incorporated into later structures in the successful process of hierarchical integration, early competence tends to promote later competence. An individual who has adaptively met the developmental challenges of the particular stage will be better equipped to meet successful new challenges in development. This is not to say that early adaptation ensures successful later adaptation; major changes or stresses in the internal and external environment may tax subsequent adaptational capacities. However, early competence does provide a more optimal organization of behavioral and biological systems thus offering, in a probabilistic manner, a greater likelihood that adaptive resources are available to encounter and cope with new developmental demands (Cicchetti, 1993; Sroufe et al., 2005).

In contrast, incompetence in development is fostered by difficulties or maladaptive efforts to resolve the challenges of a developmental period. Accordingly, incompetence in development can be conceived as a problematic integration of pathological structures. Over time, as hierarchical integration between the separate systems occurs, difficulty in the organization of one biological or behavioral system may tend to promote difficulty in which other systems are organized. The organization of the individual may then appear to consist of an integration of poorly integrated component systems. Early incompetence tends to promote later incompetence because the individual arrives at successive developmental stages with less than optimal resources available for responding to the challenges of that period. Again, however, this progression is probabilistic, not inevitable.

Although many theoreticians and researchers in developmental psychopathology have focused their efforts on childhood and adolescent disorders, a life span perspective is necessary because it is only by examining a range of conditions and populations from infancy through adulthood and into old age that developmental continuities and discontinuities can be elucidated. Moreover, since all periods of the life span usher in new biological and psychological challenges, strengths, and vulnerabilities (Erikson, 1950), the process of development may embark on an unfortunate turn at any point in the life span (Bell, 1968; Zigler & Glick, 1986). Whereas change in functioning remains possible at each transitional turning point in development, prior adaptation does place constraints on subsequent adaptation. The longer an individual continues along a maladaptive ontogenic pathway, the more difficult it is to reclaim a normal developmental trajectory (Sroufe et al., 1990). Furthermore, recovery of function to an adaptive level of developmental organization is more likely to occur following a period of pathology if the level of organization prior to the breakdown was a competent and adaptive one (Sroufe et al., 1990).

Within developmental psychopathology, disorders in childhood, adolescence, and adulthood are viewed from within the broader context of knowledge that has been accrued about normal biological and psychological processes (Cicchetti & Aber, 1998; Sameroff, 2000; Sroufe, 1990). In practice, this requires an understanding of the biological and psychological developmental transformations and reorganizations that occur over time; an analysis and appropriate weighting of the risk factors and mechanisms operating in the individual and his or her environment throughout the life course; an investigation of how emergent functions, competencies, and developmental tasks modify the expression of risk conditions or disorders or lead to new symptoms and difficulties; and a recognition that a specific stress or underlying mechanism may, at different times in the developmental process and in varied contexts, lead to different behavioral difficulties. Accordingly, individuals may experience similar events differently depending on their level of functioning across all domains of biological and psychological development. Thus, various occurrences will have different meanings for individuals because of the nature and timing of their experience. This interpretation of the experience, in turn, will affect the adaptation or maladaptation that ensues.

Zigler and Glick (1986), stated that a central tenet of developmental psychopathology is that persons may move between pathological and nonpathological forms of functioning. In addition, developmental psychopathology underscores that, even in the midst of pathology, individuals may display adaptive coping mechanisms (see also Ellis et al., 2020). Furthermore, depending on contextual constraints the definition of normality may vary. For example, affective inhibition may be adaptive for a child with maltreating parents, but it may result in victimization by peers (Cicchetti & Toth, 2016). This life span perspective on psychopathology enables developmental considerations to be brought into harmony with clinical concepts used to define the natural history of disorder, such as prodrome, onset, course, offset, remission, and residual states. Rather than competing with existing theories and facts, the developmental psychopathology perspective provides a broad integrative framework within which the contributions of separate disciplines can be fully realized in the broader context of understanding individual functioning and development.

# Developmental Psychopathology Principles

# The Interface of Normal and Atypical Development

As mentioned earlier, throughout the course of history, prominent theoreticians, researchers, and clinicians have adapted the premise that knowledge about normal and atypical development is reciprocally informative (Cicchetti, 1984b, 1990; Sroufe, 1990). These systematizers have underscored that research on the typical and atypical must proceed in tandem if we are to produce an integrative theory of development that can account for normal as well as deviant forms of ontogenesis to emerge.

Embryological research has made significant contributions to developmental theory (Gottlieb, 1976, 1983; Waddington, 1957). From their empirical efforts to unravel the mysteries of normal embryological functioning through isolation, defect, and recombination experiments and their investigation of surgically altered and transplanted embryos, embryologists derived the principles of differentiation, of a dynamically active organism, and of a hierarchically integrated system (Waddington, 1966; Weiss, 1969). Moreover, experiments conducted on genetic mutations have enhanced the understanding of normal functioning by magnifying the processes involved in normal ontogenesis (Fishbien, 1976). As Weiss (1961) stated, "even the greatest deformity is produced by the same rigorously lawful molecular and cellular interactions that govern normal development" (p. 150). Weiss (1961) articulated, that "no doubt that understanding of development has been furthered by the study of abnormalities" (p. 150).

In view of the contributions that the study of psychopathological phenomena and extreme risk conditions have made to theory development and refinement in other disciplines, it is curious that there was such a great reluctance to apply the knowledge derived from atypical populations of human participants in work in developmental and clinical psychology to normal developmental theory and research. Similar to cross-cultural research, the study of psychopathology can affirm, broaden, and challenge extant theories of normal and abnormal development by elucidating what developmental sequences are logically necessary, discovering possible alternate pathways to adaptive and maladaptive outcomes, and proffering evidence on which processes are most important for mental growth (Causadias, 2013; Cicchetti & Wagner, 1990; Garcia-Coll et al., 2000).

Often the investigation of a system in its smoothly operating normal or healthy state does not afford the opportunity to comprehend the interrelations among its component subsystems. Chomsky (1968) reflected on this state of affairs when he asserted that "One difficulty in the psychological sciences lies in the familiarity of the phenomena with which they deal. . . . One is inclined to take them for granted as necessary or somehow natural" (p. 21). Because pathological conditions such as brain damage or growing up in malignant environments enable us to isolate the components of the integrated system, their investigation sheds light on the normal structure of the system and prevents us from falling prey to the problem identified by Chomsky. Hence, empirical examinations of psychopathological populations and developmental extremes must be conducted (see Rutter, 1989). If we ignore the study of these atypical phenomena, then the eventual result is likely to be the construction of theories that are contradicted by the revelation of critical facts in psychopathology (Lenneberg, 1967).

When extrapolating from abnormal populations with the goal of informing developmental theory, it is important that a range of populations and conditions be considered. The study of a single psychopathological or risk process may result in spurious conclusions if generalizations are made based solely on that condition or disorder. However, if we view a given behavioral pattern in the light of an entire spectrum of diseased and disordered modifications, then we may be able to attain significant insight into the processes of development not generally achieved through sole reliance on studies of relatively more homogeneous nondisordered populations.

# Developmental Pathways: Diversity in Process and Outcome

Diversity in process and outcome is conceived as among the hallmarks of the developmental psychopathology perspective (Cicchetti & Rogosch, 1996; Sameroff, 2000; Sroufe, 1989). Developmental psychopathologists have articulated the expectation that there are multiple contributors to adaptive or maladaptive outcomes in any individual, that these factors and other relevant contributions vary among persons, and that there are myriad pathways to any particular manifestation of adaptive or disordered behavior (Richters & Cicchetti, 1993; Sroufe & Jacobvitz, 1989). Additionally, it is thought that there is heterogeneity among individuals who develop a specific disorder with respect to the features of their disturbance, as well as among persons who evidence maladaptation but who do not develop a disorder.

*Equifinality* refers to the observation that, in any open system, a diversity of pathways including chance events—or what biologists refer to as *nonlinear epigenesis*—may lead to the same outcome (Mayr, 1964, 1988). Stated differently, in an open system the same end state may be reached from a variety of different initial conditions and through different processes. In contrast, in a closed system the end state is inextricably linked to and determined by the initial conditions; if either the conditions change or the processes are modified, then the end state will also be modified (von Bertalanffy, 1968).

The principle of *multifinality* suggests that any one component may function differently depending on the organization of the system in which it operates. Multifinality states that the effect on functioning of any one component's value may vary in different systems. Actual effects will depend on the conditions set by the values of additional components with which it is structurally linked. Thus, a particular adverse event should not necessarily be seen as leading to the same psychological or nonpsychological outcome in every individual. Likewise, persons may begin on the same major pathway and, as a function of their subsequent "choices," exhibit very different patterns of adaptation or maladaptation (Cicchetti & Tucker, 1994; Egeland et al., 1996; Rutter, 1989; Sroufe, 1989; Sroufe et al., 1990).

#### Developmental Cascades

Developmental cascades refer to the cumulative consequences of the many interactions and transactions occurring in developing systems that result in spreading effects across levels, among domains at the same level, and across different systems or generations (Masten & Cicchetti, 2010). Theoretically, these effects may be direct and unidirectional, direct and bidirectional, or indirect through various pathways; however, these consequences are not transient: developmental cascades alter the course of development. Cascade effects could explain why some problems that arose in childhood are predictive of widespread difficulties in adolescence and emerging

adulthood whereas others are not. Given effects that spread over time for some kinds of psychopathology, well-timed and targeted interventions could interrupt negative or promote positive cascades. Moreover, if developmental cascades are common and often begin with adaptive behavior in early childhood, then this would explain why the evidence in prevention science indicates a high return on investment in early childhood interventions, such as high-quality preschool programs (Heckman, 2006; Reynolds & Temple, 2006). These effects may work by counteracting negative cascades, by reducing problems in domains that often cascade to cause other problems, or by improving competence in domains that increase the probability of better function in other domains.

Cascade effects encompass a broad array of phenomena investigated in developmental science within and across multiple levels of influence, from the molecular to the macro. Such cascade models may account for the pathways by which geneenvironment interplay unfolds over time in epigenesis to shape development, linking genes to brain function to behavior to social experience (Cicchetti 2016a, b; Gottlieb, 2007; Hanson & Gottesman, 2007; Szyf & Bick, 2013). The processes by which genetic disorders result in the development of behavioral anomalies have been described as cascades. Biological embedding of experience, as could happen when traumatic or negative experiences alter gene expression of the stress response systems of a developing child, may begin as a downward cascade (e.g., experience alters functional systems in the child) and then subsequently these altered systems may begin cascading upward consequences for brain development, stress reactivity, and symptoms of psychopathology through a complex sequences of processes (Cicchetti, 2002; Cicchetti & Cannon, 1999; Gunnar & Quevedo, 2007; Meaney, 2010; Shonkoff et al., 2009).

# Multiple Levels of Analysis

Over the past several decades, the advances that have accrued in scientific knowledge reveal that, in order to grasp the complexity inherent to the examination of the normal and abnormal human mind, it is important that a multiple levels of analysis approach and an interdisciplinary perspective be incorporated into the research armamentarium of developmentalists (Cacioppo et al., 2000; Cicchetti & Dawson, 2002; Masten, 2007; Pellmar & Eisenberg, 2000). Many of the psychopathological disorders that confront individuals today are not as effectively investigated by a single scientist or through a single disciplinary model. These scientific questions can be best addressed through an integrative interdisciplinary framework (Pellmar & Eisenberg, 2000; Staudinger, 2015). As Miller (1995) asserted "all of the different specialties—ranging from the basic to the applied and from the biological to the social and cultural—are needed to advance our common goal of better understanding human behavior" (p. 910). The more comprehensive portrayals of adaptation and maladaptation that ensue will serve not only to advance scientific understanding, but also to inform efforts to prevent and ameliorate psychopathology across the life span.

An interdisciplinary approach to research ensures that multiple levels are well represented and that the resulting theoretical advances are consistent with insights from other levels. Influences are conceived to flow bidirectionally between levels, so that no single level can be attributed causal privilege. Biology is thus not seen as the root cause of behavior, but rather as one strand of reciprocal influence in the developing system, both giving rise to and regulated by behavioral and environmental phenomena. Although biological and genetic factors are not accorded privileged causal status in developmental systems approaches (Cicchetti & Cannon, 1999; Thelen & Smith, 1998), theory and research cannot afford to overlook the contributions that genetic and neurodevelopmental processes can make to typical and atypical outcomes (Cicchetti & Walker, 2003; Romer & Walker, 2007).

The gains in scientific knowledge have led to remarkable advances in multilevel research. For example, genetic variation, known as gene-environment interaction and gene-environment interplay, has been shown to influence the effects of environmental experience on adaptive and maladaptive outcome. More recently, some developmental theorists have proposed a more general phenomenon of biological sensitivity to context (Boyce & Ellis, 2005). According to Belsky's influential theory of differential susceptibility, genetic variation affects an individual's susceptibility to environmental influences, be they positive or negative (Belsky, 2013). Belsky hypothesized that high susceptibility is dangerous in an adverse environment, but adaptive in a benign or enriched environment. Belsky's model underscores the ongoing coaction of multiple levels in determining functional outcomes and may help to guide future efforts to identify targets, timing, and types of efficacious intervention (Belsky & Van IJzendoorn, 2015).

*Epigenetics*, the environmental regulation of genetic activity, is another field in which breakthroughs have occurred (Cicchetti, 2016a; Hackman et al., 2010; O'Donnell & Meaney, 2020; Szyf & Bick, 2013). Epigenetics broadly refers to the way the environment impacts gene expression. Epigenetic modifications (e.g., methylation) change the way genes are expressed. Like a light switch, epigenetic modification can turn genes on or off or act as a dimmer switch to increase or decrease the way genes are expressed. Animal and human studies have provided a growing body of research that demonstrates that early experience affects long-term physical and mental health by regulating the expression of genes related to neural development (Cicchetti et al., 2016a, 2016b; Meaney, 2010; O'Donnell & Meaney, 2020), immune function, and stress regulation (Szyf & Bick, 2013), with downstream effects on adaptive and maladaptive behavior. Because DNA methylation is reversible, efficacious interventions may serve to reprogram adaptive systems, targeting biological processes (e.g., stress reactivity) through behavioral changes (Szyf & Bick, 2013).

## Resilience

The discipline of developmental psychopathology, with its major focus on the dialectic between normal and abnormal development, is uniquely poised to provide the theoretical and empirical foundation for resilience science. From its inception as an integrative science, developmental psychopathology spurred investigators to discover the most effective means of preventing and ameliorating maladaptive and pathological outcomes (Sroufe & Rutter, 1984). In fact, Masten and Cicchetti (2016) have stated that "resilience science is quintessential developmental psychopathology because it focuses on variation among individuals in relation to their experiences as they adapt and develop" (p. 272). Leading scholars investigating the risk for mental illness in human development realized that understanding this variation in adaptive behavior and outcomes was essential to developing an in-depth understanding of the genesis, epigenesis, prevention, and intervention of problems and disorders (Anthony & Koupernik, 1974; Garmezy, 1974; Garmzey & Rutter, 1983; Garmezy & Streitman, 1974; Rutter, 1979, 1987; Werner & Smith, 1982). Scholars and clinicians recognized that it was vitally important to discover why some individuals do well under very challenging high-risk situations, whereas others do poorly in the tasks of life or develop serious psychopathology (Luthar et al., 2000; Masten & Cicchetti, 2016).
Definitions of resilience have shifted with a broader framework in human development toward a developmental systems perspective that integrates theory and research from ecological theory (Bronfenbrenner, 1979), general systems theory (von Bertalanffy, 1968), and systems thinking in biology (Gottlieb, 2007). For the purpose of this chapter, resilience is defined thusly:

Resilience is the potential or manifested capacity of an individual to adapt successfully through multiple processes to challenges that threaten the function, survival, or positive development. (Masten & Cicchetti, 2016, p. 275)

Among the central themes in a developmental systems perspective on resilience, several principles are noted herein (for a full explication, see Masten & Cicchetti, 2016) (1) Many interacting systems shape the course of normal and abnormal development and the processes involved in resilience. (2) Resilience always reflects the current context as well as the history of the individual (or system). (3) Resilience is a dynamic developmental process (Egeland, Carlson, & Sroufe, 1993; Luthar et al., 2000). (4) Resilience per se is not a trait; however, many traits could influence resilience (Block & Block, 1980). As described earlier, the organizational perspective on development underscores the importance of studying multiple systems concurrently. Developmental psychopathologists who adhere to the organizational view of developmental processes must increasingly incorporate culturally and ageappropriate assessments of the effects of biological, psychological, and social-contextual factors within individuals, in their strivings to uncover the roots of resilient adaptation (Cicchetti & Cohen, 1995b).

Until the past two decades, research on the determinants of resilience was primarily psychosocial in nature. Research on the neurobiology and molecular genetics of resilience has finally begun in earnest (Charney, 2004; Cicchetti, 2013; Cicchetti & Curtis, 2007; Cicchetti et al., 2010; Curtis & Cicchetti, 2003; Ioannidis et al., 2020; Masten & Cicchetti, 2016). The contribution of biological factors to resilience has been demonstrated by research on neurobiological and neuroendocrine function in relation to stress regulation and reactivity, behavioral genetics research on nonshared environmental effects, and molecular research in the field of epigenetics.

One of the mechanisms through which individual functioning might be able to develop in a resilient fashion can happen on a neurobiological level via the process of *neural plasticity* (Cicchetti & Curtis, 2006; Cicchetti & Tucker, 1994). Neural plasticity can be framed as a process by which experience results in the reorganization of neural pathways across the course of development. The relation between the brain and experience is bidirectional. Experience helps shape the neural pathways in the brain, and the newly shaped brain seeks out different experiences which further alter neural pathways.

As the developmental process proceeds, neural plasticity appears to be guided by events that provide information to be encoded in the nervous system (Greenough et al., 1987). These experience-dependent processes involve the adaptation of the brain to information that is unique to the individual. Because all individuals encounter distinctive environments, each brain is modified in a singular fashion. Unlike the case with experience-expectant processes, experience-dependent processes do not take place within a stringent temporal interval because the timing or nature of experience that the individual encounters or chooses cannot be entirely and dependably envisioned (Black et al., 1998; Cicchetti, 2002).

Determining the multiple levels at which change is engendered through randomized prevention trials will provide more insights into the mechanisms of change, the extent to which neural plasticity may be promoted, and the interrelations between biological and psychological processes in maladaptation, psychopathology, and resilience. Efficacious, resiliencepromoting interventions could be conceptualized as experience-dependent neural plasticity. Efficacious interventions should change behavior and physiology through producing alterations in gene expression (transcription) that produce new structural change in the brain (Kandel, 1999).

Resilient functioning is more than a product of biological systems. Psychosocial systems are equally important. Examples of such psychosocial factors that have been found to be linked to resilient outcomes include secure attachment relationships, an autonomous self, self-determination, close friendships, supportive parenting, positive neighborhood characteristics, and variation in personality types (Masten & Cicchetti, 2016). Large longitudinal studies on the neurobiological mechanisms of resilient functioning after child maltreatment that cut across and integrate multiple levels of analysis (i.e., genetic, endocrine, and immune systems; brain structure and function; cognition, emotion, and environmental factors) and their temporal interconnections (Cicchetti, 2013;

Ehrlich et al., 2020; Ioannidis, 2020; Masten & Cicchetti, 2016).

#### Prevention and Intervention

The preeminent objective of prevention science is to intervene in the course of development to reduce or eliminate the emergence of maladaptation and mental disorder. Prevention scientists also seek to foster the recovery of function and promote resilient adaptation in individuals at risk for psychopathology. Despite the logical links that exist between the provision of intervention to infants, children, adolescents, and adults and developmental theory and research, far too few bridges have been forged between these realms of knowledge (Cicchetti & Toth, 2017; Weisz & Kazdin, 2017).

Prevention and intervention randomized controlled trials (RCTs) can provide a lens through which the processes responsible for the development, maintenance, and alteration of typical and atypical patterns can be discerned (Cicchetti & Toth, 1992; Howe et al., 2002). Because prevention trials tend to occur earlier in development than most intervention trials and because prevention tends to be concerned with key risk factors for the development of psychopathology, they are particularly relevant to informing developmental theory (Howe et al., 2002). Prevention and intervention efforts also should be designed to elucidate the mediators and moderators of resilience and the recovery of adaptive function.

Psychosocial factors are particularly relevant to informing intervention efforts to promote resilience through adulthood and across developmental contexts. Investigations of psychosocial systems can help to identify ways in which interventions might be able to alter the environment to introduce protective factors that will increase the likelihood that individuals will have resilient outcomes. Community- or school-level interventions can be designed to promote factors that are linked to resilient functioning (such as community parenting classes or fostering peer relationships in classrooms). Although it is valuable to integrate biological systems when conducting psychosocial studies to help inform social interventions (Cicchetti & Gunnar, 2008), it is most practical for interventions to target social systems. Luthar and Cicchetti (2000) observed that research on resilience has substantial potential to guide the development and implementation of interventions for facilitating the promotion of adaptive function and development in diverse high-risk populations.

#### Child Maltreatment: Illustration from a Developmental Psychopathology Perspective

What happens to individual development when there are severe disturbances in the child-rearing environment? How do these atypical organism– environment interactions and transactions influence development across the life span? By studying child maltreatment, we can learn more about the functions of typical and atypical environments as they influence developmental processes. Both the concept of an average expectable environment and a dynamic systems view of development will help to formulate the analysis of the developmental consequences of child maltreatment.

Child abuse and neglect is a serious public health problem in critical need of attention. In 2018, Child Protective Services received reports for more than 3.5 million children. As a nation, we have not responded to child abuse and neglect for decades, considering it an individual problem: bad parenting, parental mental illness, substance abuse, the perfect storm. However, it is now well-established that child abuse and neglect must be considered within a multilevel developmental lens, integrating risk factors at the individual, interpersonal, community, societal, and cultural levels (Cicchetti & Lynch, 1993, 1995).

Child maltreatment is one of the most adverse and stressful challenges that confront children. Child maltreatment constitutes a severe environmental hazard to children's adaptive and healthy mental, emotional, social, physical, and neurobiological development. Although child maltreatment occurs at all socioeconomic levels, the vast majority of maltreated children reside in low-income, highly impoverished environments. Consequently, maltreated children are exposed not only to intrafamilial stressors, but also to poverty, high levels of domestic and community violence, crime, poor schools, and diminished local resources. Child abuse and neglect and domestic violence constitute toxic conditions whereby children are exposed to chronic, severe, and prolonged stress and trauma, often occurring in the absence of protective factors.

Consistent with the organizational perspective on development described earlier in this chapter, the experience of child maltreatment initiates a probabilistic path of epigenesis for abused and neglected children that is marked by an increased likelihood of repeated disruptions in developmental processes that may create a cascade of maladaptation across diverse domains of neurobiological, neuroendocrine, immunological, socioemotional, and cognitive development. Specifically, maltreated children are likely to manifest atypicalities in neurobiological processes, physiological responsiveness, emotion recognition and emotion regulation, attachment relationships, self-system development, representational processes, social information processing, peer relations, school functioning, and romantic relationships (Cicchetti, 2016b; Cicchetti & Toth, 2015). Another way in which maltreatment may exert its harmful effects is by becoming embedded in the activity of neurobiological systems that regulate metabolic function. Holochwost and colleagues (2021) hypothesized that the literature supports a common account of activity among the parasympathetic nervous system, the sympathetic nervous system, and the hypothalamic-pituitary axis under homeostatic and stressful conditions.

Maltreatment experiences may potentiate neural systems to proceed along a trajectory that deviates from that taken in normal neurobiological development (Cicchetti & Tucker, 1994; Courchesne et al., 1994). For example, early maltreatment, either physical or emotional, may condition young neural networks to produce cascading effects through later development, possibly constraining the child's flexibility to adapt to new challenging situations with new strategies rather than with old conceptual and behavioral prototypes. Thus early psychological trauma may eventuate not only in emotional sensitization, but also in pathological sensitization of neurophysiological reactivity (Cicchetti & Tucker, 1994).

Children who are endowed with normal brains may encounter a number of experiences (e.g., poverty, community violence, child maltreatment) that exert a negative impact on developing brain structure, function, and organization and contribute to distorting these children's experiences of the world (Hackman et al., 2010). This provides a unique opportunity for comprehending how environmental factors can bring about individual differences in neurobiological development.

Children maybe especially vulnerable to the effects of pathological experiences during periods of rapid creation or modification of neuronal connections. Pathological experience may become part of a vicious cycle, and the pathology induced in the brain structure may distort the child's experiences, with subsequent alteration in cognition or social interactions, thereby causing additional pathological experience and added brain pathology (Cicchetti & Tucker, 1994). Because experience-expectant and

experience-dependent processes may continue to operate during psychopathological states, children who incorporate pathological experience may add neuropathological connections into their developing brain instead of functional neuronal connections (Black et al., 1998).

As has been stated, child maltreatment affects both neurobiological and psychological processes. Physiological and behavioral responses to maltreatment are interrelated and contribute to children's making choices and responding to experiences in ways that typically produce pathological development. Because maltreated children experience the extremes of caretaking casualty (Sameroff & Chandler, 1975), they provide one of the clearest opportunities for scientists to discover the multiple ways in which social and psychological stressors can affect biological systems. Numerous interconnected neurobiological systems are affected by the various stressors associated with child abuse and neglect (De Bellis, 2001, 2005). Moreover, each of these neurobiological systems influences and is influenced by multiple domains of biological and psychological development. Furthermore, in keeping with the principle of multifinality, the neurobiological development of maltreated children is not affected in the same way in all individuals. Of note, not all maltreated children exhibit anomalies in their brain structure or functioning, and identifying protective mechanisms in these children emerges as an important area of future research.

In general, the literature indicates that exposure to child maltreatment increases the risk for a greater lifetime prevalence of high levels of many psychopathological symptoms and disorders in later life (Cicchetti & Toth, 2015; Vachon et al., 2015; Widom et al., 2009). These include, but are not restricted to posttraumatic stress disorder, mood and anxiety disorders, dissociation and suicidal behavior, substance use disorders, disruptive and antisocial behaviors, thought problems, and psychosis (Cicchetti & Toth, 2016; Toth et al., 2011).

The occurrence of resilient outcomes in some maltreated children points out that self-righting tendencies in human development may be strong even in the face of deviance and failure in the environment (Cicchetti, 2013; Ellis et al., 2020; Waddington, 1957). Discovering how maltreated children develop and function resiliently despite experiencing a multitude of stressors offers considerable promise for expanding, affirming, and challenging extant developmental theories regarding pathways to adaptive functioning in maltreated children. Because resilience is a dynamic developmental process, it is critical to conduct multilevel longitudinal studies on the pathways to resilient functioning in maltreated and non-maltreated children. This information would be extremely useful for developing preventive interventions that are developmentally informed, timed, guided, and implemented with the goal of reducing or eliminating maladaptation and psychopathology in maltreated children (Toth, Gravener, et al., 2013).

Preventive interventions strive to alter the environment to bring about positive outcomes. Scientific research on epigenetics has shown how environmental influences affect gene expression. Thus, this suggests that prevention and intervention also may change the epigenome and also could result in improved outcomes (O'Donnell et al., 2018). If we are to understand the mechanisms through which early adverse experiences such as child maltreatment impact maladaptation, psychopathology, and resilience, then it is critical that we also examine genetic variation and epigenetic modifications.

Research on gene–environment interaction  $(G \times E)$  and on epigenetics needs to incorporate a developmental perspective (i.e.,  $G \times E \times D$ ). Genes may affect how environmental experience affects the developmental process, and this may operate differently at various developmental periods. Moreover, the effects of genes and experiences at a particular period may be influenced by the effects of prior development. Environments may affect the timing of genetic effects and gene expression. Additionally, there are experience effects of the epigenome, and these also would operate differently across the course of development (Cicchetti et al., 2016a, 2016b; Cicchetti & Handley, 2017).

Chronic and toxic stressors, like child maltreatment, can initiate epigenetic changes, representing one potential mechanism for how maltreatment can lead to adverse physical and mental health outcomes. Studies have begun to uncover the ways that child maltreatment influences future psychological and health outcomes via epigenetic mechanisms. Cicchetti and colleagues (2016a, 2016b) examined epigenetic changes in genes that influence how we feel pleasure, respond to stress, and process alcohol. Their results revealed significant differences in methylation, a marker of epigenetic change, between maltreated and non-maltreated school-age youth. Children who experienced maltreatment in early life had significantly more methylation on a gene site related to how we experience pleasure (i.e., dopamine). Maltreated boys, specifically those who experienced maltreatment early in life, had significantly more methylation on the gene related to risk for alcohol use disorders.

In another study Cicchetti and Handley (2017) investigated the role of maltreatment in predicting methylation on a gene involved in the stress response (i.e., the glucocorticoid receptor gene NR3C1). They found that the more severe and frequent the child's maltreatment experiences were, the more likely they were to have excessive methylation on the glucocorticoid receptor gene. The glucocorticoid receptor gene is related to the body's stress response system and how individuals respond to stressful situations. In turn, this methylation was associated with mental health problems including externalizing behavior problems and depression.

#### Depression: Illustration from a Developmental Psychopathology Perspective

Depression is one of the most prevalent, recurrent, costly, and debilitating mental disorders worldwide. Almost 20% of the US population will experience a clinically significant episode of depression during their lifetime, and approximately 80% of depressed individuals will experience recurrent episodes. The disorder is multifaceted and affects afflicted individuals' emotions, thoughts, sense of self, interpersonal relationships, productivity, and life satisfaction (Cicchetti & Toth, 1998; Goodman & Gotlib, 1999).

Depression is of particular interest to developmental psychopathologists because of the complex interplay of psychological (e.g., affective, cognitive, and interpersonal) and biological (e.g., genetic, neurobiological, neurophysiological, immunological, neuroendocrine) systems that are involved. Notably, these varied systems do not exist in isolation. Rather, they are completely interrelated and mutually interdependent. Thus, understanding the interrelations among these biological and psychological systems is vital for delineating the nature of the disorder, as well as elucidating how these systems also promote adaptive functioning. Furthermore, depressive conditions may be conceived as forming a spectrum of severity from transient dysphoria universally experienced, to elevated levels of depressive symptoms that do not meet the criteria for disorder, to long-term periods of dysthymia and episodes of major depressive disorder. Even within more narrowly defined disorders such as a major depressive disorder, there are likely to be heterogeneous conditions with phenotypic similarity despite differences

in etiology. Although there are diverse pathways leading to depressive disorders (equifinality), potential risk factors for depression may result in a multitude of outcomes, of which depression may be one (multifinality). Moreover, depressive phenomena and disorders are present throughout the life span, from early childhood through senescence. Because of the continuities and divergences from normal functioning manifested in depressive disorders across the life course, the study of depression holds promise for understanding the interface of normal and abnormal adaptation. Not only does knowledge of normative development and functioning assist in characterizing the deviations evident among individuals with depression, but also, in understanding the aberrations in functioning among depressed persons, it elucidates how normal adaptation is achieved.

Stressful life events play a substantial role in the development of depression across the life course and are one of the leading precipitating factors for the onset of depressive episodes. Environmental stressors can include things such as childhood poverty, child maltreatment, natural disasters, and death of a loved one, to name a few. Experiencing stressors typically precedes the initial elevation of depressed symptoms and increases the likelihood of episode recurrence. In fact, Hammen (2005) concluded that the experience of a life stressor was 2.5 times more likely among depressed cases compared to controls, and 80% of depressed cases were preceded by stressful major life events. Moreover, depressed parents often face co-occurring problems, such as socioeconomic stressors, marital or relational conflict, or insufficient social support. Cicchetti, Rogosch, and Toth (1998) found that families with a depressed parent were shown to experience more contextual risk, including greater perceived stress, parenting hassles, family conflict, and lower perceived social support and marital satisfaction.

Given the multiplicity of systems affected by depressive disorder, a developmental psychopathology approach also directs attention to an examination of early developmental attainments that may be theoretically related to later appearing patterns of depressive symptomatology (Palmer et al., 2019). For example, obtaining an understanding of the deviations in emotion regulation or the core negative attributions about the self observed in depressed persons may begin by examining the early development of these features, their developmental course, and their interrelations with other psychological and biological systems of the individual.

Single risk factors can rarely be conceived as resulting in depressive outcomes. Rather, the organization of biological and psychological systems, as they have been structured over development, must be fully considered. The concept of a depressotypic developmental organization has much heuristic value in guiding thinking about the diverse processes that underlie symptom expression and depressive outcomes (Cicchetti & Toth, 1998). The developmental position challenges us to move beyond identifying isolated aberrations in cognitive, affective, interpersonal, and biological components of depressive presentations to understand how those components have evolved developmentally and how they are integrated within and across biological and psychological systems.

Caspi et al. (2003) conducted a prospective study that found an interaction between stressful life events and the serotonin transporter gene (i.e., 5-HTT) was related to the risk of developing depression. The promoter region of the 5-HTT gene contains either a short (S) or long (L) repeat allele. The short allele leads to less efficient transcription compared to the long allele. Individuals in the study who were carriers of the short allele were more sensitive to stressful life experiences and were likely to develop depression (Caspi et al., 2003).

A number of subsequent studies have failed to replicate the results of the Caspi et al. (2003) candidate gene study. These discrepant findings have triggered an ongoing debate about the methodological challenges facing G×E studies (e.g., Caspi et al., 2010; Duncan & Keller, 2011; Risch et al., 2009). Specific gene effects become increasingly complicated when the role of developmental timing on the impact of environmental events, genetic expression, and depressive phenotypes is considered. In addition, there are potential interactions among genetic variants, downstream biological mechanisms, and improperly accounted for confounding variables such as ethnicity, gender, age, or socioeconomic status.

Genome-wide association studies (GWAS) also have become increasingly prominent in the field of psychopathology as an alternative method to candidate gene approaches to investigate the role of genes in the development of disorders. GWAS utilize genome-wide sets of common genetic variants known as *single nucleotide polymorphisms* (SNPs) to differentiate which variations are associated with observable traits or behaviors. This method allows scientists to conduct scans of whole genomes to see if multiple genetic variants are related to the expression of a depressive disorder.

Early GWAS studies of depression have produced largely underwhelming results. Although these GWAS investigations had sample sizes comparable to successful GWAS studies for other common diseases and phenotypes, no significant SNPs emerged in these early investigations of depression. Thus, the effect of most SNPs on depression are small in magnitude, and a large sample size is necessary to identify the genetic loci associated with depression. A paucity of studies have attempted to take a developmental approach by using GWAS to analyze which molecular genetic SNPs correlate with age of onset for major depressive disorder.

GWAS often fail to account for environmental influences on genetic expression. In contrast, epigenetics focuses on how DNA can be influenced by the environment. Epigenetics involves functional changes to the genome, where certain genes may be turned on or off without altering the nucleotide sequence. Examples include changes to DNA methylation and histone acetylation (Cicchetti & Handley, 2017; Cicchetti et al., 2016a, 2016b; Sun et al., 2013). The heterogeneous nature of depression and "missing heritability" between epidemiological investigations and molecular studies make for an ideal candidate for epigenetic studies.

The developmental psychopathology perspective provides important insights useful to prevent depressive disorders as well as to intervene once depression has occurred. In addition, treatment for depression may need to vary depending on the history of prior depressive disorders. Post (1992) studied the developmental progression of episodes among mood-disordered individuals and concluded that the more automatic triggering of episodes later in the course of these disorders likely requires different treatments. For first episodes of depressive disorder, interpersonal psychotherapies may have greater utility in reorganizing the affective, cognitive, and interpersonal difficulties depressed individuals exhibit. However, later episodes of depression may become increasingly primed biologically, and psychopharmacological interventions combined with more directive cognitive-behavioral therapy are likely to be more essential. Additionally, alternative drug treatments may become necessary as the progression of episodes and concomitant biological alterations may make previously effective drugs no longer effective (Post, 1992; Post et al., 1996).

Behavioral and psychological interventionists are interested in epigenetic effects on treatment. It

is largely appreciated that interventions do not succeed for all participants; however, our understanding of how individual factors influence intervention efficacy is still in its infancy. Most of this work is guided by differential susceptibility models which suggest that those most likely to be adversely affected by negative environmental experiences are also those most likely to benefit from contextual support. This theory implies that specific characteristics of people make it more likely that both positive and negative experiences will, respectively, affect the individual's positive and negative functioning and development (e.g., Belsky & Pluess, 2013). For example those carrying one or more serotonin transporter-linked polymorphic region gene (i.e., 5-HTTLPR) short alleles have shown both increased positive and negative outcomes depending on rearing environments. Although these genetic factors have been thought to inform risk, there is also experimental evidence to suggest that those who carry the "risk allele" benefit more from interventions (e.g., Cicchetti, Toth, & Handley, 2015; Drury et al., 2012; Kegel et al., 2011). This suggests that we may be able to utilize genetic information to improve treatments for individuals suffering from depression or at risk for developing depression. However, not all interventions guided by a differential susceptibility perspective are focused on genetic or epigenetic markers for sensitivity to the environment. Behavioral (e.g., temperament; Belsky et al., 2007) and physiological (e.g., vagal tone; Conradt et al., 2013) markers are also often theorized to denote differences in sensitivity.

Science has made huge strides in our understanding of how genes function (or don't function) in relation to complex behavioral phenotypes such as depression. However, we still have a long way to go until we even begin to crack the genetic code to common psychopathologies. Research on human genetics and psychopathological phenotypes is becoming increasingly collaborative. Current work and theory suggest that we can expect to find hundreds to even thousands of genetic variants and gene-by-environment interactions that contribute to the depressive phenotype. This may even vary dependent on sex, ethnicity, developmental timing of disease onset, and/or specific sets of symptoms. Scientists aim to unveil a variety of biological pathways to generate a deeper understanding of the processes which underlie the development of psychiatric disorders. Furthermore, we suggest that genetic work should shift its focus on to specific symptoms of depression such as sleep disturbances,

irritability, or hopelessness. It also will be important to take into account the developmental timing of environmental events and symptom onset when considering the impact of genetic and epigenetic factors.

In recent years, advances in research methods to investigate brain mechanisms have provided the opportunity to examine the neural correlates of depressive psychopathology and its risk factors. Identification of the neural signatures of mental disorders will accelerate accurate diagnosis and contribute to efficacious treatment. Electroencephalogram (EEG) and structural magnetic resonance imaging (MRI) and functional MRI (fMRI) provide insight into general and specific neuroanatomical regions and neural circuits that play a role in depression.

Early research on the neural correlates of depression centered around EEG findings. The frontal cortex is lateralized for negative and positive affect, with left frontally activated individuals showing less negative affect and greater positive affect than right frontally activated individuals (Tomarken et al., 1992). From a developmental perspective, insecurely attached infants of depressed mothers also have been shown to have relative right-sided EEG frontal asymmetry (Dawson et al., 1992).

In his important book, *Neural Darwinism*, Edelman (1987) describes the great variability found in patterns of synaptic connection and states that some of this heterogeneity takes place as a result of differential experiences during sensitive periods for synaptogenesis. The findings of Dawson and colleagues (1992) were consistent with Edelman's (1987) thesis and suggest that a mother's emotional condition, and implicitly with her interactions with her baby, can impact on developing patterns of synaptogenesis in the early years of life (Cicchetti & Tucker, 1994).

A large recent literature has begun using imaging technology to determine the neural correlates of depression development. Research in the field of developmental affective neuroscience has focused on the amygdala and the prefrontal cortex (PFC), areas critical for emotion processing and regulation. The amygdala is critical for detecting emotional salience of environmental stimuli and for developing conditioned fear responses. It has repeatedly been shown to activate in response to emotional stimuli. The PFC inhibits this amygdalar response, restraining emotional reactivity. The PFC is critical for executive functioning abilities, including cognitive control and behavioral inhibition.

Research investigations also have identified changes in immune function associated with depression, sparking interest in the role of neuroimmune function and inflammation in the ontogeny of depression. Depressed persons have been found to have increased levels of inflammatory markers; particular emphasis has been placed on the cytokine interleukin-6 (i.e., IL-6). Depressed individuals also have a greater likelihood of developing inflammatory illnesses. Inflammation has been proposed to work in concert with early life adversities to increase risk for internalizing symptoms and disorder (Cicchetti, Handley, & Rogosch, 2015). Individuals who experienced high childhood adversity and went on to develop depression exhibited accompanying increased levels of inflammatory biomarkers IL-6 and C-reactive protein (CRP). In contrast, adolescents who were not exposed to early adversity do not show the same effects, consistent with findings that only depressed adults who experienced child maltreatment exhibited elevated inflammation (Danese et al., 2008).

A longitudinal investigation of African American youth also found a coupling between the development of depression and inflammation as a result of harsh parenting during childhood (Beach et al., 2017). Moreover, this study discovered that the relationship between harsh parenting and depression and inflammation is mediated by stress and the nature of romantic relationships during the child's young adulthood, suggesting that parenting practices impact inflammation and depression through their effects on the child's future relationship styles. Thus, early stressors pave the way for inflammatory pathways to disease.

The field of developmental psychopathology conceptualizes "mental illness as involving dysfunction across multiple and transacting developmental processes" (Cicchetti & Toth, 2009, p. 20). Mental disorders are conceived as being dynamic and should be studied from an interdisciplinary perspective and a multiple levels of analysis approach (Cicchetti & Dawson, 2002; Cicchetti & Toth, 2009). Such an approach entails investigating bidirectional and transactional interactions among genetic, neurobiological, social, environmental (pre- and postnatal), and cultural influences over the course of the life span. Adapting a multiple levels of analysis approach enables developmental psychopathologists to achieve one of their major goals: to understand the full complexity of psychopathology and discover the mechanisms underlying individual patterns of adaptation through investigating the whole

organism (Sroufe & Rutter, 1984; Zigler & Glick, 1986). The concurrent examination of biological, psychological, and environmental-contextual processes and their interplay at different developmental periods provides an integrative conceptualization of the course of psychopathology (Cicchetti & Cohen, 1995a; Garber & Bradshaw, 2020).

In keeping with its integrative focus, contributions to developmental psychopathology have come from many disciplines of the biological and social sciences. A wide array of content areas and methodologies have been germane. Risk and protective factors and processes have been identified and validated at multiple levels of analysis and in multiple domains. The increased emphasis on a multilevel, dynamic systems approach to psychopathology and resilience; the increased attention paid to geneenvironment interplay in the development of psychopathology and resilience; and the application of a multiple levels of analysis developmental perspective to mental illnesses that have traditionally been examined nondevelopmentally not only have contributed to a deeper understanding of dysfunction, but also have educated the public about the causes and consequences of mental disorder.

Furthermore, advances in G×E interactions and epigenetics; growth in the understanding of neurobiology, neural plasticity, and resilience; and progress in the development of methodological and technological tools, including brain imaging, neural circuitry, immunology, hormone assays, social and environmental influences on brain development, and statistical analysis of developmental change have paved the way for interdisciplinary and for multiple levels of analysis research programs and collaborations that will significantly increase the knowledge base of the development and course of maladaptation, psychopathology, and resilience. Moreover, randomized control prevention and intervention trials are beginning to be based on developmentally informed models. These RCTs will increasingly shed light on the processes and mechanisms contributing to developmental change at both the biological and psychological levels (Cicchetti & Gunnar, 2008).

Developmental psychopathologists have incorporated concepts and methods derived from other disciplinary endeavors that are too often isolated from each other, thereby generating advances in knowledge that might have been missed in the absence of cross-disciplinary dialogue. It is apparent that increasingly prospective longitudinal research programs should be conducted that not only investigate high-risk and mentally disordered individuals, but also follow up comparable matched normal comparisons over developmental time. Moreover, these multidomain longitudinal investigations should endeavor to begin before a period of significant developmental change takes place (e.g., neurodevelopmental research on schizophrenia should begin in the prenatal period) and follow up individuals through when the emergence of the disorder is at its highest (for research on schizophrenia at least through the period of later adulthood) (Cicchetti & Cannon, 1999). Such longitudinal research will be critical to discover trajectories to developmental adult psychopathology.

Future research in this area must employ methodological pluralism and strive for fidelity between the current systems theory models of brainbehavior relations and the nature of the methods and measures utilized. In the search to discover the mechanisms linking various developmental pathways to the same psychopathological outcome, study designs should incorporate sufficiently large samples to permit the identification of relatively homogenous profiles of individuals that can be subjected both to variable-oriented and personoriented statistical analyses.

Finally, researchers should continue with the implementation of a multiple dynamic systems approach that integrates biological contributors to psychopathology and the psychological and social factors that are operative in the genesis and maintenance of disorders. The continuation and elaboration of a multiple levels of analysis framework within and across disciplines interested in normal and abnormal development not only will enhance the science of developmental psychopathology, but also will increase the benefits to be derived for individuals with high-risk conditions or mental disorders, families, and society as a whole.

The multiplicity of pathways contributing to the development of depression directs us toward studying the interface between normal and abnormal development. Developmental psychopathology draws attention to both the similarities and differences among normal and psychopathological conditions. Accordingly, researchers can discern the specific pathways leading to depression as well as discover the commonalities underlying normal development, depressive illness, and related disorders. In particular, increased attention to the pathways and trajectories taken by individuals who avoid developing depression despite the presence of enduring vulnerabilities and transient challenges may help inform prevention and intervention efforts.

#### Intervention

Developmentally informed psychosocial interventions have been implemented for children maltreated early in life, the young offspring of depressed mothers, and depressed teens. For example, Cicchetti, Rogosch, and Toth (2006) conducted an RCT with maltreated infants and their mothers. Child-parent psychotherapy (CPP), an evidenced-based trauma treatment model that facilitates change through promoting positive motherchild attachment relationships, was the psychosocial treatment utilized. CPP is based on the fundamental assumption that challenges in the parent-child relationship are not the result of a deficit in parenting knowledge or skill. Rather, CPP recognizes that a caregiver's insensitivity or lack of appropriate responsivity to a child is likely the result of their own childhood experiences with caregivers. CPP aims to help parents recognize the role that their own childhood experiences with caregiving may have in their current parenting practices. CPP focuses on fostering a secure parent-child attachment by helping parents become more responsive, sensitive, and attuned to their child. The RCT of Cicchetti et al. (2006) documents CPP as efficacious at promoting attachment security in maltreated infants (see also Guild et al., 2017; Pickreign Stronach et al., 2013; Toth et al., 2002).

Cicchetti, Rogosch, and Toth (2000) found that CPP was efficacious in fostering cognitive development in toddlers of depressed mothers. In addition, Toth, Rogosch, Manly, and Cicchetti (2006) discovered that CPP fostered secure attachment in toddlers of depressed mothers.

Toth, Rogosch, Oshri, Gravener-Davis, Sturn, and Morgan-Lopez (2013) conducted a randomized trial of interpersonal psychotherapy (IPT) with economically disadvantaged mothers with major depressive disorder. The women in this RCT also had extensive histories of trauma, with nearly 90% of the women receiving IPT having histories of maltreatment and with more than 90% experiencing at least one lifetime traumatic event. Depressive symptoms at the conclusion of treatment and at 8 months post-intervention were significantly lower among women who received IPT than among those who received treatment generally available in the community. Social adjustment and perceived stress also were identified as mediators of sustained positive treatment effects (Toth, Rogosch et al., 2013).

Handley et al. (2017) conducted an RCT with a sample of racially and ethnically diverse, socioeconomically disadvantaged mothers of infants.

Mothers were randomized to IPT or an enhanced community standard control group. Engagement with IPT led to significant decreases in maternal depressive symptoms at 8 months post-treatment. Moreover, reductions in maternal depression posttreatment were associated with less toddler insecure disorganized attachment characteristics, more maternal adaptive perceptions of toddler temperament, and improved maternal parenting efficacy 8 months following the completion of IPT. These results document the potential benefits in children of successfully treating maternal depression. Alleviating maternal depression appears to initiate a cascade of positive adaptation among both mothers and offspring, which may alter the wellreplicated risk trajectory for offspring of depressed mothers (Cicchetti & Toth, 1998; Goodman & Gotlib, 2002).

In contrast to earlier writings that claimed depression arising in childhood will diminish over time if left to run its course, we now possess longitudinal data demonstrating that once depression remits, it often reemerges and impairs children's ability to negotiate developmental tasks competently. Likewise, a number of investigations have followed up adults with depressive disorders over time and found that serious psychological impairments often occur both during the illness proper and in the period of remission. Now that developmental psychopathologists have discovered how depressed individuals negotiate a number of the stage-salient issues throughout the life course, we are in a position to assess not only how an incompetent organization of biological and behavioral systems can contribute to the development of depression, but also to discover how the presence of depression affects competence both during an episode and in remission.

#### Conclusion

There remains a great deal to be accomplished in advancing an integrative, multilevel developmental understanding of maladaptation, psychopathology, and resilience. The developmental considerations raised in this chapter make clear that progress toward a process-level understanding of normal and abnormal development will require research designs and strategies that allow for the simultaneous consideration of multilevel analysis and multiple domains of variables within and outside the individual. Moreover, the organizational perspective, with its emphasis on understanding the organization of biological and psychological development and its focus on studying the "whole person" in context, will play an important role in framing the questions as we seek to continue examining the nature of the relation between biological and psychological factors in the symptoms, causes, course, sequelae, and treatment responsivity of risk, maladaptation, psychopathology, and resilience. The cross-fertilization of the neurosciences with psychology and related disciplines will result in major advances in our comprehension of normality and pathology, especially if a developmental perspective to the interdisciplinary ventures is adopted by the investigators.

Although the challenges are great in the quest to arrive at a sufficiently integrative approach to understanding pathological phenomena, a developmental psychopathology approach holds great promise for elucidating necessary future questions and suggestion strategies to apply to such an undertaking.

# PART II

## Major Clinical Syndromes

CHAPTER

### Generalized Anxiety Disorder, Panic Disorder, Social Anxiety Disorder, and Specific Phobia

Richard E. Zinbarg, Alexander L. Williams, Amanda M. Kramer, and Madison R. Schmidt

#### Introduction

In this chapter, we cover several *DSM-5* anxiety disorders, including generalized anxiety disorder (GAD), panic disorder (PD), social anxiety disorder (SAD), and Specific Phobia (SP). Whereas obsessive-compulsive disorder (OCD) and posttraumatic stress disorder (PTSD) were classified as anxiety disorders in earlier *DSM* editions, they were moved into new groupings in *DSM-5* and will be covered in later chapters in this volume. Two other diagnoses (separation anxiety disorder, selective mutism) that are rare in adults and were not classified with the other anxiety disorders in earlier *DSM* editions were moved into the anxiety disorders grouping in *DSM-5* but will not be covered in this chapter.

We begin by describing anxiety and fear, the core constructs that define and differentiate these diagnoses. Following Barlow (2002), anxiety is a future-oriented mood state associated with preparation for possible harm, whereas fear is an alarm response when danger is perceived to be present. Put differently, fear-or panic (we use the terms interchangeably)-involves a triggering of the fight-flightor-freeze (FFF) mechanism when danger is perceived to be present, whereas anxiety involves a priming of (i.e., simultaneous excitatory and inhibitory input to) the FFF mechanism when danger is perceived to be possible at a later point in time (Zinbarg, 1998). Viewed from this perspective, there are both overlapping and distinctive features between anxiety and panic. Anxiety and panic overlap in that they both involve perception of danger and excitatory input to the FFF mechanism. However, they are different in their temporal aspects, given that anxiety is futureoriented and fear is an alarm response to present danger. They are also different in that anxiety involves simultaneous inhibitory input to the FFF mechanism, whereas panic involves purely excitatory input to this mechanism.

DSM-5 distinguishes two types of panic attacks: unexpected and expected. If the individual is aware of a cue or trigger at the time of the attack, then the attack is expected; if not, the attack is unexpected. Whereas panic attacks of some sort are ubiquitous across the anxiety disorders and even in major depression (Craske et al., 2010), panic/ fear is not central to the *definition* of GAD. In contrast, anxiety is central to the definition of each anxiety disorder, including PD/A, SAD, and SPdisorders in which fear plays an important role. For example, the primary distinction between the group of nonclinical panickers-individuals who experience recurrent panic attacks-and those with PD/A is that those with PD/A experience anticipatory anxiety about their attacks, whereas those with nonclinical panic do not (Telch et al., 1989).

The central features of PD in *DSM-5* are (1) recurrent, unexpected panic attacks and (2) persistent

Abbreviations				
AS	Anxiety sensitivity			
BIS	Behavioral inhibition system			
DD	Dysthymic disorder			
GAD	Generalized anxiety disorder			
MDD	Major depressive disorder			
PD	Panic disorder			
PD/A	Panic disorder with agoraphobia			
PE/E	Positive emotionality/extraversion			
SAD	Social anxiety disorder			
SP	Specific Phobia			

worry about having attacks or the development of significant, maladaptive behavioral changes designed to avoid having attacks. Note that if all the individual's attacks are of the expected variety, a diagnosis other than PD would be made, perhaps SAD, SP, PTSD, or OCD. A common complication of PD is agoraphobia-the fear and avoidance of situations from which it would be difficult to leave or get help in the event of a panic attack. However, in recognition of the data from some epidemiological studies suggesting a substantial population of individuals with agoraphobia and without panic symptoms (e.g., Wittchen et al., 2008), DSM-5 has reverted to identifying agoraphobia as an independent diagnosis, as it had been in DSM-III. Thus, someone with PD who develops fairly extensive agoraphobia receives two DSM-5 diagnoses (PD and agoraphobia), whereas in DSM-III-R, DSM-IV, and DSM-IV-TR they would have received a single diagnosis (PD with or without agoraphobia; PD/A). This chapter includes results published before the DSM-5, which therefore pertain to the pre-DSM-5 single diagnosis convention (PD/A).

In *DSM-5* the cardinal feature of GAD is excessive, uncontrollable worry about numerous life circumstances, accompanied by at least three common manifestations of anxiety, like muscle tension, sleep disturbance, or irritability.

DSM-5 divides SP into five subtypes: animal (fear cued by animals or insects, such as dogs, snakes, or spiders), natural environment (cued by an object in the natural environment, such as heights, thunderstorms, or water), blood-injury-injection (cued by seeing blood, injury, or receiving an injection), situational (cued by specific situations, such as driving, enclosed places, or flying), and other (cued by other triggers, such as a fear of falling down, a fear of costumed characters such as clowns, or emetophobiathe fear of vomiting). To receive a DSM-5 diagnosis of SP, the phobic cue must almost invariably provoke an immediate fear response and the fear must be excessive and associated with either avoidance of the phobic cue or endurance of exposure to that cue with intense fear. In addition, fear must be associated with some functional impairment or significant distress about the fear before diagnosing a SP. Some individuals are judged by diagnosticians to exhibit excessive fear even though they themselves do not recognize their fear as excessive. Thus, the judgment of excessiveness in DSM-5 has been made a clinician judgment rather than a self-judgment (as it had been in DSM-IV-TR).

The key feature of SAD is persistent and marked fear of social situations in which one might be judged or evaluated by others. Exposure to feared social situation(s) must almost invariably provoke an immediate fear response, and the fear must be associated with either avoidance of the phobic cue or endurance of exposure to it with intense fear or anxiety. *DSM-IV-TR* included the additional criterion that the individual must recognize the fear as excessive, but, as with SP, in *DSM-5* the excessiveness is a clinician judgment.

However, there is some controversy in the field as to whether the different DSM anxiety disorder diagnoses truly represent distinct categories. The alternative view is that the different DSM anxiety disorders represent variations of a broader syndrome that differs superficially and solely at the descriptive level in terms of the content of apprehension (Andrews et al., 1990; Brown & Barlow, 2009; Tyrer, 1990). Even if this alternative view proves to be invalid, theory and empirical evidence in this area suggests a great deal of overlap in the factors and processes involved in the development and maintenance of GAD, PD/A, SAD, and SP. Thus, we focus primarily on them as a group and their common etiological and maintenance factors rather than presenting largely redundant analyses of each diagnosis separately.

## Epidemiology: Prevalence, Course and Comorbidity

Most recent estimates of lifetime prevalence rates are based on *DSM-IV* criteria from a reanalysis of the National Comorbidity Survey Replication (NCS-R) and Adolescent Supplement (NCS-A) (Kessler et al., 2012) and of the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC; Grant & Dawson, 2006). Table 7.1 summarizes many of these results. As seen in Table 7.1, these disorders tend to be more prevalent in women (e.g., Kessler et al., 2012).

SP is the most prevalent of the anxiety disorders (Kessler et al., 2012; Stinson et al., 2007). There is some inconsistency in average age of onset, ranging between 5 to 9 (Stinson et al., 2007) and 15 to 17 years (Kessler et al., 2012). For adults, the mean number of fears reported by an individual is approximately three, with the most common subtypes of SPs being natural environment, situational, animal, and blood-injection injury (Stinson et al., 2007). SP is highly comorbid with PD, PD/A, SAD, and GAD (Stinson et al., 2007).

(GAD), panic disorder (PD), and panic disorder with agoraphobia (PD/A), by gender and age cohort					
	SP	SAD	GAD	PD/A	
12-month prevalence (%)	7.1–12.1	2.8–7.4	2-2.1	2.1–2.4	
Lifetime prevalence (%)	9.4–15.6	5-10.7	4.1-4.3	3.8-5.1	
Lifetime prevalence by age					
Adolescent (13–17) (%)	20	8.6	2.2	2.3	
Adult (18–64) (%)	13.8	13	6.2	5.2	
Older adult (65+) (%)	6.8	6.3	3.3	2.1	
Lifetime prevalence by gender					
Adolescent (13–17)					
Female (%)	23*	11.2*	2.8	2.5	
Male (%)	17.7	6.2	1.6	2.1	
Adult (18–64)					
Female (%)	17.5*	14.2*	7.7*	7*	
Male (%)	9.9	11.8	4.6	3.3	
Older adult (65+)					
Female (%)	9.1*	7.1	4.8*	2.5	
Male (%)	3.6	5.1	1.3	1.6	
Mean age of onset	5-9, 15-17	15	30	28–32	
Median years delay to treatment <sup>a</sup>	20	16	9	10	
Comorbid diagnoses <sup>b</sup>	3.4	3.5	3.8	4.5	
Comorbid personality disorder (%)	38.3	61.0	60.6	44.1-69.4	

**Table 7.1** Epidemiology for Specific Phobias (SP), social anxiety disorder (SAD), generalized anxiety disorder (GAD), panic disorder (PD), and panic disorder with agoraphobia (PD/A), by gender and age cohort

<sup>a</sup>Median years delay to treatment are estimated reported by Wang et al. (2005).

<sup>b</sup>Comorbid diagnoses represent average number of both mental and physical conditions in the National Comorbidity Survey Replication reported by Gadermann et al. (2012).

\* Indicates statistically significant gender difference.

SAD is the second most common of the anxiety disorders covered in this chapter (Grant, Hasin, Blanco, et al., 2005; Kessler et al., 2012). Furthermore, there is some evidence to suggest between-group racial and ethnic differences, with a higher percentage of White Americans being diagnosed than Black/African, Hispanic/Latino, and Asian Americans (Asnaani et al., 2010), but a higher percentage among Native Americans compared with White Americans (Grant, Hasin, Blanco et al., 2005). The hazard rate for onset of SAD was bimodal, with a first peak at 5 years and a second one at 13-15 years according to the NESARC (Grant, Hasin, Blanco et al., 2005). The most common fears reported are those related to performancebased situations (e.g., public speaking, participating in class, performing in front of others). SAD is highly comorbid with other mood, anxiety, and personality disorders (particulalry avoidant personality disorder; Grant, Hasin, Stinson et al., 2005). The most common comorbid anxiety disorders are PD, SP, and GAD (Grant, Hasin, Stinson et al., 2005).

GAD is also fairly common (Grant, Hasin, Stinson et al., 2005; Kessler et al., 2012). Although mean age of onset is around 30 years of age across epidemiological studies (Grant, Hasin, Stinson et al., 2005; Kessler et al., 2012), evidence suggests a bimodal distribution in the age of onset, with many individuals with GAD recalling onset in early childhood (Campbell et al., 2003; Hoehn-Saric et al., 1993). White Americans are more likely to be diagnosed than Black/African, Hispanic/Latino, and Asian Americans (Asnaani et al., 2010; Grant, Hasin, Stinson et al., 2005). Of those with comorbid disorders, 71.4% meet criteria for a mood disorder, and 90% have a comorbid anxiety disorder, the most common being PD and SAD (Grant, Hasin, Stinson et al., 2005).

The occurrence of panic attacks (which often do not warrant a diagnosis) is high, with a lifetime prevalence of about 23% (Kessler et al., 2006). PD/ A, by contrast, is less common (Kessler et al., 2012). Separating PD Agoraphobia (PDA) from PD without agoraphobia (PD), PD/A is less common than PD (Grant et al., 2006). The mean age of onset for PD/A was slightly earlier than that for PD without agoraphobia, at 28 versus 32 years according to the NESARC (Grant et al., 2006); however, this estimate is notably higher than the estimate of 23 years provided by the NCS-R/A (which collapsed PD and PD/A into one category) (Kessler et al., 2006). Furthermore, individuals with PD/A were more likely to seek treatment for the disorder than those with PD. Individuals with PD/A also report higher rates of comorbidity with mood disorders as well as other anxiety disorders, including SAD, SP, and GAD, compared to those with PD (Grant et al., 2006; Kessler et al., 2006).

#### Factor Analytic Models of Anxiety Disorders

#### The Need for Factor Analyses

DSM categorizes all anxiety disorders into a single class that is separate from other disorder classes (e.g., mood disorders). Within this anxiety disorder category, specific disorders represent a second level of differentiation (e.g., GAD, SP) and subtypes of these disorders a third level of differentiation (e.g., animal and blood-injury-injection SPs). However, this taxonomy is based on shared phenomenological features rather than on empirically observed correlations among these disorders and does not reflect certain empirical findings, such as the high rates of comorbidity of disorders belonging to different classes (e.g., anxiety and mood disorders).

To address this limitation of the DSM, research has been dedicated to analyzing correlational patterns among these disorders or their symptoms using factor analysis. In factor analysis, disorders and/or symptoms are grouped together based not on their DSM categories, but on how closely the disorders and/or symptoms are correlated to one another and to the presumed factor common to them. Though DSM-5 continues to adopt a rational classification scheme, our knowledge of the factor structure of unipolar depression, anxiety disorders, and their symptoms could lead to a more empirically informed classification system.

#### THE BROADEST LEVEL: A SINGLE GENERAL FACTOR

Studies examining the structure of depression and anxiety symptoms and disorders have largely converged on certain key principles (Watson, 2005). A vast amount of evidence supports a hierarchical conceptualization wherein broad latent factors are thought to account for the covariation between disorders. At the broadest level, a single general factor (labeled General Distress, Negative Affect, or Internalizing) is posited to account for the covariation among anxiety disorders (e.g., Zinbarg & Barlow, 1996), as well as between anxiety disorders and depressive disorders. For instance, the tripartite model (Clark & Watson, 1991) identified a nonspecific general distress factor, marked by symptoms of high negative affect (e.g., irritability, restlessness, interpersonal sensitivity) that was shared by both anxiety and depression. The Negative Affect factor is thought to be the state manifestation of a trait/temperament variable-alternatively referred to as *negative emotionality* or *neuroticism* that is associated with a tendency toward a broad range of negative mood states such as guilt, hostility, anxiety, and sadness (Watson & Clark, 1984). This nonspecific symptom dimension is consistent with factor-analytic analyses of diagnostic data from 10 DSM diagnoses showing that anxiety and depressive disorders are best grouped into a single category of "internalizing" disorders (Krueger, 1999). Therefore, it is unsurprising that a general factor similar to Negative Affect has continued to be identified in most of the prominent factor analytic models since the tripartite model (e.g., Kotov et al., 2017; Mineka et al., 1998; Prenoveau et al., 2010; Watson, 2005; Zinbarg & Barlow, 1996).

#### THE NARROWER LEVEL: HOW MANY FACTORS?

In addition to this single general factor (e.g., Negative Affect), most prominent models suggest that additional, narrower factors are necessary to address the heterogeneity in symptoms of anxiety and depression. They disagree, however, on the number and nature of the narrower factors. Some models include only two narrow factors, such as Fear and Anxious-Misery (e.g., Krueger, 1999; Watson, 2005). Others, however, include several relatively disorder-specific narrow factors (e.g., Mineka et al. 1998; Zinbarg & Barlow, 1996).

#### Two Factors: The Tripartite Model, Kreuger's Model, and the Quantitative Structural Model

One class of models posits that there are only two lower-level factors beneath the general distress (e.g., Negative Affect or Internalizing) factor. These two factors most frequently correspond to a "Fear" factor (e.g., Fear or Physiological Hyperarousal) characterized by intense physical symptoms of fear as in PD or SPs, and a "Misery" factor (e.g., Anxious-Misery or Positive Affect), characterized by more pervasive anxiety, sadness, or lack of positive emotions as in depression or GAD.

The first of these models, the tripartite model (Clark & Watson, 1991), proposed two narrower factors that were meant to differentiate anxiety and depressive disorders (see Figure 7.1). The first, Positive Affect, was thought to be unique to depressive disorders. This factor was thought to be the state manifestation of a temperamental sensitivity to positive stimuli that results in positive affective states such as feeling cheerful, lively, and optimistic. Those low in Positive Affect experience diminished interest and pleasure in otherwise pleasant activities (e.g., feeling withdrawn from others, feeling slowed down). Importantly, Negative Affect and Positive Affect do not represent two ends of a single dimension; rather, they are thought to be two orthogonal dimensions (Watson & Tellegen, 1985) that arise from separate biological systems (e.g., Thayer, 1989; Watson et al., 1999) and can operate separately from each other (e.g., Gold et al., 1995).

The second narrower factor, made up of symptoms characterized by Physiological Hyperarousal, was thought to be unique to anxiety. This factor contains items representing somatic manifestations of anxiety and panic (e.g., feeling dizzy, experiencing shortness of breath). Therefore, beneath the general Negative Affect factor, there was one factor specific to depression and one specific to anxiety.

However, the tripartite model has certain limitations. It was suggested that a single anxiety-specific factor was not sufficient to account for the heterogeneity among the anxiety disorders (Mineka et al., 1998; Zinbarg & Barlow, 1996). For instance, Physiological Hyperarousal was found to relate specifically to PD and PTSD (Brown & McNiff, 2009), rather than to all the anxiety disorders as a group (Brown et al., 1998). Some researchers have proposed that Anxious Apprehension, a futureoriented mood state marked by high levels of worry about future negative outcomes, might represent an anxiety-specific factor, separate from Physiological Hyperarousal (Barlow, 1991). Supporting this claim, studies have demonstrated that Physiological Hyperarousal and Anxious Apprehension are separable dimensions, and researchers have hypothesized that Anxious Apprehension is mostly linked to GAD (Nitschke et al., 2001). However, others have speculated that Anxious Apprehension may instead relate to all anxiety disorders, as well as to depression, and therefore be thought of as a facet of Negative Affect (Watson, 1999). More research is

Figure 7.1 Prenoveau et al.'s (2010) tri-level model. For clarity of presentation, only 18 of the 67 item descriptions were included. Item numbers can be found in the original paper. Choke, Felt like I was choking; Shake, Was trembling or shaking; Diff. Swal, Had trouble swallowing; Happy, Felt really happy; Fun, Felt like I was having a lot of fun; Up/Lively, Felt really up or lively; Irritab., Felt irritable; Sad, Frequency/ intensity of sadness; Discouraged, Felt discouraged; Blush, "I fear I may blush when I am with others"; Face others, "I would get tense if I had to sit facing other people on a bus or a train"; Carry tray café, "I would get tense if I had to carry a tray across a crowded cafeteria"; Worms, Fear of worms; Rats/Mice, Fear of rats or mice; Spider, Fear of spiders; Gas at dentist, Fear of getting gas at a dentist; Long dist. home, Fear of going long distances from home alone; Effects of alc, Fear of feeling the effects of alcohol.

needed to clarify the role of Anxious Apprehension as an anxiety-specific dimension. In addition to the oversimplification of the anxiety-relevant factor, low Positive Affect was linked to SAD in addition to major depressive disorder (MDD), suggesting that this factor was not entirely unique to depression (Brown et al., 1998; Chorpita et al., 2000). These discrepancies suggested that the two narrower factors of the tripartite model may have been too few.

That said, later models suggested that two factors may indeed be appropriate, but not along clear lines between anxiety and depression. In his analysis of 10 common mental disorders including MDD, dysthymic disorder (DD), PD, agoraphobia, SAD, SP, GAD, alcohol dependence, drug dependence, and antisocial personality disorder, Krueger (1999) found that the mood and anxiety disorders clustered under a single general Internalizing factor. Within the Internalizing factor, there were two additional factors that further distinguished the disorders: a Fear factor (made up of PD, agoraphobia, SAD, and SP) and an Anxious-Misery factor (made up of MDD, DD, and GAD).

Similarly, the quantitative structural model (Watson, 2005) specified two factors relevant to anxiety under its general factor. The first was a Distress factor, made up of MDD, DD, GAD, and PTSD, that was similar to Krueger's (1999) Anxious-Misery factor. Citing Kreuger's work, the Anxious-Misery factor was referred to as Distress by Watson to signify the large amount of general distress variance characterizing these disorders. The second was a Fear factor (made up of PD, agoraphobia, SAD, and SP) that was nearly identical to Kreuger's Fear factor. Unlike the two lower-level factors of the tripartite model, these factors do not neatly distinguish anxiety from depression, as GAD is clustered with the depressive disorders. Instead, they separate disorders characterized by presentmoment fear from those characterized by pervasive negative affect.

This hierarchical structure with a broad Internalizing factor and two correlated lowerlevel factors of Distress and Fear was replicated by Vollebergh et al. (2001) using *DSM-IV* diagnostic data from the Netherlands Mental Health Survey and Incidence Study and by Slade and Watson (2006) using *DSM-IV* and *ICD-10* disorders in an Australian epidemiological sample. More recently, Eaton et al. (2013) found support for the twosubfactor conceptualization of internalizing disorders using the NESARC dataset. The structure was replicated across two waves of assessments, 3 years apart, for both men and women. Importantly, Fear at Wave 1 significantly predicted Fear (but not Distress) at Wave 2, and Distress at Wave 1 significantly predicted Distress (but not Fear) at Wave 2, suggesting that Fear and Distress are two unique pathways toward developing or maintaining internalizing disorders.

#### More Factors

Though one class of prominent models posits that there are only two narrower factors in addition to the general factor, another class argues that two is not enough to represent the heterogeneity of the anxiety disorders and depression. For example, Zinbarg and Barlow (1996) examined the factor structure of anxiety symptom measures and found six narrow factors that differentiate the specific anxiety disorders and depression from each other: Generalized Dysphoria, Social Anxiety, Agoraphobia, Fear of Fear, Obsessions and Compulsions, and Simple Fears. Furthermore, they performed discriminant function analyses to examine the relationships of these six narrow dimensions and a general Negative Affect dimension with DSM-III-R diagnoses. They found that the general Negative Affect factor distinguished each of the anxiety-disordered groups from a no mental disorder control group. Furthermore, the Fear of Fear, Agoraphobia, Social Anxiety, and Obsessions and Compulsions factors provided the bases for discriminating among the patient groups.

Mineka et al. (1998) proposed the integrative hierarchical model in which each disorder consists of a common Negative Affect component and a unique component that differentiates it from other disorders. Moreover, not all disorders contain the same level of common factor variance. Particularly, MDD and GAD are characterized by a larger amount of Negative Affect variance than other anxiety disorders, such as SP and PD/A (Kessler et al., 2005; also see Watson et al., 2005, for more detail). Also, the specificity of symptoms that differentiate disorders is relative, so that some disorder-specific symptoms could be shared by more than one disorder. This explained the finding that low Positive Affect was linked to SAD as well as MDD and the finding that Physiological Hyperarousal was not common to all anxiety disorders but related more specifically to PD/A as well as to PTSD.

## Integration: The Tri-Level Model and HiTOP THE TRI-LEVEL MODEL

Integrating the strengths of both the two-factor and multifactor models, Prenoveau et al. (2010) included factors at three levels of breadth (see Figure 7.1). Thus, they posited a tri-level model in which intermediate breadth factors like Fear and Anxious-Misery make up a second level and the disorderspecific narrow factors make up a third level. At the narrowest level of the hierarchy, there were five group factors. Four of these related to anxiety: Anxious Arousal, Social Fears, Specific Fears, and Interoceptive/Agoraphobic Fears. Additionally, Narrow Depression emerged as a depression-related narrow group factor. There were two factors of intermediate breadth that were each loaded on by items that loaded on several of the narrowest factors. The first intermediate-breadth factor was labeled Anxious-Misery with loadings from some Narrow Depression items (e.g., hopelessness), some Social Fears items (e.g., felt self-conscious), and some items with negative loadings reflecting high Positive Affect (e.g., felt really happy). A second intermediate breadth factor was labeled Fears, with loadings from Social Fears, Interoceptive/Agoraphobic Fears, and Specific Fears items. A General Distress factor (loaded on by all symptoms) was obtained as the broadest factor.

By accounting for both intermediate- and narrow-level factors, the tri-level model was able to account for both the symptoms that are common to many disorders and those that are more unique to a disorder or cluster of disorders. In fact, in a conceptual replication of the tri-level model, Naragon-Gainey et al. (2016) found that each level of the tri-level model accounted for substantial variance in the data and that the model provided a superior fit relative to more parsimonious competing models. Naragon-Gainey et al. also found that patient impairment was associated with all three levels of the model, suggesting each level has meaningful variance independent of the other two. As would be expected given the broad nature of the general factor, comorbidity within patients was most strongly associated with the general factor. Finally, at the narrow level, convergent and discriminant validity were found such that the narrow factors strongly related to their associated disorder and not to other disorders (e.g., the Specific Fears factor correlated with SP but not PD diagnoses).

In an unpublished conceptual replication and extension, Zinbarg et al. (2022) found that the trilevel model could be extended to include clinicianrated measures of symptoms. This suggests that General Distress does not entirely reflect method variance. It also suggests that the tri-level model is not purely a model of self-report symptoms, but of symptoms more broadly.

#### THE HIERARCHICAL TAXONOMY OF PSYCHOPATHOLOGY

Recently, the HiTOP Consortium put forth the Hierarchical Taxonomy of Psychopathology (HiTOP; Kotov et al., 2017), a theoretical structural model of psychopathology (see Figure 7.2). Like the tri-level model, HiTOP is a hierarchical model with factors that become narrower at each level. The broadest level (superspectra) is made up of dimensions that may be common to all psychopathology. The second level (spectra) includes several broad categories of disorders (including Somatoform, Internalizing, Thought Disorder, Disinhibited Externalizing, Antagonistic Externalizing, and Detachment). The third level (subfactors) includes intermediate-level groupings (such as Sexual Problems, Eating Pathology, Fear, Distress, and Mania under Internalizing). The fourth level (syndromes/disorders) includes specific disorders (such as SAD, SP, PD/A, and OCD under Fear), the fifth level (components) includes various symptom components and maladaptive traits, and the sixth level (symptoms) includes specific signs and symptoms. Thus, HiTOP is more inclusive than other models discussed earlier in that it includes a broader range of disorders and adds factor levels for increased specification. The Internalizing spectrum including the Fear and Distress subfactors and their associated syndromes/disorders are most relevant to the anxiety disorders and map closely to the broad, intermediate, and narrow factors of the tri-level model.

At the time of this writing, there are no published empirical tests of the Internalizing spectrum, though papers published on the tri-level model (e.g., Prenoveau et al., 2010) provide support for this spectrum given its close alignment with the tri-level model. Though it is not without criticism (see Wittchen & Beesdo-Baum, 2018), HiTOP is becoming one of the most cited models of psychopathology.

#### SUMMARY

To summarize, there is consensus that an overarching factor representing high negative affect often labeled Internalizing or General Distress—is shared by all anxiety disorders and their symptoms. This factor also accounts for the empirical overlap between anxiety and depression. Beneath this general factor, there is support for two intermediatelevel factors—Fear, which underlies SP, SAD, PD, and agoraphobia, and Anxious-Misery/Distress,

model, such as spectra and subfactors, were empirically derived from an accumulation of factor analytic evidence (see Kotov et al., 2017). Dashed lines indicate that the relation or dimension depicted is Figure 7.2 The current Hierarchical Taxonomy of Psychopathology (HiTOP) Model. Symptom components and maladaptive traits form the base of the HiTOP model. Higher-level dimensions of the included on a provisional basis pending additional data collection.

which underlies unipolar depression and GAD. Finally, there is evidence that we can identify narrow factors that may provide the basis for differentiating individual disorders from each other. However, we have not yet reached consensus about the exact number and nature of these narrow factors.

## Etiology and Maintenance Models and Factors

#### Temperament and Personality

Anxiety disorders show links to personality which can in turn inform models of the origins of these disorders. A number of models have been proposed to account for these links (e.g., Ormel et al., 2013; Krueger & Tackett, 2003). The vulnerability model suggests that personality traits are risk factors for anxiety disorders. In contrast, the common cause model holds that disorders are extreme manifestations of personality traits. In the scar model, the experience of psychopathology impacts personality. Finally, the pathoplasty model proposes that personality modifies the course or expression of a disorder. Longitudinal studies of premorbid assessments of personality and subsequent onsets of anxiety disorders provide a good design for testing the etiological role of personality characteristics (e.g., Clark et al., 1994).

Temperament is an important component of personality that, as discussed in more detail below, is relevant for anxiety disorders. Different theorists define temperament in different ways (see Goldsmith et al., 1987). We define temperament as relatively stable individual differences in emotionality that emerge early in life and have a biological basis.

#### NEUROTICISM

The term "neuroticism" is used to label a set of covarying personality descriptors (such as fretful, moody, insecure, self-critical, and envious)-identified through factor analyses of self-report personality measures-thought to represent a dimension of emotional instability (e.g., Costa & McCrae, 1987; Eysenck, 1970). In fact, neuroticism is thought to be a partially heritable sensitivity to experience negative emotions and is hypothesized to be a common diathesis (i.e., risk factor) for all of the anxiety disorders and MDD (e.g., Eysenck, 1967; Gray & McNaughton, 2000; Griffith et al., 2010; Zinbarg & Yoon, 2008). Following Shackman et al. (2016), Mineka et al. (2020) distinguished between several paths through which neuroticism may confer vulnerability for psychopathology. The stably elevated *negative affect hypothesis* states that neuroticism raises risk for symptom exacerbation via negative affect that is elevated in almost all situations. In contrast, the *stress amplification hypothesis* holds that neuroticism interacts with stressors to generate psychopathology. Mineka et al. reported greater support for the stably elevated negative affect hypothesis but further research is needed to compare the relative importance of these paths in the etiology onset of anixety disorders.

Neuroticism has been shown to have robust cross-sectional associations with internalizing disorders, including anxiety (e.g., Bienvenu et al., 2004; Griffith et al., 2010; Rosellini & Brown, 2011; Zinbarg et al., 2010). Longitudinal evidence has also shown that neuroticism predicts the onset of anxiety disorders (e.g., Zinbarg et al., 2016). Uliaszek et al. (2009) evaluated the differential predictive ability of the anxiety facet of neuroticism (which overlaps with anxiety symptoms) and a General Neuroticism Factor (GNF) that was common to all neuroticism items. They found that the GNF was associated with a latent Anxiety symptom factor beyond the anxiety facet of neuroticism (Uliaszek et al., 2009), demonstrating that the association between neuroticism measures and anxiety symptoms cannot be entirely attributed to item overlap. Zinbarg et al. (2016) reported similar findings at the diagnostic level.

There is limited evidence for a reciprocal relationship between neuroticism and anxiety symptoms. Jylhä et al. (2009) reported that change in anxiety symptoms accounted for only a small fraction of what baseline neuroticism accounted for in follow-up neuroticism in a multiple regression model. A comprehensive study comprised of healthy participants and those with current or past emotional disorders revealed that among participants with remitted disorders, scar effects on neuroticism were present 2 years later but these effects were not significant 4 years later (Spinhoven et al., 2013). Similarly, in a sample of highly neurotic older adolescents, Williams et al. (2021) found that vulnerability effects of neuroticism were greater in magnitude than scar effects. Scar effects were nonsignificant when examined with the symptom dimension of General Distress, the general, latent factor common to all anxiety and depression symptoms.

#### BEHAVIORAL INHIBITION

Another construct that has been implicated in the etiology of anxiety disorders is behavioral inhibition (BI). This was described by Kagan and colleagues (1984) as a specific behavioral response style elicited by novel situations among children as young as 21 months. This response style, observed in about 15–20% of young children, was defined as "an early appearing syndrome characterized by shyness, withdrawal, avoidance, uneasiness, fear of unfamiliar situations, people, objects and events" (Turner et al., 1996). BI was found to be moderately stable from age 21 months to 7.5 years and was linked to physiological correlates (e.g., higher heart rate in response to stressors), thus representing a temperamental construct (see Fox et al., 2005, for a review).

Rosenbaum and colleagues (1988, 1991) found a higher incidence of anxiety disorders among parents with behaviorally inhibited children than among those with uninhibited children. More directly, BI is associated with risk for developing SAD and avoidant personality disorder among children (Biederman et al., 2001) and SAD among adolescents (Hayward et al., 1998). Indeed, Clauss and Blackford (2012) conducted a meta-analysis of seven primary studies and reported a sevenfold increase in the odds of developing SAD in later childhood among those classified as behaviorally inhibited in childhood.

BI is thought by many to be a developmental precursor to and facet of neuroticism (e.g., Turner et al., 1996; Zinbarg et al., 2010). Indeed, Gray's (1982; Gray & McNaughton, 2000) construct of BI system (BIS) reactivity, which he hypothesized as underlying neuroticism (as described earlier), relates conceptually to Kagan et al.'s (1984) behavioral description of BI in children. Unfortunately, few studies have empirically tested the association between the two. One of the challenges in doing so is that neuroticism has been primarily examined in adults, whereas Kagan's BI model has been rooted in studies using child samples. Zinbarg et al. (2016) shed light on this question, finding that subscales of the Behavioral Inhibition Scale (Carver & White, 1994) loaded significantly on a GNF defined by neuroticism scales as well as related cognitive vulnerability measures (e.g., Dysfunctional Attitudes Scale; Weissman & Beck, 1978). Zinbarg et al.'s measurement model shows that there is substantial shared variance between traditional neuroticism and behavioral inhibition items.

#### ANXIETY SENSITIVITY

A third trait that has received a great deal of attention in etiological theories of anxiety disorders is anxiety sensitivity (AS; Reiss et al., 1986). AS represents individual differences in the fear of fear, hypothesized to arise from beliefs that symptoms of anxiety or fear will cause illness, embarrassment, or additional anxiety (Reiss et al., 1986). For example, an individual with high AS may be more likely to misinterpret a pounding heart as an impending heart attack. These negative beliefs in turn amplify existing anxiety levels, resulting in a cycle that increases risk for panic attacks and anxiety disorders.

AS is commonly assessed using the Anxiety Sensitivity Index (ASI; Reiss et al., 1986). Using this measure, researchers have shown that AS is associated with anxiety disorders among adults (Olatunji & Wolitzky-Taylor, 2009), children, and adolescents (Noël & Francis, 2011). Several longitudinal studies have also found evidence that AS prospectively predicts panic attacks and PD/A symptoms, as well as other anxiety disorders (e.g., GAD, SAD) (e.g., Hayward et al., 2000; Li & Zinbarg, 2007; Schmidt et al., 1999; Schmidt et al., 2006; Schmidt et al., 2008). These findings provide support for AS being a risk factor for developing anxiety disorders. Among the anxiety disorders, AS has been most extensively linked to vulnerability for PD/A (McNally, 2002).

Factor-analytic studies using the ASI have found a hierarchical structure with a general factor and three group factors: (a) Physical Concerns involving the fear of physical symptoms, (b) Social Concerns involving the fear of publicly observable symptoms, and (c) Mental Incapacitation Concerns (e.g., Rodriguez et al., 2004; Zinbarg et al., 1997, 1999). Studies examining the unique role of these facets in predicting panic have yielded inconsistent results. Schmidt et al. (1999) studied Air Force cadets and found that of the three AS facets, only Mental Incapacitation Concerns significantly predicted spontaneous panic attacks during a 5-week period, when statistically adjusting for trait anxiety and history of panic. Consistent with these findings, Li and Zinbarg (2007) found that Mental Incapacitation Concerns, but not the other two facets, uniquely predicted panic onset over a 1-year period among college undergraduates. Other studies have implicated alternative facets in the etiology of panic.

For instance, Hayward et al. (2000) reported that only Physical Concerns predicted the onset of four-symptom panic attacks over a 4-year period among high school students. Results from Jurin and Biglbauer (2018) showed that Physical Concerns was the only significant AS facet that predicted PD/A symptoms over a span of 3 years in a healthy student sample. These findings are consistent with a recent cross-sectional analysis that compared AS facet elevations in a clinical sample assessed for the presence of anxiety disorders. In that study, Physical Concerns was elevated in outpatients with only PD/A relative to those with only MDD, SAD, GAD, or OCD (Baek et al., 2019).

Zinbarg et al. (2016) found that AS shares substantial variance with neuroticism and other cognitive vulnerability indicators. They found evidence for an AS factor in addition to a broader neuroticism factor on which the AS facets also loaded. Thus, it appears that relationships between BI, AS, and neuroticism are best described by a hierarchical structure in which AS and BI measures represent facets of vulnerability toward anxiety disorders that also share some variance with a General Neuroticism Factor. Naragon-Gainey and Watson (2018) showed that AS uniquely accounted for variance (between 9% and 20%) in symptoms of several emotional disorders (PD/A, SAD, MDD, and PTSD) after adjusting for neuroticism. That is, AS, unlike several other vulnerability factors examined in this study (experiential avoidance, intolerance of uncertainty), provided incremental validity for some, but not all, emotional disorders. However, one limitation from that study was its cross-sectional nature. Zinbarg et al. examined unique effects of AS facets prospectively and found that only Mental Incapacitation Concerns was uniquely associated with an increased risk of developing PD (and, in a perplexing fashion, was also associated with a decreased risk of developing MDD). More research is needed into the incremental predictive validity of AS.

#### POSITIVE EMOTIONALITY/EXTRAVERSION

Although research on personality risk factors for the anxiety disorders has largely focused on traits related to Negative Emotionality (e.g., neuroticism, BI, and AS, as described earlier), there is increasing interest in the risk associated with low levels of traits related to Positive Emotionality (PE), most notably extraversion. Extraversion is generally considered to be a higher-order dimension that subsumes trait PE along with sociability facets (e.g., Watson & Clark, 1997; but see Smillie et al., 2012). To explicitly emphasize both of these facets, we will refer to this higher-order trait as positive emotionality/extraversion (PE/E).

The relative focus on risk factors associated with Negative Emotionality versus PE/E is attributable in part to early structural models of the emotional disorders. As already mentioned, the tripartite model (Clark & Watson, 1991) posited that high Negative Emotionality is common across the emotional disorders, whereas low PE/E distinguishes depressive from anxiety disorders. One disconfirmation of the tripartite model predictions was that SAD has also consistently been linked to low PE/E (e.g., Brown et al., 1998; Kashdan, 2007). Thus, structural models were updated to account for this discovery (e.g., Mineka et al., 1998), and more attention has since been devoted to studying low PE/E as a risk factor for at least some anxiety disorders.

The cross-sectional research linking low PE/E to SAD generally suggests that the magnitude of the inverse association is significant but weaker than that with depression (see Watson & Naragon-Gainey, 2010). Interestingly, there is evidence that the *facets* of PE/E may differentially relate to the symptoms of social anxiety and depression. For example, one study identified four lower-order facets of PE/E: PE, sociability, ascendance, and fun-seeking (Naragon-Gainey et al., 2009). In this study, it was found that social anxiety was negatively related to all four facets, whereas depression was strongly related only to low PE and also more modestly with sociability.

Less attention has been devoted to the relations between PE/E and the remaining anxiety disorders. However, there is some evidence that low PE/E may be associated-alone and/or in interaction with high neuroticism-with other anxiety disorders. For example, findings from a large meta-analysis revealed that nearly all of the anxiety disorders, with the possible exception of the SPs, were associated with lower PE/E in addition to elevated neuroticism (Kotov et al., 2010). These studies are consistent with the hypothesis that low PE/E may confer risk for the anxiety disorders covered in this chapter, particularly SAD, and perhaps least likely the SPs. However, a number of factors limit the conclusions that can be drawn and highlight directions for future work. The overwhelming majority of available studies are cross-sectional; prospective longitudinal work is sorely needed to determine directionality. As for higher-order traits, most studies do not account for the shared variance of trait PE/E with neuroticism, despite evidence that neuroticism is both a strong predictor of psychopathology and a correlate of PE/E (see Kotov et al., 2010). At the lower-order level, analyses are needed to determine if the specific facets of PE/E differentially relate to the different anxiety disorders.

A final consideration pertains to the study not only of low PE/E but also of personality risk factors

more broadly: it will be important to distinguish between trait and state variance in putatively "trait" measures to avoid their contamination by the state dimension. Evidence indicates that psychological constructs consist, to varying degrees, of both stability and change (see Roberts & DelVecchio, 2000). Advances in longitudinal analysis (e.g., Cole et al., 2005; Hamaker et al., 2015; Kenny & Zautra, 1995; Steyer & Schmitt, 1994) enable isolation of each of these components. Teasing apart traits and states will enhance confidence in the conclusions drawn regarding the associations between traits and disorders by minimizing the possibility that it is actually the state dimension-rather than the trait dimension-that is largely responsible for the observed associations with disorders.

#### Biology

#### BEHAVIOR GENETICS

Behavior genetics (BG) studies reveal that anxiety disorders are heritable (e.g., Domschke & Reif, 2012; Smoller, 2016). Multivariate BG studies-BG studies that focus on several disorders simultaneously rather than on a single disorder-have been pioneered by Kendler and colleagues (e.g., Hettema et al., 2005; Kendler et al., 2003). These can potentially answer the question of whether any of the anxiety disorders share a genetic vulnerability or whether they each have unique genetic bases. In general, these studies point to genetic factors that largely correspond to the two subfactors of Internalizing that emerged from the phenotypic factor analyses described earlier. That is, these studies reported evidence for two genetic factors within the anxiety disorders and MDD. The first is loaded on by MDD and GAD and is characterized as a vulnerability to Anxious-Misery disorders; the second is loaded on by PD/A and SP and is characterized as a vulnerability to Fear disorders (e.g., Kendler et al., 2003). Interestingly, these two genetic factors are moderately positively correlated, which is consistent with a second-order genetic factor common to all the anxiety disorders and MDD (Kendler et al., 2003; for a review, see Purves al., 2020).

The existence of a genetic factor common to all the anxiety disorders and MDD is also consistent with research on the genetic factors associated with neuroticism. Multivariate BG studies have shown that the genetic factor associated with neuroticism overlaps substantially with the genetic vulnerability to all the anxiety disorders and MDD (e.g., Andrews et al., 1990; Hettema, Neale, et al., 2006; Hettema et al., 2004). Thus, neuroticism appears to be the phenotype associated with the genotype that confers common vulnerability to all the anxiety disorders and MDD. Whereas BG studies tell us that there is a heritable—and therefore biological component of the anxiety disorders, in the next three sections we turn to studies of molecular genetics, brain lesions and genetic engineering in animals, and human neuroimaging that shed light on the specific biological substrates and genes involved in vulnerability to the anxiety disorders.

#### MOLECULAR GENETICS

Much evidence indicates abnormalities in serotonin (5-HT) systems' functioning in patients with MDD and the anxiety disorders (Hariri & Holmes, 2006). In addition, many medications effective in treating MDD and the anxiety disorders are known to affect 5-HT systems and transmission (Hariri & Holmes, 2006). That the 5-HT system is also involved in the regulation of various forms of negative affect including hostility, anxiety, and fear (e.g., Grabe et al., 2005), implies a link between 5-HT systems and neuroticism—the trait that overlaps substantially with the genotype for anxiety disorders and major depression.

One particular polymorphism related to 5-HT systems that has been the focus of a lot of molecular genetics research is the serotonin transporterlinked polymorphism (5-HTTLPR). 5-HTTLPR refers to an insertion/deletion polymorphism in the promoter region of the serotonin transporter gene, SLC6A4, that yields a transcriptionally less efficient short (*S*) allele and a relatively more efficient long (*L*) allele (Heils et al., 1996). Evidence supports a gene by environment (G×E) interaction effect in depression where individuals with the *S* allele report greater depression under increasing stress relative to L/L homozygotes (Karg et al., 2011; Vrshek-Schallhorn et al. 2014).

There has not been as much research examining associations of the 5-HTTLPR gene with anxiety disorders as there has been with MDD. In the only relevant study that we are aware of, the 5-HTTLPR gene did not significantly moderate the effects of stressful life events on risk for GAD (Kendler et al., 2005). However, knockout strains of mice lacking the 5-HTTLPR gene demonstrate evidence of elevated anxiety (for a review, see Hariri & Holmes, 2006). Also, meta-analyses have indicated a small but significant association between the 5-HTTLPR gene and "avoidance traits" such as neuroticism (e.g., Munafò et al., 2005; Schinka et al., 2004). Taken together, these findings suggest that the 5-HTTLPR gene may play a role in anxiety disorders.

There have also been some molecular genetics studies implicating a role for genes other than the 5-HTTLPR gene in anxiety disorders. For example, motivated by the observation that a gamma-aminobutyric acid (GABA) receptor is the site of action for the anxiolytic effects of the benzodiazepines and barbiturates, Hettema, An, and colleagues (2006) studied associations between genes involved in the production of glutamic acid decarboxylase-an enzyme responsible for synthesizing GABA from glutamate-and common genetic risk for anxiety disorders, major depression, and neuroticism. They found that variations in one of these glutamic acid decarboxylase genes may contribute to susceptibility to anxiety disorders and major depression. Similarly, Thoeringer et al. (2009) found an association between the severity of panic attacks and genetic variation in a polymorphism involved in the production of the GABA transporter. However, Pham et al. (2009) failed to detect associations between GABA receptor genes and common genetic risk for anxiety disorders, major depression, and neuroticism. In addition, the researchers who reported the glutamic acid decarboxylase gene and GABA transporter genes emphasized that their findings need to be replicated in independent samples. Thus, these findings are very preliminary, but they are also very exciting and suggest that further studies of the glutamic acid decarboxylase gene and GABA transporter gene are warranted.

Finally, whereas large-scale genome-wide association studies (GWASs) of anxiety disorders have lagged behind that of other major psychiatric diagnoses, some have recently begun to appear (e.g., Levey et al., 2020; Purves et al., 2020; for a review, see Smoller, 2020). These GWAS studies have implicated several genetic loci in anxiety disorders. Examples include PDE4B, a gene previously implicated in schizophrenia; GAD2, which encodes a GABA gene implicated in mouse models of anxiety; SATB1 and SATB1-ASI, an antisense gene (i.e., a DNA strand that a cell uses as a template for producing messenger RNA), which regulate transcription and chromatin structure of several other genes involved in neuronal development; and CRHR1, the corticotropin-releasing hormone receptor gene, a key component of the hypothalamic-pituitaryadrenal axis function associated with anxiety and stress responses.

Reminiscent of the multivariate BG results pioneered by Kendler and colleagues (e.g., Hettema et al., 2005; Kendler et al., 2003), Levey et al. (2020) also conducted analyses of data from a wide range of GWASs and found a widespread genetic correlation between anxiety and many other psychiatric and nonpsychiatric problems. Other GWASs have reported similar patterns (Smoller, 2020). Much work remains to be done, however, as it is likely that many genetic loci contribute to vulnerability to anxiety disorders (and other diagnoses), and we need to better understand the pathways that link these genes to anxiety disorders phenotypes (Smoller, 2020).

#### ANIMAL LESION STUDIES

Jeffrey Gray's model of the neuropsychology of anxiety uses as its starting point the behavioral effects of the antianxiety drugs (Gray, 1982; Gray & McNaughton, 2000). Gray synthesized the voluminous literature on the effects of the antianxiety drugs in animals by hypothesizing that antianxiety drugs exert their effects by modulating the output of the BIS. The BIS is described as responding to signals of punishment or signals of frustrative nonreward (but not to punishment or frustrative nonreward itself) and as having three major outputs: an increase in arousal, BI, and negative cognitive bias. By comparing the effects of the antianxiety drugs to the effects of brain lesions, Gray (1982) originally proposed that the septohippocampal system (SHS) is the anatomical substrate of the BIS. Gray and McNaughton (2000) expanded the neuroanatomical seat of anxiety to include the interactions of the SHS system with the amygdala. Gray's model spans multiple levels of analysis, including personality. Thus, according to this model, individual differences in reactivity of the BIS; that is, the SHS (and its interactions with the amygdala) underlie the closely related traits of anxiety and neuroticism.

There are two major projections to the SHS: one noradrenergic that originates in the locus coeruleus and the other serotonergic that originates in the raphe nucleus (Gray & McNaughton, 2000). Thus, the discoveries described above that link the 5-HTTLPR gene with anxiety (in 5-HTTLPR knockout mice), neuroticism, and MDD are consistent with Gray's model. Indeed, several predictions regarding the anxiety disorders and MDD can be derived from Gray's model, and the evidence to date is largely supportive of each (for a review, see Zinbarg & Yoon, 2008).

#### HUMAN NEUROIMAGING

A great deal of basic functional magnetic resonance imaging (fMRI) research on fear in healthy human participants has been conducted. Much of this research was motivated by animal studies, which have reliably identified the amygdala as being a necessary brain structure in the acquisition and expression of conditioned fear (e.g., Davis, 1998; LeDoux, 1995, 2000). Several fMRI studies with healthy human participants have found the amygdala to be involved in human fear conditioning as well (e.g., LaBar et al., 1998; Phelps & LeDoux, 2005; Whalen, 1998). Other studies with healthy human participants have extended this research by showing the amygdala to be activated by more subtle fear-related stimuli, such as pictures of fearful facial expressions-even when the fearful expressions have been masked so that the participants are not aware of them-and uncertain threat (e.g., Hur et al., 2020; Phelps & LeDoux, 2005; Whalen, 1998). Though more limited, some basic fMRI research with healthy humans has focused on areas other than the amygdala that may be involved in anxiety or fear. For example, Somerville et al. (2010) conducted an fMRI study with healthy participants that was motivated by the animal research by Davis (1998) implicating the amygdala in fear responses and the bed nucleus of the striaterminalis (BNST) in anxiety. Interestingly, the BNST receives projections from the ventral hippocampus (Lee & Davis, 1997) and thus might be considered part of the SHS. Hur et al. (2020) found the BNST is active in both certain threat (i.e., fear) and uncertain threat (i.e., anxiety) conditions (for reviews, see Fullana et al., 2016, and Chavanne & Robinson, 2021). Somerville et al. (2010) found that activity in the BNST correlated with individual differences in trait anxiety levels while participants were engaged in continuous processing of potential signals of threat, much as we would expect if the SHS underlies trait anxiety and neuroticism, as hypothesized by Gray (1982; Gray & McNaughton, 2000).

There have also been several fMRI studies of participants with anxiety disorders. Compared with findings in control participants, greater activation of the amygdala has been found in patients with GAD (McClure et al., 2007; Monk et al., 2008; Nitschke et al., 2009), SAD (Birbaumer et al., 1998; Etkin & Wager, 2007; Evans et al., 2008), PD/A (van den Heuvel et al., 2005; for a related case study, see Pfleiderer et al., 2007), and SP (Etkin & Wager, 2007). There are also at least two fMRI studies implicating SHS-related structures in anxiety disorders. For instance, Bystritsky et al. (2001) found increased activity relative to controls in the hippocampus and the anterior cingulate—a structure which receives projections from the hippocampus—in patients with PD/A. Similarly, McClure et al. (2007) found increased activity in the anterior cingulate in patients with GAD compared with that in controls.

#### Conditioning

J. B. Watson and Rayner (1920) hypothesized that SPs are intense, classically conditioned fears that develop when a neutral stimulus is paired with a traumatic event. They demonstrated this process in their famous experiment in which Little Albert, a young boy who did not show fear of a white rat to begin with, acquired an intense fear of rats after hearing a frightening gong paired with the presence of a white rat. The gong was said to be a unconditioned stimulus (US) and the fear an unconditioned response (UR) and then a conditioned response (CR). This study ushered in an era in which conditioning approaches were the dominant empirically grounded theoretical perspective on anxiety disorders.

That era continued until the 1970s, but such approaches have been widely criticized since then (e.g., Mineka, 1985; Rachman, 1978, 1990). Many of these criticisms focused on the apparent inability of conditioning approaches to account for the diversity of factors involved in the origins of anxiety disorders. More recently, however, a resurgence of interest in conditioning approaches has occurred as they have incorporated complexity predicted by contemporary conditioning theory and research (e.g., Bouton et al., 2001; Mineka and Zinbarg, 1996; Zinbarg & Mineka, 2007).

#### DIRECT CONDITIONING

Öst and Hugdahl (1981) asked phobic patients to recall how they acquired their phobic fears. Almost 60% of the patients endorsed direct learning experiences. Given the prevalence of direct conditioning experiences in the etiology of phobic fears, researchers have developed tools to examine these processes.

Researchers rely on direct fear conditioning protocols as a model for understanding the onset and maintenance of clinically significant fears (Lonsdorf et al., 2017). The most common direct conditioning paradigm focuses on differential responding between two initially neutral conditional stimuli (CS). During the acquisition phase, one of the CS is repeatedly paired with an aversive stimulus (e.g., an electric shock). The other CS is never associated with an aversive stimulus, serving as the safety signal. Participants then undergo an extinction phase wherein they are exposed to both CS in the absence of aversive stimulation. Defensive responding can be measured in a number of ways, including by selfreport and psychophysiological methods.

By instigating mild fears in humans with and without anxiety disorders, researchers have found evidence for maladaptive fear conditioning patterns in anxiety-disordered samples. Duits et al. (2015) reported anxiety-disordered groups respond more defensively to the safety cue relative to controls during the acquisition phase. Anxiety-disordered groups also tended to resist extinction to the danger cue.

A proliferation of complex conditioning designs have appeared that purport to more closely approximate the learning processes observed in anxiety disorders. For instance, the process of fear generalization, which is implicated in the expansive scope of worries observed in GAD, can be studied by introducing new CSs which differ in terms of their visual similarity to the original CSs. In this way, their threat value is ambiguous, unlike that of the original CSs. Lissek et al. (2014) reported evidence for increased overgeneralization of learned fear to generalization stimuli in patients with GAD relative to healthy controls. Similarly, earlier work (Lissek et al., 2010) showed that PD patients were more susceptible to overgeneralization relative to nondisordered controls.

#### VICARIOUS CONDITIONING

One criticism of early conditioning approaches was that many phobics do not appear to have had any relevant history of *direct* classical conditioning. To account for the origins of fears and SPs in these individuals, clinicians have long speculated that vicarious conditioning (i.e., simply observing others experiencing a trauma or behaving fearfully) could be sufficient for some fears and SPs to develop. Indeed, retrospective studies have found evidence consistent with this idea, for PD/A, SAD, and SP (e.g., Bruch & Heimberg, 1994; Öst & Hugdahl, 1981; Rapee & Melville, 1997; see Muris & Mercklebach, 2001).

The work of Mineka and her colleagues on a primate model showed that strong and persistent fears can be learned rapidly through observation (e.g., Cook et al., 1985). A particularly fascinating finding is that vicarious conditioning occurred simply through watching videotapes of models behaving fearfully (Cook & Mineka, 1990), suggesting that humans are also susceptible to acquiring fears vicariously through movies and television.

There is now a burgeoning literature on vicarious conditioning in humans (e.g., Golkar et al., 2015; Olsson et al., 2016). The typical human vicarious fear conditioning protocol (see Haaker et al., 2017) involves video presentations of a stranger receiving aversive stimulation in the context of a particular CS. Participants are then presented with the CSs from the observation phase directly on a computer screen and their physiological or subjective responses are recorded. Existing research suggests that direct and vicarious conditioning are governed by similar psychobiological systems (Debiec & Olsson, 2017; Lindström et al., 2018; cf. Esser et al., 2020).

We are unaware of data linking individual differences in vicarious conditioning to anxiety disorder diagnoses but some evidence suggests that vicarious conditioning could play a role in the acquisition of SPs and other anxiety disorders. Selbing and Olsson (2019) reported that healthy participants scoring higher on trait anxiety showed more difficulty determining the threat value of a safe versus threatening cue. Trait anxiety, in turn, is elevated in those with anxiety or depressive disorders (Knowles & Olatunji, 2020) and has sometimes been implicated in compromised CS discrimination in direct conditioning experiments (Sjouwerman et al., 2020). However, Williams and Conway (2022) did not find evidence that vicarious threat learning was correlated with common or specific emotional disorder symptom dimensions in a sample of undergraduates. Thus, more work is needed in this area.

## SOCIAL REINFORCEMENT AND INSTRUCTIONAL LEARNING

Direct social reinforcement and verbal instruction are also likely to play a role in the acquisition of anxiety disorders. Ehlers (1993) found that patients with PD/A, individuals with infrequent panic, and patients with other anxiety disorders reported that they received more parental encouragement for sick-role behavior during their childhood experiences of panic-like symptoms (e.g., "Take care of yourself and avoid strenuous activities") than did nonanxious controls. When anxious children discuss potentially threatening situations with their parents, such discussions have been found to strengthen the anxious children's avoidant tendencies (Barrett et al., 1996). Experimental research confirms that providing healthy participants with contingency information (i.e., that a CS will signal

an aversive outcome) before direct encounters with CSs can instill robust fear responses (Mertens et al., 2018). In addition, fear can intensify when verbal instruction is augmented with direct contingency experience (Mertens et al., 2016), suggesting that fear learning pathways can operate synergistically.

#### SELECTIVE ASSOCIATIONS

A second criticism of early conditioning models of the acquisition of SPs and anxiety disorders is their equipotentiality assumption. That is, early conditioning models predicted that fears, SPs, and anxiety would be acquired to any random group of objects and stimuli associated with traumatic outcomes. However, clinical observations show that people are much more likely to have fears of snakes, water, heights, enclosed spaces, elevated heart rate, and other people than they are of bicycles, guns, or cars. This is remarkable given that, today, the latter objects are at least as likely to be associated with trauma as the stimuli that commonly trigger anxiety in individuals with anxiety disorders. To explain the nonrandom distribution of phobic objects, Seligman (1971) hypothesized that primates are evolutionarily prepared to rapidly associate certain kinds of objects (such as snakes, spiders, water, heights) with aversive events, as there should have been a selective advantage for primates who rapidly or strongly acquired fears of such objects or situations. The term prepared fears refers to those fears that are not truly inborn or innate but which are very easily acquired and/or especially resistant to extinction.

Preparedness theory has been tested in a series of human conditioning experiments conducted by Öhman and his colleagues. Consistent with predictions, they found superior conditioning using slides of snakes and spiders or of angry faces as fearrelevant (FR) CSs, and mild shock as the unconditioned stimulus (US), compared to what is found using more fear-irrelevant (FI) CSs such as slides of flowers, mushrooms, electric outlets, or neutral or happy faces (e.g., Öhman & Dimberg, 1978; Öhman et al., 1985; Öhman & Mineka, 2001). Other studies have also shown that with FR-CSs (but not with FI-CSs) conditioning can even occur using subliminal presentations of the CSs (i.e., CSs that cannot be consciously identified; e.g., Esteves et al., 1994; Öhman & Soares, 1998). Such results may help explain the irrationality of SPs; that is, a person can claim to "know" rationally that a SP object or social situation is safe and still experience anxiety that is nonconsciously activated.

Cook and Mineka (1989, 1990) demonstrated that observer monkeys can easily acquire fears of FR stimuli (e.g., a toy snake or a toy crocodile) but not of FI stimuli (e.g., flowers or a toy rabbit). These observer monkeys had no previous exposure to any of the FR or FI stimuli before participating in these experiments. Thus, whereas recent critiques have raised some challenges for preparedness theory (Coelho et al., 2019), the results reported by Cook and Mineka strongly support the role of evolutionary factors in the greater conditionability of FR than FI stimuli (Mineka & Öhman, 2002).

#### UNCONTROLLABILITY AND UNPREDICTABILITY

A third criticism of early conditioning models of the acquisition of SPs and anxiety disorders is that they do not explain why many individuals who undergo traumatic experiences do not develop an anxiety disorder (e.g., Mineka & Zinbarg, 1996; Rachman, 1990, 2010). That is, many nonphobics retrospectively report having had traumatic experiences in the presence of some potentially phobic object without having acquired a SP (e.g., Poulton & Menzies, 2002).

From the perspective of a modern conditioning approach, however, these observations of resilience in the face of trauma can be easily accommodated. For example, several different features of conditioning events themselves can have a strong impact on how much fear is acquired. Far less fear is conditioned, for instance, when the aversive event is escapable than when it is inescapable (e.g., Mineka et al., 1984).

Perceptions of uncontrollability are a likely source of individual differences not only in the acquisition of SPs but also in the other anxiety disorders. For example, animal research has shown that uncontrollable (but not controllable) electric shock increases social submissiveness (e.g., Williams & Lierle, 1986). In addition, animal studies (e.g., Uhrich, 1938) of repeated social defeat (an uncontrollable stressor) show that it also leads to increased submissiveness. Moreover, repeated social defeat in animals produces many of the classic "learned helplessness" effects usually associated with uncontrollable shock, including escape deficits (Hebert et al., 1998) and exaggerated-fear CRs (Williams & Scott, 1989). Williams and colleagues concluded from such findings that the deleterious effects of social defeat are probably mediated by perceptions of uncontrollability. Such research and theorizing suggest that perceptions of uncontrollability are likely to play a role in the etiology of SAD. Indeed, cross-sectional evidence documents a moderate to strong association between generalized perceptions of uncontrollability and SAD (e.g., Kennedy et al., 1998).

Sanderson et al. (1989) conducted a fascinating study demonstrating the role of perceptions of controllability in panic attacks experienced by those with PD/A. Patients with PD/A underwent a panic provocation procedure involving the breathing of air with higher than normal levels of carbon dioxide  $(CO_2)$ . The patients were told that if the experience became too unpleasant, if and when a light in the room came on, they could turn a dial to reduce the amount of CO<sub>2</sub> they were breathing. The patients were then randomly assigned to either a condition in which the light actually came on during the CO<sub>2</sub> inhalation (perceived control) or to a condition in which the light never came on (no perceived control). Eighty percent of the participants in the noperceived control group reported experiencing a panic attack during the inhalation compared with only 20% in the perceived control group (despite the fact that the only participant in the study who actually attempted to turn the dial was in the no perceived control group).

More recent experimental work also supports the notion that controllability impacts the strength of acquired fear responses. Hartley and colleagues (2014) reported an effect of an escapable versus inescapable stressor on subsequent fear extinction and recovery. In the escapable stressor condition, participants were able to escape or avoid the delivery of electrical stimulation in a computer task. Those in the inescapable stressor condition, however, were not able to evade electrical stimulation through their task-related actions. Instead, they received the same number of shocks with the same timing as their yoked participant in the escapable condition. When tested 1 week later, participants in the inescapable stressor condition saw diminished fear extinction and more recovery of fear responses to the CS signaling threat relative to the safety signal. Thus, the experience of an unrelated, inescapable stressor in one setting may predispose one to develop extinction-resistant fear responses in another.

#### TEMPERAMENT/PERSONALITY AND CONDITIONING

Another part of the explanation of resilience in the face of trauma may involve temperamental or personality variables. Theorists ranging from Pavlov (1927) to Eysenck (1967) and Gray (1982; Gray & McNaughton, 2000) have hypothesized that individual differences on variables such as trait anxiety

or neuroticism are related to the speed and strength of conditioning and thus play a role in the origin of anxiety disorders. There is experimental evidence demonstrating that individuals high on trait anxiety have difficulty discriminating between CSs that signal threat versus safety (e.g., Gazendam et al., 2013; Sjouwerman et al., 2020). Other evidence, however, has not supported the role of trait anxiety (e.g., Arnaudova et al., 2013; Morriss et al., 2016). Lonsdorf and Merz (2017) reviewed fear conditioning studies that examined the association between putative vulnerability measures like neuroticism and trait anxiety and fear conditioning responses. They found that, in most studies, across physiological and subjective response measure types, there were not significant associations between neuroticism or trait anxiety and fear learning patterns. However, an important limitation of their review is that it did not use meta-analytic methods to synthesize findings across studies, and some individual studies have found significant results (e.g., Zinbarg & Mohlman, 1998). A quantitative synthesis of this literature is needed to provide a firmer conclusion regarding the role of personality in conditioning.

In particular, research designs that account for overlap among vulnerability measures could improve our understanding of risk for conditioning abnormalities. Sjouwerman et al. (2020), for instance, used a structural equation modeling approach to capture the overlap between trait anxiety, neuroticism, and intolerance of uncertainty in a general factor that was labeled Negative Emotionality. The modeling strategy allowed analysis of the unique effects of the risk measures. In this study, there was a unique effect of trait anxiety on physiological CS discrimination, adjusting for the overlap between trait anxiety and neuroticism. The overarching Negative Emotionality factor did not predict individual differences in a fear learning factor defined by CS discrimination response measures. More research that adjusts for the overlap among vulnerability measures will be needed to shed additional light on their unique contributions to conditioning patterns.

There is accumulating evidence from prospective studies, as described earlier, that trait anxiety, neuroticism, and related constructs serve as nonspecific vulnerability factors for the subsequent development of SPs, SAD, and MDD (e.g., Biederman et al., 1990; Hayward et al., 2000; Kendler et al., 2004; Krueger et al., 1996; Schwartz et al., 1999; Zinbarg et al., 2016). These findings of nonspecific vulnerability are consistent with findings of common conditioning deficits in anxiety-disordered groups (Duits et al., 2015). However, given the conclusions of Sjouwerman et al. (2020), which failed to find support for nonspecific Negative Emotionality as a predictor of fear learning, more work is needed on the role of fear conditioning in the vulnerability conferred by neuroticism and related constructs.

#### INTEROCEPTIVE CONDITIONING

In *interoceptive conditioning*, the CSs are internal sensations (e.g., Razran, 1961). Bouton et al. (2001) proposed that when low-level somatic sensations of anxiety/panic precede and are paired with full-blown panic, the low-level somatic sensations of anxiety/panic come to be CSs that elicit high levels of anxiety and panic. That is, Bouton et al. propose that interoceptive conditioning may contribute to the fear-of-fear vicious cycle described earlier regarding the personality trait of AS.

Bouton et al. (2001) also reviewed a great deal of clinical evidence that is consistent with several of the predictions that follow from their interoceptive conditioning model of PD/A. For example, panic is predicted to be preceded by heightened anxiety if anxiety becomes a CS for panic. Studies using experience sampling and careful monitoring have found this to be the case, rather than panic truly coming from out of the blue, as is often experienced subjectively by patients. Bouton et al. noted that the initial attacks experienced by patients with PD/A are generally terrifying, with thoughts of going crazy or dying being common symptoms, and this terror is more than sufficient to allow powerful conditioned responses to develop. Moreover, initial attacks are often perceived as unpredictable and uncontrollable, and, as discussed earlier, these perceptions should augment the intensity of the conditioning that results from an initial panic. Consistent with this prediction many patients with PD/A report that their anxiety about having more panic attacks develops rapidly after their first panic attack.

#### SUMMARY

The origins of anxiety disorders are considerably more complex than was assumed by early conditioning models. However, these complexities are expected from the perspective of contemporary research on conditioning, which reveals a variety of vulnerability (e.g., temperament) and contextual (e.g., controllability and fear relevance of stimuli) variables that may impact the outcome of direct, vicarious, and interoceptive conditioning experiences.

#### Information Processing Biases ATTENTIONAL BIAS

Several types of information processing biases have been identified in anxious populations, and the most-studied among them is an attentional bias that favors the processing of threat stimuli. This bias is demonstrated in both increased attentional engagement toward threatening stimuli (Lange et al., 2011; Seefeldt et al., 2014; Shechner et al., 2012) and *decreased* attentional disengagement away from threatening stimuli (Chen et al., 2012; Liang et al., 2017; Schofield et al., 2012). That is, groups characterized by anxiety are both more likely to pay attention to threats and have a harder time shifting their attention away from threats. However, these two types of attentional bias are uncorrelated-that is, an individual could display one type of bias without displaying the other, and vice versa (Rudaizky et al., 2014).

A variety of factors appear to influence the strength of this attentional bias. For instance, this bias appears to interact with state anxiety such that the attentional bias is strongest among highly trait-anxious individuals who also have high state anxiety, such as the kind of anxiety that comes when final exams are coming soon (MacLeod & Mathews, 1988; MacLeod & Rutherford, 1992; Mogg et al., 1994). When state anxiety is high, low trait-anxious individuals show less attentional bias toward threat whereas high trait-anxious individuals show more. This pattern appears most salient at a moderate level of threat. For instance, a strong threat, such as the threat of electric shock, produces similar levels of attentional vigilance between high and low trait-anxious groups (Notebaert et al., 2011). But when threat intensity can be manipulated, threats of moderate intensity provoke the largest differences in anxiety-linked attentional bias (Koster et al., 2006; Wilson & MacLeod, 2003). And, of course, attentional bias is particularly strong when the threat is relevant to the main triggers of one's anxiety (Mathews & MacLeod, 1985; McNally et al., 1994). Attentional vigilance is particularly strong for disorder-relevant stimuli, such as panic-relevant stimuli for those with PD (Buckley et al., 2002), social stimuli for those with SAD (Maidenberg et al., 1996), obsession-related stimuli for those with OCD (Cisler & Olatunji, 2010), and trauma-relevant stimuli for those with PTSD (Ashley et al., 2013). Indeed, meta-analytic findings demonstrate that the magnitude of the attentional bias to threat is significantly greater

when the stimuli matches the diagnosis (Pergamin-Hight et al., 2015).

In recent years, studies have continued to demonstrate that groups characterized by a vulnerability toward anxiety (such as those with high trait anxiety or those with anxiety disorder diagnoses) are more likely to attend to threatening information than are controls (Cisler & Koster, 2010; Mathews & MacLeod, 2005). This effect has been seen using a variety of stimuli including words (Amir et al., 2003), auditory narratives (Foa & McNally, 1986), expressive faces (Waters et al., 2008), and complex images (Rudaizky et al., 2014). In a large metaanalysis, Bar-Bar-Haim et al. (2007) found that this effect was replicated across a variety of anxiety diagnoses and under a variety of experimental paradigms/conditions, and meta-analytic reviews have continued to find that groups with increased anxiety vulnerability demonstrate a greater attentional bias toward threat (Armstrong & Olatunji, 2012; Dudeney et al., 2015; Price et al., 2016).

However, despite the substantial literature on this attentional bias in anxiety, recent papers have called attention to the fact that measures of attentional bias demonstrate low internal consistency and low reliability (MacLeod et al., 2019; Rodebaugh et al. 2016). These authors note that whereas the group effects are reliable, the low reliability limits what can reasonably done with the data. For instance, in keeping with the aim of Research Domain Criteria (RDoC; Cuthbert & Kozak, 2013), researchers have looked to attentional bias as a potential marker for anxiety disorders, but the low reliability of the measures limits their ability to distinguish individuals with anxiety rather than groups characterized by anxiety. That is, whereas measures of attentional bias are useful at the group level, they are likely to be unhelpful at the individual level (MacLeod et al., 2019). Researchers are currently looking for ways to ameliorate this concern, such as by taking multiple measurements of attentional bias (Enock et al., 2014; McNally, 2019; Price et al., 2015) or by examining the dynamic fluctuations in attentional bias over time (e.g., Iacoviello et al., 2014; Zvielli et al., 2015).

Importantly, recent studies have manipulated attentional bias using attention bias modification tasks (ABMTs), including studies that have attempted to induce attention bias and others that have attempted to ameliorate it. Research suggests that ABMT manipulations have causal effects on anxiety in the predicted directions (for reviews, see Hakamata et al., 2010; Hallion & Ruscio, 2011).

That is, inducing attention bias increases anxiety responses to subsequent stressors, whereas ameliorating attentional bias decreases such responses. These results provide evidence that attentional bias favoring the processing of threat plays a causal role in the etiology and/or maintenance of anxiety. They also suggest that ABMTs ameliorating attentional bias can be an effective treatment for anxiety. Over the past decade, research on the use of ABMTs in the treatment of anxiety has exploded, and the results are largely positive. Recent meta-analyses have demonstrated that ABMTs significantly reduce both attentional bias and symptoms of anxiety (Beard et al., 2012; Mogoașe et al., 2014), and recent reviews have highlighted both the strengths and limitations of this novel therapeutic technique (Kuckertz & Amir, 2015; Mogg et al., 2017).

#### MEMORY BIAS AND INHIBITORY DEFICITS

Evidence regarding a memory bias in anxiety disorders is inconclusive (Craske et al., 2009). While some studies suggest that anxious participants demonstrate enhanced memory for threatening material (e.g., Cloitre et al., 1994; Reidy, 2004; Reidy & Richards, 1997), others fail to demonstrate such a bias (e.g., Bielak & Moscovitch 2012; Bradley et al., 1995; Mathews & MacLeod, 1985; Mogg et al., 1989; Nugent & Mineka, 1994). There is not only discrepancy in the directionality of the findings, but in the effect sizes as well, with between-groups effect sizes ranging from -1.28 to 1.27 (Mitte, 2008). Mitte also found that, in general, there were no significant effects of anxiety on implicit memory but that anxiety did influence recollection such that anxious individuals demonstrated a memory bias toward threat-relevant information. According to one review, these biases may be more prevalent in some disorders than others. Coles and Heimberg (2002) found that there was more evidence for explicit memory bias in PD (and possibly in PTSD and OCD), but not in GAD and SAD. However, the findings for all disorders were mixed. Furthermore, in the few cases in which superior memory for threat-related stimuli has been demonstrated, the effects could be due to increased processing and encoding resulting from the attentional bias (Mathews & MacLeod, 2005). Though recent research has suggested explanations for these discrepancies, such as the notion that threats that can be controlled are more easily remembered but threats that are uncontrollable are not (Large et al., 2016), there are few conclusive findings on memory biases in those with anxiety disorders.
Interestingly, there is some evidence suggesting that there may be conditions in which anxious patients have difficulty forgetting threat representations when it would be adaptive to do so while healthy controls can forget them. This is evidenced through use of the retrieval-induced forgetting paradigm, in which practice of words reliably inhibits memory for related, unpracticed words in healthy participants. For instance, a few practice trials at encoding of the word "strawberry" tend to impair recall of the word "apple." People with SAD, however, do not adaptively inhibit as many unpracticed negative social words as do controls (Amir et al., 2001), nor do individuals with GAD (Kircanski et al., 2016). State anxiety induced in a psychosocial laboratory stressor also has been shown to prevent adaptive forgetting, or inhibition, from occurring (Koessler et al., 2009). In this way, anxious individuals may be less able to forget threatening or painful information, contributing to the greater impact of such information. In one such demonstration, when asked to retrieve negative (and not positive) reviews, as an individual with social anxiety might do, participants recalled the reviews of a public speaking task as more negative and less positive both 5 minutes and 1 week later, suggesting a lasting impact of remembering negative over neutral or positive information (Glazier et al., 2021).

#### INTERPRETIVE BIAS

Each day we are confronted with ambiguous information, such as a rustling noise outside the bedroom window at night or a coworker's blank face as we speak at work in the afternoon. Interpretive bias reflects the tendency to resolve such ambiguous information in a particular way.

There is a wealth of evidence from self-report studies consistent with the notion that people with clinical and subclinical anxiety of all types interpret ambiguous information that is salient to their emotional concerns in a negative fashion (Mathews & MacLeod, 2005). For example, in one study, when presented with descriptions of ambiguous social situations (e.g., "You have visitors come by for a meal and they leave sooner than expected"), patients with SAD were more likely than those with other anxiety disorders or healthy controls to draw negative conclusions (Stopa & Clark, 2000).

Of course, it is possible that the findings from these self-report studies reflect a response bias for endorsing negative options, rather than an interpretive bias per se. Study designs that employ *implicit* 

measures of interpretive bias address this concern. In the first implicit interpretive bias study, MacLeod and Cohen (1993) asked participants to read passages of text, pressing a button in order to view each successive sentence. Although participants were led to believe that the data of interest were their responses to questions about the passages, the critical data were actually the delays between button presses, which provided an index of the comprehension latency for each sentence. Comprehension latency should be inversely related to the degree to which a participant expected the continuation of the preceding text (e.g., Haberlandt & Bingham, 1978). Indeed, MacLeod and Cohen found that participants with high trait anxiety selectively imposed threatening interpretations on ambiguous sentences, whereas participants with low trait anxiety did the opposite. Another set of implicit studies showed that people with elevated social anxiety are more likely than others to interpret neutral faces in a threatening manner (Yoon & Zinbarg, 2007, 2008).

Most recently, interest has turned to interpretive bias modification procedures, in which negative interpretive biases are systematically altered. Although these methods were originally developed to elucidate the causal role of cognitive biases in mental disorders, they have been shown also to have therapeutic benefits (see MacLeod & Mathews, 2012). Findings indicate that a single interpretive bias modification session may reduce symptoms related to anxiety sensitivity (Steinman & Teachman, 2010), chronic worry (Hirsch et al., 2009), or GAD (Hayes et al., 2010). Moreover, extended sessions appear to significantly reduce trait anxiety (Salemink et al., 2009). There is even evidence that interpretive bias modification is effective with adolescents (Lothmann et al., 2011). Thus, the evidence from interpretive bias modification studies demonstrates that a bias favoring threatening interpretations of ambiguity plays a causal role in the etiology and/or maintenance of anxiety. That said, research on this treatment approach is still in its infancy. Future research will benefit from the application of randomized controlled trials to the study of interpretive bias modification, along with modification procedures for cognitive biases more broadly (cf. MacLeod, 2012).

#### COURAGEOUS MINDSET

Because behavioral avoidance is a hallmark symptom of the anxiety disorders, we might infer that patients with anxiety disorders have a difficult time accessing a "courageous mindset" (i.e., the belief or representation of oneself as being able to face one's fears; Kramer & Zinbarg, 2019). Recent research on individuals with specific fears suggests it may be possible to temporarily prime a courageous mindset and thereby reduce avoidance by prompting recall of memories of courageous behavior (Kramer & Zinbarg, 2019). After writing about a time when they encountered a feared stimulus and avoided it (e.g., individuals who were anxious about public speaking avoiding a public speaking task), individuals were more likely to report they "could not do" fear-relevant tasks (like giving a speech in front of a small audience) and did so more quickly. This suggests a tendency in anxious individuals, when recalling memories of past failures in approach, to see fear-relevant tasks as difficult (or even impossible) at both an explicit and an implicit level. However, when individuals were asked to write about a time when they encountered a feared stimulus and faced it (such as actually *delivering* the speech), they reported they "could do" more fear-relevant tasks and did so more quickly, thus demonstrating that fear-relevant tasks were seen as more possible both explicitly and implicitly. Therefore, the act of recalling an instance of "courage," or facing a feared situation, helped override negative beliefs and made feared situations seem more approachable, at least temporarily. As with other modification treatments addressed above, future studies are needed to address the potential long-term effects of such a priming intervention, perhaps in the context of treating anxiety.

#### SUMMARY

Anxious individuals demonstrate a variety of information-processing biases. They attend more readily to threatening stimuli and have a harder time redirecting their attention away from such stimuli, especially when state (in addition to trait) anxiety is high, when the threat is moderate, and when the threat is in line with the main triggers for their anxiety. Anxious individuals may also have difficulty forgetting information that would be adaptive to forget. Finally, they are more likely to interpret ambiguous information as threatening at both an explicit and an implicit level. However, research on bias-modification tasks, such as ABMTs and interpretive bias modification procedures (IBMPs), provides hope for reducing these biases by providing new treatment methods for individuals with anxiety.

# Interpersonal Factors in Etiology and Disorder Maintenance

# ATTACHMENT

It is well established that adverse early life events are a robust risk factor for psychopathology (Kessler et al., 2010; McLaughlin et al., 2012). In addition, interpersonal and systemic variables are gaining increased attention in the anxiety disorders literature as possible risk factors (e.g., Beck, 2010). Indeed, at least some of the anxiety disorders are associated with difficulties in interpersonal relationships (Whisman, 1999; Whisman & Baucom, 2012). Accordingly, there is a growing body of work highlighting the relevance of attachment, interpersonal functioning, and expressed emotion in the anxiety disorders.

Bowlby (1973) viewed attachment as an evolutionary drive whereby infants develop a relationship to primary caregivers as a survival mechanism. Thus, the development of a secure attachment that is characterized by close proximity with the caregiver and by the perception of safety is hypothesized to allow the infant a secure base from which to explore the world and environment. Conversely, insecure attachment is hypothesized to develop when the caregiver does not provide the conditions of safety and security and is rejecting, inconsistent with attention, or overcontrolling.

These early life experiences in attachment are proposed to lead to the development of an *internal working model*, or a cognitive framework that informs how one interacts with others and the world. These internal working models are reflected in attachment styles that are either secure, insecure-avoidant, or insecure-ambivalent. The development of an insecure attachment style is proposed to be one pathway to development of anxiety disorders (Colonnesi et al., 2011; Esbjørn et al., 2012).

One meta-analysis that examined attachment style and childhood anxiety disorders showed a modest relationship (r = .3) of insecure attachment style with childhood and adolescent anxiety disorders (Colonnesi et al., 2011), especially with insecure-avoidant attachment. Furthermore, a fairly consistent finding is that adult anxious patients retrospectively report having, as children, had an insecure attachment style with their caregivers (e.g., Cassidy et al., 2009; Eng & Heimberg, 2006). For example, Cassidy and colleagues (2009) found that patients with GAD reported poor attachment with their caregivers that was characterized by increased role-reversal/enmeshment in the caregiving relationship, high maternal rejection, and low maternal love. Furthermore, the more cumulative risk factors one endorsed, the greater the likelihood of a diagnosis of GAD. Similarly, Eng et al. (2001) found that patients with a diagnosis of SAD fell into either an anxious-attachment cluster, which was associated with greater symptomatology, or a secure-attachment cluster, which was associated with less symptomatology. Taken together, these studies suggest that early development of insecure attachment styles may represent a risk factor for the development of an anxiety disorder and potentially serve a role in maintenance through adulthood through ineffective styles of interpersonal functioning (Snyder et al., 2010).

#### INTERPERSONAL PROBLEMS

Interpersonal pathoplasticity builds on the pathoplasty model introduced earlier to emphasize the role of interpersonal functioning in the expression of psychopathology. *Interpersonal pathoplasticity*, then, refers to the role of interpersonal functioning in the expression of psychopathology (Klein et al., 1993; for a review see Pincus et al., 2010). An emphasis on interpersonal theory and psychopathology can be traced back to the work of Harry Stack Sullivan, who viewed the expression of psychopathology and personality as occurring through interpersonal situations and relationships (Sullivan, 1953).

Sullivan's ideas were further refined and formalized into a model of interpersonal functioning that could account for the range of interpersonal behavior: the *interpersonal circumplex model* (IPC; Leary, 1957). The IPC is a two-dimensional circular model for organizing interpersonal behavior around two central axes. In Leary's (1957) original model, the poles for each axis are labeled as dominance-submission on the vertical axis and hostility-affection on the horizontal axis. All forms of interpersonal behavior are conceptualized as a combination of these two axes. Although variations of circumplex models have since been proposed, they all share in common the central axes (Fournier et al., 2010).

One of the most commonly used circumplex measures is the Inventory of Interpersonal Problems (IIP; Horowitz et al., 2000). Results of several IIP investigations support the identification of interpersonal subtypes for GAD (Eng & Heimberg, 2006; Przeworski et al., 2011; Salzer et al., 2011). In particular, intrusiveness (inappropriately selfdisclosing, attention seeking, difficulty spending

time alone), exploitable (difficulty feeling and expressing anger for fear of offending others, easily taken advantage of by others), cold (inability to express affection toward others, difficulty forgiving others, difficulty making long-term relationships), and nonassertive (difficulty making needs known to others, difficulty being assertive) appear to emerge as four salient interpersonal clusters. Additionally, IIP studies of interpersonal problems in SAD found in common a friendly-submissive (i.e., exploitable) interpersonal cluster (e.g., Kachin et al., 2001). Another study found an overly nurturant cluster to be associated with the association between anxiety and depression among late adolescents with clinical levels of anxiety (Viana & Stevens, 2013). The relevance of interpersonal problems in anxiety disorders and depression has clear treatment implications. For example, interpersonal problems at pretreatment are associated with reduced response to cognitivebehavioral therapy (CBT) for GAD (Borkovec et al., 2002) and SAD (Cain et al., 2010).

An interpersonally based conceptualization of PD/A has been proposed (Chambless, 2010). However, whereas there does appear to be some evidence that PD/A is associated with interpersonal difficulties; whether interpersonal difficulties represent a unique factor compared with other stressful life events is unclear (Marcaurell et al., 2003). The association between interpersonal problems and agoraphobia appears more robust. For example, Goldstein and Chambless (1978) identified a subset of patients with agoraphobia for whom interpersonal problems was the most common antecedent in the development of PD/A. Similarly, Kleiner and Marshall (1987) found that 84% of agoraphobics recalled experiencing marital/relationship conflicts prior to the onset of the disorder. Furthermore, a notable portion of this sample reported a long history of unassertiveness, dependency, and fear of negative evaluations.

#### EXPRESSED EMOTION

Expressed emotion (EE)—criticism, hostility, and emotional overinvolvement expressed toward a patient by a family member—has received attention as a possible anxiety disorders maintenance factor. Criticism in this context are remarks directed toward the patient expressing disproval or dislike of a specific action the patient does. Hostility may be understood as a more extreme form of criticism that devalues or shames the patient.

Although EE has received considerable attention in the areas of schizophrenia, mood disorders, and eating disorders (Butzlaff & Hooley, 1998; Hooley, 2004), it has only recently been given increased attention in research on anxiety disorders. Research in this area shows that high levels of EE, particularly hostility, are associated with suboptimal treatment response for PD/A (Chambless et al., 2017), SAD (Fogler et al., 2007), and GAD (Zinbarg et al., 2007). Furthermore, high levels of interpersonal conflict are also associated with increased rates of relapse after treatment (McLeod, 1994). However, not all forms of criticism appear to be detrimental to the patient (Chambless & Steketee, 1999; Zinbarg et al., 2007). Whereas hostile forms of criticism are associated with suboptimal treatment response, criticism presented in a nonhostile manner is associated with improved treatment responses for patients with PD/A, GAD, and OCD. However, the precise mechanisms of how hostility and nonhostile criticism influence the maintenance and treatment of anxiety still need to be delineated. A recent development that may foster such research is the creation of a self-report measure distinguishing hostile and nonhostile forms of perceived criticism (Klein et al., 2016).

#### **Conclusion and Future Directions**

Great progress has been made in understanding the anxiety disorders, with widespread consensus on several points. The anxiety disorders are not entirely independent; rather, there are broad factors shared by these disorders (and the unipolar mood disorders). Furthermore, anxiety disorders are heritable, but learning histories, information processing biases, and interpersonal factors also contribute to their etiology or maintenance.

Despite the consensus on several key points that exists in the field, there are still topics regarding the anxiety disorders that require additional research. Thus, whereas a prospective association showing that neuroticism is a marker of risk for anxiety disorders has now been replicated across independent laboratories, prospective longitudinal work is sorely needed to determine directionality of the association between trait PE/E and anxiety disorders. Future research will also benefit from the application of randomized controlled trials to the study of interpretive bias modification, along with modification procedures for cognitive biases more broadly (cf. MacLeod, 2012). Relatedly, future studies are needed to address the potential long-term effects of a courage priming intervention for treating and perhaps even preventing anxiety disorders.

Of the various questions for the field that remain to be addressed, however, two appear most fundamental to us. The first is whether the different anxiety disorder diagnoses truly represent distinct categories (or dimensions that differ in fundamental ways) or inconsequential variations of a broader syndrome that differ superficially in terms of the content of apprehension. The second question is whether several of the risk factors discussed earlier (e.g., neuroticism, BI, anxiety sensitivity, information-processing biases, genetic vulnerability) represent distinct pathways and have unique predictive power. Thus, what the field needs are more studies that include multiple anxiety disorder diagnoses (or dimensions) as outcomes and multiple risk factors. Such designs will enable us to sort out both whether the various anxiety disorders differ at a deep level and whether any of the various risk factors identified to date have unique predictive power.

# Obsessive-Compulsive and Related Disorders

Jonathan S. Abramowitz

Obsessive-compulsive disorder (OCD) is among the most destructive of psychological conditions. Its symptoms often interfere with occupational, academic, interpersonal, and leisure pursuits, not to mention activities of daily living (e.g., watching television, childcare). It is also a complex and highly heterogeneous syndrome, and numerous conceptual approaches have been proposed in an attempt to understand its seemingly perplexing psychopathology. Moreover, the most recent iteration of the DSM shifts OCD from its traditional classification as an anxiety disorder to a new class of conditions: the obsessivecompulsive and related disorders (OCRDs). OCD is the flagship diagnosis within this group of disorders that also includes hoarding disorder (HD), hair-pulling and skin-picking disorders, and body dysmorphic disorder (BDD), all of which are less common than OCD (contrary to what might be assumed, obsessive-compulsive personality disorder (OCPD) is not among the OCRDs in DSM-5). This chapter addresses the nature of OCD and the other OCRDs. The phenomenology and major conceptual models are reviewed, along with their strengths and limitations. The chapter also provides a critical evaluation of the basis for the OCRD category.

# Phenomenology of OCD

Whereas everyone (whether or not they meet the official criteria for "having" OCD) experiences unwanted thoughts and performs ritualistic behavior once in a while, OCD is characterized by *obsessions* and *compulsions* (defined below) severe enough to be time-consuming and which cause distress or functional interference. The severity of the obsessions and compulsions occurs in nature on a continuum from occasional "annoying" intrusive thoughts and compulsive acts to ubiquitous unwanted thoughts, doubts, and urges that, while seemingly senseless, are perceived as signs of danger and threat, along with near constant performance of compulsive rituals. Let us look more closely at these signs and symptoms.

# Obsessions

While the term "obsession" is frequently used in our vernacular to refer to a preoccupation or fixation (e.g., "He's obsessed with his new car"), in the context of OCD, obsessions are persistent repetitive *unwanted* private experiences (i.e., thoughts, images, doubts, and ideas) that the person judges to be senseless or repugnant and that provoke distress in the form of anxiety or guilt. Although highly person-specific, obsessions generally distill into themes such as contamination (e.g., concerns about germs or disgust), responsibility for causing or preventing harm (e.g., "Did I hit a pedestrian, or was that just a speed bump?"), unwelcome thoughts about taboo subjects (e.g., sex, violence, and blasphemy), and the need for order and symmetry ("If I

Abbreviations

BDD	Body dysmorphic disorder
HD	Hoarding disorder
IU	Intolerance of uncertainty
OCD	Obsessive-compulsive disorder
OCRDs Obsessive-compulsive and related	
	disorders
OFC	Orbitofrontal cortex
RFT	Relational frame therapy
SSRI	Selective serotonin reuptake inhibitor
TAF	Thought-action fusion

don't align the book just right, I can't stand to look at the bookshelf").

Unlike other types of repetitive thoughts often described as "obsessive," clinical obsessions are experienced as unwanted or uncontrollable in that they "invade" into and persist in one's consciousness. They often seem to occur spontaneously at what seems like the most inconvenient times (e.g., a blasphemous thought about occurs while in a house of worship) or are triggered by something in the environment (e.g., seeing a knife provokes unwanted thoughts of stabbing a loved one). Obsessions are also inconsistent with the person's self-image (i.e., they are "ego-dystonic"); for example, a man who considers himself intolerant of racism might be plagued by thoughts of yelling racial epithets. Finally, obsessions are resisted: individuals try to "deal with," neutralize, or completely avoid these kinds of experiences. The motivation to resist is activated by the fear that if action is not taken, negative consequences will ensure.

# Compulsions

Compulsions are urges to engage in deliberate overt or mental behaviors (often called *rituals*) in an effort to reduce the distress associated with obsessions (or the obsessional thought itself). Rituals, which are functionally related to obsessions (e.g., checking to allay obsessional doubts of leaving the door unlocked), typically belong to the following categories: decontamination (washing/cleaning), checking (e.g., ensuring that the stove is off, repeatedly asking for reassurance), repeating routine activities (e.g., rewriting one's name or walking back and forth through a doorway), ordering and arranging (e.g., books on a shelf), and mental rituals (e.g., repeating a prayer or mantra). These behaviors are often performed according to self-prescribed rules and are usually recognized (at least to some extent) as senseless and excessive (although, discussed further below, insight into the senselessness of these symptoms varies from person to person).

In contrast to involuntary repetitive behaviors such as motor tics, rituals are calculated. That is, the person willfully performs the behavior. This relates to the final defining feature of compulsive rituals: they have a specific function—namely, to reduce distress. This function stands in contrast to *impulsive* behaviors (e.g., hair-pulling or skinpicking), which are carried out because they produce pleasure, distraction, or gratification. Yet although rituals often lead to a reduction in distress, such relief is usually temporary. Moreover, rituals maintain obsessional fear by preventing the natural extinction of fear. That is, if the person with OCD routinely ritualizes (e.g., washes her hands), she never has a chance to learn that her obsessions (e.g., fears of becoming ill from contamination) are not true danger signals.

# Avoidance

Although not mentioned in the DSM-5 criteria for OCD, avoidance behavior is another strategy commonly deployed in response to obsessions, usually to avert unwanted thoughts, negative outcomes, uncertainty, and compulsive urges. Avoidance is intended to prevent exposure to situations that would provoke obsessions and necessitate compulsive rituals. For example, one woman avoided driving past cemeteries because they evoked unwanted obsessional thoughts of loved ones dying. Other people engage in avoidance so that they do not have to carry out time-consuming or embarrassing rituals. For example, one person avoided home and garden stores so that he would not have to engage in extensive showering rituals, which he believed were necessary if he was exposed to pesticides and other household chemicals. Ultimately, avoidance is problematic because it does not provide an opportunity for the individual to come into contact with the feared situation and learn that the feared outcomes are unlikely to materialize. Thus, like rituals, avoidance maintains obsessional fear by preventing the natural extinction of obsessional fears. This leads to the escalating vicious cycle typical of OCD.

# Symptom Dimensions

Research has identified reliable and valid symptom dimensions comprised of both obsessions and compulsions (e.g., Abramowitz et al., 2010; McKay et al., 2004). These dimensions include (a) contamination (contamination obsessions and decontamination rituals), (b) responsibility for harm and mistakes (obsessions about harm or mistakes and checking/reassurance-seeking rituals), (c) incompleteness (obsessions about order or exactness and arranging rituals), and (d) unacceptable taboo violent, sexual, or blasphemous thoughts with mental rituals. These themes often overlap and many people experience multiple themes, thus these dimensions are not ways to categorize individuals with OCD (e.g., "washers" or "checkers"), but rather for categorizing the different manifestations of OCD. Even so, this categorization system is far from perfect. Some individuals with obsessional thoughts about sex, for example, use decontamination rituals to "wash away their dirty thoughts." Others may experience obsessions that seem difficult to fit into any of these categories (e.g., obsessional thoughts about existential questions or about whether one is "really" in love with her partner).

# Ego Dystonicity

Ego dystonicity refers to the degree to which one's obsessions are inconsistent with the ways in which he or she views him- or herself with respect to ideals and morals (Clark, 2004). Given that obsessions typically focus on topics that are repugnant to the individual, they are perceived as a threat to one's self. Not surprisingly, the nature of obsessive concerns may lead one to question his or her character ("What if I really am a pedophile!?"). Ego dystonicity is most apparent in the unacceptable (taboo) thoughts symptom dimension, as obsessional thoughts about blasphemy, unbidden sexual ideas (e.g., incest), or violently murdering someone run counter to traditional moral codes. Furthermore, obsessions focused on vulnerable people (i.e., ideas of harming young children, the weak, or frail; Berman et al., 2012) may elicit increased guilt and distress and cause individuals to fret about "latent sexual and aggressive desires" (Clark, 2004, p. 29). Ego dystonicity also arises among meticulous individuals with OCD who may be troubled by obsessive doubt related to making mistakes, which could be considered intolerable and out of line with one's standards. This quality of ego dystonicity among obsessive beliefs also separates obsessions and compulsions in the context of OCD from other repetitive behaviors such as hair-pulling, which may produce pleasure.

#### Insight

As already alluded to, the insight one has into the senselessness of his or her obsessions and compulsions varies widely. While some individuals recognize the irrationality of their OCD symptoms (e.g., "I realize the probability of dying from using a public bathroom is very low, but I just can't take the chance"), others hold a firm conviction that these intrusive thoughts and behaviors are rational (e.g., "Public bathrooms are extremely dangerous and I would get sick and die if I did not avoid them"). Insight may shift over time and can vary according to different symptom domains. For example, one might recognize that her obsessive thoughts about bad luck from the number 666 are senseless yet simultaneously have poor insight into the irrationality of her obsessions about contamination.

DSM-5 criteria for OCD include the specifiers "good or fair insight," "poor insight," and "absent insight" (p. 237) to denote the degree to which the person views his or her obsessional fears and compulsive behavior as reasonable. Although many individuals with OCD recognize-to some degree-that their obsessions and compulsions are senseless and/or extreme, about 4% are convinced that their symptoms are realistic (i.e., poor or absent insight; Foa et al., 1995). Individuals with poor insight lack self-awareness regarding their obsessions and compulsions. Individuals with delusional conviction believe that their obsessions are realistic and reasonable, and such poor insight appears to be associated with religious obsessions, fears of mistakes, and aggressive obsessional impulses (Tolin et al., 2001).

#### Need for Certainty

Intolerance of uncertainty refers to beliefs about the necessity of being certain, the capacity to cope with unpredictable change, and beliefs about how to function in situations which are inherently ambiguous (Obsessive Compulsive Cognitions Working Group, 1997). Intolerance of uncertainty is a key cognitive phenomenon associated with OCD as individuals often report pathological doubt with their obsessions (e.g., "I need to know for certain that I have not sinned"). Those with a greater intolerance of uncertainty characteristically find uncertainty to be stressful and upsetting, believe that uncertainty should be avoided at all costs, and experience impairment in uncertain or ambiguous situations. Although this uncertainty may be most visible and applicable in certain overt rituals (e.g., checking behaviors within the responsibility for harm symptom domain), it is present across OCD symptom manifestations. This doubt may be due to impairments in memory and/or diminished confidence in one's memory (Foa et al., 1997); relatedly, rituals may stem from a heightened desire for certainty (i.e., intolerance of uncertainty) and memory vividness.

#### **Prevalence and Course**

The lifetime prevalence estimates of OCD are between 0.7% and 2.9% (Kessler et al., 2005), with slightly higher prevalence rates among females than among males (Bogetto et al., 1999). The disorder typically begins by age 25 but can onset at any age; childhood or adolescence onset is common. Average age of onset, however, is slightly earlier in males (about 21 years) than in females (22–24 years; Rasmussen & Eisen, 1992). The course of OCD tends to be chronic and deteriorating, with a low rate of spontaneous remission. Left untreated, symptoms fluctuate and are often exacerbated during periods of increased life stress. Although effective treatments exist, full recovery is the exception rather than the rule.

#### Interpersonal Aspects of OCD

OCD often occurs in an interpersonal context and negatively impacts the person's relationships, including family relationships and intimate partnerships (e.g., marriage). In turn, dysfunctional relationship patterns can promote the maintenance of OCD symptoms such that a vicious cycle continues. In an attempt to demonstrate care and concern for an affected individual, a family member, partner, or spouse might inadvertently behave in ways that maintain OCD symptoms by helping with compulsive rituals and avoidance behavior (i.e., symptom accommodation). Conversely, arguments about the seeming illogic of one's OCD symptoms may also create relationship distress and conflict, which further exacerbate the anxiety and obsessional symptoms (Boeding et al., 2013).

# Symptom Accommodation

Accommodation occurs when a friend or relative without OCD participates in (or facilitates) rituals, avoidance strategies, assumes daily responsibilities for the person with OCD, or helps to resolve problems that have resulted from that person's obsessions and compulsions. Accommodation can occur at the request (or demand) of the affected individual, who intentionally solicits help for controlling his or her anxiety. In other instances, loved ones voluntarily accommodate as a way of expressing care and concern or to prevent their loved one from becoming highly anxious. Conceptually, this sort of accommodation perpetuates OCD symptoms by the same mechanism as avoidance and compulsive rituals. For instance, consider a man with obsessional fears of assaulting loved ones who requests that his partner keep all of the knives locked away. By assisting with locking up the knives (i.e., by accommodating her partner's OCD symptoms), she prevents her partner from learning that he's unlikely to act on these unwanted thoughts. Furthermore, he misses the opportunity to learn that he could manage the temporary anxiety that accompanies his repugnant obsessions.

# Relationship Conflict

Relationship stress and conflict play an important role in the maintenance of OCD as well. Families in which a member suffers from OCD often report problems with interdependency, unassertiveness, and avoidant communication patterns that foster stress and conflict. This is likely a bidirectional relationship, as OCD symptoms and relationship distress influence each other. For example, a husband's contentious relationship with his wife might contribute to overall anxiety and uncertainty that feeds into his obsessional doubting. His excessive checking, reassurance seeking, and overly cautious actions could also precipitate frequent disagreements. In particular, poor problem-solving skills, hostility, and criticism might increase distress and contribute to OCD.

# **Conceptual Models of OCD**

Models Based on Conditioning and Learning Theory

Throughout the twentieth century, conditioning models were developed to understand fear-based problems (including "obsessional neurosis," which would later come to be called OCD). A predominant approach was Mowrer's two-factor theory (Mowrer, 1960), which proposed that obsessional fears were acquired by classical conditioning and maintained by operant conditioning (i.e., negative reinforcement). For example, an obsessional fear of harming one's child could arise from an incident in which the person had an aversive experience (the unconditioned stimulus, which could include an unwanted thoughts and anxiety) in the presence of their child (the conditioned stimulus), leading to a classically conditioned fear. Negative reinforcement then maintains the obsessional fear. That is, avoiding or escaping from distress (e.g., by avoiding one's niece) or engaging in compulsive rituals (e.g., by "neutralizing" the unwanted thoughts with a mantra such as "I am a good person") serves to reduce anxiety and prevent the disconfirmation of feared consequences.

Conditioning models, however, have their limitations. For one thing, many people with OCD do not recall conditioning experiences in the context of their obsession that would have led to the development of obsessional fear. Conversely, many people who have experiences expected to lead to the development of obsessions do not develop OCD. Second, learning models have difficulty explaining the emergence, persistence, and content of repugnant sexual, religious, and violent obsessions (e.g., obsessional images of Jesus with an erection on the cross). Third, this model fails to explain why the themes and content of obsessions and compulsions may shift for an individual over time. With these limitations in mind, theorists in the latter half of the twentieth century began to consider the role that cognitive processes play in the development and persistence of OCD.

# **Cognitive Deficit Models**

One school of thought was that people with OCD have cognitive *deficits*—dysfunctions in thought or mental processing, which may have neurobiological or neuropsychological origins. The idea that individuals with OCD suffer from cognitive processing deficits is tempting since it appears that, for example, those with checking rituals have a memory problem that keeps them from being able to recall whether or not they completed an action, such as locking the door. Alternately, individuals could have a deficit in their ability to accurately recall whether they actually turned off the oven or merely imagined doing so (i.e., a reality monitoring deficit). Research findings, however, provide little support for these and other types of memory or executive functioning problems in OCD (Abramovitch et al., 2013; Abramovitch & Cooperman, 2015). In fact, rather than memory deficits, the most consistent finding in the literature has been that individuals with OCD have less confidence in their own memory than do individuals without OCD (Woods et al., 2002).

Cognitive deficit proponents have also examined whether the intrusive, repetitious, and seemingly uncontrollable quality of obsessional thoughts is the result of deficits in cognitive inhibition—the inability to stop thinking about something. Perhaps, for example, individuals with OCD are less able than neurotypical (healthy) individuals to forget or dismiss thoughts about senseless mental stimuli. Indeed, on tests of recall and recognition, individuals with OCD have more difficulty forgetting negative material (and material related to their OCD concerns) relative to positive and neutral material than do healthy control subjects (Tolin et al., 2002).

Poor cognitive inhibition might explain the high *frequency* of obsessional thoughts, yet the idea that OCD arises from general cognitive deficits has not added to our understanding of or ability to treat the problem. Apparent memory and processing deficits are better accounted for by *cognitive biases* in which obsessional anxiety leads to preoccupation and preferential processing of threat-relevant stimuli. For example, individuals who possess a biased

perception that they are responsible for negative events or outcomes may have reduced confidence in their memory, leading to compulsive checking. Checking rituals may function as a way of reducing doubts that have arisen because of mistaken beliefs about one's memory and ability to manage uncertainty and pathological overestimates of responsibility for harm. These types of mistaken beliefs are the focus of the cognitive specificity hypothesis of OCD, as described next.

# **Cognitive Bias Models**

Borrowing from Beck's (1976) cognitive model of depression, cognitive bias models of OCD propose that obsessions and compulsions arise from certain types of maladaptive interpretations (i.e., dysfunctional beliefs). For example, exaggerated beliefs about personal responsibility might cause one to become excessively concerned and engage in excessive checking rituals when the everyday thought, "Am I sure I locked the door before leaving the house?" comes to mind (Salkovskis, 1985). Beliefs about the overimportance of thoughts might have a similar effect. For example, the belief that it is wrong, dangerous, or otherwise personally significant to think about immoral topics (e.g., "Only rapists think about rape") has been linked to certain dimensions of OCD symptoms (e.g., Wheaton et al., 2010).

Given the heterogeneity of OCD symptoms, a number of overlapping cognitive bias models have proliferated. Among these is Salkovskis's (1985) cognitive approach, which starts with the finding that virtually everyone experiences unwanted thoughts at some point (i.e., thoughts, images, and impulses that intrude into consciousness; e.g., Rachman & de Silva, 1978). Such "normal" or "nonclinical" unwanted thoughts tend to be less frequent, less distressing, and shorter in duration than "clinically significant" obsessions that are characteristic of individuals with OCD. Clinical and nonclinical obsessions, however, share similar thematic content such as violence, contamination, sex, and doubts. Thus, a model of OCD must delineate why many individuals experience intrusive thoughts, yet only a small percentage experience clinical obsessions.

Salkovskis suggested that intrusive thoughts reflect the person's current concerns and are triggered by internal or external cues that remind the person of his or her concerns. For example, intrusive thoughts about accidentally hitting pedestrians with an automobile may be evoked by driving past people walking on the side of the road. Salkovskis asserted that nonclinical intrusive thoughts only escalate into obsessions when they are appraised as having consequences for personal responsibility (e.g., the intrusive image of pushing a stranger in front of an oncoming train). Although upsetting, most people experiencing such an intrusion would not regard it as personally meaningful or as having harm-related implications (i.e., it would be considered, and subsequently dismissed, as "mental noise"). Such an intrusion might develop into a clinical obsession, however, if the person appraises it as indicating that he or she has the responsibility for causing or preventing the accompanying disastrous consequences. For example, if the person made an appraisal such as the following: "Thinking about pushing a stranger in front of an oncoming train means that I'm a dangerous and immoral citizen who must take extra care to ensure that I don't lose control." Such interpretations evoke distress and motivate the individual to try to suppress or remove the unwanted intrusion (e.g., by replacing it with a "good" thought) and to attempt to prevent the content of the intrusion from actually occurring (e.g., by avoiding subway platforms). Thus, compulsive rituals are cast in this model as efforts to remove intrusions and prevent any perceived harmful consequences.

The question remains: Why do some, but not all, people interpret and appraise intrusive thoughts in terms of harm and responsibility? Beck (1976) proposed that our experiences form the basic assumptions we hold about ourselves and the world, including beliefs about personal responsibility and about the significance of unwanted thoughts (e.g., the core belief that all our thoughts are significant). Such beliefs may be acquired from a strict moral or religious upbringing or from other experiences that teach the person extreme or rigid codes of conduct and responsibility (Salkovskis et al., 1999).

Why doesn't a person with OCD recognize these thoughts as senseless and dismiss them? Salkovskis proposed that rituals develop and persist as coping strategies for obsessional thoughts for two reasons. First, compulsive rituals are reinforced by the immediate (albeit temporary) reduction in obsessional distress that they often produce (i.e., negative reinforcement, as in the conditioning model). Second, they maintain obsessions by preventing the person from learning that his or her beliefs and appraisals are unrealistic. That is, when a person ritualizes, she fails to learn that obsessional thoughts and situations aren't dangerous. Instead, she continues to believe that a catastrophe would have occurred had she not performed the ritual. Other theorists (Rachman, 2003) have similarly proposed that compulsive rituals increase the frequency and repetitiveness of obsessions by serving as reminders of intrusions (i.e., retrieval cues) and thereby triggering their reoccurrence. For example, compulsive reassurance seeking can remind the person of his or her obsessional doubts. Therefore, attempts to distract one's self from obsessional thoughts can paradoxically increase the frequency of these thoughts and images. Rituals can also strengthen one's perceived responsibility. For example, when the feared consequences of thinking a violent thought do not occur after performing a mental ritual, it strengthens the perception of personal responsibility (i.e., that the person is solely responsible for removing the potential threat and must continue to prevent it from happening in the future).

In summary, cognitive bias models of OCD "cognitive-behavioral (often termed models" because they involve both cognitive and behavioral processes) propose that obsessions and compulsions develop when a person habitually misinterprets normal intrusive thoughts as posing a threat for which he or she is personally responsible. This leads to distress and attempts to remove the intrusion to alleviate discomfort and prevent the feared consequences. But this response paradoxically increases the frequency of intrusions. Thus, the intrusions become persistent and distressing, and they escalate into clinical obsessions. Compulsive rituals maintain the obsessions and prevent the person from evaluating the accuracy of his or her interpretations. Avoidance is analogous to compulsive rituals in that avoidance functions as a strategy for reducing anxiety. Avoidance and rituals differ in that avoidance is a passive anxiety reduction strategy and ritual use is an active strategy.

Salkovskis's model emphasizes the role of responsibility appraisals of intrusive thoughts. Other authors, however, have developed additional cognitive models by expanding on the types of dysfunctional beliefs and appraisals that contribute to OCD. Although these cognitive models differ in some ways, they are more similar than they are different. Most of the differences between these models relate to the emphasis that they give to certain types of dysfunctional beliefs. Rachman (2003), for example, focuses on beliefs concerning the significance of intrusive thoughts (e.g., "If I think an immoral thought, it means I'm an immoral person"). Thus, for Rachman, obsessions arise when the person misinterprets the intrusive thought as implying that he

or she is bad, mad, or dangerous. Thought-action fusion (TAF) is an important concept in this model (Shafran et al., 1996). TAF refers to the notion that one's unwanted thoughts will inevitably be translated into actions (i.e., likelihood TAF; e.g., "I might cause my father to have a car accident just by thinking about it") or that thoughts are the moral equivalent of actions (i.e., moral TAF; e.g., "Thinking about pushing a stranger in front of an oncoming train is just as bad as actually doing it"). The most comprehensive contemporary cognitive model of OCD was developed collaboratively by members of the Obsessive Compulsive Cognitions Working Group (OCCWG; Frost & Steketee, 2002). The OCCWG model accounts for the heterogeneity of OCD symptoms by proposing that particular beliefs (or patterns of beliefs) are important for specific types of OCD symptoms.

#### Implications of the Model

From a cognitive-behavioral perspective, OCD can be understood as involving intact learning (conditioning) processes and normally functioning (albeit biased and maladaptive) cognitive processes. Avoidance and compulsive rituals are excessive responses to obsessional fears because the threat level is objectively low, yet they keep the person afraid by preventing him from recognizing this. That is, when a ritual is performed, the individual attributes safety to the ritual, rather than changing his danger expectations. Thus, a self-perpetuating vicious cycle develops, which we call "OCD."

This approach also implies that the successful treatment of OCD must (a) correct the maladaptive beliefs and appraisals that give rise to obsessional fear and (b) halt avoidance behavior and rituals that block the correction of maladaptive beliefs. Put differently, effective cognitive behavior therapy (CBT) for OCD promotes an evaluation of obsessional stimuli as nonthreatening and not requiring any further action by the individual. The person must understand their problem not in terms of the risk of feared outcomes, but rather in terms of how they are responding to obsessional thoughts and cue stimuli that objectively represent a low risk of danger.

#### Empirical Status

A review of numerous cross-sectional studies revealed a consistent relationship between OCD symptoms and the tendency to overestimate the likelihood of harm and interpret intrusive thoughts as meaningful, threatening, or in terms of responsibility for harm (Abramowitz et al., 2014). Yet the correlational data in these studies do not address causal relationships. Laboratory experiments, which can be used to draw causal conclusions, have also consistently shown that cognitive distortions can lead to obsessive-compulsive phenomena in a laboratory setting (e.g., Rassin et al., 1999). Such studies, however, do not necessarily generalize to the development of OCD in naturalistic settings. Thus, longitudinal studies in which individuals are assessed for cognitive variables and then followed up after some critical event have been conducted to address this limitation. In one such study, Abramowitz and colleagues (e.g., Abramowitz et al., 2006) administered measures of OCD-related dysfunctional beliefs to samples of first-time expecting parents (mothers and fathers-to-be) during the third trimester of pregnancy. Between 2 and 3 months after childbirth, these new parents were again assessed for the presence and intensity of OCD symptoms. These investigators found that after controlling for baseline levels of obsessive-compulsive symptoms and trait anxiety, OCD-related dysfunctional beliefs pre-child birth were a significant predictor of obsessive-compulsive symptom intensity in the postpartum period.

As additional evidence for this model, Timpano, Abramowitz, Mahaffey, Mitchell, and Schmidt (2011) developed a prevention program that taught expecting parents with high levels of TAF about the normalcy of intrusive thoughts and how to use cognitive-behavioral methods based on the Salkovskis's (1985) model to manage such intrusions if and when they occurred once their child was born. Indeed, relative to a group that received a parallel control intervention, the group receiving the cognitive-behavioral prevention program demonstrated reduced distress associated with intrusive thoughts during the postpartum.

# Psychological Models Emphasizing Acceptance of Unwanted Thoughts

Despite the strong empirical support for cognitive-behavioral models of OCD, cognitive biases such as TAF do not entirely account for OCD symptoms in statistical models (e.g., Taylor et al., 2006). Accordingly, scholars have applied constructs relevant to acceptance and commitment therapy (ACT) to understand and treat OCD. Grounded in functional contextualism and relational frame theory (RFT), ACT (Hayes et al., 2011) is an experiential approach to conceptualizing and treating psychological conditions that shares philosophical assumptions with behavioral

187

approaches and suggests that the context (e.g., historical, situational) in which behavior evolves is useful for predicting and changing psychological events. Events with a similar *form* may serve different *functions*; for example, checking the oven is only conceptualized as a compulsion in OCD when considered in relation to the presence of obsessional thoughts of responsibility for starting a fire and the function of the checking behavior.

Two constructs from within this framework are thought to be related to OCD: experiential avoidance and cognitive fusion. Experiential avoidance refers to attempts to control or avoid unwanted internal experiences such as emotions (e.g., anxiety). Cognitive fusion is the tendency to take internal experiences (e.g., thoughts) as literal facts rather than viewing them simply as private events. A growing literature supports the relationship between these constructs and OCD symptoms (e.g., Reuman et al., 2018), as well as the efficacy of ACT in the treatment of OCD (see Bluett et al., 2014, for a review). Within ACT, the client is helped to observe (i.e., accept) unwanted private experiences (e.g., obsessional thoughts, anxiety, and uncertainty), rather than seeing them as important or requiring avoidance or ritualistic responses. The client is also helped to commit to pursuing important life activities despite the presence of unwanted private experiences.

#### **Biological Models**

#### SEROTONIN HYPOTHESIS

Serotonin is a monoamine neurotransmitter thought to play a role in the regulation of mood, appetite, and sleep. Originally proposed in the context of depression, the "serotonin hypothesis" proposes that OCD symptoms arise from abnormalities in this neurotransmitter system, specifically a hypersensitivity of the postsynaptic serotonergic receptors (Zohar & Insel, 1987). Three lines of evidence are cited to support this idea: medication outcome studies, biological marker studies, and biological challenge studies in which OCD symptoms are evoked using serotonin agonists and antagonists. Published pharmacotherapy studies consistently show that selective serotonin reuptake inhibitor (SSRI) medications (e.g., fluoxetine), which are thought to manipulate available levels of serotonin, are more effective than placebo and medications with other presumed mechanisms of action (e.g., imipramine) in reducing OCD symptoms. Yet studies of biological markers—such as blood and cerebrospinal fluid levels of serotonin metabolites—have provided inconclusive results (Insel et al., 1985). Similarly, pharmacological challenge studies are largely incompatible with the serotonin hypothesis (Hollander et al., 1992).

#### STRUCTURAL MODELS

Structural models posit that OCD is caused by neuroanatomical and functional abnormalities in the brain's orbitofrontal-subcortical circuits, which are thought to connect brain regions involved in processing information with those involved in the initiation of behavioral responses. These models spring from neuroimaging studies in which activity levels in specific brain areas are compared between people with and without OCD. Investigations using positron emission tomography (PET) have found that increased glucose utilization in the orbitofrontal cortex (OFC), caudate, thalamus, prefrontal cortex, and anterior cingulate is correlated with the presence of OCD (i.e., greater in patients compared to nonpatients; e.g., Baxter et al., 1988). Studies using single photon emission computed tomography (SPECT) have reported decreased blood flow to the OFC, caudate, various areas of the cortex, and thalamus in OCD patients compared to nonpatients (for a review, see Whiteside et al., 2004). Finally, studies comparing individuals with OCD to healthy controls using magnetic resonance spectroscopy (MRS) have reported decreased levels of various markers of neuronal viability in the left and right striatum and in the medial thalamus (e.g., Fitzgerald et al., 2000). Although findings vary, a meta-analysis of 10 PET and SPECT studies revealed that individuals with OCD display more activity in the orbital gyrus and the head of the caudate nucleus in comparison to healthy controls (Whiteside et al., 2004).

#### GENETIC CONTRIBUTIONS

Although some findings suggest that OCD symptoms are heritable, with "likely common genetic influences of modest effect" (Stewart et al., 2013), there is no evidence that a particular gene influences OCD symptoms (Stewart et al., 2013). OCD is also more common among first-degree relatives with OCD than among first-degree relatives of people without the disorder (Hettema et al., 2001). Moreover, twin studies suggest that obsessivecompulsive symptoms are heritable (van Grootheest et al., 2007). Although this is commonly understood to imply that genes are responsible, familial environmental factors cannot be ruled out, of course.

#### EVALUATION OF BIOLOGICAL MODELS

One key limitation of the serotonin hypothesis is that its strongest evidence come from the apparent superiority of serotonergic medication over other sorts of pharmacotherapies. Yet since the serotonin hypothesis originated from the findings of preferential efficacy of serotonergic medication over nonserotonergic antidepressants, the assertion that the effectiveness of these medications supports the serotonin hypothesis is circular. There is also a logical fallacy in drawing conclusions about the cause of a problem from its treatment. This is a logical fallacy called post hoc ergo proper hoc (i.e., "after this therefore because of this"), which is exemplified by the example: "the rooster crows before sunrise, therefore the crowing rooster causes the sun to rise." Similarly, just because a serotonergic agent reduces OCD symptoms doesn't mean a dysfunction in serotonin (which has not been found in direct studies of this neurotransmitter system) caused the symptoms to begin with.

Another problem with biological causal models is that they are based on correlational studies, which do not address (a) whether true abnormalities exist, and (b) whether the observed relationships are causal. That is, whereas neuroimaging studies comparing OCD patients to control participants show associations between OCD symptoms and brain structure or function, they do not reveal whether any differences in the brain predate the development of OCD or whether it is something about having OCD that causes changes in the brain. Unassessed third variables might also influence both OCD and the brain. Moreover, most neuroimaging studies compare individuals with OCD to nonpatients, rather than to people with other psychiatric diagnoses. Thus, there is no way to know whether the findings are specific to individuals with OCD or a characteristic of those with various sorts of psychopathology. Despite decades of research on biological models of OCD, the evidence that specific biological factors play an etiological role is weak. In fact, a large international study group reviewed the existing literature and reached the consensus that there are no biological or genetic markers of OCD (Bandelow et al., 2016, 2017).

# **Obsessive-Compulsive Related Disorders**

The rationale for moving OCD out of the anxiety disorders and into the new OCRD category in *DSM-5* was that OCD and the proposed "related disorders" overlapped in terms of their overt symptom presentation (Hollander et al., 2011). Later, this rationale was expanded to include the idea that these disorders fall along a continuum of failure in behavior inhibition (i.e., the inability to cease one's actions), with compulsive and impulsive behaviors at opposite ends of the spectrum (Hollander et al., 2011). At one end of the continuum are "compulsive disorders" such as OCD and BDD; impulse control problems (e.g., skin-picking and hair-pulling) fall at the other end of the continuum. This section provides an overview of the disorders currently grouped within this category.

# Hair-Pulling Disorder

Hair-pulling disorder (formerly known as trichotillomania) involves recurrent hair-pulling resulting in hair loss despite repeated attempts to stop. The hair-pulling behavior may be automatic (i.e., outside of the person's awareness) or focused (i.e., in response to an urge, impulse, or negative affect). It is easy to see how the repetitive (seemingly "compulsive") nature of hair-pulling might appear similar to that of repetitive compulsive rituals in OCD. A more nuanced examination, however, reveals key distinctions. Although OCD and hairpulling disorder both involve repetitive behavior, the intrusive anxiety-evoking obsessional thoughts that occur in OCD are not present in hair-pulling disorder. Whereas obsessional fear motivates rituals in OCD, it is feelings of general tension, depression, anger, boredom, frustration, indecision, or fatigue that precipitate urges to "compulsively" pull hair (Christenson et al., 1993). Hair-pulling, unlike rituals in OCD, also leads to pleasurable feelings (e.g., Schreiber et al., 2011).

Behavioral models of hair-pulling emphasize the role of learning. For instance, Azrin and Nunn (1973) argued that urges to pull hair become conditioned responses to one or more situations (e.g., being alone), internal sensations (e.g., tension), or activities (e.g., reading). Pulling is followed by feelings of sensory stimulation or gratification that serve as an escape from negative feeling states, thereby reinforcing (both positively and negatively) the pulling behavior (Woods et al., 2008).

More recently, cognitive factors have been incorporated into models of hair-pulling. Franklin and Tolin (2007), for example, argued that dysfunctional beliefs can increase negative emotion in people with hair-pulling disorder, thereby increasing urges to pull. These include perfectionistic beliefs, beliefs about the persistence and controllability of urges to pull (e.g., "The urge will last forever unless I pull"), beliefs about the hair-pulling habit itself ("This is an appalling behavior"), and beliefs about negative evaluation from others ("Other people will notice my hair loss and won't want to associate with me"). Episodes of hair-pulling may also be exacerbated by beliefs about the positive effects of hair-pulling (e.g., "Hair-pulling will make me feel better") and facilitative thoughts (e.g., "I'll just pull one more").

Few studies, however, have examined the role of cognition in hair-pulling disorder. Norberg and colleagues (2007) assessed, in a self-described sample of people with hair-pulling problems, beliefs pertaining to appearance and shame or social rejection in regard to hair-pulling. These beliefs were correlated with the severity of the person's hair-pulling. Similarly, Rehm and colleagues (2019) found that negative self-beliefs, perfectionism, and low coping efficacy were significantly related to hair-pulling severity in a study of individuals with self-reported hair-pulling behaviors. Although these findings are consistent with a cognitive perspective on hairpulling disorder, it remains unclear whether the faulty beliefs are a cause or consequence of increased hair-pulling behavior.

# Skin-Picking Disorder

With nearly identical diagnostic criteria to hairpulling disorder, skin-picking disorder (i.e., excoriation disorder) also does not involve obsessional thoughts, and repetitive skin-picking functions differently than do compulsive rituals in OCD. Clinically significant skin-picking may be triggered by an array of antecedents (e.g., general stress, apprehension, boredom, tiredness; e.g., Arnold et al., 2001), and emotion regulation difficulties (i.e., emotional reactivity) have been shown to be associated with skinpicking (Snorrason et al., 2010). Skin-picking can also be triggered by the feel (e.g., a bump or unevenness) or look (e.g., a blemish or discoloration) of the skin. In contrast to deliberate, anxiety-reducing compulsive behavior in OCD, episodes of skin-picking often begin outside of the person's awareness (i.e., they are unfocused), and the individual becomes more fully aware of his or her skin-picking after a period of time (Keuthen et al., 2000).

Skin-picking behaviors frequently co-occur with hair-pulling, and the two disorders share characteristics such as automatic and focused styles and a similar range of negative emotional states as triggers. As with OCD, skin-picking disorder involves repetitive, compulsive behaviors, albeit specifically related to skin-picking, which are often completed in a ritualistic manner (Phillips & Stein, 2015); however, functional differences exist between OCD and skin-picking. That is, there are no obsessions or obsessional fears that lead to "compulsive" skin-picking.

Conceptual models of skin-picking disorder focus on reinforcement and emotion regulation (Lang et al., 2010). As with hair-pulling, skinpicking may be preceded by emotional or sensory antecedents and subsequently reinforced by the removal of these negative stimuli. The role of cognition in skin-picking remains largely uninvestigated, except as part of treatment studies exploring the use of cognitive, cognitive-behavioral, or other treatments (Lochner et al., 2017). Commonly encountered dysfunctional cognitions include those related to low self-efficacy and impaired control (Schuck et al., 2011).

# Body Dysmorphic Disorder

BDD is characterized by a preoccupation with perceived physical defects or appearance flaws (e.g., the belief that one's ears are too large) and excessive repetitive behaviors (e.g., checking one's appearance) or mental acts (e.g., comparing oneself to others) that are performed to relieve the distress associated with the preoccupation. The appearancerelated preoccupations in BDD are similar to obsessions in OCD because both trigger anxiety or distress. Similarly, avoidance and excessive behaviors to conceal, correct, check, or seek reassurance about the imagined defects among people with BDD serve a similar function as compulsive rituals in OCD; namely, to reduce distress. For instance, some individuals with BDD check their appearance for prolonged periods of time, looking in mirrors, windows, and so forth. Others focus their energies on avoiding all reflective surfaces. Additional compulsive behaviors include comparing oneself to others, defect-related skin-picking, reading all relevant information on the body part(s) of concern, measuring the "flawed" body part(s), and seeking cures (e.g., cosmetic procedures) for perceived defects (Fang & Wilhelm, 2015).

Veale's cognitive-behavioral model (2004) is the best articulated conceptual model of BDD. It begins with the proposition that episodes of heightened concern with body image in BDD are often precipitated by "external representations" of the individual's appearance (e.g., seeing one's reflection), which triggers a dysfunctional mental image. Through selective attention toward appearancerelated details, the individual experiences heightened awareness of specific characteristics within the image and thereby assumes that the perceived defect is clearly apparent to other people. This imagery is associated with heightened self-focused attention, to the extent that, in more severe cases of BDD, all of the individuals' attention may be focused on the distorted image and on the negative evaluation of the image.

According to this conceptualization, the afflicted person also negatively appraises his or her appearance in the context of dysfunctional beliefs about the importance of physical appearance. The individual may hold beliefs such as, "If I'm unattractive, life isn't worth living." Beliefs regarding inadequacy, worthlessness, abnormality, and rejection are also implicated as the person compares his or her "defective" features with the ideal. These emotional responses lead to behaviors such as avoidance or active escape and concealment of the imagined defect, to prevent the feared outcomes and reduce distress. Although these avoidant behaviors may temporarily alleviate distress, in the long run they maintain the self-consciousness preoccupation with the imagined defect and negative appraisal of oneself.

There are a number of studies that support this model (see Fang & Wilhelm, 2015, for a review). For example, studies show that people with BDD pay close attention to minute details and features rather than to global figures, which might explain the focus on specific appearance-related details (Feusner et al., 2007). Grocholewski and colleagues (2012) found that individuals with BDD demonstrated greater selective attention to imagined defects in their faces and corresponding areas on unfamiliar faces compared to healthy controls or individuals with social phobia. These findings are consistent with the attentional biases and imagerelated preoccupations proposed in the cognitivebehavioral model.

#### Hoarding Disorder

HD is characterized by excessive acquisition and difficulty discarding or parting with possessions even those of limited value—due to (a) the perceived need to save such items and (b) distress associated with discarding them. Many individuals also demonstrate compulsive acquisition of items (Nicoli de Mattos et al., 2018; Vogel et al., 2019), which appears to be associated with greater hoarding severity (Turna et al., 2018). HD may be associated with severe functional impairment and cost to society. As a result, large numbers of possessions accumulate and clutter the person's living areas so that living spaces can no longer be used for their intended purposes. Once considered a symptom of OCD, hoarding is now recognized as a separate diagnostic entity because, indeed, it differs in important ways from OCD. First, although hoarding may involve recurring thoughts of acquiring and maintaining possessions, these thoughts are not experienced as fear-provoking in the same way that obsessions are for individuals with OCD and they are not intrusive or unwanted (Rachman et al., 2009; Wheaton et al., 2011). Moreover, the extreme acquiring and saving that characterizes HD does not function as an escape from obsessional anxiety in the way that washing or checking rituals do in OCD.

Conceptual models of hoarding emphasize exaggerated beliefs related to the overattachment to material possessions and exaggerated consequences of not having these possessions (Frost & Hartl, 1996; Steketee & Frost, 2003). Collectively called saving cognitions, these beliefs include (a) unrealistic ideas about the value of saved items (e.g., "I'll probably need that empty soup can in the future"), (b) intense sentimental or aesthetic attachment (e.g., "It represents my grandfather"), (c) fears of being without the item (e.g., "I might need this in the future for something important"), (d) anthropomorphizing (e.g., "This item will be hurt if I throw it away"), and (e) excessive guilt about discarding (e.g., "I would be a bad parent if I discarded my child's old art projects from school") (Frost et al., 2015).

Individuals who hoard most frequently save objects for either anticipated practical use or an aversion to waste (e.g., "This can be used in the future") or excessive sentimental attachment (e.g., souvenirs, photos, children's art projects) (Frost et al., 2015). Frequently, the reason for keeping the object is fear of a negative emotional experience such as guilt or anxiety in parting with the object, rather than the object eliciting a positive emotion when it is retained. Whereas individuals with hoarding may report that they are willing to part with their hoarded possessions, the process of making decisions about what to discard becomes time-consuming and overwhelming. For items that reflect personal attachment and are unlikely to hold practical value to others (i.e., sentimental items such as photos, inherited mementos), beliefs about memory and excessive guilt in discarding the item are often cited as a primary reason for saving (e.g., "I feel that discarding this item is like throwing away the memory of my mother," or "I will forget my son's graduation day unless I save this reminder").

Some neuropsychological research indicates that individuals with HD have specific executive functioning deficits (Woody et al., 2014). Few studies have directly compared perceived cognitive ability with actual cognitive ability, but, in general, individuals with HD tend to self-report difficulty with memory and attention (Tolin et al., 2018), while existing neuropsychological test batteries do not consistently report deficits in these areas (e.g., Woody et al., 2014). In addition, one study used a behavioral paradigm of a computerized task examining reaction time and error detection (a stop-change task) and found that individuals with HD were less accurate in their estimation of their own error rates despite making similar numbers of errors as healthy controls (Zakrzewski et al., 2018). Negative self-perception about cognitive ability is likely to contribute to HD symptoms as well because individuals with HD often report engaging in hoarding behaviors to compensate for the perceived lack of confidence in their memory (e.g., "I have to save this information so I don't forget it," or "I have to leave things lying out or I will forget them") (Hartl et al., 2004).

# A Critical Examination of the OCRD Category

Through DSM-IV-TR, OCD was included among the anxiety disorders along with social and specific phobias, panic disorder and agoraphobia, posttraumatic stress disorder (PTSD), and generalized anxiety disorder (GAD). This grouping made sense on two levels. First, at a purely descriptive level, OCD symptoms are remarkably similar to the main features of anxiety disorders: excessive fear, anxious apprehension, and avoidance or ritualistic escape behavior. Although not mentioned in DSM, "rituals" such as checking for safety (in PTSD), asking for reassurance (in GAD), and seeking repeated medical evaluations (in panic disorder) also appear in both OCD and anxiety disorders. The second level on which OCD overlaps with the other anxiety disorders, however, is of greater interest because it transcends mere descriptive psychopathology and has greater treatment implications: OCD and the anxiety disorders are all maintained by the same psychological mechanisms involving (a) overestimates of the likelihood and severity of threat and (b) avoidance and anxiety reduction behaviors that reduce anxiety in the short term but prevent longterm fear extinction. Moreover, these conditions all respond to a specific intervention that promotes fear extinction-exposure therapy (Abramowitz et al., 2019).

Yet OCD was moved in *DSM-5* on the basis of the opinion that it bears an even *greater* similarity to the disorders described earlier in this chapter (i.e., the OCRDs) that seemingly share "compulsive behavior and failures in behavioral inhibition" rather than anxiety (Fineberg et al., 2011, p. 21). Ultimately, those who made decisions about the *DSM-5* (e.g., Fineberg et al., 2011) provided the following arguments for shifting OCD out of the anxiety disorders and creating the new OCRD classification:

- (a) The major symptoms of OCD and the OCRDs are repetitive thoughts and behaviors and a failure of behavior inhibition;
- (b) OCD and the OCRDs overlap in demographic features such as their age of onset, comorbidity, and family loading;
- (c) OCD and the OCRDs share brain circuitry and neurotransmitter abnormalities; and
- (d) OCD and the OCRDs share similar treatment response profiles.

Thus, it is worth examining the validity of these arguments, as I do next. A more comprehensive critique of the OCRD classification can be found in Abramowitz and Jacoby (2015).

#### Overlaps in Repetitive Thoughts and Behaviors

There are problems with grouping disorders together based on the mere presence of repetitive behaviors. Consider the following:

- Repetitive vomiting is a symptom of bulimia nervosa.
- Repetitive vomiting is a symptom of salmonella poisoning.
- Therefore, bulimia and salmonella poisoning are part of the same family of disorders.

Of course, there is no relationship between bulimia and salmonella, and one would not classify them together in any diagnostic system. Yet this is the approach the *DSM* has used to group together the OCRDs, and, from this perspective, it is easy to see how hair-pulling and skin-picking, for example, might end up seeming if they are related to OCD. Yet, as previously pointed out, when a functional (behavioral) perspective is applied to understanding the phenomenology (i.e., function) of the repetitive behaviors, it becomes clear that, of the OCRDs, only the repetitive thinking and behavior in BDD actually is at all similar to OCD. Moreover, both OCD and BDD are phenomenologically more similar to anxiety disorders than to the other puta-tive OCRDs.

# Overlaps in Demographic Features

Indeed, OCD and the other OCRDs typically onset in adolescence through early adulthood and follow similar courses (e.g., Bjornsson et al., 2013; Flessner et al., 2010; Grisham et al., 2006; Odlaug & Grant, 2012; Wilhelm et al., 1999). Yet similarity in age of onset and course is not a persuasive argument for grouping disorders together because it is not specific to the OCRDs. In fact, most mood, anxiety, somatic symptom, dissociative, sexual, sleep, personality, substance-related, psychotic, and eating disorders also begin during this time of life and evidence a somewhat variable yet generally chronic course if effective treatment is not sought.

There is also little evidence for high rates of comorbidity among the OCRDs. Bienvenu and colleagues (2000), for example, found that about 15% of patients with OCD also met criteria for BDD, yet the rate for hair-pulling disorder was only 4%. Other studies have reported largely similar results (Jaisoorya et al., 2003; Lovato et al., 2012), suggesting that, other than BDD, the OCRDs are rather uncommon among individuals with OCD. More striking, however, is that OCD is much more comorbid with anxiety disorders. For example, 13% of OCD patients meet criteria for GAD, 20.8% for panic disorder, 16.7% for agoraphobia, 36% for social phobia, and 30.7% for specific phobias (Nestadt et al., 2001). Using the reasoning of the DSM-5 then, OCD is 5- to 10-fold more closely related to the anxiety disorders than to most of the OCRDs!

Another problem is that the presence of comorbidity does not necessarily indicate meaningful overlaps among disorders. Substance use disorders and PTSD, for example, are highly comorbid (Kramer et al., 2014) yet one would not suggest they are part of the same diagnostic category (the stress of PTSD often leads to maladaptive substance use). Similarly, at least half of OCD sufferers also meet criteria for depression, yet the *DSM-5* does not group depression as part of the OCRD cluster. Thus, comorbidity patterns are of limited value in drawing links among OCRDs.

The problem is similar with using family patterns to group the OCRDs. The lifetime prevalence of hair-pulling disorder, for example, in first-degree relatives of adults with OCD is about 1% (Bienvenu et al., 2000). In contrast, the rates of anxiety disorders among first-degree relatives of people with OCD are far higher than the rates of OCRDs among relatives of OCD sufferers (e.g., Bienvenu et al., 2000; Nestadt et al., 2001). So, the assertion that a familial pattern represents a valid basis for grouping together the OCRDs again more strongly supports grouping OCD among the anxiety disorders.

# Overlaps in Brain Circuitry and Neurotransmitter Abnormalities

As previously discussed, some neuroimaging studies suggest that individuals with and without OCD show differences in variables related to brain structure and function (for a review and consensus statement, see Bandelow et al., 2016), and similar research replicates this finding with the OCRDs (e.g., Buchanan et al., 2013). Proponents of the OCRD classification interpret these studies as indicating the presence of a common causal brain abnormality or deficit across the OCRDs (e.g., Fineberg et al., 2011), yet no studies have examined whether it is the same brain-related variables that differ from healthy individuals across the OCRDs. There are also no comparisons between patients with OCRDs and those with other disorders (e.g., eating disorders) to determine whether any brain differences found in OCRDs are specific to OCRDs or associated with mental disorders more generally. Similarities among (and specificity to) the OCRDs have been assumed chiefly on the basis of independent studies (many with small sample sizes), as opposed to direct comparisons, and despite inconsistencies across studies (Whiteside et al., 2004).

An important yet often overlooked limitation of brain imaging studies is that they are cross-sectional and correlational. At best, they can detect associations between variables-in this case between an OCRD diagnosis and brain structure or function. But just because a certain variable is correlated with the symptoms of a mental disorder does not imply the presence of an "abnormality" with etiological significance. In the absence of experimental manipulation, conclusions regarding OCD and brain imaging findings must be restricted to those allowed by correlational data. It is plausible that the observed differences in brain structure and function between OCRDs and controls are the result of having an OCRD or that the differences are caused by one or more extraneous variables not measured in brain scan studies.

Probably the most consistent (and yet still overstated) finding in the biological literature on OCD is that pharmacotherapy by SSRIs (e.g., fluoxetine, sertraline) can be effective (Greist et al., 1995). This, and a small literature comparing serotonergic and nonserotonergic processes in OCD patients (Insel et al., 1985), led to the "serotonin hypothesis" that OCD is caused by a "chemical imbalance"abnormalities in the serotonergic system (Barr et al., 1993; Zohar et al., 2004). Acknowledging the lack of empirical support (see further below) for the serotonin hypothesis (including the mere 20-40% response rate to SSRIs), authors later suggested that dopamine plays a role in OCD-largely on the basis of admissions that dopamine mechanisms play a role in the effects of SSRIs (Denys et al., 2008; Zurowski et al., 2008). That is, SSRIs might be less selective than was once thought.

It is, however, logically incorrect to use the effectiveness of SSRIs to infer that an abnormally functioning serotonin or dopamine system is the cause of OCD/OCRDs. For one thing, the serotonin hypothesis was derived from the effectiveness of serotonin medications. But the circularity of this argument aside, it also is an example of post hoc ergo propter hoc reasoning. This fallacy is exemplified by the example: "When I take aspirin, the headache goes away; therefore the headache was caused by abnormally low aspirin levels." Neurotransmitter models of OCRDs could be supported by evidence from experimental studies showing differences in serotonergic or dopaminergic functioning between individuals with and without OCD or by studies in which these neurotransmitters are manipulated leading to increased symptom expression. Yet despite a considerable amount of energy (and funds) devoted to biological marker and challenge studies in OCD, there are no consistent findings. A further problem is that virtually no neurotransmitter research has been conducted on OCRDs other than OCD.

#### Overlaps in Treatment Response

The *DSM-5* notes the "clinical utility" (p. 235) of grouping together the OCRDs, which some authors argues is based on their similar response to SSRIs (Fineberg et al., 2011). This argument, however, is only clinically useful in delineating a class of OCRDs if (a) preferential response to SSRIs is observed uniformly among the OCRDs, (b) the preferential response to SSRIs is *only* observed among the OCRDs, and (c) SSRIs are the best treatment for the OCRDs. Careful examination of the data,

however, indicates that none of these conditions is satisfied. First, although randomized controlled trials indicate the efficacy of SSRIs relative to placebo for OCD (Eddy et al., 2004; Greist et al., 1995) and BDD (Phillips et al., 2002), SSRI response in the other OCRDs is quite inconsistent (e.g., Bloch et al., 2007, 2014). Second, numerous studies show that SSRIs are efficacious in the treatment of many conditions outside the OCRDs, including unipolar depressive disorders (e.g., Fournier et al., 2010; Schatzberg & Nemeroff, 2013) and anxiety disorders such as SAD (Hedges et al., 2007). Third, cognitive-behavioral interventions have been shown to be at least as effective as medications (if not more so) in the treatment of OCD and OCRDs (e.g., Bloch et al., 2007; Grant et al., 2012; Romanelli et al., 2014). Thus, SSRIs are not the most effective treatment for any of the OCRDs.

# Conclusion

OCD is characterized by (a) intrusive unwanted thoughts that the person misappraises as threatening and (b) attempts to reduce the chances of danger, or control the thought itself, with tactics such as compulsive rituals, avoidance, or other neutralizing strategies. These strategies become habitual because they often reduce obsessional fear immediately; yet they maintain the problem in the long run by interfering with the natural extinction of obsessional fear. This cognitive-behavioral conceptualization forms the basis for effective cognitivebehavioral interventions, namely exposure therapy and response prevention. In the DSM-5, OCD is categorized with other conditions thought to be "related" to OCD, including BDD, hoarding, skinpicking, and hair-pulling, yet, with the exception of BDD, these conditions are behaviorally distinct from OCD. Accordingly, grouping them in the same diagnostic class gives the clinician the false impression that these "OCRDs" should be conceptualized and treated in a similar fashion.

# Posttraumatic Stress Disorder and Dissociative Disorders

Richard J. McNally

# **Posttraumatic Stress Disorder**

Clinicians have long recognized that traumatic events can produce psychiatric symptoms in previously well-adjusted individuals, but prevailing opinion held that stress-induced symptoms are transient (Jones & Wessely, 2007). Persistent symptoms implied the presence of another neurotic or characterological disturbance.

The psychiatric sequelae of the Vietnam War altered this view. Many veterans began to report chronic symptoms, often long after reentering civilian life. Instead of viewing these men as suffering from preexisting conditions worsened by the war, clinicians concluded that combat itself could cause lasting psychiatric disability (Lifton, 1973; Shatan, 1973).

Antiwar psychiatrists and leaders of Vietnam veterans' organizations lobbied for the inclusion of a "post-Vietnam syndrome" diagnosis in the then-forthcoming *DSM-III*. They realized that for veterans to receive treatment and disability compensation from the Veterans Administration (VA), they had to show that veterans' symptoms were attributable to military service, not to preexisting problems or vulnerabilities. Making the case was especially challenging when symptoms erupted years after the war. Indeed, no single diagnosis in the *DSM-III* captured the delayed onset of stress-related symptoms.

Leaders of the *DSM* revision process initially opposed this proposal, maintaining that combinations of traditional diagnoses covered the problems of Vietnam veterans. Moreover, a goal for *DSM-III* was to devise an atheoretical system comprising diagnoses explicitly defined by their signs, symptoms, and course rather than by oftendebatable etiological notions. Ratification of a post-Vietnam syndrome would be inconsistent with this goal.

Veterans' advocates made common cause with mental health professionals who had been working with survivors of rape (Burgess & Holmstrom, 1974), disaster (Rangell, 1976), and concentration camps (Chodoff, 1963). Similarities in survivors' symptoms produced a consensus that any terrifying, life-threatening event could cause a chronic syndrome such as that suffered by the traumatized Vietnam veteran. An influential member of the DSM-III task force agreed (Andreasen, 2004). Indeed, she had observed a similar pattern of psychiatric symptoms in patients who had been severely burned. Her support ensured that posttraumatic stress disorder (PTSD) appeared in DSM-III classified as an anxiety disorder.

The diagnostic criteria have evolved over subsequent *DSM*s, but the core features of PTSD remain intact. The central idea is that a traumatic event establishes a memory that gives rise to a distinctive profile of signs and symptoms (McNally, 2003a,

pp. 105–124; Rubin et al., 2008). Although many people experience intense emotional distress in the immediate wake of trauma, the persistence of symptoms long after danger has passed is what justifies PTSD as a disorder.

According to DSM-5, PTSD comprises four symptomatic clusters. The intrusion cluster (B criteria) includes reexperiencing symptoms such as traumatic nightmares, intrusive sensory images of the trauma, and physiological reactivity to reminders of the trauma. The avoidance cluster (C criteria) includes efforts to avoid feelings, thoughts, and reminders of the trauma. The cluster covering negative alterations in cognitions and mood (D criteria) includes symptoms such as emotional numbing, distorted blame of self or others, and pervasive negative emotional states (e.g., shame and anger). The cluster covering alterations in arousal and reactivity (E criteria) includes symptoms such as exaggerated startle, aggression, reckless behavior, and hypervigilance.

# What Counts as a Traumatic Stressor?

To qualify for PTSD, a person must meet Criterion A: exposure to a traumatic stressor. For two reasons, exposure to trauma is essential to the conceptual integrity of PTSD (McNally, 2009). First, several core symptoms possess Brentano (1889/1984) *intentionality* (i.e, "aboutness"). That is, they are not merely *caused* by trauma; they are *about* the trauma. To have intrusive images, for example, is to have intrusive images about something: namely, the trauma.

Second, many symptoms of PTSD overlap with those of other disorders (e.g., loss of pleasure in activities, insomnia); it is the memory of the trauma that unites them into a coherent syndrome (Young, 1995, p. 5). Hence, the syndrome would unravel if we dispensed with Criterion A.

The *DSM-III* concept of PTSD presupposed that only *traumatic* stressors falling outside the boundary of everyday experience could produce the disorder's symptomatic profile. Such canonical traumas included combat, rape, torture, and natural disasters—events that would presumably produce intense distress in nearly everyone. Conversely, ordinary stressors presumably could not cause PTSD.

Two key findings complicated this assumptive framework. First, epidemiological studies documented that most people exposed to Criterion A traumatic stressors do not develop PTSD (Breslau et al., 1991). Second, other studies showed that people who neither experienced nor witnessed a canonical trauma could still fulfill the symptomatic criteria for the disorder, such as learning about the violent death of a loved one (e.g., Saigh, 1991). Accordingly, in 1994, the *DSM-IV* broadened the concept of trauma exposure to include being "confronted with" information about a threat to the "physical integrity" of another person, not necessarily a friend or family member.

Other reports appeared, showing stressors falling far short of Criterion A could apparently trigger PTSD (for a review, see Dohrenwend, 2010). For example, people encountering obnoxious jokes in the workplace (McDonald, 2003), giving birth to a healthy baby (Olde et al, 2006), and having a wisdom tooth removed (de Jongh et al., 2008) reportedly developed PTSD or PTSD symptoms. One study showed that 4% of Americans living far from the sites of the 9/11 terrorist attacks developed apparent PTSD (Schlenger et al., 2002), apparently from watching the events on television. Not only could one now qualify as a "trauma survivor" without having been at the scene of the trauma, one did not even have to know the people whose physical integrity had been threatened (McNally & Breslau, 2008).

The concern that suffering people would be denied the diagnosis and reimbursable treatment motivated the "conceptual bracket creep in the definition of trauma" (McNally, 2003b, p. 231). Yet broadening the concept had other consequences, too. It meant that nearly everyone qualifies as a trauma survivor, as Breslau and Kessler (2001) discovered. Studying residents of Southeastern Michigan, they found that 89.6% of adults had been exposed to a *DSM-IV* Criterion A stressor.

However honorably motivated, conceptual bracket creep may render it difficult to ascertain the psychobiological mechanisms mediating the symptoms of PTSD. It seems unlikely that survivors of fender-benders have much in common with survivors of the Holocaust. Also, the more we broaden the concept of trauma, the less plausibly we can assign causal significance to the stressor itself, and the more we must emphasize vulnerability factors. Diagnosing PTSD in people exposed to relatively minor events presumably produces a backgroundforeground inversion whereby risk factors move into the causal foreground while the trauma recedes into the background. Shifting the causal burden away from the stressor undermines the very rationale for having a diagnosis of PTSD in the first place.

What should we make of people whose apparent PTSD emerges after exposure to relatively minor

stressors? Do they carry an especially heavy burden of risk factors relative to people who develop PTSD only after exposure to canonical stressors? Consistent with this background-foreground inversion hypothesis, McNally and Robinaugh (2011) found that the effect size between cognitive ability and PTSD caseness was much larger for women whose childhood sexual abuse was mild in severity relative to those whose abuse was moderate in severity. That is, the less severe the stressor, the more important was the risk factor of lower cognitive ability in predicting PTSD. Yet in an epidemiological study, Breslau et al. (2013) found that the importance of risk factors (e.g., preexisting depression, parental alcohol abuse) did not differ for less severe categories of trauma (accidents) than for more severe categories of trauma (sexual assault).

Perhaps people living under conditions of safety, peace, and prosperity are especially likely to develop PTSD following exposure to relatively minor stressors. This may explain why PTSD is more common among British adolescents than among members of the British military (Jones, 2019). It may also explain the "vulnerability paradox in the cross-national prevalence of PTSD" (Dückers et al., 2016, p. 300), the finding that although low socioeconomic status (SES) is a risk factor for PTSD in individuals exposed to trauma, the opposite holds for nations. That is, low-SES countries have a lower prevalence of PTSD than do high-SES ones even when their rates of trauma exposure do not differ. However, the apparent paradox vanishes if one avoids falling prey to the ecological fallacy (Robinson, 1950)-the mistake in assuming that correlations between variables at the level of the person must hold at the level of the group (or vice versa). Certain stressors, such as automobile accidents, may be more pathogenic in otherwise safe, comfortable nations than in those accustomed to struggling with adversity (McNally, 2018).

To address problems with Criterion A, the *DSM*-5 committee members required that people who learn of physical threats to others must be a close friend or relative of the threatened person. They also disqualified trauma exposure mediated by the media as satisfying Criterion A unless it was related to the person's occupation (e.g., first responder).

# Sex Ratio

Men are exposed to traumatic events more often than are women (Tolin & Foa, 2006), yet the rate of PTSD is twice as great in women as in men. One hypothesis for this sex difference in PTSD prevalence is that women more frequently experience extreme stressors more often than men do (Cortina & Kubiak, 2006). This hypothesis, however, appears incorrect. Even when one controls for type of trauma (e.g., rape), sex differences in the severity and prevalence of PTSD remain (Tolin & Foa, 2006), implying that men and women differ in ways that influence their risk of developing PTSD following exposure to trauma.

Hormonal differences between male and female trauma survivors may account for the heightened risk of PTSD in the latter (Pineles et al., 2017). For example, Pineles et al. (2016) twice tested traumaexposed women with or without PTSD in a conditioned stimulus (CS)+/CS- Pavlovian differential fear conditioning paradigm involving skin conductance as the measure of fear. One test occurred when their levels of the gonadal hormones estradiol and progesterone were low (i.e., early follicular phase of the menstrual cycle) and the other occurred when levels of these hormones were high (i.e., during the midluteal phase). An extinction phase immediately followed the acquisition phase. The results indicated that women with PTSD exhibited impaired retention of extinction when in the midluteal phase relative to women without PTSD.

#### Epidemiology

According to the National Comorbidity Survey Replication (NCS-R; Kessler et al., 2005), the lifetime prevalence rate of *DSM-IV-TR* PTSD in the United States is 6.8%. According to the NCS-R, 9.7% of women and 3.6% of men develop PTSD at some point in their lives (http://www.hcp. med.harvard.edu/ncs/ftpdir/table\_ncsr\_by\_gen der\_and\_age.pdf).

In the World Mental Health (WMH) Surveys, Koenen et al. (2017) found that among traumaexposed people, 5.6% developed PTSD at some point in their lives, and 2.8% had PTSD during the previous 12 months. The lifetime and 12-month prevalence rates for high-income countries were 6.9% and 3.6%, respectively, and greater than for low- and lower-middle income countries combined (3.0% and 1.5%, respectively). For the United States, the 30-day, 12-month, and lifetime prevalence rates for PTSD among the trauma-exposed were 2.1%, 4.3%, and 8.3%, respectively.

Military personnel are at heightened risk for exposure to trauma. According to the National Vietnam Veterans Readjustment Study (NVVRS), 30.9% of all men who had served in Vietnam
developed *DSM-III-R* PTSD, whereas 15.2% still had the disorder in the late 1980s when the survey occurred (Kulka et al., 1990).

However, for two reasons, historians of military psychiatry suspected that the NVVRS team overestimated the prevalence of PTSD (e.g., Jones & Wessely, 2005, pp. 133–134; McNally, 2007a; Shephard, 2001, p. 392). First, only about 12.5% (King & King, 1991) of Vietnam veterans had served in direct combat roles during the Vietnam War (e.g., rifleman in an infantry platoon). The historians found it odd that twice as many men developed PTSD than were in combat roles. Even when one considers the additional 15% of men who served in combat support roles (e.g., medic) and hence could encounter danger, the prevalence rate was puzzlingly high.

Second, only 3.5% of all psychiatric casualties in Vietnam itself received a diagnosis of combat exhaustion (Marlowe, 2001, p. 86). As Marlowe (2001) put it, "Vietnam produced an extremely low proportion of proximate combat stress casualties and produced or is claimed to have produced massive numbers of postcombat casualties. Therefore, Vietnam breaks with the past normative pattern of combat and war zone stress casualty production" (p. 73).

In response to these concerns, Dohrenwend et al. (2006) reanalyzed the NVVRS data, applying rigorous criteria for PTSD caseness. Before accepting a case as PTSD-positive, they did three things prior to recalculating prevalence estimates. First, they included only those veterans whose PTSD developed from war-related trauma, not events occurring before or after the war. Second, they included only those veterans for whom archival data were consistent with their self-reported war traumas, thereby corroborating 91% of the PTSD cases. Third, they used scores on the Global Assessment of Functioning (GAF; Spitzer et al., 1987) scale to assess functional impairment, as impairment was not a diagnostic requirement for DSM-III-R PTSD. Dohrenwend et al. used GAF ratings, assigned by clinical interviewers in the NVVRS, as a proxy for the then-nonexistent DSM impairment criterion. They considered a veteran as impaired if he had received a rating of 1 through 7 on the 9-point GAF scale. One is the lowest level of functioning, and 9 is the highest level of functioning. The modal PTSD case was rated a 7, defined as "Some difficulty in social, occupational, or school functioning, but generally functioning pretty well, has some meaningful interpersonal relationships OR some mild symptoms (e.g., depressed mood and mild insomnia, occasional truancy, or theft within the household)" (p. 2).

Dohrenwend et al.'s (2006) adjustments reduced both the lifetime and current prevalence rates of PTSD by 40%, thereby confirming the hypothesis of the historians (McNally, 2006a). The lifetime prevalence dropped from 30.9% to 18.7%, and the current prevalence rate dropped from 15.2% to 9.1%. However, had Dohrenwend et al. used a slightly more stringent definition of impairment (i.e., GAF score of 1 through 6 ["moderate" impairment]), the current prevalence estimate would have dropped by 65%; that is, from 15.2% to 5.4% (McNally, 2007b).

A follow-up study of surviving male theater veterans from the original NVVRS study revealed current and lifetime rates of *DSM-5* war-related PTSD of 4.5% and 17.0%, respectively, according to structured diagnostic interview (Marmar et al., 2015). Using a 20-point change in a dimensional measure of PTSD symptom severity to gauge clinically relevant change, the authors found that 16.0% of the theater veterans experienced worsening since the first administration, whereas 7.6% experienced improvement.

Requiring impairment affects prevalence rates in civilian samples, too. In two epidemiological studies, Breslau and Alvarado (2007) found that requiring that symptoms produce impairment lowered the prevalence of PTSD in men by 33% and 44% and in women by 25% and 30%, respectively.

In striking contrast to previous wars, the ones in Iraq and Afghanistan have prompted American, British, and Dutch authorities to assess their troops before, during, and after deployment to these war zones (McNally, 2012a). A comprehensive review of rigorous American and British studies indicated that between 2.1% and 13.8% of American and British service members have developed PTSD (Sundin et al., 2010).

Smith et al. (2008) conducted the methodologically strongest study on American military personnel deployed to Iraq and Afghanistan. They used data from the US Millennium Cohort, a prospective, longitudinal investigation of active duty and Reserve/National Guard service members. Administering the PTSD Checklist (PCL; Weathers et al., 1993) to 47,837 members of the Armed Forces, they found that 4.3% of those deployed to Afghanistan and Iraq developed PTSD. Among those exposed to combat, 7.6% developed PTSD, whereas 1.4% of those denying combat exposure did so. Among never-deployed personnel, 2.3% developed PTSD from stateside traumatic events (e.g., accidents on bases). Smith et al. (2008) ensured that PTSD symptom data were unconnected with subjects' official military files, thereby ensuring the confidentiality of symptom disclosure for personnel concerned about the stigma of mental health problems (Hoge et al., 2004).

Excluding subjects whose PTSD predates their enlistment provides the best estimate of warattributable PTSD. For example, using the PCL, Hoge et al. (2004) found that as many as 5% of combat troops met criteria for PTSD prior to deploying to Iraq, whereas 12.6% qualified for PTSD following combat exposure in Iraq. If one rules out preexisting PTSD among Hoge et al.'s combatants, one obtains a deployment-attributable rate of PTSD of 7.6%-the same estimate reported by Smith et al. (2008) for combat-exposed personnel in Iraq and Afghanistan.

On the other hand, studies show that the percentage of military personnel with PTSD rises slightly within the first 6 to 12 months *after* their return from Iraq or Afghanistan (Sundin et al., 2010). Some service members may initially fail to report certain symptoms that are adaptive in a war zone (e.g., hypervigilance and numbing), yet subsequently endorse them on the PCL if symptoms fail to remit months postdeployment.

#### Longitudinal Course of PTSD

Acute stress symptoms are common following exposure to traumatic events. For example, studying help-seeking rape victims, Rothbaum and Foa (1993) found that 95% met PTSD symptom criteria within 2 weeks of the trauma. But the proportion still meeting symptom criteria at 1, 3, and 6 months postrape declined to 63.3%, 45.9%, and 41.7%, respectively. Likewise, Rothbaum and Foa found that, among victims of nonsexual assault, 64.7% met PTSD symptom criteria 1 week after the crime, whereas the proportion still fulfilling criteria at 1, 3, 6, and 9 months postassault declined to 36.7%, 14.6%, 11.5%, and 0%, respectively.

Symptoms of PTSD usually emerge within hours or days of the trauma, making delayed-onset PTSD extremely rare (Jones & Wessely, 2005, p. 184). In a civilian epidemiologic study (Breslau et al., 1991), only 1 person among the 93 diagnosed with PTSD appeared to have a delayed onset.

People who meet criteria for PTSD only after 6 months following the trauma qualify for delayedonset PTSD. However, few, if any of them, are symptom-free during the months following the trauma (Andrews et al., 2007). The modal case suffers symptoms all along, finally experiencing an increase that bumps them above the diagnostic threshold. Others may develop the full syndrome immediately following the trauma but seek help only years later (Solomon et al., 1989). However, such delayed help-seeking is not delayed onset.

In a prospective, cohort investigation, Goodwin et al. (2012) administered the PCL twice to 1,397 British military personnel who had served in Iraq. The first assessment occurred between 2004 and 2006, and the second assessment occurred between 2007 and 2009. Soldiers completed the questionnaire in reference to symptoms during the previous month. Cases of probable PTSD had a score of at least 50 on the PCL, and cases of subthreshold PTSD had a score of 40 to 49. PCL scores can range from 17 to 85. Cases of delayed-onset PTSD qualified for the syndrome at the second assessment, but not at the first one.

Although 94% of the subjects were free of PTSD at both time points, 3.5% of them developed delayed-onset PTSD. That is, of those who had PTSD, 46% met criteria only at the second assessment point. Of the 44 cases of delayed-onset PTSD, 12 already had symptoms sufficiently severe as to qualify them for subthreshold PTSD. Delayed onset seems more likely with war veterans than for others exposed to trauma.

In a study of 100 men seeking treatment for PTSD years after they reported fighting in Vietnam, Frueh et al. (2005) sought to verify their reported traumatic events by obtaining each patient's military personnel file. For only 41% of the cases did the archival data corroborate the self-reported trauma, and 7% had either never served in Vietnam or never served in the military at all. Yet the clinical assessors had diagnosed PTSD in 94% of the subjects. For example, the uncorroborated cases reported exposure to battlefield atrocities at twice the rate of corroborated cases, and many of the former reported extremely implausible events (e.g., a cook who said he was a prisoner in North Vietnam).

Analyzing a huge federal dataset, labor economists Angrist et al. (2010) concluded that financial need, not psychiatric disorder, is the chief cause of the recent massive increase in PTSD disability claims among Vietnam veterans. They found that the increase largely occurs among veterans whose limited vocational skills make it very difficult for them to make a decent living. Moreover, Angrist et al. found that combat exposure (and therefore PTSD) could not account for the increase in claims. Accordingly, they concluded, "This leaves the attractiveness of VDC [veterans' disability compensation] for less-skilled men and the work disincentives embedded in the VDC system as a likely explanation for our findings" (p. 824). Taken together, these data have prompted some scholars to suggest that the apparent emergence of PTSD decades after exposure to trauma may reflect financial need rather than delayed emergence of psychiatric illness (McNally & Frueh, 2012), whereas other scholars disagree (Marx et al., 2012).

Finally, a longitudinal study spanning 20 years on a national sample of post-9/11 war veterans in the care of the VA indicated that the modal course was above PTSD threshold symptoms that persist for many years, decreasing only gradually over time (Lee et al., 2020). This clinically disappointing outcome either underscores the urgency to improve evidence-based treatments for PTSD, as the authors concluded, or indicates fear of losing disability compensation should they improve.

# Comorbidity

Pure PTSD is unusual. In the NVVRS, 98.8% of the veterans who qualified for a lifetime diagnosis of PTSD also qualified for at least one other mental disorder, compared with 40.6% of those without PTSD (Kulka et al., 1990). The most common comorbid disorders in male veterans with PTSD were alcohol abuse, depression, and generalized anxiety disorder (GAD), whereas the most common comorbid disorders in female veterans were depression, GAD, alcohol abuse, and panic disorder.

Comorbidity is common in cases of civilian PTSD, too. Breslau et al. (1991) found that about 80% of PTSD cases had at least one other disorder at some point in their lives. Likewise, Kessler et al. (1995) reported lifetime comorbidity rates of 88.3% in men and 79% in women with PTSD. Major depression and alcohol dependence were among the most common comorbidities. Retrospectively reported ages of onset implied that other anxiety disorders usually preceded PTSD, whereas alcohol and mood disorders usually followed the emergence of PTSD.

# **Risk Factors for PTSD**

There are two aspects to risk for PTSD (Bowman & Yehuda, 2004): risk for exposure to trauma and risk for PTSD given exposure to trauma. Regarding the former, in one study, retrospectively ascertained risk factors for exposure to trauma included

extroversion, neuroticism, male sex, having less than a college education, a personal history of childhood conduct problems, and a family history of psychiatric disorder (Breslau et al., 1991). This research group also did a 3-year prospective study finding that extroversion and neuroticism predicted exposure to trauma (Breslau et al., 1995). Black subjects had a higher rate of exposure than did Whites.

Risk factors for PTSD among those exposed to trauma include female sex (e.g., Tolin & Foa, 2006); neuroticism (e.g., Breslau et al., 1991); lower social support (e.g., Boscarino, 1995); lower IQ (e.g., Macklin et al., 1998; McNally & Shin, 1995); preexisting psychiatric illness, especially anxiety (Kessler et al., 2018) and mood disorders (e.g., Breslau et al., 1991); family history of anxiety, mood, or substance abuse disorders (e.g., Breslau et al., 1991); neurological soft signs (e.g., nonspecific abnormalities in central nervous function; Gurvits et al., 2000); and small hippocampi (Gilbertson et al., 2002). Some risk factors, such as low social support, have been assessed after individuals have developed PTSD, making it unclear whether early symptoms alienated potential sources of support or whether lack of support impeded recovery from trauma, or both. A recent prospective study of war veterans from the National Guard provided evidence for both hypotheses, especially for the claim that symptoms predict diminished support (Shallcross et al., 2016).

Using data from the Dunedin longitudinal study, Koenen et al. (2008) discovered that PTSD almost never developed in response to trauma during adulthood unless the subject had received a mental disorder diagnosis, often in childhood. That is, of new cases of PTSD occurring between the ages of 26 and 32, 96% had already experienced a mental disorder and 77% had received the diagnosis before the age of 15. Anxiety, mood, and conduct disorders were the three most common syndromes that preceded adult-onset PTSD. Previous disorders may signify vulnerability to develop PTSD in response to trauma, may themselves increase risk for exposure to trauma, or both.

Some scholars have adduced evidence suggesting that previous exposure to traumatic events sensitizes people so that they experience increased risk of developing PTSD in response to subsequent stressors (e.g., King et al., 1996). In these studies, people with PTSD are asked about previous traumatic events they had experienced prior to the trauma that triggered their disorder.

Unfortunately, these researchers had not assessed how individuals had responded to their earlier trauma. Indeed, Breslau et al. (2008) have shown that previous exposure to trauma does not increase risk for PTSD in response to subsequent trauma unless the person developed PTSD in response to the first trauma. Trauma-exposed individuals who do not develop PTSD in response to the earlier event are not at heightened risk for PTSD.

Likewise, Solomon et al. (1987) found that prior combat exposure did not increase risk for an acute combat stress reaction among Israeli soldiers who fought in the 1982 Lebanon War unless the soldier had experienced an acute combat stress reaction during a previous war. That is, prior combat per se did not predict breakdown in response to subsequent combat.

How victims respond during a trauma may predict whether they develop PTSD. Studying peritraumatic predictors involves asking victims hours, days, weeks, or sometimes years after the event how they recall responding during the trauma. Peritraumatic dissociation predicts PTSD (e.g., Shalev et al., 1996). That is, people who reported feeling disconnected from their body, feeling that events were happening in slow motion, and so forth were especially likely to develop the disorder.

Ehlers and Clark (2000) have observed that trauma victims' interpretation of their acute symptoms may affect whether they develop the disorder. A trauma victim's negative appraisal of acute symptoms predicts whether the person will develop PTSD (Dunmore et al., 2001; Ehring et al., 2006). For example, if trauma victims construe startle responses and nightmares as signs of personal weakness or flashbacks as signs of impending psychosis, they are at heightened risk for failing to recover from the acute effects of trauma.

There is, however, a potential conceptual problem with work on peritraumatic predictors and symptom appraisals. Researchers have isolated these phenomena, treating them as independent variables predictive of the dependent variable of persistent PTSD. Yet peritraumatic reactions are themselves aspects of the outcome researchers are trying to predict (Breslau, 2011). Peritraumatic dissociation, catastrophic appraisal of symptoms, and PTSD may be manifestations of the same pathological process or a consequence of a common vulnerability (e.g., neuroticism). The predictive capacity of these variables may be an artifact of how researchers parse the phenomenon, spuriously distinguishing responses during the trauma from those occurring somewhat later as if they were distinct phenomena.

Most work on risk and resilience concerns individual variables. However, group cohesion, morale, and leadership function as buffers against battlefield stress (Jones & Wessely, 2007).

# **Cognitive Aspects of PTSD**

Researchers have investigated cognitive aspects of PTSD from both a phenomenologic and an information-processing perspective (McNally, 2006b).

# Phenomenology of Traumatic Memory

Memories of trauma are different from memories of other events in terms of their content and emotional qualities. Do they differ in other ways? Are they represented and processed differently (Brewin, 2014)? Porter and Peace (2007) conducted a longitudinal study of individuals in the community who had experienced a traumatic event, often a crime. In addition to having the individuals rate the emotional qualities and vividness of the traumatic memory, they had each subject select and rate a very positive memory. Relative to memories of trauma, memories of positive events tended to fade in terms of vividness and emotional intensity, and their accuracy (relative to the baseline description) tended to diminish over the course of several years.

Rubin, Deffler et al. (2016b) assessed 60 adults from the community, half of whom had current PTSD, whereas the others had never developed it. The groups did not differ on potentially confounding variables (e.g., social class, percentage of minorities or women, histories of substance abuse and dependence, symptoms or diagnoses of depression), nor did they differ types of trauma (e.g., sexual abuse, accidents, combat, natural disasters). The subjects were asked to describe their three most traumatic, positive, and important memories. Rubin et al. audiotaped and transcribed the oral narratives before analyzing them via 28 methods of measuring their coherence or fragmentation. These indices included self-ratings of coherence, judges' ratings, and computerized algorithmic metrics of referential cohesion, temporal connectives, concreteness, and so forth. Rubin et al. found that trauma memories were no less coherent than positive memories and important memories, irrespective of a subject's PTSD status. For certain indices, trauma memories were slightly less coherent than positive and important memories, whereas, for others, trauma memories were more coherent.

In a critique of Rubin et al.'s study, Brewin (2016) revised the narrative (in)coherence hypothesis, stating that Rubin and colleagues assessed *global*, not *local*, coherence. That is, he said that clinicians most often observe fragmentation when survivors with PTSD attempt to recount the "hot spots" the most emotionally disturbing parts—of their experience. Accordingly, although survivors may be capable of providing a coherent, *global* account of their trauma, the hot spots are those most likely to be disorganized, fragmented, or exhibiting "amnesic gaps" (Brewin, 2016, p. 1015). Brewin predicted that a focus on such "hot spots" (Brewin, 2016, p. 1014) would have corroborated the hypothesis that trauma impairs narrative memory.

In reply, Rubin, Bertsen et al. (2016a) noted that 21 of the 28 measures did assess local coherence yet failed to reveal fragmentation in those with PTSD. The debate about the best indices for gauging memory fragmentation continues (McNally et al., 2022), but at best, the evidence remains inconclusive. Also, Malaktaris and Lynn's (2019) phenomenological study of flashbacks in people with PTSD or subthreshold PTSD uncovered no evidence of fragmentation.

Finally, Taylor et al. (2022) conducted two experiments revealing that *how* an individual retrieves and recounts memories, including traumatic ones, affects an individual's judgments of the memory's coherence. If people are asked to narrate an experience, they regard their account as more coherent than if they first attempt to answer a series of difficult questions about the experience (e.g., "What were you wearing at the time of the event? Describe your entire outfit"). These experiments indicate that judgments of coherence are attributions influenced by the mode of retrieval rather than properties of the memory itself.

The importance of narrative fragmentation of trauma memories presumably rests on their maintenance of PTSD. Once the memories become integrated into a coherent narrative of the trauma, intrusive recollections, nightmares, and flashbacks presumptively diminish in frequency and intensity. Bedard-Gilligan et al. (2017) tested this hypothesis in a study of PTSD patients who received prolonged exposure therapy or sertraline for PTSD. Patients provided three narratives: one concerning their trauma, one concerning a positive experience, and one concerning a negative but nontraumatic experience. Using self-report ratings, independent ratings, and objective measures of narrative structure, Bedard-Gilligan et al. assessed fragmentation of these memories before and after treatment.

The results revealed that, across measures, memory fragmentation did not reliably change across the course of treatment. Neither treatment type nor response to treatment was related to change in fragmentation. In fact, pretreatment fragmentation in the nontraumatic negative and positive narratives correlated with fragmentation in trauma narratives. For some patients, fragmentation was a characteristic style of recounting autobiographical memories in general.

### Autobiographical Memory

As with depressed people (Williams et al., 2007), those with PTSD experience difficulty recalling specific personal memories in response to cue words on the Autobiographical Memory Test (AMT; e.g., McNally et al., 1994). For example, in response to the word *happy*, they often recall a categoric memory exemplifying a class of events (e.g., "I'm always happy whenever the New England Patriots win") or sometimes recall an extended memory spanning more than one day (e.g., "I was happy during the summer after college graduation"). In contrast to such "overgeneral memories," those that healthy subjects recall refer to specific events (e.g., "I was happy on the day that I got married"). An overgeneral retrieval style may imply avoidance of thinking specifically about one's emotionally disturbing past (Williams et al., 2007). It may also reflect deficits in executive control and working memory, essential to searching through one's autobiographical memory database to identify specific episodes in response to cue words (Dalgleish et al., 2007).

Overgeneral memory has important clinical correlates. PTSD patients exhibiting overgeneral memory are especially impaired in their problem-solving performance (Sutherland & Bryant, 2008). Brown et al. (2013) found that American combat veterans of the Afghanistan and Iraq wars who developed PTSD retrieved fewer specific memories than did healthy combat veterans of these wars. Moreover, relative to healthy combat veterans, those with PTSD likewise had difficulty envisioning specific future events.

Although Iranian combat veterans of the Iran-Iraq war with PTSD retrieved fewer specific memories than did healthy combat veterans who, in turn, retrieved fewer specific memories than did control subjects without combat exposure (Moradi et al., 2012), most studies show that PTSD, not trauma exposure alone, predicts overgeneral memory (Moore & Zoellner, 2007). Research on trauma survivors indicates that difficulties retrieving specific memories predict PTSD (e.g., Kleim & Ehlers, 2008). To test whether overgeneral memory precedes trauma exposure as well as PTSD, Bryant et al. (2007) tested 60 trainee firefighters who were free of PTSD and had yet to encounter the occupational stressors common in their line of work. Four years later, all had experienced trauma, and 15% had developed PTSD. Bryant et al. found that difficulty retrieving specific memories to positive words during their training predicted severity of PTSD symptoms. Hence, an overgeneral retrieval style may be a risk factor for PTSD among those exposed to trauma.

Vietnam veterans with PTSD who wore war regalia, combat fatigues, military patches, and so forth in everyday life had especially great difficulty retrieving specific memories (McNally et al., 1995). Relative to healthy combat veterans, these men seemed stuck in the past. Likewise, Sutherland and Bryant (2005) reported that trauma victims with PTSD more often mention traumatic memories as self-defining than do victims without PTSD. Having one's identity intertwined with one's trauma history appears predictive of poor mental health.

To investigate this issue, Berntsen and Rubin (2006) developed the Centrality of Event Scale (CES), a questionnaire that taps how strongly trauma survivors believe that the trauma is a central event in their life story (for a review, see Gehrt et al., 2018). They found that scores on the CES positively correlated with severity of PTSD symptoms among trauma-exposed college students. Others have replicated this finding in veterans of the wars in Iraq and Afghanistan with PTSD (Brown et al., 2010) and in women who reported histories of childhood sexual abuse (Robinaugh & McNally, 2011). Importantly, Boals and Ruggero (2016) found that event centrality prospectively predicts PTSD symptoms, but not vice versa.

As Berntsen and Rubin (2007) concluded, findings regarding the CES "contradict the widespread view that the poor integration of the traumatic memory into one's life story is a main cause of PTSD. Instead, enhanced integration appears to be a key issue" (p. 417).

# The Emotional Stroop Paradigm

People with PTSD report reexperiencing their trauma in the form of intrusive thoughts, nightmares, and flashbacks. These phenomenologic reports imply that involuntary cognitive processes mediate these symptoms. To test whether traumatic information is automatic in PTSD, researchers have applied versions of the *emotional Stroop paradigm* (McNally, 2006b).

In this paradigm, subjects are asked to view words of varying emotional significance and to name the colors in which the words are printed while ignoring the meaning of the words (Williams et al., 1996). *Stroop interference* occurs when the meaning of the word becomes intrusively accessible, thereby slowing the subject's naming of its color. If information related to trauma is, indeed, automatically accessed in PTSD and difficult to inhibit, subjects with the disorder ought to exhibit greater Stroop interference for trauma words relative to other words and relative to trauma-exposed people without PTSD.

In one study, Vietnam veterans with PTSD, relative to veterans without PTSD, took longer to name the colors of words related to the war (e.g., *firefight*) than to name the colors of other negative words (e.g., *filthy*), positive words (e.g., *friendship*), or neutral words (e.g., concrete; McNally et al., 1990). Similar results have occurred for subjects whose PTSD resulted from rape (Cassiday et al., 1992), shipwrecks (Thrasher et al., 1994), automobile accidents (Bryant & Harvey, 1995), and childhood sexual abuse (Dubner & Motta, 1999). Unlike those with PTSD, rape victims who have recovered following treatment do not exhibit Stroop interference for trauma words (Foa et., 1991). Actors trained to mimic the effect were unable to do so (Buckley et al., 2003). Instead, they named the colors of all words slowly. However, other studies, often unpublished, failed to replicate the emotional Stroop effect in PTSD (Kimble et al., 2009).

# **Biological Aspects of PTSD**

Biological research on PTSD has been flourishing, and reviews of this field have appeared, both narrative (Pitman et al., 2012) and meta-analytic (Pole, 2007).

#### Cognitive Neuroscience and the Emotional Stroop

Scientists have studied the neural mechanisms mediating the emotional Stroop effect in PTSD. In a positron emission tomography (PET) experiment, Bremner et al. (2004) found that women with PTSD related to childhood sexual abuse, relative to victims without PTSD, had less anterior cingulate activation during the emotional Stroop task. The groups did not differ in terms of anterior cingulate activation while performing the standard Stroop task. Hence, the activation deficit in the PTSD group was confined to the processing of traumarelated information.

Employing functional magnetic resonance imaging (fMRI), Shin et al. (2001) found that Vietnam veterans with PTSD exhibited diminished rostral anterior cingulate activation when exposed to war-related words in the emotional counting Stroop. In this task, subjects view displays comprising from one through four copies of a word varying in emotional valence (e.g., *firefight*, *firefight*, *firefight*). They push a key corresponding to the correct number of copies of the word (e.g., 3). Subjects will be slower to count the number of copies to the extent that the meaning of the word captures their attention.

Cognitive neuroscience research on variants of the emotional Stroop in PTSD supports a pathophysiologic model that highlights abnormalities in medial prefrontal cortex (PFC) and amygdala (Bremner et al., 1999; Rauch et al., 2000; Shin, Rauch et al., 2005). The medial PFC comprises medial frontal gyrus, anterior cingulate cortex (ACC), and subcallosal cortex. The downward projections of the PFC inhibit activation of amygdala, thereby explaining why an intact PFC is vital for the extinction of conditioned fear (Milad & Quirk, 2002). Disturbing, intrusive recollections of traumatic events, accompanied by increased physiologic arousal, are consistent with either a hypoactive medial PFC, a hyperresponsive amygdala, or both (Shin et al., 2006).

# Prefrontal Cortical Abnormalities

An fMRI study found that PTSD subjects exhibited increased amygdala responses and reduced medial PFC responses to photographs of fearful versus happy facial expressions (Shin, Wright et al., 2005). In fact, signal changes in the amygdala and symptom severity negatively correlated with signal changes in the medial PFC. These findings are consistent with those of a previous study in which briefly presented and backwardly masked (subliminal) fearful faces provoked increased amygdalar responses in PTSD subjects (Rauch et al., 2000). PTSD patients have exhibited attenuated medial prefrontal/anterior cingulate activation while listening to audiotaped scripts of their traumatic experiences (Shin et al., 2004). A study of Vietnam combat veterans and their nonveteran identical co-twins suggests that attenuated activation of medial PFC during recollection of highly stressful memories is an acquired characteristic (Dahlgren et al., 2018); the nonveteran co-twins did not exhibit it.

As Shin et al. (2006) noted, not only have scientists found attenuated medial PFC activation in PTSD, but they have also observed smaller ACC volumes in individuals with PTSD relative to traumaexposed individuals without the illness (Rauch et al., 2006; Woodward et al., 2006; Yamasue et al., 2003). Furthermore, the smaller the ACC volume, the worse was symptom severity in two of these studies (Woodward et al., 2006; Yamasue et al., 2003). Most subjects had recovered from PTSD in Yamasue et al.'s study, thereby implying that diminished ACC volume may be either a vulnerability factor or a "scar" from PTSD rather than being a correlate of the illness.

A subsequent study suggests that the scar hypothesis is correct. Using data from Gilbertson et al.'s (2002) monozygotic twins, Kasai et al. (2008) found that reduced volume (gray matter density) in the pregenual ACC in Vietnam veterans with combat-related PTSD was not present in their combat-unexposed co-twins. Moreover, these PTSD cases had smaller pregenual ACC volumes than did combat veterans without PTSD and their co-twins. Hence, reduction in the size of this region is associated with chronic PTSD, not merely exposure to trauma or a preexisting vulnerability factor.

Taken together, these data are consistent with a model of PTSD whereby the ventromedial PFC, including the pregenual (or "emotional") region of the ACC, inhibits acquired fear responses mediated by the amygdala (Rauch et al., 2006). If smaller volume of the ACC signifies diminished function, then these data provide an anatomical clue to why fearrelated reexperiencing symptoms erupt in PTSD (Pitman et al., 2012).

# Hippocampal Volume

Preclinical research indicates that certain stress hormones, such as the glucocorticoid cortisol, may produce atrophy in the hippocampus, a brain structure integral to autobiographical memory (Sapolsky, 1996). Reasoning that traumatic stress may have similar consequences, Bremner et al. (1995), using MRI methods, found that Vietnam veterans with PTSD had smaller hippocampi than did nonveteran control subjects. These findings have replicated among adults whose PTSD was associated with sexual and physical abuse during childhood (Bremner et al., 1997; Stein et al., 1997). If diminished size is associated with diminished function, then small hippocampi may make it difficult for people with PTSD to process contextual cues signifying safety (Pitman et al., 2012).

Gurvits et al. (1996) further clarified this phenomenon by comparing hippocampal volume across three groups of subjects: Vietnam combat veterans with PTSD, Vietnam combat veterans without PTSD, and nonveteran control subjects. The healthy combat veterans and the nonveterans did not differ in hippocampal volume. The PTSD group had smaller volume than did the other two groups. In studies failing to replicate the small hippocampus effect (e.g., Bonne et al., 2001), PTSD symptoms tend to be less severe than in studies replicating the effect (Pitman et al., 2012).

Third, individuals with Cushing's syndrome, an endocrine disorder characterized by chronic cortisol output five times higher than normal, do exhibit hippocampal atrophy. Treatment, however, not only normalizes their cortisol levels but also reverses their hippocampal atrophy (Starkman et al., 1999). Therefore, chronically high levels of cortisol, if corrected, did not produce lasting damage.

Fourth, small hippocampi in PTSD appear to be a vulnerability factor for PTSD, not a consequence of traumatic stress. This conclusion comes from a landmark study by Gilbertson et al. (2002). They measured hippocampal volume in monozygotic (MZ) twin pairs: 17 pairs in which 1 twin developed PTSD after serving in Vietnam and whose psychiatrically healthy twin had not been in combat, and 23 twin pairs in which 1 twin had seen combat in Vietnam, but did not have PTSD and whose twin had neither been in combat nor had PTSD. The results confirmed that veterans with PTSD had smaller hippocampi than did veterans without PTSD. Most striking, however, is that the nontraumatized, healthy co-twins of the PTSD subjects had hippocampi just as small as the hippocampi of their brothers. These findings imply that small hippocampi are a marker for vulnerability for developing PTSD among individuals exposed to trauma.

Yet a meta-analysis revealed that the hippocampi of trauma-exposed subjects without PTSD are smaller than the hippocampi of subjects without trauma exposure (Woon et al., 2010). These findings are subject to three interpretations (Pitman et al., 2012). Small hippocampi may be associated with subsyndromic levels of PTSD symptoms, may increase risk for trauma exposure, or may indicate that trauma exposure alone may shrink the hippocampus to some extent.

# Genetics

True et al. (1993) studied 4,042 male Vietnamera MZ and dizygotic (DZ) twin pairs to ascertain

the relative contributions of heredity, shared environment, and unique environment to variance in PTSD symptoms. The results revealed that MZ twins were more concordant for combat exposure than were DZ twins. Controlling for extent of combat exposure, True et al. found that between 13% and 30% of the variance in reexperiencing symptoms was associated with genetic variation. Likewise, heritability estimates for avoidance symptoms ranged from 30% to 34%, and heritability for arousal symptoms ranged from 28% to 32%. Indices of shared environment during childhood and adolescence (e.g., family upbringing, parental SES) were unrelated to variance in PTSD symptoms. Taken together, about one-third of the variance in PTSD symptoms is associated with genetic variance, whereas the remaining is chiefly associated with unique environmental experiences (e.g., heavy combat).

However, the classic twin design overestimates the genetic contribution to variation by obscuring the effects of both gene  $\times$  environment interaction and gene and environment correlation (Sauce & Matzel, 2018).

Other studies strongly imply genetic vulnerability for PTSD. Gilbertson et al. (2006) administered IQ and other neurocognitive tests to monozygotic twin pairs. They tested four groups: men with combat-related PTSD from Vietnam, their identical twins with no combat exposure and no PTSD, Vietnam combat veterans who had not developed PTSD, and their identical twins with no combat exposure and no PTSD. The findings were strikingly consistent: on almost every test, combat veterans with PTSD and their identical twins performed very similarly, and both groups performed in the normal range. However, they performed worse than did the healthy combat veterans and their co-twins.

This study suggests several conclusions. First, trauma exposure has little or no effect on measures of IQ or on other tests of neurocognitive functioning. Second, the striking similarity in the test scores between co-twins strongly implicates genetic influence on performance. Third, because the PTSD group scored within the normal range on all but one test, above average cognitive ability appears to confer protection against PTSD. Indeed, consistent with an early study (Macklin et al., 1998), the mean IQ of the healthy combat veteran group was 118, and more than 40% of this group scored in the superior range (>120). The mean IQ of the PTSD group was 105. Neurological soft signs are more common in combat veterans with PTSD than among combat veterans without PTSD (Gurvits et al., 2006). The non-trauma-exposed identical co-twins of the PTSD group exhibit higher scores than the identical co-twins of the healthy combat veterans, thereby implying that subtle neurological compromise is a genetic (or at a least constitutional) vulnerability factor for PTSD rather than being a consequence of trauma or PTSD.

Other studies have further implicated cognitive ability as a buffer against PTSD. Breslau et al. (2006) obtained the IQ scores of 6-year-old children from either the inner city of Detroit or its suburbs. In follow-up interviews with these children at age 17, Breslau et al. assessed them for exposure to trauma and for PTSD. Subjects whose IQ at age 6 was greater than 115 were at lower risk for exposure to traumatic events by age 17, and they were at lower risk for developing PTSD if they had been exposed to trauma. Children with below average IQ and average IQ were at similar risk for PTSD. These findings imply the higher IQ is protective rather than lower IQ being a vulnerability factor.

Studying Vietnam veteran twins, Kremen et al. (2007) found that higher pre-deployment cognitive ability protected against subsequent PTSD. More specifically, the highest quartile on the cognitive ability measure had a 48% lower risk for PTSD than did the lowest quartile on this measure. Further analyses confirmed that genetic variance entirely accounted for variance in the cognitive ability measure.

Investigators have conducted genome-wide association studies (GWASs) to identify genetic variants associated with PTSD (Daskalakis et al., 2018). In contrast to the earlier, theory-driven candidate gene approach, which is subject to statistical and other possible biases, the GWAS method scans for associations between genetic loci and disorders throughout the entire genome. For example, Stein et al. (2016) identified two loci significantly associated with PTSD in a cohort of post-9/11 wars American soldiers from the Army Study to Assess Risk and Resilience in Servicemembers (Army STARRS) consisting of PTSD cases (n = 3, 167) and healthy trauma-exposed cases (n = 4,607), but the results failed to replicate in a second cohort of PTSD cases (n = 947) and healthy trauma-exposed controls (n = 947)= 4,969). Stein et al. also found evidence of genetic pleiotropy between PTSD and psoriasis and rheumatoid arthritis.

Pooling data from 11 multiethnic datasets, Duncan et al. 2018) conducted the largest GWAS study on PTSD involving 20,070 subjects including cases with PTSD and mostly trauma-exposed individuals without PTSD. Across the dataset, no single nucleotide polymorphism (SNP) was statistically significant, thus revealing a failure to replicate all previously reported genetic links to PTSD. The authors computed SNP-based heritability values for PTSD, finding an  $h_{\rm SNP}^2$  of 15% for subjects of European ancestry, chiefly driven by an  $h^2_{\text{SNP}}$  of 29% for women and an  $h^2_{\text{SNP}}$  of 7% for men that did not differ from zero. There was no evidence for the heritability of PTSD in people of having other ancestral origins (e.g., Africa, Asia). Finally, they reported a significant genetic overlap between PTSD and schizophrenia, but not with major depressive disorder.

In summary, the field of psychiatric genomics is very young, and it is grappling with many challenges such as very small effect sizes, underpowered studies, and findings that fail to replicate (Banerjee et al., 2017). Given that there are 636,120 different combinations of symptoms that qualify for a *DSM-5* diagnosis (Galatzer-Levy & Bryant, 2013), investigators may wish to probe for associations between genetic loci and specific symptoms (e.g., flashbacks, emotional numbing) or combinations thereof rather than PTSD per se.

#### Resting Psychophysiological Levels

In his meta-analysis, Pole (2007) examined 58 studies providing data on baseline levels of psychophysiological arousal. Subjects with PTSD had higher resting heart rate (HR), skin conductance level (SCL), systolic blood pressure (SBP), and diastolic blood pressure relative to trauma-exposed subjects without PTSD.

Moreover, severity of PTSD symptoms positively correlated with resting levels. Surprisingly, studies involving exposure to a post-baseline stressor (e.g., trauma stimuli, startling sounds) were associated with lower levels of resting psychophysiology than were studies involving post-baseline stressors. These findings indicate that anticipatory anxiety about imminent stressors cannot explain elevated levels of psychophysiology in PTSD.

A meta-analysis has furnished evidence of autonomic nervous system (ANS) dysfunction in people with PTSD (Schneider & Schwerdtfeger, 2020). Relative to healthy comparison subjects, those with PTSD exhibit greater HR and diminished HR variability (HRV) both at rest and while performing stress tasks in the laboratory. Taken together, these results suggest parasympathetic dysfunction and cardiac function that is insufficiently attuned to environmental changes. A large study of American Marines (n = 1,415) revealed that diminished HRV prior to combat deployment predicted heightened risk for subsequent PTSD (Minassian et al., 2015).

# Physiological Reactivity to Trauma-Related Cues

Researchers have assessed reactivity to trauma cues in two ways. In the first, subjects are exposed to standardized audiovisual stimuli relevant to traumatic events. Thus, Malloy et al. (1983) found that slides and sounds of combat evoked greater HR responses in Vietnam combat veterans with PTSD than in healthy combat veterans or in veterans with other psychiatric disorders. Likewise, Blanchard and his colleagues reported that PTSD subjects exhibit enhanced HR, systolic BP, and electromyographic (EMG) responses to audiotaped battle sounds and that these enhanced responses do not occur in healthy nonveterans, healthy combat veterans, combat veterans with other mental disorders, or nonveterans with specific phobias (Blanchard et al., 1982, 1986; Pallmeyer et al., 1986).

In his meta-analysis, Pole (2007) included 17 studies involving exposure to standardized trauma stimuli. He found that HR response and, to a lesser extent, skin conductance response (SCR) distinguished PTSD from control groups. EMG and blood pressure responses trended in the same direction.

In the second approach, researchers ask subjects to imagine traumatic events recounted in audiotaped scripts (Orr et al., 2004). These script-driven imagery studies have revealed that combat veterans with PTSD exhibit greater HR, SCR, and facial EMG (lateral frontalis) responses than do healthy combat veterans (Orr et al., 1993; Pitman et al., 1987, 1990); this effect is more pronounced for scripts that recount autobiographical than for scripts recounting generic traumatic events. Moreover, combat veterans with anxiety disorders other than PTSD do not exhibit the script-driven reactivity exhibited by combat veterans with PTSD (Pitman et al., 1990). Similar findings have emerged in civilians whose PTSD arose from childhood sexual abuse (Shin et al., 1999) or from automobile accidents or terrorist attacks (Shalev et al., 1993).

HR reactivity to trauma scripts distinguishes PTSD subjects from non-PTSD subjects with a specificity ranging from 61% to 88% and a sensitivity of 100% (Orr et al., 1993; Pitman et al., 1987). Moreover, psychophysiologic reactivity can distinguish between veterans with combat-related PTSD and veterans who are asked to fake PTSD (HR; Gerardi et al., 1989; EMG; Orr & Pitman, 1993).

Keane et al. (1998) conducted the largest study on the psychophysiology of PTSD. Recruiting Vietnam veterans from hospitals throughout the United States, they tested 778 veterans with current PTSD, 181 with past PTSD, and 369 with no history of PTSD. During both standardized audiovisual combat presentations and autobiographical combat scenes during script-driven imagery, veterans with current PTSD had greater HR, EMG, skin conductance, and diastolic blood pressure than did those with no history of the disorder. The group with past PTSD tended to fall midway between the other groups in terms of physiologic reactivity.

The magnitudes of the effects appear smaller than earlier studies on script-driven imagery in Vietnam veterans with PTSD (Pitman et al., 1987), and about one-third of the current PTSD group was nonreactive physiologically. It is unclear why the findings were so modest and why the PTSD group was statistically indistinguishable from the past PTSD group.

In his meta-analysis of 22 of these studies, Pole (2007) reported that PTSD subjects, relative to control subjects, exhibited greater EMG responses (frontalis and corrugator muscles), HR response, SCR, and DBP.

#### Exaggerated Startle Response

Consistent with self-reports of enhanced startle, sudden, loud tones evoke larger eyeblink EMG responses in combat veterans with PTSD than in healthy combat veterans (e.g., Morgan et al., 1996; Orr et al., 1995). Likewise, civilians and veterans with PTSD tend to exhibit larger EMG magnitudes than do people with other anxiety disorders or no disorder (Shalev et al., 1992). PTSD and non-PTSD groups, however, do not differ in the rates at which their EMG responses habituate to these repeated tones (Morgan et al., 1996; Orr et al., 1995; Shalev et al., 1992).

Three studies have revealed greater HR responses to loud tones in PTSD groups than in non-PTSD groups (Orr et al., 1995; Paige et al., 1990; Shalev et al., 1992). One study found larger SCRs as well (Shalev et al., 1992), whereas another did not (Orr et al., 1995). Finally, SCR magnitude habituates more slowly in PTSD subjects than they do in non-PTSD subjects (Orr et al., 1995; Shalev et al., 1992). An MZ twin study indicated that Vietnam veterans with PTSD exhibited larger HR responses to startlingly loud tones than did their non-combatexposed co-twins and Vietnam combat veterans without PTSD and their co-twins (Orr et al., 2003). The authors concluded that heightened startle reactions are a consequence of PTSD rather than a vulnerability factor for the disorder.

Pole (2007) examined 25 studies measuring startle responses to auditory stimuli in his meta-analysis. In these studies, researchers typically measured responses to tones or bursts of white noise. Relative to control subjects, PTSD subjects exhibited larger HR responses to startling sounds, and their SCRs took longer to decline. Indeed, the delayed decline in habituation of SCRs to startling sounds implies deficit regulatory processing signifying a failure to adapt (Pole, 2007).

#### Noradrenergic Dysregulation

Exposure to uncontrollable stressors activates the noradrenergic (NA) system, as exemplified by the enhanced release of norepinephrine (NE) by the brainstem locus ceruleus (Charney et al., 1993). Southwick et al. (1993) conducted a yohimbine challenge study with Vietnam combat veterans with PTSD and healthy control subjects. Yohimbine antagonizes the alpha-2 autoreceptor. Ordinarily, release of NE activates the autoreceptor, which then brakes further NE release, thereby serving as a negative feedback mechanism. By briefly blocking the autoreceptor, yohimbine enables NE to surge unimpeded. The results revealed that 70% of the PTSD subjects experienced a yohimbine-induced panic attack, and 40% experienced a concurrent flashback. Consistent with the NE dysregulation hypothesis, yohimbine produced more pronounced biochemical and cardiovascular effects in PTSD subjects than in control subjects.

#### **Emerging Themes**

During the past 10 years, the number of publications on PTSD has been far greater than those on other anxiety, OCD, and stress-related disorders (Asmundson & Asmundson, 2018). The field defies easy synopsis. There are several new themes contributing to its growth.

#### Network Analysis

PTSD has often been haunted by controversy regarding its ontological status (McNally, 2012b). Is it a biological disease entity or a socially constructed idiom of distress? Are its symptoms reflective of an underlying taxonic common cause or a latent dimension of stress-responsiveness?

Distinct from these options has been the network approach to mental disorders pioneered by Borsboom, Cramer, and their associates (e.g., Borsboom, 2017; Borsboom & Cramer, 2013; Cramer et al., 2010). Network investigators view syndromes as emergent phenomena issuing from dynamic interactions among their constitutive symptoms. They have devised computational methods for visualizing and exploring diverse disorders (Robinaugh et al., 2020), including PTSD (e.g., McNally et al., 2015, 2017). In fact, PTSD has been among the most thoroughly studied syndromes and the focus for the first network meta-analytic study (Isvoranu et al., 2020). This fast-moving field continues to devise new solutions to numerous computational and conceptual challenges it faces (McNally, 2021).

#### "Big Data" and Machine Learning

International consortia enabling the pooling of data across many clinical research centers is a growing trend. For example, in a prospective longitudinal study of 2,473 injured trauma survivors assessed in emergency rooms, Shalev et al. (2019) found that initial PTSD symptom severity scores *alone* were remarkably accurate at predicting PTSD 4–15 months later as evinced by a logistic regression model (i.e., r = .976 between predicted and raw probabilities).

Investigators have begun to apply machine learning algorithms to datasets featuring many biological and psychological variables to discover optimal algorithms for predicting PTSD (Ramos-Lima et al., 2020). Unfortunately, despite impressive results, early studies did not test the classificatory algorithm in a fresh sample of trauma survivors. However, Schultebraucks et al. (2020) used 70 biological and psychological variables to develop an algorithm to identify which of 377 injured trauma survivors would have chronic PTSD 12 months after being assessed in a hospital emergency room in Atlanta. Using latent growth mixture modeling, they identified four trajectories of posttraumatic stress: resilience, recovery, worsening symptoms, and non-remitting symptoms. They reported impressive discriminatory accuracy (i.e., area under the curve [AUC] = 0.84%) for distinguishing a resilient course versus a non-remitting one, and they replicated this effect in another prospective cohort of 377 emergency department trauma survivors in New York City (i.e., AUC = 0.83%). Of all patients predicted

to have non-remitting PTSD at 12 months, 90% did so. Only 5% of resilient patients were incorrectly predicted to have PTSD at 12 months.

#### Oxidative Stress and Inflammation

People with chronic PTSD are at heighted risk for developing metabolic syndromic, cardiac conditions, neurogenerative disease, and dementia findings that have prompted investigators to examine biological risk factors for these conditions, such as markers of oxidative stress and inflammation (Miller et al., 2018). Among the correlates presumably, consequences—of chronic PTSD are cellular aging, signaled by shortening telomeres and other markers.

A surprising prospective longitudinal study of trauma survivors admitted to the emergency department showed that *diminished* inflammatory response within hours of the trauma predicted PTSD several months later (Michopoulos et al., 2020). In contrast, patients who recovered from acute posttraumatic stress symptoms or who remained resilient by exhibiting few symptoms exhibited a robust inflammatory response following the traumatic event. As Heim (2020) observed, the striking discrepancy between elevated levels of inflammation in people with chronic PTSD and a blunted inflammatory response in the immediate wake of trauma is reminiscent of the equally counterintuitive findings of Yehuda and her colleagues who repeatedly found cortisol levels in the low-normal range in patients with chronic PTSD (Yehuda et al., 1990). If PTSD is merely an exaggerated stress response syndrome, then one would expect *elevated* tonic levels of circulating cortisol. Yehuda (2002) interpreted her findings as indicative of regulatory dysfunction in the hypothalamic-pituitary-adrenal (HPA) axis, showing that PTSDS was not merely an extreme version of a stress response.

Likewise, Michopoulos et al.'s findings imply dysfunction in the neuroimmune system. Yet interpretive caution is warranted. As Dunlop and Wong (2019) concluded in their review of HPA dysfunction in PTSD: "Despite the breadth of studies that have examined HPA axis functioning in PTSD, inconsistency in results is unfortunately the rule not the exception" (p. 373).

#### Resilience

Because most people exposed to trauma do not develop PTSD, researchers have increasingly studied people who experience only short-lived symptoms of distress without developing PTSD. *Resilience* is a rich, complex topic (Horn et al., 2016; Southwick et al., 2014). Resilience has been considered from multiple perspectives. Bonanno (2004) distinguishes between trauma-exposed people who exhibit a resilient course and those who develop PTSD but then recover. The former, he says, exhibit transitory, relatively mild symptoms before regaining their equilibrium.

Others conceptualize resilience in terms of relatively stable ("trait-like") attributes known to predict a benign posttrauma course, such as dispositional optimism and self-efficacy (e.g., Gallagher et al., 2020), intelligence (e.g., Macklin et al., 1998), or propensity to exhibit elevated levels of neuropeptide Y during acute stress(e.g., Schmeltzer et al., 2016). Finally, others focus on what people do in the wake of trauma in terms of emotion regulation techniques, for example, most likely to foster resilience (e.g., Pencea et al., 2020). For example, a prospective longitudinal study of Marines suggested that adaptive coping immediately after trauma predicted whether their symptoms were few, mild, and stable after combat deployment (Nash et al., 2015). Relatedly, others have explored the circumstances whereby people experience (or report) posttraumatic growth after undergoing major stressors (e.g., Bellet et al., 2018; Tedeschi & McNally, 2011).

#### Two Views of PTSD: DSM-5 Versus ICD-11

In recent decades the American Psychiatric Association (APA) and the World Health Organization (WHO) have endeavored to coordinate their revisions of the DSMs and the mental disorders section of the ICDs. Yet eminent international clinical scholars involved in the revision of the latest manuals, DSM-5 and ICD-11 (to become official on January 1, 2022), have been dramatically opposed to one another in their respective approaches to the nosology of PTSD (e.g., Brewin, 2013; Friedman, 2013a, 2013b). The DSM-5 team increased the number of PTSD symptoms from 17 to 20, organizing them into four, not three, subsyndromic clusters. Invoking a substantial body of research (Friedman et al., 2016), they aimed to formulate comprehensive criteria that capture the complexity of PTSD while remaining as faithful as possible to the previous, evidence-based version of the DSM.

Unconstrained by fidelity to tradition, the *ICD* team aimed to streamline criteria to foster ease of administration, especially for assessors in resource-strapped, conflict-ridden regions of the developing

world (Maercker & Perkonigg, 2013). Moreover, they aimed to streamline the diagnostic process by identifying a few hallmark symptoms of PTSD, thereby enabling assessors to distinguish the syndrome from related disorders (e.g., depression). Hence, the proposed criteria comprise only six symptoms, and a diagnosis requires at least one of the two symptoms per cluster (i.e., *Reexperiencing*: flashbacks or nightmares; *Avoidance*: avoidance of thinking about the trauma or avoidance of activities and situations reminiscent of the trauma; and *Arousal*: exaggerated startle or hypervigilance).

Trauma researchers have begun to compare the two diagnostic systems, testing whether they pick out the same individuals as PTSD-positive. One study revealed that there were a substantial number of 510 injured and hospitalized trauma civilian trauma survivors who qualified for the diagnosis under one system but not the other (O'Donnell et al., 2014). The investigators also observed that the *DSM-5* diagnosed PTSD in more of the survivors than did the provisional *ICD-11* (6.7% vs. 3.0%). It may be wise to use the *DSM-5* to diagnose PTSD in research settings because one can readily diagnose the *ICD-11* version by extracting the relevant symptoms from the *DSM-5* set.

#### **Dissociative Disorders**

The dissociative disorders category comprises syndromes whose chief feature is dissociation, defined as "a disruption of and/or discontinuity in the normal, subjective integration of one or more aspects of psychological functioning, including but not limited to—memory, identity, consciousness, perception, and motor control" (Spiegel et al., 2011, p. 826). This broad, overarching definition embraces a diversity of phenomena that do not necessarily have a common psychobiological source. For example, one self-report measure of dissociation includes mundane occurrences, such as staring off into space and being unaware of time passing, as well as eerie ones, such as failing to recognize oneself in a mirror (Bernstein & Putnam, 1986).

Other phenomena dubbed *dissociative* include feelings of unreality (depersonalization and derealization), emotional numbing, a sense of time slowing down, and claims of inability recall encoded information too excessive to count as ordinary forgetting. However, as McHugh (2008) has emphasized, calling phenomena dissociative "is merely a description with a professional ring masquerading as an explanation. One really knows no more about a case of amnesia or fugue by saying the patient 'dissociates' than by saying the patient behaved as though he or she couldn't remember" (p. 45).

The *DSM-5* recognizes three dissociative disorders (other than unspecified and other specified ones): (1) dissociative identity disorder (DID; formerly multiple personality disorder, MPD), (2) dissociative amnesia (including dissociative fugue), and (3) depersonalization/derealization disorder.

Clinicians specializing in dissociation argue that "dissociative disorders are common in general population samples and psychiatric samples" (van der Hart & Nijenhuis, 2009, p. 462). For example, one representative community survey reported an annual prevalence of 1.5% of DID, 0.8% of depersonalization disorder, 1.8% of dissociative amnesia, and 4.4% of Dissociative Disorders Not Otherwise Specified (DDNOS; Johnson et al., 2006).

# Dissociative Identity Disorder

People diagnosed with DID act as if different personalities ("alters") seize control of the person. The personalities vary in their behavior, thoughts, and feelings, and each has its own name, history, and memories. Most DID specialists believe that it arises from chronic, severe sexual and physical abuse during childhood. The victim's sense of self dissociates into multiple personalities (or states), and some presumably harbor memories of trauma too horrific for the host personality to entertain consciously. Specialists now favor the term DID over MPD because many patients seem to lack a single, integrated identity rather than having multiple, fully formed, and coherent personalities.

Case reports of dual personalities seldom appeared in the psychiatric literature prior to 1980s. One comprehensive review cited a mere 76 cases that had appeared in the previous 128 years (Taylor & Martin, 1944). Yet, following the publication of *Sybil* (Schreiber, 1973), a bestselling book about a case of MPD that soon became a made-for-TV movie, an epidemic of diagnosed cases of MPD erupted in North America. As Putnam exclaimed in 1986, "more cases of MPD have been reported in the last 5 years than in the preceding two centuries" (F. W. Putnam, quoted in McHugh, 2008, p. 20).

In contrast to most previous cases that had one or two additional personalities, Sybil had 16, and, in contrast to previous cases, Sybil supposedly harbored horrific memories of childhood sexual and physical abuse. This case introduced the idea that MPD resulted from horrific childhood trauma of which the patient's host personality was entirely unaware. As one MPD expert said, "The book *Sybil*, with its graphic treatment of the amnesias, fugue episodes, child abuse, and conflicts among alters, served as the template against which other patients could be compared and understood. . . . Schreiber's account is both detailed and accurate enough to serve as mandatory clinical reading for students of MPD" (F. W. Putnam, 1989, p. 35, quoted in Borch-Jacobsen, April 24, 1997).

Hence, the Sybil case inspired the idea that MPD was an unusually severe form of PTSD. Assuming that the mind can protect itself by dissociating memories of horrific trauma from awareness, MPD theorists argued that childhood trauma fractures the mind of patients, creating alter personalities that contain memories that the patient must recall via hypnosis for recovery to occur.

Publications on DID and other dissociative disorders peaked in the mid-1990s before plummeting dramatically in the early twenty-first century (Pope et al., 2006). Malpractice lawsuits against dissociative experts accused of inadvertently fostering false memories of satanic ritual abuse in patients they suspected of having DID may have reduced enthusiasm for detecting hidden multiplicity among one's caseload of patients, thereby contributing to the end of the epidemic (Acocella, 1999). Other clinicians outside the community of dissociative specialists argue that DID constitutes a culturally shaped idiom of distress influenced by dramatic media portrayals of the syndrome and by misguided therapeutic practices, such as hypnotic elicitation of alter personalities (Lilienfeld et al., 1999).

Recent scholarship on the Sybil case has uncovered many startling facts (Borch-Jacobsen, 2009; Nathan, 2011). Sybil's mother was neither abusive nor psychotic. Rather than being a survivor of horrific abuse, Sybil was an imaginative only child who enjoyed a comfortable, somewhat pampered childhood. As a young woman, she moved to New York City to pursue an artistic career, and dissatisfaction with her life led her to seek psychoanalytic treatment with the psychiatrist Cornelia Wilbur. Fascinated by the recent case depicted in "The Three Faces of Eve," Wilbur was keen to encounter another case of multiple personality. Using hypnosis, sodium pentothal ("truth serum"), and other medications, Wilbur elicited Sybil's dramatic alters and her dissociated memories of horrific childhood trauma. Recently scrutinized audiotapes of Wilbur's sessions with Sybil document her inadvertent shaping of Sybil's multiple personalities. On one tape, Sybil admits to manufacturing her trauma stories and multiple personalities, but Wilbur refused to accept

this admission. Ironically, the patient who inspired the epidemic of MPD and the trauma theory of the disorder was never a trauma survivor after all.

The controversy over DID concerns its etiology, not its reliability. Indeed, the interrater reliability of the diagnosis is satisfactory (Gleaves et al., 2001). Reliable diagnoses have permitted experimental researchers to test hypotheses about DID in the laboratory.

Huntjens and her colleagues have conducted experiments testing hypotheses about interidentity amnesia in Dutch patients diagnosed with DID. Their basic strategy is to test three groups: patients diagnosed with DID, control subjects trained to simulate DID, and a nonsimulating control group. The simulators view a documentary about the disorder and receive coaching on how to role-play DID.

In one study, subjects memorized names of animals, vegetables, and flowers (Huntjens et al., 2003). The DID and simulating subjects then switched to a second personality who memorized names of other animals, other vegetables, and furniture. A recall test and a recognition test 1 week later for words they had memorized indicated that both control groups and the DID group remembered words from the first list as well as words from the second list. Therefore, the second personality remembered material encoded by the first personality, documenting interidentity transfer of information, a finding inconsistent with purported amnesia. Similar findings emerged for emotionally valenced words (Huntjens et al., 2007).

Testing DID and control subjects, Kong et al. (2008) extended these findings, showing that interidentity transfer in DID cannot plausibly be attributable to implicit memory effects. That is, they had one personality encode words auditorily and then tested the other, amnesic personality visually. Memory transfer across identities occurred despite cross-modality (i.e., auditor vs. visual) between encoding and testing.

Using a concealed information task, Huntjens et al. (2012) documented interidentity transfer of autobiographical information in patients diagnosed with DID. They recruited three groups of subjects, all women: patients diagnosed with DID, amateur actors trained to simulate DID, and another group consisting of nonactors. The authors administered an autobiographical questionnaire to all subjects, asking about the name of their best friend, their favorite food, favorite sport, and so forth. The DID patients completed the questionnaire twice, once as the trauma identity who reported memories of childhood sexual abuse, and again as an identity reportedly amnesic for memories of abuse. For example, a DID trauma identity might have written down the words *Janet, pizza*, and *swimming* in response to questions about the name of her best friend, favorite food, and favorite sport, whereas the amnesic identity might have written down the answers *Mary, steak*, and *tennis*. The authors had subjects rate the personal emotional relevance of words drawn from these questionnaires, plus many other irrelevant words, and the DID patients did so in their amnesic identity, thus enabling the authors to select words from the trauma identity's questionnaire that the amnesic identity rated as personally irrelevant.

Two weeks later, subjects performed a concealed information task whereby they viewed a series of words in uppercase letters on a computer screen. They had to decide as quickly as possible whether they recognized the word as a member of the previously memorized target set of three words (e.g., SUSAN, CHOCOLATE, BOWLING) or whether the word was a nontarget word. Among the nontarget items were the three words having autobiographical significance for a DID patient's trauma identity (e.g., JANET, PIZZA, and SWIMMING) and the three words having autobiographical significance for the patient's amnesic identity (e.g., MARY, STEAK, and TENNIS). The computer recorded the reaction times for the recognition/classification decisions.

The results revealed that subjects were very fast to classify irrelevant words, and they were slow to classify nontarget words that possessed autobiographical significance (e.g., their best friend's name). The slowed reaction times signified recognition of the word's personal relevance. That is, they had to inhibit the impulse to respond "yes" to the question of recognition. Accordingly, in the DID group, the amnesic identities performed this task, and their reaction times to respond "no" to words having considerable autobiographical significance was very slow (e.g., MARY, STEAK, and TENNIS), signifying their recognition of the personal importance of these items. Crucially, these patients were just as slow to respond to the corresponding items of their trauma identity of which they were allegedly amnesic (e.g., JANET, PIZZA, and SWIMMING). These data are inconsistent with the notion of interidentity amnesia. Indeed, if the amnesic identity were truly unable to access the autobiographical material of the trauma identity, then the reaction times to classify these items would not have been as slow as

those for classifying the autobiographical items of the amnesic identity. Taken together, experimental research does not support claims of interidentity amnesia in DID.

Using positron emission tomography (PET), Reinders and her colleagues have investigated central and peripheral psychophysiological responses to trauma-relevant and neutral autobiographical memory scripts in a group of 11 women diagnosed with DID (Reinders et al., 2006). They tested two personalities of each of the patients. The traumatic identity state had access to traumatic memories, whereas the neutral identity state had "a degree of amnesia for traumatic memories ranging from lack of personalization of the traumatic past to total amnesia" (Reinders et al., 2006, p. 730). They used a script-driven imagery paradigm whereby each personality (identity state) heard two autobiographical memory scripts, one traumarelevant and one neutral. The results showed significant increases in subjective and cardiovascular responses to trauma scripts than to neutral scripts, and these increases were more pronounced when the traumatic identity state heard the scripts than when the neutral identity state heard them. The two personalities also exhibited different patterns of cerebral blood flow when they listened to the trauma scripts.

Although these data indicate marked distress and psychophysiological activation to the trauma scripts, these responses do not confirm the authenticity of the memories per se. Indeed, marked psychophysiological activation occurred among people reporting having been abducted by space aliens when they heard scripts describing their (presumably false) memories of their most traumatic encounters with aliens (McNally et al., 2004). Moreover, it is a straightforward matter for neutral identities to attenuate their responses to trauma scripts evocative for trauma identities; neutral identities merely need to distract themselves from attending to the otherwise evocative script.

Reinders et al. (2012) subsequently enrolled two groups of healthy control subjects, one scoring high on a measure of fantasy proneness and the other scoring low on this measure. They coached both groups to simulate DID. Each simulating subject heard two autobiographical memory scripts, one neutral and one trauma related. Reinders et al. compared the results from these two simulating control groups with those of the DID patients from their previous study. The results revealed that neither control group mimicked the cerebral or peripheral responses of the DID group when all groups heard their trauma scripts. Because the high fantasy group failed to mimic the psychophysiology of the DID group, the authors concluded "that DID does not have a sociocultural origin" (Reinders et al., 2012, p. 1).

However, the data do not compel this conclusion. To be sure, high fantasy proneness in healthy control subjects is insufficient to incite marked psychophysiological responses to stressful scripts in psychologically healthy people who endeavor to mimic the responses of DID patients. Yet this did not mean that elevated fantasy proneness fails to contribute to the emergence of DID in distressed individuals undergoing hypnotic interventions to elicit alter personalities who presumably harbor dissociated memories of trauma.

#### Dissociative Amnesia

*DSM-5* characterizes dissociative amnesia as an inability to retrieve important, encoded, personal information that cannot be attributable to ordinary forgetting or to a toxic or physical insult to the brain or to DID. Dissociation theorists emphasize that the information is often related to an extremely stressful or traumatic experience. The *DSM-5* recognizes three types: localized amnesia (i.e., inability to recall events from a certain period), selective amnesia (i.e., only a part of the traumatic event can be recalled), and rare, generalized amnesia (i.e., complete loss of one's personal history and identity).

Distilling the key points of this perspective in his book entitled *Repressed Memories*, Spiegel (1997) emphasized that the nature of traumatic dissociative amnesia is such

that it is not subject to the same rules of ordinary forgetting; it is more, rather than less, common after repeated episodes; involves strong affect; and is resistant to retrieval through salient cues. (p. 6)

That is, dissociation theorists hold that the more often trauma occurs and the more emotionally distressing it is for the victims, the more likely they will be unable to remember having suffered any trauma. Moreover, encoded, consolidated but dissociated—memories of trauma will not be accessible by ordinary means, such as merely interviewing people about their trauma histories. These assumptions justified the use of hypnosis, guided imagery, and other methods to recover the otherwise inaccessible dissociated memories, process them emotionally, and incorporate them into the narrative of their lives. Discussing the work of Jean Charcot, Pierre Janet, and Sigmund Freud, the historian of psychiatry Borch-Jacobsen described "the birth of a true psychiatric myth, fated to a grand future: *the patient is entirely ignorant of the trauma that caused his symptoms*" (2009, p. 30). Indeed, using Internet search engines, Pope and his colleagues were unable to identify a single case of alleged traumatic dissociative amnesia in the world literature of fiction, history, or medicine prior to 1786 (Pope et al., 2007a, 2007b). They concluded that claims of dissociative amnesia are a culture-bound idiom of distress.

Janet and Freud further developed and popularized the concepts of traumatic dissociative amnesia and repression, respectively. Despite their minor theoretical differences, both theorists agreed that the mind protects itself by dissociating or repressing emotionally disturbing material, rendering it inaccessible to awareness. Recovery of this material, processing it emotionally, and integrating it into one's autobiographical narrative was the road to healing and symptomatic recovery, notions that resurfaced in the discredited "recovered memory therapy" of the late twentieth century (Crews, 1995, pp. 216–218).

Clinicians specializing in dissociation have claimed that survivors of diverse trauma events ranging from childhood sexual abuse to the Holocaust have exhibited dissociative amnesia (Brown et al., 1999; van der Hart & Nijenhuis, 2009). Yet an extensive analysis of documented cases of trauma found no instance of victims being incapable of recalling their trauma except when they had sustained a head injury or had experienced the event in the first years of life and thus during the period of childhood amnesia (Pope et al., 1999).

Strikingly, dissociative amnesia theorists (e.g., Brown et al., 1999) and their critics (e.g., Piper et al., 2000) often cite the same studies in support of their diametrically opposed conclusions. How can this be? The answer is that dissociative amnesia theorists seemingly misunderstand the very data they cite in support of their position. For example, the memory phenomena those dissociation theorists have adduced in support of the claim that people can encode traumatic experiences yet be unable to recollect them are wide-ranging (for an extensive review, see McNally, 2003a, pp. 186-228). They have confused everyday forgetfulness following trauma for an inability to remember the trauma itself. They have confused reluctance to disclose trauma with an inability to recall it. They have confused not thinking about something for a long time with an inability to remember it. They have confused failure to encode aspects of a trauma with inability to remember trauma. They have confused childhood amnesia and organic amnesia with dissociative amnesia.

*Fugue* is a syndrome is characterized by aimless wandering, often coupled with amnesia for parts of the journey (Kopelman et al., 1994). One scholar of psychiatry conceptualized it as a transient mental illness that flourishes only as long as the cultural niche that produces it remains (Hacking, 1998). He described an epidemic of fugue erupting in late nineteenth-century France, often among soldiers bored in the barracks who went on unauthorized leaves. The epidemic ended shortly after World War I.

Although the *DSM-5* implicates overwhelmingly stressful or traumatic events as the precipitants of dissociative fugue, trauma seldom figures in most of the historical case studies. For example, Stengel (1941) described 25 cases of fugue, noting that trauma seldom triggered the fugue. Moreover, many cases did not claim amnesia for the period when they fled. Stengel suggested that head injury, suicidal ideation, interpersonal problems, epilepsy, and growing up with disturbed parents appeared to be risk factors. In all likelihood, sudden, seemingly aimless travel has diverse antecedents.

#### Depersonalization/Derealization Disorder

During a depersonalization episode, people feel emotionally numb, feel disconnected from their body, and experience the world as an unreal dream (i.e., derealization). Many people will experience brief episodes of depersonalization or derealization when exhausted, during marijuana intoxication, during a panic attack, or when encountering sudden danger. However, people with the disorder experience an unrelenting state that may last for months or years; others experience recurrent episodes interspersed with periods of normal consciousness. The onset is usually sudden, and many people fear for their sanity.

Though appearing under the dissociative disorders rubric, there is scant evidence pertaining to its etiology, pathophysiology, or its relation to other dissociative syndromes. This eerie disturbance in consciousness may arise from corticolimbic disconnection. For example, Sierra and Berrios (1998) have suggested that activation of the right dorsolateral PFC and reciprocal inhibition of the anterior cingulate may produce the sensation of mind emptiness. Left prefrontal inhibition of the amygdala would foster hypoemotionality and emotional detachment from the world. Although there is more theory than data on this syndrome, research is slowly accumulating (e.g., Sierra et al. 2012).

# Conclusion

Since the appearance of the Sybil case, many clinicians have interpreted dissociative disorders as arising from trauma (Dalenberg et al., 2012). Many patients diagnosed with these syndromes surely have trauma histories; indeed, epidemiological studies show that most people are trauma survivors (Breslau & Kessler, 2001). More controversial are claims that DID and dissociative amnesia arise from horrific experiences of which patients are unaware. The notion that these patients encode traumatic experiences yet become incapable of recalling them, except under certain circumstances (e.g., hypnosis), runs counter to research on trauma, emotion, and memory. Moreover, experimental research on DID has repeatedly shown that information-neutral, emotional, or autobiographical-transfers across identities, thus undermining the central claim of amnesia. The notion that these syndromes are extreme versions of PTSD is a claim without convincing empirical support. A multifactorial account of these syndromes involving variables such as suggestibility, fantasy proneness, and suggestibility seems warranted (Lynn et al. 2014).

# CHAPTER

# Mania and Bipolar Spectrum Disorders

June Gruber, Victoria Cosgrove, Alyson Dodd, Sunny J. Dutra, Stephen P. Hinshaw, Stevi G. Ibonie, Piyumi Nimna Kahawage, Thomas D. Meyer, Greg Murray, Robin Nusslock, Kasey Stanton, Cynthia M. Villanueva, *and* Eric A. Youngstrom

When you're high it's tremendous. The ideas and feelings are fast and frequent like shooting stars, and you follow them until you find better and brighter ones. Shyness goes, the right words and gestures are suddenly there, the power to captivate others a felt certainty. . . . The fast ideas are far too fast, and there are far too many; overwhelming confusion replaces clarity. Memory goes. Humor and absorption on friends' faces are replaced by fear and concern.

—Jamison (2004, p. 67)

Bipolar disorder (or BD) is a serious and recurrent psychological disorder. As described in the above quote by Kay Redfield Jamison, BD is characterized by episodic and prolonged mood episodes that range between abnormally and persistently elevated mood phases lasting a week or longer (mania) and frequently periods of dysphoria mood (depression) lasting 2 weeks or longer (DSM-5). Importantly, BD is associated with significant and dire consequences including occupational, social, and even mortality costs (e.g., Coryell et al., 1993; Dilsaver, 2011; Romans & McPherson, 2002). BD has been associated with significant increases in suicidality and is rated as one of the leading causes of disability worldwide (e.g., Murray & Lopez, 1996; Schaffer et al., 2015). This chapter (a) provides an overview of the phenomenology and assessment of BD; (b) reviews associated psychobiological processes across cognitive, affective, neural, and circadian rhythm dimensions; (c) considers the influence of context and social environment on BD; (d) synthesizes empirically supported interventions to prevent and treat BD; and (e) highlights future directions in the study of BD that focus on increasing diversity and representation of marginalized communities and addressing stigma about BD and related psychiatric disorders.

#### Phenomenology and Diagnostic Criteria

In the *DSM-5*, bipolar spectrum disorders (BSDs) refer to a broad umbrella of mood-related difficulties that progress along a spectrum that encompasses varying degrees of depression and mania or hypomania-like severity and duration. This typically includes four categories: bipolar I (BD I, defined by the occurrence of at least one manic episode; bipolar II (BD II), which requires a lifetime combination of a major depressive episode and at least one hypomanic episode; cyclothymic disorder, characterized by hypomanic and depressive symptoms not severe enough to warrant a manic or major depressive label, yet still impairing and often more persistent. The last category, which had been referred to as BD Not

Abbreviations	
BD	Bipolar disorder
BSDs	Bipolar spectrum disorders
FFT	Family-focused treatment
HPS	Hypomanic Personality Scale
ICM	Integrative cognitive model (of mood
	dysregulation)
IDAS	Inventory for Depression and Anxiety
	Symptoms
IPSRT	Interpersonal and social rhythm
	therapy
MDQ	Mood Disorder Questionnaire
OFC	Orbitofrontal cortex
SCN	Suprachiasmatic nucleus

Otherwise Specified (BD-NOS) is a residual group for cases where there are mood symptoms that are clearly a change from baseline and that are associated with impairment, but which fail to meet strict criteria for one of the other mood disorders.

Both the current DSM-5 and ICD nosologies note that the depressed phases of BSDs have the usual symptoms of unipolar depression and also a lot of anxiety (Youngstrom & Van Meter, 2013). The hypomanic and manic presentations have high energy, rapid speech, and distractibility (shading into flight of idea) that can look similar to attention deficit hyperactivity disorder (ADHD); and the impulsive, goal-directed, rule-breaking behavior can lead to substantial interpersonal conflict and conduct problems. Periods of unusually elated, goofy mood or decreased need for sleep without fatigue (or even with increased energy) are less likely to be the focus of a clinical referral, but are more suggestive of hypomania than irritability alone, for example. The depressive phases of BSDs can have acute or gradual onset (more typical of persistent depressive or cyclothymic presentations) and often have a mix of increased energy and other manic symptoms, appearing as an "agitated depression" with an irritable mood. Hypomania also may be irritable as well as elated or euphoric, as might manic episodes. These, too, can have mixed presentations where anxious or depressive symptoms may be juxtaposed. Some data indicate that mixed presentations are even more common in youth than in later life. Data are inconsistent about whether the first episode is more likely to be a depressive or hypomanic episode (Van Meter, Burke, Youngstrom et al., 2016). The most helpful way to differentiate mood disorders from other issues is if the behaviors are a change from typical functioning, wax and wane, or manifest sometimes without an obvious environmental trigger (Youngstrom et al., 2008).

Epidemiological data indicate that cyclothymic disorder and otherwise specified bipolar and related disorders (OS-BRDs) are three to four times more common than BD I or II (Moreira et al., 2017; A. Van Meter et al., 2019), also consistent with the dimensional statistical models and our emerging understanding of etiology as involving both multiple genes and environmental risk factors. All the BSDs are associated with substantial impairment, and cyclothymia and OS-BRD have high rates of progression to BD I or II. Some data suggest that remission may be possible in a subset of cases, particularly with early and titrated intervention (e.g., Cicero et al., 2009). Other differential diagnoses to consider include all major depression and persistent depressive disorders (which will not have a history of hypomanic or manic episodes), anxiety disorders (which also will not have the hypomanic/ manic history, though they may have the motor agitation and poor concentration), oppositional and conduct problems and ADHD (which will tend to be more chronic and less likely to show fluctuations in sleep or energy), and trauma or abuse (which could also be linked with an acute change in functioning). Because comorbidity is common, it is possible to have both BSDs and any of these, and BSDs may be a trigger as well as an outcome of some of these issues (Youngstrom & Algorta, 2014).

#### Assessment of Bipolar Disorders

To accurately determine a mood disorder diagnosis requires a longitudinal perspective. Because the course can be intermittent and with different polarities of episode, any single snapshot of clinical presentation provides an incomplete view. Only after gathering a careful developmental history, not just asking about current mood and functioning, but also looking for past episodes, are we ready to proceed with diagnostic formulation. The clinical encounter in which BD is assessed can be divided into four phases: preparation, prediction, prescription, and process/progress, described below.

#### PREPARATION

Before first meeting the patient, a psychologist or clinician can prepare to do a rapid yet accurate evaluation by having a good framework in place. This includes having a set of benchmarks for common issues, helping calibrate where BD ranks compared to other presenting problems. Reviews have gathered these across a variety of clinical settings (e.g., Youngstrom et al., 2020). Looking at the clinical prevalence of disorders in outpatient mental health clinics shows that conduct problems, ADHD, depression, and anxiety are the most common problems, with BSDs falling in a tier similar to the prevalence of posttraumatic stress disorder (PTSD) or conduct disorder. These in turn are more common than autistic spectrum or schizophrenia in the child and adolescent population typically coming to general purpose outpatient clinics. Such benchmarks provide a helpful anchor for clinical evaluations and decision-making. Having a rating scale toolkit1

<sup>&</sup>lt;sup>1</sup> https://en.wikiversity.org/wiki/Evidence-based\_assessment/Bipolar\_disorder\_in\_youth\_(assessment\_portfolio)

along with semi-structured interview modules gathered ahead of time allows clinicians to rapidly follow up on clues to arrive at a case conceptualization.

#### PREDICTION

Several rating scales and checklists are wellsuited for screening or rapid information gathering before the first appointment. These could be mailed ahead of time, completed in the waiting room, or even done online with automated scoring. A "core battery" should gather data about common issues (anxiety, depression, trauma, externalizing and attention problems, substance use), ideally from more than one informant's perspective. Less obviously, this is an opportunity to also gather family history (Algorta et al., 2013), and there are free, brief measures to get an indication of pubertal stage. There are more than a dozen scales focused specifically on manic symptoms for youths (Youngstrom et al., 2015), and more than 40 for use with adults (Youngstrom et al., 2018). Free PDFs of these in English, Spanish, and several other languages are available online, and some are available with free administration and scoring guides (https://www. hgaps.org/for-clinicians.html).

#### DURING PRESCRIPTION

During the prescription phase, the clinician will review the presenting problem, look at the results from the scales used in the prediction phase, and revise the probabilities attached to our list of hypotheses. They will use the interview to probe for confirming or disconfirming evidence and arrive at a working diagnosis and case formulation. The information-gathering here is in service of coming up with a treatment plan that addresses the key problems and guides our intervention selection to best meet the needs of the patient. Using more structured methods increases reliability and improves detection of comorbidity (Jensen-Doss et al., 2020).

#### PROCESS AND PROGRESS

During the next phase, assessment shifts to seeing how treatment is going. Process measures include keeping track of no-shows and short cancellations versus kept visits, whether the patient is doing "homework," and other indicators of engagement. Process measures could also include brief, direct ratings of therapeutic alliance, knowledge acquisition (especially with more psychoeducational modalities), sleep tracking apps, life charts, and mood records. There are a large and growing number of options for tracking whether we are "doing the work" together. Progress measures, in contrast, focus on "is treatment helping?" These measures can include brief symptom checks (e.g., severity ratings on mood charts), short forms of symptom scales, or nomothetic benchmarks for clinically significant change (Freeman & Young, 2020). A plan for long-term monitoring and early detection of relapse would be an excellent component of treatment termination planning, given the high recurrence risk associated with BSDs (Youngstrom et al., 2020).

# Contextualizing Assessment Within Dimensional Frameworks

When diagnosing and assessing BSDs, recent attention has been given to considering alternative and more dimensional approaches to symptom severity and diagnosis. Specifically, decades of research indicate limitations of disorder definitions as described in the DSM-5, including poor interrater reliability, high levels of disorder co-occurrence, and within-disorder heterogeneity, among other issues (Kotov et al., 2020). As an example of within-disorder heterogeneity in the context of BSD diagnosis, two individuals could report mutually exclusive histories of specific hypomanic symptoms, but both could be diagnosed with BD II. For instance, the first individual could report a history of expansive mood, grandiosity, decreased need for sleep, and a marked increase in goal-directed activities, whereas the second could report a history of irritable mood, pressured speech, racing thoughts, distractibility, and engagement in risky or dangerous activities, yet both individuals would receive the same diagnostic label. Issues concerning interrater reliability and diagnostic comorbidity complicate treatment planning by making it difficult for clinicians to determine which presenting issues are primary and most impairing (e.g., individuals diagnosed with BD often also meet criteria for substance use disorders, personality disorders, and other disorders). Many DSM-5 disorder descriptions also remain largely agnostic regarding etiological factors and mechanisms accounting for symptom onset and maintenance. Relatedly, many of these descriptions provide limited consideration of how social and contextual factors influence symptom presentation, symptom course, and treatment.

Accurate BSD diagnosis can be challenging because many individuals with a hypomania/ mania history often present for treatment at times when depressed mood, anxiousness, interpersonal difficulties, or other issues are present, rather than when hypomanic/manic symptoms are most prominent. Researchers have raised concerns about BSD underdiagnosis (Carta & Angst, 2016) because hypomania/mania symptom histories may go undetected if clinicians fail to adequately assess for a hypomania/mania history in individuals presenting to treatment for other issues. Measures such as the Mood Disorder Questionnaire (MDQ; Hirschfeld et al., 2000) have become commonly used to retrospectively assess for a hypomania/mania history. Still, many individuals may have difficulty accurately recalling their symptom histories.

Other researchers have cautioned that BSDs are overdiagnosed rather than underdiagnosed because some individuals may have symptom histories better accounted for by disorders such as borderline personality disorder (Zimmerman et al., 2019). These issues may arise as a result of the hypomania/mania criteria seemingly overlapping with internalizing (e.g., irritability with anxiety disorders), externalizing (e.g., impulsivity with personality disorders), and psychotic disorders (e.g., grandiose views with schizophrenia). For example, it may be challenging for diagnosticians to determine whether experiences of intense irritability are indicative of BSDs because elevated levels of irritability are listed as a criterion for many disorders and are commonly reported by many individuals seeking treatment irrespective of diagnosis (Stanton et al., 2019).

As a result of these challenges associated with diagnosing BSDs and other disorders from a DSMbased perspective, the Hierarchical Taxonomy of Psychopathology (HiTOP; Kotov et al., 2020) has been proposed as an alternative to the DSM for improving diagnosis and understanding how various symptom experiences are interconnected. The HiTOP framework adopts a dimensional approach to conceptualizing psychopathology, recognizing that most symptoms are continuous rather than categorical in nature (e.g., experiences of irritability range from minor to very severe rather than present or absent). For example, from the HiTOP perspective, many symptom types defining DSM-5 depressive, anxiety, and other disorders characterized by experiences of intense and/or persistent negative affect (e.g., sadness, pervasive worry, feelings of guilt) would be classified under a broad internalizing spectrum. The "hierarchical" descriptor for the HiTOP reflects that internalizing also is defined by sub spectra labeled fear and distress. Considering even more nuanced levels of specificity, the fear and distress sub spectra are defined by even more

specific symptom dimensions (e.g., trembling, racing heart, and sweating are indicators of fear; worry and sadness are indicators of distress).

As an example illustrating the application of this approach, a clinician using the HiTOP model would identify dysphoric mood dimensionally as indicating distress-based problems associated with internalizing psychopathology (Ruggero et al., 2019); with the *DSM*-based approach, clinicians would seek to determine which *DSM* label or labels (e.g., different depressive disorders, PTSD) best reflect an individual's experiences of dysphoric mood, which can prove challenging. In addition to internalizing, other HiTOP spectra include thought disorder (e.g., positive symptoms of psychosis), antagonistic externalizing (e.g., callousness), disinhibited externalizing (e.g., irresponsibility), and detachment (e.g., aloofness).

Hypomania/mania is provisionally identified as a component of thought disorder due to its phenotypic and genetic overlap with DSM disorders such as schizophrenia. However, hypomania/mania (a) also overlaps strongly with the internalizing spectrum and (b) has features that distinguish it from other forms of psychopathology defining thought disorder (e.g., a more episodic course; being linked to reward hypersensitivity; Kotov et al., 2020). Thus, it is possible that some hypomanic/manic dimensions do not align neatly with the existing HiTOP structure and may reflect a hypomania/ mania spectrum distinct from other spectra such as internalizing and thought disorder. Most studies examining the classification of hypomania/mania within the HiTOP have focused on composite, diagnostic ratings (i.e., *present* or *not present* ratings) which has precluded examinations of the degree to which different hypomania/mania symptoms converge to define the same spectrum of symptoms (e.g., irritability, but not other hypomania/mania symptoms, may define internalizing). Therefore, future efforts explicating the classification of hypomanic/manic symptom dimensions within comprehensive dimensional models are needed to inform clinical assessment.

#### Existing Measures for the Dimensional Assessment

Although research is needed to inform hypomania/mania assessment in the ways described, existing measures are available for dimensionally assessing hypomania/mania in a manner consistent with the HiTOP. For example, the Expanded Version of the Inventory for Depression and Anxiety Symptoms (IDAS-II; Watson et al., 2012) includes Euphoria (5 items, e.g., "had so much energy") and Mania (5 items, e.g., "thoughts raced") scales that efficiently assess interrelated but distinct hypomania/ mania dimensions. The Euphoria scale assessing high-arousal positive emotional experiences may be particularly useful for distinguishing hypomania/mania from overlapping internalizing or personality disorders (Stanton et al., 2019). Other relevant measures include the 48-item Hypomanic Personality Scale (HPS; Eckblad & Chapman, 1986; Schalet, Durbin, & Revelle, 2011), which assesses traits (e.g., excitability, self-perceived charisma) relevant to BD risk. Researchers frequently use HPS total score cutoffs to identify individuals at risk for hypomania/mania. More specific facet scales of Social Vitality (e.g., "persuade and inspire others"), Mood Volatility (e.g., "moods change easily"), and Excitement (e.g., "am a hyper person") also can be scored with the HPS items, with these facet scales appearing to show distinctive correlates in many ways (e.g., Social Vitality associates strongly with measures of social dominance, but Mood Volatility does not; Schalet et al., 2011).

It also should be noted that the HPS is only one example of dimensionally oriented assessment measures, as several other well-validated assessment tools also are available for efficiently assessing BD risk, such as the General Behavior Inventory (GBI; Depue et al., 1989), and current hypomania/mania symptoms in a dimensional manner (see Meyer et al., [2020] for a review).

#### Developmental Considerations

The onset of BD most commonly occurs in childhood or adolescence (Leverich et al., 2007; Perlis et al., 2004). BD in childhood and adolescence often presents with a severe and protracted course, including severe depressive symptomatology, mixed episodes, longer episode durations, psychosis, cooccurring psychopathology (e.g., substance use disorders, anxiety disorders, etc.), and psychosocial adversity (e.g., legal problems, academic impairment) (Birmaher et al., 2006; Cosgrove et al., 2013; Geller et al., 2002; Perlis et al., 2004; Saxena et al., 2020; Yapıcı Eser et al., 2020) compared with adults. More than 50% of adults with BD report onset of illness before age 18, while more than 20% identify age at onset before 13 (Perlis et al., 2004). Symptoms in youth may include dysregulation of emotion, heightened arousal when presented with emotional stimuli, and hypersensitivity to criticism (Peters et al., 2018; Weintraub et al., 2014). Major depressive episodes and cyclothymia are often harbingers of symptoms of mania. About half of all adults with BD I or II report that their first episode was major depression (Lish et al., 1994).

Issues surrounding the commonness of earlyonset BD have been contentious in recent decades, associated with dramatic increases in reported community prevalence (Carlson & Glovinsky, 2009; Luby & Navsaria, 2010; Moreno et al., 2007). However, meta-analyses have repeatedly confirmed that rates of BD in youth are not increasing over time and are indeed similar across Western countries (A. R. Van Meter et al., 2011, 2019). While appreciable debate has persisted in recent years (Parry et al., 2018; A. Van Meter et al., 2019) regarding the legitimacy of the diagnosis, longitudinal studies have clearly documented the recurrent course of early-onset BD and its effect on functioning and quality of life (Birmaher et al., 2009; Chang, 2010)). It is clear that without early intervention, the socioemotional and intellectual growth of youth with BD may be jeopardized (Miklowitz, Schneck et al., 2020).

Among youth who have a parent with BD I or BD II, clinical presentation is often subthreshold, with some symptoms emerging many years prior to the onset of threshold BD (Shaw et al., 2005). Subthreshold symptomatology, in conjunction with a family history of BD, exacerbates child or adolescent vulnerability for progression to BD I or II unless interrupted by pharmacological and/or psychosocial intervention (West & Pavuluri, 2009). Risk of conversion from BD-NOS to BD I or II during a 4year follow-up is substantial (i.e., 58%) for youth with a family history, compared to 32% for youth with no family history. BD in youth results from a complex interplay of genetic vulnerability, individual personality, and characteristics of a youth's family environment. For example, emotional dysregulation may intensify conflict within families and raise levels of expressed emotion in caregivers (i.e., high criticism, hostility, negative communication cycles), which can in turn exacerbate symptomatology in youth with BD (Miklowitz, Wisniewski et al., 2005). Adolescents with BD in low-conflict families experience more rapid symptom improvement during treatment than do those from highconflict families (Sullivan et al., 2012; Sullivan & Miklowitz, 2010). In one seminal study, adolescents with BD from families high in expressed emotion showed longer times to symptom remission and were more symptomatic during a 12-month follow-up period than those from families low in expressed emotion (Miklowitz et al., 2013). Such impairments have been proposed to be associated with deficits in social cognition (Keenan-Miller et al., 2012), with potential downstream implications for the development and maintenance of important peer relationships.

Adolescents with BD who experience chronic stress in family, peer, or romantic relationships tend to experience poorer symptomatic outcomes than those with lower levels of chronic stress (Kim et al., 2007). Although exposure to stressful environments is a risk factor for mood disorders, less is known about how adolescents with BD respond to stress. In both healthy and clinical samples of youth, responses to stress (i.e., active problem-solving and acceptance) have been found to be associated with positive mental health outcomes and academic and social competence (Compas et al., 2001).

#### **Relevant Psychobiological Processes**

In this section, we review relevant cognitive, emotional, neural, and circadian rhythm processes that are relevant to the onset, course, and profile of BSD.

# **Cognitive Processes**

Aaron Beck's seminal cognitive model of emotional disorders (see Beck & Haigh, 2014, for a review) was one of the first theoretical frameworks to place cognitive styles (e.g., beliefs, ways of interpreting experiences) as central to the development and maintenance of psychopathology. Specifically, negative beliefs about the self, world, and others were linked to depression. This includes dysfunctional assumptions, which are negative "if-then" beliefs (e.g., "If I fail, then I am useless"). These can shape the way that someone with depression thinks about everyday situations and interacts with the world. As depressed mood is a common experience among people with BD, psychologists postulate that negative dysfunctional attitudes may also play a role in BD.

But what about mania (i.e., a diagnosis of BD)? This was traditionally viewed as "opposite" to depression (*bi*-polar). As such, mania has been theoretically linked to overly *positive* cognitive styles. For example, people with BD who had a higher "sense of hyper-positive self," characterized by excessive confidence and productivity, were more likely to relapse even after receiving cognitive therapy—potentially because they viewed the emerging symptoms of a (hypo)manic episode as desirable and due to their own positive attributes (Lam, Wright, & Sham, 2005). Heightened goal attainment beliefs (e.g., believing you need to be "outstanding") have been associated with current manic symptoms (Atuk & Richardson, 2020). In line with this, a body of work has focused on *goal dysregulation* and BD. This theory postulates that the behavioral activation system (BAS), which controls reward responsivity, is overly sensitive in BD. This oversensitivity means that people with BD find it difficult to regulate response to reward and goal-related events. Goal-relevant cognitive styles, including extreme aspirations for the future (particularly popular fame and financial success) and greater expectation of success, have been linked to BD (Johnson, Carver et al., 2012; Johnson et al., 2017).

Taken together, results suggest that both negative and positive cognitive styles are implicated in BD. Cognitive models of BD need to address the experience of mood fluctuation (highs and lows) that are part of BD. Cognitive theories of BD further suggest that the symptoms of BD manifest from making self-referent interpretations (or internal appraisals) of the mood changes linked to disrupted sleep (Jones et al., 2006). These appraisals can be negative (e.g., interpreting low mood as indicating failure) or positive (e.g., interpreting heightened mood and increased energy as indicating success and productivity). These themes overlap with dysfunctional attitudes (negative appraisals) and goal-relevant cognitions (positive appraisals). For example, if someone experienced increased energy and alertness after disrupted sleep and interpreted this experience as evidence of their own strengths (e.g., "I am full of good ideas and others are too slow"), they might then start to do more and sleep less, prompting an escalation of manic symptoms. There is evidence that internal appraisals are elevated in people with BD and relate to mood symptoms (Banks et al., 2016; Jones et al., 2006).

Building on these findings, the *integrative cognitive model* (ICM) of mood dysregulation (Mansell et al., 2007) proposed that positive and negative appraisals of internal experiences are central to the mood dysregulation characteristic of BD. In the ICM, these appraisals of changes to internal state are extreme, with personally significant meaning (e.g., "I have the energy to do anything I want"). To address the mood fluctuations seen in BD, the ICM contends that appraisals of high mood are not always positive, and appraisals of low mood may not necessarily be negative—in fact, those vulnerable to mood fluctuation have multiple, conflicting appraisals of how they are feeling. For example, high energy could be interpreted positively, with excessive expectations of goal attainment and success, self-confidence, and optimism. However, the same internal state could also be appraised negatively, such as feeling the need to make excessive effort to avoid failure or taking a self-critical or catastrophic perspective (e.g., losing control). These beliefs are elevated in BD compared to both nonclinical and clinical controls and associated with mood symptoms (Dodd et al., 2011; Kelly et al., 2017). However, there is limited research on extreme appraisals of low mood derived from the ICM, especially around more positive appraisals of these experiences.

#### ATTENTION AND MEMORY

We have already seen that how people interpret their experience is important-but how do they come to notice certain aspects of their surroundings and situation in the first place? As with cognitive styles, do people with BD tend to notice particularly negative and positive aspects of their environment over more neutral aspects? Research findings are mixed and may depend on the context in which attention biases are measured as well as the current mood or clinical state of the BD participant. For example, some research indicates that people with BD who were not currently manic or depressed were no more drawn to positive or negative emotional stimuli than nonclinical controls (Purcell et al., 2018). However, another study of young adults at risk for developing BD did demonstrate an attentional bias for positive emotional stimuli (e.g., Gruber et al. 2021). It may be that there is an attentional bias to reward-relevant stimuli (Mason et al., 2016), and attentional biases may be present only during mood episodes (e.g., processing positive information faster when manic) but not a characteristic of BD more generally (Garcia-Blanco et al., 2013).

With respect to emotional memory, there is some evidence that people with BD have difficulties remembering both personal experiences and external events across childhood, adolescence, and adulthood (Bozikas et al., 2019). These deficits in episodic memory have been replicated across studies alongside impaired working memory—and there is some evidence that these difficulties are pronounced in more severe manifestations of BD (Cotrena et al., 2020). Furthermore, there is evidence that people with BD recall emotional stimuli more than do nonclinical controls (Fijtman et al., 2020). Linked to biases in attention and memory, vivid and highly emotive mental imagery may play a role in the mood dysregulation seen in BD. Rich, personally relevant images of the future could directly amplify mood or indirectly amplify mood by influencing thoughts and behavior, particularly in the context of goals and reward (Ivins et al., 2014; Di Simplicio et al., 2016).

In sum, the interplay between *negative* cognitive processes and overly *positive* cognitive processes is a defining feature of BD. The cognitive processes outlined here are not mutually exclusive. In fact, these processes are often studied together (e.g., Fletcher et al., 2014). In cognitive models of BD, appraisals of *current* affect are influenced by underlying beliefs about the self, world, and others which can be considered analogous to the dysfunctional attitudes outlined by Aaron Beck for depression. Cognitive styles are linked to cognitive emotion regulation strategies, which can amplify or dampen affect. Much in the same way as thoughts, personally meaningful, overly positive or negative mental imagery may prompt cognitive and behavioral responses that exacerbate mood symptoms. Goalrelevant appraisals could prompt increased goaldirected activity and sleeping less, which could in turn destabilize circadian rhythms and the BAS, intensifying the cycle of mood instability. Overall, there are multiple cognitive processes linked to BD, with a particular emphasis on how individuals appraise and respond to their experiences.

#### **Emotional Processes**

BD is centrally a disorder of emotion. Emotional processes in BSD have been characterized by heightened and persistent positive emotion reactivity, difficulty with positive and negative emotion regulation, and altered emotional understanding or perceptions of others people's emotions. With respect to emotion reactivity, prior work suggests that BSDs are associated with increased positive emotion reactivity that appears to persist across different types of emotional and nonemotional contexts (e.g., Gruber, 2011; Gruber et al., 2019). Specifically, individuals diagnosed with a clinical history of BD by a trained interviewer or who are at self-reported risk for future BD onset self-report greater positive feelings in response to a variety of laboratory stimuli, including short film clips, static pictures or images, and also monetary reward and positive feedback (e.g., Gruber et al., 2008; Gruber, 2011; Johnson, 2007; M'Bailara et al., 2009). In addition, young adults at self-reported risk for BD as well as adults with a DSM diagnosis of BD I have been found to exhibit elevated levels of parasympathetic activity

(as measured via respiratory sinus arrhythmia, for example) in laboratory studies while watching emotional film clips, interpreted as a physiological correlate of positive mood (Gruber et al., 2008; Gruber, Harvey, & Purcell, 2011). Some neuroimaging studies further suggest that people with BSDs exhibit greater neural reactivity in reward-related brain regions (such as the ventral striatum) and networks in response to rewarding stimuli (e.g., Dutra et al., 2015; Nusslock et al., 2011). More detail on neural processes in BSDs are described further below.

With respect to emotion regulation, it has been defined as the processes individuals engage to influence the intensity, duration, display, and type of emotions experienced, and these can occur consciously or automatically (e.g., Gross, 2015); research suggests that individuals with BSDs demonstrate difficulties with emotion regulation in the laboratory and everyday life when spontaneously (or naturalistically) regulating their emotions. Specifically, BD adults who are not currently manic or depressed (i.e., inter-episode) report less success effectively regulating their momentary emotions in everyday life using a 1-week experience-sampling period (e.g., Gruber et al., 2013). In the laboratory, inter-episode BD adults self-report more trouble successfully regulating the intensity of the emotions they experienced in response to watching brief, standardized positive and negative emotionally evocative film clips (Gruber, Harvey, & Gross, 2012). Furthermore, when asked which emotion regulation strategies they tend to utilize in their daily lives, inter-episode BD adults also report using emotion regulation strategies (such as rumination) that amplify mood states and impede problemsolving (e.g., Dodd et al., 2019; Gruber et al., 2011, 2012). This suggests that although BSD individuals might employ effort in regulating emotions but may ultimately use strategies that are less successful in managing intense mood states.

Despite these clear difficulties regulating emotions in BD, when inter-episode BD adults are instructed to follow specific regulation strategies in the laboratory, they demonstrate an intact ability to successfully decrease emotion intensity across a variety of strategies, including cognitive reappraisal, mindfulness, and cognitive distancing techniques (e.g., Gilbert et al., 2014; Gruber et al., 2009, 2012). Inter-episode adults with BD also successfully select or choose regulation strategies that match the context in a manner like healthy controls (Hay et al., 2015). Taken together, this suggests that BD individuals nonetheless have an intact ability to regulate their emotions successfully despite experiencing difficulties on their own in the lab and in daily life. The latter finding suggests important avenues for psychological therapies focused on assisting BD individuals in implementing these strategies successfully on their own.

Finally, when examining emotional understanding (or perception) in BD, research indicates that those with a BD diagnosis or subclinical BD risk or symptoms may have an inaccurate perception of other people's feelings. This bias in perceiving others' emotions has been found among young adults at risk for BD who self-report overestimating another person's positive emotions when they are describing a personal and negative life event in a brief film (e.g., Devlin et al., 2016) or during a difficult conversation with a romantic partner (Dutra et al., 2014). Other research suggests that BD adults who are currently manic may also be less accurate in detecting negative facial expressions (e.g., Lembke & Ketter, 2002). Further work is needed to understand whether those with BD may exhibit a positive bias toward perceiving the social world and identify putative underlying neural and related mechanisms.

# Neural Processes

BD is characterized by alterations in brain systems that help us process threatening and rewarding stimuli in our environment, regulate our emotions, and consolidate memories. For example, individuals with BD display structural and functional alterations in the amygdala, a brain region implicated in processing threatening stimuli in the environment (Foland-Ross et al., 2012; Lopez-Jaramillo et al., 2017). Studies of neural connectivity, which examine the relations between brain regions, indicate that BD also is associated with structural and functional alterations in the coupling between the prefrontal cortex and the amygdala (Manelis et al., 2021; Phillips et al., 2008). This suggests that individuals with BD may have difficulty attenuating or regulating amygdala reactivity in the face of stressors, which also is consistent with behavioral, clinical, and self-report data. Finally, BD is associated with deficits in portions of the prefrontal cortex and the hippocampus important for executive control (e.g., behavioral inhibition, goal-directed behaviors, attention) and working memory (Phillips & Vieta, 2007).

Intriguingly, other psychiatric disorders show similar alterations in these brain systems. A heightened sensitivity to threatening stimuli and deficits

235

in executive control and working memory are present in major depression (Hamilton et al., 2012) and anxiety disorders (Etkin & Wager, 2007; Shackman & Fox, 2016), and schizophrenia is associated with abnormalities in both the prefrontal cortex (Radhu, et al., 2015; Selemon & Zecevic, 2015) and the hippocampus (Kalmady, et al., 2017; Smeland, et al., 2018). Such findings are helpful in identifying risk factors that cut across or are common to multiple psychiatric disorders. This work also can help break down potentially arbitrary distinctions between categorically defined psychiatric disorders and account for comorbidity among DSM-5 categories. In addition to identifying risk factors that are common across disorders, initiatives such as HiTOP and the Research Domain Criteria (RDoC) also aim to identify mechanisms that are unique to specific psychiatric disorders and symptoms and that reflect signatures of differential risk for these symptom profiles. This is important for understanding and unpacking the within-disorder heterogeneity discussed above and for identifying clinically meaningful subtypes. We suggest that brain systems that help identify, pursue, and process rewards are important.

Although many regions in the brain respond to rewards, a cortico-striatal neural circuit involving the ventral striatum and orbitofrontal cortex (OFC) are at the heart of the reward system (Berridge, 2019; Haber & Knutson, 2010). Activation of this circuit is typically associated with positive or rewarding emotions and a desire to pursue rewards or goals in the environment, whereas deactivation leads to lower motivation and emotions such as sadness and anhedonia. Individuals with high levels of activity and connectivity in this circuit tend to be highly responsive to rewards in their environment and have heightened motivation to pursue these rewards and goals (Hahn et al., 2009; Simon et al., 2010).

As mentioned earlier, there is growing evidence that individuals with and at risk for BD display heightened sensitivity to rewarding stimuli and an increased motivation toward rewards and goals (e.g., Johnson et al., 2005, 2015; Nusslock & Alloy, 2017). This hypersensitivity to reward can lead to an excessive increase in motivation (e.g., working excessively long hours) during life events involving the pursuit or attainment of rewards, which, in the extreme, is reflected in hypomanic or manic symptoms or episodes. It also can lead to an excessive decrease in such motivation and reductions in goal-directed behaviors in response to losses or failures to attain a desired reward, which is reflected in bipolar depression. In line with this model, individuals with and at risk for BD display a heightened sensitivity to rewards on self-report, behavioral, and neurophysiological measures (Alloy, Bender et al., 2012; Gruber & Johnson, 2009; Harmon-Jones, et al., 2008; Johnson et al., 2017). A heightened sensitivity to rewards also predicts first onset and recurrences of BSDs (Alloy, Bender et al., 2012) and progression to more severe BD diagnoses (e.g., BD I) among individuals with milder variants of the disorder (e.g., BD II, cyclothymia) (Alloy, Urosevic et al., 2012; Nusslock, Harmon-Jones et al., 2012).

Functional magnetic resonance imaging (fMRI) studies provide partial support for elevated rewardrelated brain function in manic and euthymic (i.e., not currently manic, depressed or mixed) individuals with BD. These individuals display elevated activation in the ventral striatum (Hassel et al., 2008; Lawrence et al., 2004), OFC (Elliott et al., 2004), and amygdala (Bermpohl et al., 2009) to pictures of happy faces and pleasant stimuli compared to healthy controls (although see Liu et al., 2012, for evidence of decreased striatal and OFC activation in bipolar individuals to happy vs. neutral faces). A number of studies also report that individuals with BD display elevated OFC and ventral striatal activation to both monetary and social reward cues during manic and euthymic episodes (e.g., Abler et al., 2008; Bermpohl et al., 2010; Dutra et al., 2015; Nusslock, Almeida et al., 2012), although other studies have not observed this effect (Johnson et al., 2019; Trost et al., 2014; Yip et al., 2015). Finally, individuals with a diagnosis of BD II and individuals at elevated risk for BD who have not yet developed the disorder (i.e., hypomanic temperament) display elevated OFC and ventral striatal activation to reward cues (Caseras et al., 2013; Harada et al., 2019). This suggests that heightened reward-related brain function may reflect a preexisting risk factor for BD, as opposed to a consequence of the illness.

In contrast, a blunted sensitivity to rewarding stimuli, reduced motivation toward rewards and goals, and low positive affect have long been considered hallmarks of risk for unipolar depression (without a history of hypomania or mania) (see Nusslock & Alloy, 2017, for review). Individuals with major depressive disorder and at-risk offspring of depressed parents report a lower sensitivity to rewards and greater anhedonia (Kasch et al., 2002; Kazdin, 1989; Luby et al., 2004) and are less responsive to both the anticipation and receipt of rewards on neural and behavioral indices (Forbes et al., 2009; Olino et al., 2010; Pizzagalli et al., 2008; Ng et al., 2019). In prospective studies, a low sensitivity to reward assessed with behavioral tasks, neurophysiology, and brain imaging predicts later depressive symptoms and episodes (Bress et al., 2013; Forbes et al., 2007; Morgan et al., 2013; Nelson et al., 2016; Nusslock et al., 2011). Furthermore, other conditions such as ADHD (Volkow et al., 2009) and schizophrenia (Smucny et al., 2021) are associated with a blunted neuronal response to rewards, which, in the case of schizophrenia, is likely implicated in the negative symptoms or motivational deficits of the illness (Whitton et al., 2015). Taken together, this suggests that BD is characterized by a profile of heightened reward-related brain function that distinguishes it from other psychiatric disorders including depression, schizophrenia, and ADHD. We propose that what differentiates BD from other psychiatric illnesses is mania, and one of the primary risk factors for mania involves a propensity to experience abnormally elevated energy and motivation. Thus, reward-related brain systems are clearly important for understanding what distinguishes BD from other disorders, whereas threat, executive control, and working memory processes may be more relevant for understanding what is common or transdiagnostic across these illnesses.

#### Circadian Rhythms and Sleep Processes

There is growing interest in sleep and circadian pathways in the pathogenesis of BD, with numerous reviews drawing together heterogeneous circumstantial evidence for cross-sectional, prospective, and causal links (e.g., Logan & McClung, 2019; McCarthy, 2016; Murray 2019; Takaesu, 2018). This brief section will outline evidence for circadian and sleep parameters as elements in the web of mechanistic pathways underpinning BD. Following some background about the structure, function, and measurement of circadian and sleep-wake systems, evidence for circadian mechanisms is critically introduced (focusing on genetic and behavioral levels of analysis).

#### STRUCTURE AND FUNCTION OF THE CIRCADIAN SYSTEM

Human biology is rhythmic. A complex network of biological clocks—the circadian system coordinates this "predictive homeostasis," adapted to optimize fitness in the context of Earth's 24-hour light–dark cycle. The molecular basis of the circadian system is well characterized: intrinsic 24-hour rhythmicity is coordinated through clock genes that are responsible for generating circadian rhythms in physiology, behavior, and cognition (Mohawk et al., 2012). Example 24-hour rhythms with a known circadian component include core body temperature (nadir around 4:00 AM), melatonin secretion (commences around 9:00 PM), and alertness (peaking around 10:00 AM) (Refinetti, 2006). The master oscillator of the human circadian system is in the suprachiasmatic nucleus (SCN), a small structure with cells operating autonomously and as part of a network. A critical feature of the circadian system is its sensitivity to environmental cues, which adapts the system to be entrained daily to shifting times of sunrise and sunset (Reppert & Weaver, 2002). The sleep-wake cycle is sometimes described as the most obvious circadian rhythm in humans, but circadian function has a complex relationship with the sleepwake cycle. Borbély's two-process model of sleep regulation (Borbély, 1980; Borbély et al., 2016) proposes that the circadian system regulates sleep timing and architecture in a bidirectional interaction with sleep homeostasis. Sleep homeostasis increases with wake time and dissipates with sleep, while the circadian system sends alerting signals during the day which decrease at night. Optimally, these two processes work together to promote wakefulness during the day and sleep at night (Fuller et al., 2006).

Importantly, growing evidence links circadian function to BD. At the genetic level, animal studies have been informative because core circadian genes (i.e., CLOCK genes) are strongly conserved across evolution. The *Clock* $\Delta$ 19 mutant mouse, for example, provides a well-characterized animal model of mania, exhibiting increased dopamine transmission, hyperactivity, increased reward-seeking and impulsivitylike behaviors, and reduced depressive-like behavior. Intriguingly, these abnormalities are partly reversible by lithium (Dzirasa et al., 2010; Mukherjee et al., 2010; Roybal et al., 2007). Clock∆19 mice encode a dominant-negative CLOCK protein, causing arrhythmic behavior under constant darkness and reduced amplitude, long period, and delayed phase under a light-dark cycle (Vitaterna et al., 1994). In human candidate gene studies, common polymorphisms in CLOCK have generally, but not universally, been found to associate with BD and related phenotypes (Benedetti et al., 2003, 2007; Lee et al., 2010; Soria et al., 2010).

Given the broad acceptance of chronobiologically informed behavioral interventions for BD (Gottlieb et al., 2019), it is not surprising that numerous studies have used behavioral methods to explore the possibility of chronobiological correlates of observable behavior. The most-studied behavioral
variables are those derived from actigraphy-based measurement of locomotor activity and selfreported chronotype (Murray et al., 2020). Lower 24-hour activity compared to healthy populations has been found in people with BD (De Crescenzo et al., 2017; Scott et al., 2017; Shou et al., 2017), and people with BD also appear to have less robust (Jones et al., 2005; Rock et al., 2014), more unstable (Krane-Gartiser et al., 2016), and phase-advanced 24-hour activity rhythms (Salvatore et al., 2008). In people with BD, differences across the phases of the illness can also be observed. The manic phase of BD appears to be characterized by more disorganized and complex patterns of activity, particularly in the morning, whereas the depressive phase of BD appears to be characterized by higher minuteto-minute variability (Krane-Gartiser et al., 2014). On average, euthymic BD individuals report being of evening chronotype and exhibit delayed physiological measures of circadian phase (Kanagarajan et al., 2018; Melo et al., 2017; Nurnberger et al., 2000). For example, a review by Melo et al. (2017) identified 15 studies using the Composite Scale of Morningness, most of which found BD to be associated with eveningness. This association with self-reported eveningness chronotype has been corroborated in actigraphically measured chronotype (Gershon et al., 2018).

Consistent with emerging dimensional approaches to psychopathology (e.g., HiTOP, see above), circadian vulnerability is probably not specific to BD. A recent international task force review highlights that circadian abnormalities are present in the phenotypes of various psychiatric disorders, with evidence strongest for BD, major depression, and schizophrenia (McCarthy et al., 2021). For example, polygenic scores in genome-wide association studies (GWAS) for morningness (the trait of preferring activities to commence relatively earlier in the day) are negatively associated with presence of all three of these disorders (Hu et al., 2016; Jones et al., 2019; Lane et al., 2016), while polygenic scores for low amplitude are associated with BD as well as the general vulnerability trait of neuroticism (Ferguson et al., 2018; Lyall et al., 2018). In cell lines and postmortem brain, miRNAs-29a/c and 106b have been linked to the circadian clock and have been independently linked to BD as well as to major depression and schizophrenia (Geaghan & Cairns, 2015). In sum, there is great interest in the chronobiology of BD, and there is a broad range of evidence pointing to an array of circadian abnormalities that may be important in the pathogenesis of BD.

# Context and Social Environment Influences

In recent years researchers have begun to better understand how and why the social environment is important in BSDs. We review the literature on social functioning and life events in BD to better appreciate the real-world and social contexts individuals with BD face and its influence on symptom presentation and course.

# Social Context and Functioning

A large body of work has documented associations between BSDs and lower social functioning and social support (Johnson et al., 1999; Castanho de Almeida Rocca et al., 2008) as well as increased social conflicts (Romans & McPhearson, 1992). People with a diagnosis of BD self-report having less contact with friends compared to both people with major depressive disorder and nonpsychiatric controls (Johnson et al., 1999). In one qualitative study, Michalak and colleagues (2006) reported that many individuals with a diagnosis of BD noted that they had lost friendships and social connections due to their illness, especially during manic or hypomanic episodes. Furthermore, lower social support was a significant risk factor for lifetime recurrence of mood episodes in BD (Cohen et al., 2004). At the same time, early clinical observations among individuals with BD suggests increased social interest and motivation among adults with BD (Goodwin & Jamison, 2007). Furthermore, Ong, Zaki, and Gruber (2017) found individuals with BD who were currently interepisode also were more cooperative on a standardized computer task compared to those with a history of major depression as well as those without a psychiatric history. Taken together, this suggests that, despite some work highlighting increased social interest and cooperative behavior, social functioning and quality of social relationships is frequently impaired among adults diagnosed with BD.

# Life Events and Context

Both positive and negative life events have been found to predict the course of BD, generally with negative, stressful, and traumatic life events predicting a more severe and impairing course of the disorder broadly (Agnew-Blais & Danese, 2016; Daruy-Filhod et al., 2011; Koenders et al., 2014; Lex et al., 2017) and with positive and goal attainment life events predicting manic episodes (Alloy et al., 2008; 2009; Johnson et al., 2000, 2008).

Negative and stressful life events play an important role in the onset and course of BD. Research in this area has examined adverse events that occur early in life prior to the onset of the disorder, and those that occur after onset in relation to the timing of subsequent mood episodes. Many empirical studies and reviews and meta-analyses of these investigations have consistently found that childhood maltreatment is associated with a more severe course of illness for those with BD (Agnew-Blais & Danese, 2016; Daruy-Filhod et al., 2011; Garno et al., 2005; Leverich & Post, 2006; Sala et al., 2014). For example, Daruy-Filho and colleagues (2011) found that childhood maltreatment was strongly associated with early onset, substance abuse, and suicidality among those with BD. A more recent meta-analysis of 30 studies compared individuals with BD and childhood maltreatment (abuse, neglect, or family conflict) to those with BD without childhood maltreatment (Agnew-Blais & Danese, 2016). Results indicated that those with histories of childhood maltreatment had more severe and more frequent episodes of mania and depression, more severe psychosis, higher risk of suicide attempts, and higher risk of comorbid diagnoses including PTSD, anxiety disorders, and substance use disorders.

Stressful life events occurring after disorder onset have also been associated with more frequent and severe mood episodes. Lex et al. (2017) reported that stressful life events occurred more frequently preceding acute mood episodes compared to euthymic periods. A prospective study that followed hospitalized individuals with BD prospectively for at least 1 year found that those who experienced severe negative life events took more than three times as long to achieve recovery (defined as minimal or absent symptoms for 2 consecutive months) compared to those without severe life events (Johnson & Miller, 1997). Similarly, in a study of BD outpatients assessed quarterly for 2 years, negative life events were associated with the subsequent severity of both mania and depression, as well as with higher levels of functional impairment (Koenders et al., 2014). These data suggest that stressful life events are associated with a more severe course of BSDs.

Positive life events have also been consistently found to predict subsequent increases in mania symptoms, though the boundary conditions around which types of events are most associated with mania onset and how these should best be conceptualized are slightly less clear. One line of work in BD has focused on life events involving goal striving or attainment, based on prior evidence discussed above that those with BD self-report greater levels of ambitious goal setting and striving (Alloy, Bender et

al., 2012; Gruber & Johnson, 2009; Johnson, 2005; Johnson, Eisner, & Carver, 2010). For example, Johnson and colleagues (2000) followed individuals with BD I monthly over a 2-year period and found that mania symptoms increased in the 2 months following events involving goal attainment. Notably, there was no relationship between goal attainment events and subsequent symptoms of depression. In a larger prospective study, Johnson and colleagues (2008) found that goal attainment life events predicted increases in mania symptoms. More recently, Tharp et al. (2016) found that when BD I individuals were asked to describe their goals in a laboratory session, the goals described by the BD group were objectively rated as more difficult to achieve compared to healthy control participants, and these ambitious goals among the BD participants were found to predict increased mania over time. These findings are consistent with work described earlier in this chapter suggesting that BSDs involve greater sensitivity to reward and goal striving and attainment events, which may predispose BSD individuals toward increased mania and hypomania symptoms (Alloy et al., 2009; Bender et al., 2010; Urošević et al., 2010).

Taken together, this research demonstrates a clear relationship between life events and the subsequent course and severity of BD. Negative and potentially traumatic life events appear to portend shorter time to onset of new symptoms, more severe symptoms, and higher rates of comorbidity broadly. Positive events, particularly those related to goal attainment and/or engagement of the BAS system, are associated with increases in mania symptoms prospectively. With these patterns established, researchers have largely turned toward better understanding the neuroanatomical and neurochemical correlates of these relations (e.g., Hanford et al., 2019; Sato et al., 2018) and to identifying risk and protective factors that may serve to moderate the relations between life events and illness course (e.g., Chan & Tse, 2018; Ng et al., 2016; Stange et al., 2012, 2013).

### **Psychotherapy and Prevention**

Compared to other mental health problems such as anxiety or unipolar depression, research on the effectiveness of psychosocial treatments in the context of BD is still young and only recently was expanded upon in the 1990s. The need for psychological treatments has been made apparent by findings that BD patients, even when treated pharmacologically, report subsyndromal symptoms, functional impairments in everyday life, and recurrent mood episodes (e.g., Goldberg & Harrow, 2011; Treuer & Tohen, 2010). Psychological approaches evaluated in sufficiently statistically powered randomized controlled trials (RCTs) can be grouped into four classes: psychoeducation, interpersonal and social rhythm therapy (IPSRT), cognitive-behavioral therapy (CBT), and family and conjoint interventions.

Psychoeducation refers to an interactive therapeutic situation in which patients and/or relatives discuss with a mental health professional the disorder, its causes and course, and treatment options that integrate and build on the individual experiences of the patient (and sometimes their loved ones). Psychoeducation has also been widely evaluated as a stand-alone intervention, within both individual and group settings (e.g., Candini et al., 2013; Colom et al., 2003; Perry et al., 1999). Colom and colleagues (2003, 2009) were able to demonstrate that their 21-session program had protective effects against recurrence of mood episodes for as long as 5 years. Additionally, the feasibility of effectively delivering psychoeducation within community mental health teams was assessed. It was evidenced that, while there was a nonsignificant advantage of psychoeducation with regards to recurrence risk, psychoeducation significantly increased social and occupational functioning (i.e., Lobban et al., 2010). At this point, psychoeducation has shown to be beneficial as a stand-alone intervention; however, all the previously described approaches consider psychoeducation as an integral part of psychological therapy for BD.

IPSRT (Frank, 2005) integrates interpersonal therapy (Klerman et al., 1984) with therapeutic strategies aimed at stabilizing circadian and social rhythms (Frank, 2005); it is rooted in the social zeitgeber model (Ehlers et al., 1988). IPSRT postulates three core mechanisms to reduce symptoms: medication adherence, stable social rhythms and daily routines, and improved interpersonal functioning. Frank and colleagues (1999, 2005) were able to illustrate that acutely symptomatic patients with BD who had received IPSRT in the acute phase had less recurrences over time than those who had received an intense clinical management, regardless of what treatment they were assigned to during the maintenance phase of their treatment. Additionally, IPSRT was considered for use as a stand-alone therapy under specific circumstances (Swartz et al., 2018). For depressed patients with BD II, they were able to provide equivalent effectiveness of IPSRT to quetiapine with regards to the outcome, and differences were only noted in the time to response and side-effect profile.

CBT, originally developed for unipolar depression (Beck, 1991), was also adapted for BD, and several manuals have been published on this treatment option (e.g., Lam et al., 2010; Meyer & Hautzinger, 2013; Newman et al., 2002). A case formulation from a CBT perspective interprets manic and depressive symptoms reflecting dysfunctional changes in behavior, thoughts, and emotions. The likelihood of recurrent mood episodes is therefore hypothesized to be achieved by targeting underlying dysfunctional attitudes, beliefs, behavioral habits, and cognitive errors (e.g., all-or-nothing thinking, overgeneralizations) in therapy. While research has shown that patients with BD show similar cognitions as depressed patients, a few are more specifically related to (hypo)mania (e.g., Johnson, Carver, & Gotlib, 2012; Lex et al., 2011; Shapero, et al., 2015; van der Gucht et al., 2009). Traditionally, CBT works toward a shared case formulation of individual problem areas and treatment goals based on psychoeducation and the derived individual relapse signature, which includes, for example, prior course of the disorder, early warning symptoms of mood episodes, and identified triggers (e.g., life events, interpersonal conflicts, changes in daily routines). The case conceptualization will inform what behavioral and cognitive strategies might be most helpful to cope with future emerging mood symptoms. Tailored to the individual, modules focus on problem-solving, communication skills, or stress reduction strategies, if there is indication that such additional skills will be beneficial to prevent the development or maintenance of mood symptoms. More recently, the focus of CBT has shifted from focusing primarily on reducing symptoms and preventing recurrence to highlighting individual recovery (e.g., Jones et al. 2015; Murray et al., 2017) and incorporating techniques related to mindfulness and acceptance (e.g., Williams et al., 2008).

Several studies have compared outcomes between individuals receiving CBT and individuals in no therapy (waiting list), treatment-as-usual, and supportive therapy groups (e.g., Lam et al., 2003; Meyer & Hautzinger, 2012; Parikh et al., 2012; Scott et al., 2001; Zaretsky et al., 2008). A review of these studies shows the evidence for CBT to be mixed, which is not surprising considering the variety of control conditions, primary outcome variables, and sample composition. For example, Lam and colleagues (2003) demonstrated that CBT reduced risk for relapse in a sample of euthymic BD patients (i.e., not currently manic, depressed, or mixed); however, the effects diminished during the second year of follow-up (see Lam et al., 2005). Conversely, a study involving remitted and acutely ill patients found that, while CBT did not affect recurrence rates overall, when the number of episodes were taken into account, those with fewer prior mood episodes did benefit from CBT while those with a longer illness history did not (Scott et al., 2006). While the latter two studies used treatment-as-usual as the control condition, Meyer and Hautzinger (2012) compared CBT with supportive therapy matched in frequency and intensity of sessions, and no differential effects were found aside from a trend of CBT outperforming supportive therapy during active treatment but not during follow-up. Considering effect sizes, most studies overall revealed positive effects on subsyndromal symptoms and indicators of improved psychosocial functioning (e.g., Szentagotai & David, 2010).

Family and conjoint interventions rely on diverse approaches; what they have in common is the setting in which they occur (i.e., not *individual* therapy). The approach that has received the most attention and empirical support is family-focused treatment (FFT; Miklowitz, 2010). Miklowitz and colleagues developed this treatment from research demonstrating that family communication styles and family functioning are associated with the course of BD (e.g., Miklowitz et al., 1988; Perlick et al., 2004); thus, targeting potential family processes directly or indirectly related to BD is a promising avenue for patients with BD, their significant others, and families. Several RCTs showed the efficacy of FFT in reducing risk of recurrent mood episodes (e.g., Miklowitz et al., 2003; Rea et al., 2003). Adaptations to specific groups such as adolescents (e.g., Miklowitz et al., 2008) or caregivers (e.g., Perlick et al., 2010) and to different healthcare contexts (e.g., Sharma et al., 2020) have been developed as well.

When acknowledging the whole range of adjunctive psychological interventions for BD, most systematic reviews and meta-analyses conclude that they reduce recurrence of mood episodes as well as improve symptoms and/or psychosocial impairment (e.g., Chatteron et al., 2017; Macheiner et al., 2017; Miklowitz & Scott, 2009; Schöttle et al., 2011). Some reviews note that the field is still in its early stages and that the evidence base is only low to moderate (e.g., Lynch et al., 2010; Oud et al., 2016; Szentagotai-Tätar & David, 2018). However, all these metaanalyses have never compared the relative efficacy of those psychosocial treatments with each other and only considered the active treatment relative to its control condition. This gap in the literature was addressed by a network meta-analysis recently published by Miklowitz, Efthimiou, and colleagues in 2020. These authors identified a total of 39 RCTs, including 3,863 participants, and their network analyses unveiled that empirically supported treatments were associated with lower recurrence rates than control treatments. Additionally, CBT provided the strongest evidence for reducing bipolar depressed symptoms when compared to treatment as usual, and to some extent this was also true for FFT and IPSRT (similar effects were found for manic symptoms and CBT but with lower certainty). The authors even identified that certain treatment elements were differentially related to outcome; for example, psychoeducation in a group format or involving family members, as well as use of mood monitoring, were more effective than individual psychoeducation in preventing recurrence. Contrarily, cognitive restructuring and regulating daily activities were the most potent strategies to reduce depressive symptoms (Miklowitz, Efthimiou et al., 2020).

There are still major gaps in our knowledge about mechanisms, mediators, and moderators of outcome, and our understanding is only further complicated in recognizing that most studies focus on symptoms, relapse, and recurrence only in patients after discharge from a hospital or when already stable. Fewer studies have looked at remission from acute symptoms (see the STEP-BD study; Miklowitz et al., 2006) or specifically targeted comorbidities such as substance use disorders (e.g., Crowe et al., 2020). It is also unclear how to best address coexisting mental health conditions in BD. Should they be treated sequentially or simultaneously as part of an integrative case formulation, or would a transdiagnostic approach be most appropriate? In addition, the typical primary outcomes chosen in RCTs, such as symptomatic remission, are often for patients themselves less important than functional or personal recovery (e.g., Jones et al., 2015; Murray et al., 2017).

# Looking Ahead: Advancing Work on Diversity and Anti-Stigma Approaches

In this final section we review research highlighting critical work needed in BSDs that includes expanding our understanding in diverse and underrepresented populations and addressing the stigma that still shrouds this disorder.

Most of the current research discussed in this chapter has been conducted in Westernized countries. Even within the United States, research is limited by homogeneous samples consisting of primarily White, wealthy, and highly educated individuals. Research with the largest percentages of Black, Indigenous, people of color (BIPOC) individuals with BD tends to be hospital and prison studies, whereas undergraduate and community samples are composed of limited non-White individuals. These differences in participant characteristics and clinical severity by recruitment methods influence research questions and conclusions. For example, Johnson and Johnson (2014a) found that the prevalence of BD was correlated with rewardrelevant cultural dimensions such as power distance and individualism in a cross-national study of 17 countries. Furthermore, insufficient recruitment of BIPOC individuals precludes analyses of potential racial and ethnic differences. Instead, race and ethnicity are typically "controlled for" and included as covariates in analyses-or worse, non-White participants are excluded to keep samples homogeneous, particularly in terms of genetic studies (Akinhami et al., 2017). These suboptimal research practices result in typifying White Western adults with BD as the framework for universal presentations of bipolar phenomenon. Thus, we have limited knowledge of the symptomatology, etiology, and treatment of BD in other, non-Western cultures and within minoritized racial and ethnic groups in the United States.

Research on serious mental illness (e.g., schizophrenia spectrum disorders, BSDs) suggests there may be critical differences across cultures and racial/ ethnic groups in terms of symptom presentations, diagnostic considerations, and treatment efficacy that could inform more tailored and effective interventions for diverse populations. In a 2011 review of more than 50 articles in the United States and the United Kingdom, Haeri and colleagues concluded that there are racial disparities in the diagnosis of BD. Across multiple studies, current literature indicates that Black individuals are less likely to be diagnosed with an affective disorder (including depression and BD) and more likely to be diagnosed with schizophrenia spectrum disorders compared to White individuals. Furthermore, Kilbourne and colleagues (2005) found that African American veterans with BD were less likely to receive adequate follow-up outpatient care compared to White veterans. In a representative US sample drawn from the National Comorbidity Survey Replication (NCS-R) data, Johnson and Johnson (2014b) found that no African Americans (0%) received minimally adequate treatment (defined as use of a mood stabilizer alone or in combination with an antipsychotic) in the past year, compared to 17% of Caucasian Americans who did. A similar trend was found for Latinx Americans compared to non-Hispanic whites (0% vs. 21%; Salcedo et al., 2017). In addition, previous studies have demonstrated that Black individuals are more likely than White individuals to be prescribed antipsychotics with more severe side effects, irrespective of the presence of psychotic symptoms (e.g., Kilbourne & Pincus, 2006; Szarek & Goethe, 2003). Overall, mounting evidence has indicated racial disparities in the diagnosis and treatment of BD.

Haeri et al. (2011) identified potential factors that may contribute to observed racial disparities in diagnostic rates in BD. For example, there is some evidence for differences in BD symptom presentation, with Black individuals experiencing higher rates of hallucinations and delusions compared to Whites (e.g., Gonzalez et al., 2007; Kirov & Murray, 1999; Strakowski et al., 1996). Some studies have also found higher rates of exclusively or mainly manic presentations (without a prior history of depression) in Black BD patients including British outpatients of African origin (Kirov & Murray, 1999) and Yoruba Nigerian patients (Makanjuola, 1985). These findings contrast with the much lower rates of mania-only BD presentations reported in primarily White Western samples (Boyd & Weissman, 1981). At the same time, differences in symptom presentation of psychosis may be due to differences in treatment seeking and poorer access to healthcare among Black individuals, including an overreliance on emergency room services (Snowden, 2001) and a tendency to seek treatment at later, more severe stages of mania when psychosis is more likely to occur (Mukherjee et al., 1983). There is also some evidence for differences in how clinicians weigh the same symptoms in Black versus White individuals. In a study of US adult psychiatric inpatients, the presence of negative symptoms (e.g., blunted affect, monotonous speech) in African American patients-but not in White patients-was found to contribute more toward a diagnosis of schizophrenia and away from a diagnosis of BD (Neighbors et al., 2003; Trierweiler et al., 2000). The authors suggested these findings may indicate a tendency for clinicians to overpathologize a reluctance to disclose personal information and a general mistrust of the healthcare system that is common in Black communities. In addition to potential characteristics of the individual with BSDs, other researchers have also proposed clinician biases as a contributor to the racial disparities in diagnosis and treatment for BSDs. While racial biases on the part of healthcare workers have been demonstrated in the medical field (e.g., Chapman et al., 2013), little research in mental health providers—or in clinicians diagnosing BD, in particular—has been conducted, and this remains a critical focus for future work (McMaster, 2016).

In sum, research is limited in terms of its ability to characterize BS cross-culturally and in racially and ethnically diverse communities. As discussed in previous sections of this chapter, accurate diagnosis of BD is critical to improving prognosis and treatment responsivity. Thus, an important avenue for future research is to examine BD in multiple sociocultural contexts and across more racially, ethnically, and socioeconomically diverse populations to promote equity of BD treatment and ensure that research findings are applicable to various individuals living with BD. Furthermore, the current literature highlights the importance of bolstering clinician experience with various sociocultural contexts pertinent to the patients they serve. It is likely that such endeavors will require greater community engagement to build partnerships and trust within BIPOC communities traditionally excluded from and exploited by clinical science (Akinhanmi et al., 2017).

### Mental Illness Stigma

Here we focus on the stigma incurred by people with BD. The term "stigma" has a long (and distressing) history in cultural studies, human evolution, social and clinical psychology, and psychiatry (for a crucial review, see Kurzban & Leary, 2001). It literally refers to the sharp instruments used, in Greek and Roman times, to cut or burn visible marks into the skin of members of devalued societal subgroups-with the goal of making visible the denigrated status of traitors, former slaves, or diseased individuals. Ancient texts reveal that individuals displaying features of mental illness have received stigma, been shunned or banished, and even murdered throughout recorded history (Hinshaw, 2007). Although visible marking still occurs (e.g., concentration camp inmates with numbers tattooed on their wrists; the marking of HIV-positive individuals in several nations during the 1980s), "stigma" today is inferred mainly from one's group status, thus comprising a socialpsychological "brand." Our postindustrial world includes far greater factual knowledge of mental illness than a generation or two ago, yet those experiencing mental disorders still receive and experience large amounts of stigmatization (Pescosolido et al. 2010).

Heuristic conceptual models of stigma as related to mental disorders include Link and Phelan (2001) and Pescosolido, Martin, Lang, and Olafsdottier (2008); also see the review by Martinez and Hinshaw (2016). In brief, the naturally selected propensity to define others based on key observable or inferred characteristics, called *stereotyping*, may lead to prejudice when the "other" is deemed as threatening. Discrimination, the abridgment of rights devalued individuals, is a common result, even comprising extermination. Stigma incorporates all three processes, also signaling the loss of individuality (or even fundamental humanity) of the derogated person.

Most stigmatized individuals know of the stereotypes that exist about them. As a result, they may internalize the stigma (Corrigan & Watson, 2004). For mental health conditions, such internalized stigma (self-stigma) is a major barrier to help-seeking, above and beyond symptoms such as anxiety or depression. Moreover, as defined by Goffman (1963), courtesy stigma signifies the tendency of the public to stigmatize anyone even associated with the stigmatized individual. Parents thus experience a double dose of stigma, also having been believed to directly cause their offspring's mental illness for most of the twentieth century. Clinicians and researchers also receive courtesy stigma, because they, by definition, treat or investigate members of devalued groups.

In general, the most severe forms of mental illness—particularly when psychotic features are involved—receive especially high levels of stigma (Jones et al., 1984). Extreme states of mania and/ or depression are clearly involved. Even more, BD is susceptible to societal stereotypes (Jekyll vs. Hyde; "You're just acting bipolar" [i.e., in inconsistent fashion]), often fueled by pervasive and biased media depictions.

In an essential review, Hawke, Parikh, and Michalak (2013) found that stigma related to BD is strong, in terms of self-stigma and public stigma, within school and employment-related settings and across healthcare systems in general. Consequences (reduced quality of life and increased functional impairment) are pervasive. On the other hand, Ellison, Mason, and Scior (2015) surveyed more than 700 UK residents regarding attitudes toward an individual depicted as having BD. Explicit attitudes were generally positive, especially if respondents believed that the conditions in question were biogenetic in origin and if they had experienced prior contact with someone dealing with BD. Moreover, beliefs that BD can signal creativity and positive attributes were linked to positive attitudes, potentially fueled by greater levels of disclosure by influential individuals. Yet it is not clear whether such explicitly stated attitudes reflect a deeper and less conscious set of reactions to people with BD (i.e., implicit attitudes). As well, a genetic or biochemical ascription for serious mental illness typically reduces blame on the part of the observer but at the same time increases beliefs about permanence, hopelessness, and propensities toward aggression or violence (Kvaale et al., 2013). Thus, the key solution for stigma is not simply to promote a reductionistic disease model; rather, humanization is part of the overall strategy (see Hinshaw, 2017).

The sheer inconsistency of performance in individuals with BD may be crucial. Although severe and chronic medical or psychiatric conditions receive high stigma (e.g., HIV is more stigmatized than the flu), when the public encounters someone with highly inconsistent performance—for example, a child or adult with ADHD (Nguyen & Hinshaw, 2020) or an individual fluctuating between phases of manic and depressive episodes—the perception may well be of a lack of effort or will. Such ascriptions of controllability, potentially linked to weak character or low moral fiber, are highly likely to fuel stigmatizing responses.

In terms of additional findings, Gilkes, Perish, and Meade (2019) examined self-stigma in 275 adults with BD, discovering that high self-stigma was associated with unmarried status (potentially indicating low social support) and severity of symptoms. Budenz et al. (2020) explored the nature of more than 1 million Twitter posts (and retweets) in 2016–2017. Although many general mental illness-related tweets were positive in nature, those related to BD were far less so. Also, in a provocative qualitative investigation, Richard-Lepouriel, Favre, Jermann, and Aubry (2020) analyzed complex self-reported themes among individuals with BD regarding phases of intensive self-stigmatization that eventually led to more self-accepting/destigmatizing stages. Despite the small sample size, it is inspiring to examine how individuals with BD can progress from self-negation to acceptance as a function of social support and self-enhancing attitudes.

### Conclusion

In all, as emphasized throughout this chapter, BSDs incur high levels of impairment and features a tragic level of suicidal behavior. Although significant advances have been made towards understanding emotional, cognitive, and neural processes as well as empirically supported treatments for BSDs, positive features of the disorder clearly exist, and public stigma may be improving, public acceptance does not appear to be at optimal levels, and levels of selfstigma remain far too high. Future work is needed to expand our scientific understanding, treatment advancements and dissemination, and compassion towards those with lived experience of BSDs.

# Depression: Social and Cognitive Aspects

Rick E. Ingram, Jessica Balderas, Kendall Khonle, and Joe Fulton

Depression is a disabling disorder that is associated with substantial emotional misery, severe interpersonal disruption, debilitating neurovegetative symptoms, and increased risk for physical illness and death. Although depression is an "intrapsychic" disorder, it also significantly disrupts the lives of those close to the sufferer. Depression is frequently a chronic, episodic disorder that can last for months or years, and, even after recovery, it commonly reoccurs. Although there are numerous effective treatments for many sufferers of depression, no one panacea exists. In fact, even with many effective options for treatment, a sizable number of cases are treatment-resistant. Furthermore, depression is associated with a considerable loss of productivity in both work days lost and in diminished work quality, costing the economy billions of dollars. By any indicator, depression is an extensive public health problem.

The *DSM-5* lists a variety of types of depression, and although these subtypes are important, the focus of this chapter is on unipolar depression or major depressive disorder, specifically the cognitive and social aspects of unipolar depression. We start with an overview of the history of depression and follow with an examination of the epidemiology of the disorder. Social aspects from the perspective of the life event–depression relationship are examined next, followed by a review of behavioral and interpersonal models of depression, and then cognitive models.

# Early Conceptions: A Brief History of Depression

Depression is found in the earliest human records; descriptions of conditions resembling depression can be found in the Bible as well as in Egyptian writings circa 2600 BC. The ancient

Greeks provided the first causal theories of depression: melancholia was hypothesized by Hippocrates to stem from a preponderance of black bile, "darkening the spirit and making it melancholy." These ideas of bodily fluids affecting "the spirit" paved the way for the modern conceptions of depression. Later, Araetus of Cappadocia, around 120 AD characterized melancholia by sadness, suicidal tendencies, feelings of indifference, and psychomotor agitation. In the mid-eighteenth century, Kant suggested that emotions could not cause mental illness: rather depression was seen as a somatic ailment. It was not until the early twentieth century that theorists such as Abraham (1911/1960) and Freud (1917/1950) associated psychological/emotional factors in a causal manner with depression.

One key question in early conceptions of depression regarded the issue of separating mood disorders into their own diagnostic category. Into the beginning of the twentieth century, controversy raged over whether the disorders of "mood" should be separated from psychosis and delirium. Kraepelin's (1896) systematic observations of manic and schizophrenic individuals suggested that mania, which

was often associated with a depressed state, should be considered a separate disorder from syndromes characterized primarily by psychosis, such as schizophrenia. A similar historical debate concerned the distinction between psychopathologies with both manic and depressive states versus those that were "just" depressive states. However, early depression theorists, including Freud, disregarded this distinction between what is now seen as bipolar versus unipolar disorder.

# **Epidemiology of Depression** *Prevalence*

Several epidemiological surveys have gathered data about the prevalence rates of depression. The first was the National Institute of Mental Health Epidemiologic Catchment Area (ECA) study, which interviewed more than 20,000 adults in five states (Eaton & Kessler 1985; Regier et al., 1984). A decade later, between 1990 and 1992, the National Comorbidity Survey (NCS; Kessler, 1994) was conducted using a modified version of the World Health Organization's (WHO) Composite International Diagnostic Interview (CIDI) to diagnose disorders, including depression, according to the DSM-III criteria. The National Comorbidity Survey-Replication (NCS-R; Kessler et al., 2003) later surveyed a large number of individuals in the 48 contiguous United States. The NCS-R, however, used the criteria promulgated in the DSM-IV and assessed these criteria with an extended form of the CIDI (Kessler et al., 2003). With the recent shift to the DSM-5, there has not been another replication of the NCS. However, another major measure of mental health prevalence has been the National Survey on Drug Use and Health (NSDUH). The most recent administration of this survey was in 2017; it used a nationally representative sample from the United States and collected responses from more than 56,000 participants. The survey used an adapted form of the depression module from the NCS-R to better match the DSM-5 criteria and to better fit the different administration mediums (e.g., phone, in-person, and computer administration).

Twelve-month prevalence rates reported by the ECA (Eaton and Kessler, 1985) are the lowest of all the surveys, with findings indicating a rate of 2.7%. The NCS (1990–1992) on the other hand, found a 12-month prevalence rate almost twice as high at 4.9%, while the rate was higher still in the

NCS-R (2003) findings at 6.6%. The NSDUH (2017) points to a continued increase in prevalence with a rate of 7.1% of adults reporting depression in the past year. Lifetime prevalence rates for major depressive disorder are again the lowest in the ECA, with a reported rate of 2.7%. The NCS rate in adults, defined as greater than 15, was substantially higher, with a reported rate of 15.8%. The NCS-R data are a little higher, but roughly in line with the NCS with a reported rate of 16.6%. The NSDUH did not collect lifetime prevalence data. Irrespective of the particular survey, these data clearly show that depression remains a major public health challenge.

# Ethnicity

Although the information gathered from national surveys has helped to clarify the prevalence of depression, given that such surveys have aggregated ethnicity subtypes inferences about rates of epidemiology among ethnic and native groups have been limited. In response to this limitation, Gonzalez and colleagues (2010) utilized the National Institute of Mental Health's Collaborative Psychiatric Epidemiology Surveys (CPES), which included data from several national surveys. Based on respondents' self-reported ethnicity and racial categorization, the authors created separate categories of ethnic subgroups. Notably, the study only included respondents who endorsed 12-month and lifetime depression history based on a diagnostic interview completed at the time of each survey. Results indicated that, compared to foreign-born respondents, 12-month and lifetime depression were more prevalent for US-born respondents. Furthermore, certain ethnic subgroups endorse higher rates of 12-month and lifetime depression. For example, Puerto Ricans (11.9%) reported higher prevalence rates compared to Asian groups (Chinese, 4.6%; Filipinos, 4.2%; Vietnamese, 4.2%), African Americans (6.8%), and Whites (8.3%). Reported functional impairment also varied across ethnic subgroups. African Americans reported more depressionrelated impairment compared to Whites, whereas Asian groups reported less depression-related impaired compared to Whites. Certain ethnic subgroups also seemed especially vulnerable to recurrent depression when compared to Whites, including Mexicans, Puerto Ricans, and African Americans.

### Gender Differences

Compared to men, women are at a much higher risk for depression. Although female-tomale ratios differ somewhat across studies, the average ratio is close to 2:1 (Nolen-Hoeksema, 1987). For example, the NCS study found a 21.3% lifetime prevalence among women and 12.7% rate for men. Prevalence rates for depression vary across different countries, but the gender difference remains (Nolen-Hokesema & Hilt, 2009; Salk et al., 2017). Moreover, within the United States, this difference holds generally for African American, Latina, and Caucasian women and tends to persist when income, education, and occupation are controlled (Hyde & Mezulis, 2020; Williams et al., 2007). The gender difference first appears in adolescence, although rates are similar between girls and boys in childhood (Garrison et al., 1992; Kandel & Davies, 1982; Salk et al., 2016), and, in fact, preadolescent boys are somewhat more prone to depression than girls (Twenge & Nolen-Hoeksema, 2002).

# Age and Cohort Effects

Rates of depression appear to vary with age. The rate of onset of the disorder increases dramatically during adolescence. Depression appears more commonly in younger than older adults, with rates being highest for individuals from 25 to 45. Rates of first onsets are considerably lower for individuals over 65 years old, yet compared to Americans, immigrants appear to experience higher rates of depression after 65 years of age (González et al., 2010; Klerman, 1986; Weissman & Myers, 1978). Some data suggest that younger generations are more prone to depression than comparably aged individuals in the past (Klerman, 1986; Klerman & Weissman, 1989) and, indeed, the rate of depression appears to be greater for individuals born after the mid-twentieth century (Seligman, 1990; Twenge et al., 2019). In addition, rates of depression appear to be increasing most quickly in young men, which may decrease the discrepancy between the rate of depression in men and women (Joyce et al., 1990; Twenge et al., 2019). The prevalence of certain symptoms has also increased in recent years. Between 1951 and 1976, for instance, the suicide rate doubled and the suicide attempt rate quadrupled (Somers, 1976), a trend that appears to be continuing (e.g., Curtin et al., 2016; Goodwin et al., 2006; Skegg & Cox, 1991).

# Social and Cognitive Models of Depression

Contemporary approaches to depression have become increasingly multifactorial and integrative: negative life events, genetics, biochemistry, social skills, interpersonal interactions, and cognitive processes are all involved in varying ways and degrees in the onset, maintenance, remission, and relapse of depressive episodes. Hence, distinctions among models have become blurred. For example, some life event models now explicitly integrate notions of vulnerability, cognitive mediation, and interpersonal behavior. Similarly, in addition to acknowledging the important role of the disruptive capacities of life events, behavioral and interpersonal models explicitly integrate cognitive constructs, and cognitive approaches assign important roles to life events as well as to interpersonal and behavioral functioning. Although integration is an important and positive trend, the examination of models here is structured according to the factors emphasized primarily by those models (e.g., cognitive processes for cognitive models).

# Life Events

It is easy to suppose that people get depressed because stressful things happen to them. Such has been the basic presupposition of life event approaches to depression. Life events refer to sudden, or at least relatively discriminable, changes in the external environment (Paykel & Cooper, 1992). Although early research appeared to support a relatively straightforward relationship between negative life events and depression, it has become increasingly clear that the contribution of life events to depression is more complicated, as articulated by cognitive and social models.

Perhaps the most extensive and influential life event research has been the work of Brown and Harris (1978, 1986). In prospective studies using the Bedford College Life Events and Difficulties Schedule (LEDS), these investigators found that only severe events, or events with "marked or moderate long-term threat," were clearly related to the onset of a depressive disorder. An example would be a spouse losing his or her job. In contrast, less severe life events, such as one's spouse only being threatened with a job loss, appeared insufficient to instigate depression. This is true even when multiple less-severe events are summed ("additivity effects"). Not surprisingly, however, these investigators found an additivity effect for severe events (e.g., the death of a parent and a spouse losing his or her job).

It appears that the relationship between major stressors and depression is strongest for initial depressive episodes (Mazure, 1998; Monroe & Depue, 1991). The observation that subsequent episodes can occur without major life events has led to the suggestion that recurrent episodes are only weakly, or not at all, linked to stress. This idea is embodied in the idea of "kindling" (Post, 1992, Monroe & Harkness, 2005), which suggests that early occurrences of depression increase neurobiological sensitization to the point where recurrent episodes are largely initiated by these neurobiological processes (for a meta-analytic review, see Stroud et al., 2008). In the extreme version of this hypothesis, depression becomes autonomous and occurs independent of life stress. Monroe and Harkness (2005), on the other hand, have suggested a compelling alternative to this stress autonomy model. They propose a stress sensitization model in which life events continue to play an important role in the onset of depression, but the event threshold for triggering a recurrence is lowered. Hence, whereas a major event is needed to trigger a first onset, less severe (but more common) life events can initiate recurrent episodes. In this model, life stress continues to play a central role in depression, but the parameters for triggering events change as recurrences accrue. Preliminary empirical evidence examining the role of severe and less severe life events tends to support stress sensitization models (Bandoli et al., 2017; Morris et al., 2010; Stroud et al., 2011).

Life event researchers also distinguish between acute life events (e.g., a broken engagement) and stressors of a more chronic nature (e.g., constant arguing with a spouse, poverty, chronic problems with work). Recurrent depressive episodes may be linked to these chronic stressors (Monroe, 2010; Monroe et al., 2007). The specific quality of an event has also emerged as an important dimension. In particular, severe life events that signify loss appear to be most strongly associated with depression whereas events that signify danger appear more related to anxiety disorders (e.g., Smith & Allred, 1989). For example, research has shown that depressed individuals, compared to psychologically healthy controls, report more experiences of severe life events, loss, danger, and trauma (Bifulco et al., 2019). In addition, negative life events with interpersonal conflict themes appear to be particularly associated with depression and recurrence, although depressed people may have some role in the generation of these latter events (Hammen, 2006; Liu & Alloy, 2010; Sheets & Craighead, 2014).

It is also important to note that stressful life events sometimes instigate additional negative life events. For example, research investigating the effects of job loss and unemployment has found that economic hardship can lead to additional negative life events such as child abuse (Justice & Duncan, 1977; Steinberg et al., 1981) and a worsening of the spouse's mental health (Penkower et al., 1988). The occurrence of a negative life event can also worsen the quality of a marriage and, in some cases, lead to familial and marital dissolution (Liem & Liem, 1988). Vinokur, Price, and Caplan (1996) found that job loss and financial strain resulted in more negative affect and dysfunctional interactions in couples. In turn, each member's negative affect was also found to exacerbate depressive symptoms in the other partner. As a result, each partner became less socially supportive and more likely to undermine their partner's sense of self-worth. These behaviors had an additional impact on depressive symptomatology, in effect creating a vicious depression-maintaining cycle. In short, stress tends to come in bunches, and one event is not necessarily independent of other events.

### RISK FACTORS

Although stressful life events do precede depression, the flip side of this relationship is that not all people exposed to even severe negative life events develop a depressive disorder. For example, in reviewing ten studies that used the LEDS in the general population, Brown and Harris (1989) found that three-quarters of recently depressed individuals experienced a preceding negative life event. Yet they also found that only one out of five who experienced a negative life event went on to develop depression. Consequently, life event research has attempted to improve the predictive value of life events by examining individual differences in the value placed on different life domains (e.g., parenting, marriage, employment). For instance, for individuals who place a high value on marriage, a negative life event related to marriage (i.e., divorce) would be predicted to have more impact for this individual. Evidence supports life event matching hypotheses; severe negative life events that occur in domains that are particularly valued are more potent

instigators of depression (e.g., Brown et al., 1986). Likewise, some research shows that women who experienced a severe life event in a valued domain were three times more likely to develop depression than women who experienced a severe life event in a less valued domain (Brown & Harris, 1989).

Empirical work on matching hypotheses by life event researchers bears a strong resemblance to work by personality and clinical psychologists investigating the interaction between negative life events and such personality variables as goal-orientation (Dykman, 1998; Lindsay & Scott, 2005), perfectionism (Ahrens, 1987; Flett et al., 1995), and sociotropy/autonomy (Beck, 1987). For example, Morse and Robins (2005) found that among previously depressed individuals, an increase in depressive symptoms was associated with a negative event that was incongruent with their personality (e.g., a negative event that threatened autonomy). In addition to matching strategies, life event researchers have also sought to identify risk factors that make an individual more or less susceptible to the depressing influence of negative life events. In particular, both low social support and low self-esteem have been identified as key risk factors by life event researchers (Brown & Harris, 1989).

More recently, investigators have found that individuals possessing one or two short alleles on a gene involved in serotonin reuptake (5-HTTLPR) are more likely to become depressed, but only when they have experienced severe negative life events (Assary et al., 2018; Caspi et al., 2003; Karg et al., 2011). These findings support a gene-environment interaction model, where neither genes nor negative life events in isolation are sufficient to instigate a depressive episode, but rather the co-occurrence of both the genetic vulnerability and negative life events is what is required. Cognitive models of depression have also increasingly reemphasized the idea that negative cognitive patterns must be activated by life events before they eventuate in depression (Ingram et al., 2011; Ingram et al., 1998). Life events are clearly critical in many depressions but mainly in the context of other factors.

#### STRESS GENERATION

It has become increasingly recognized that depressed people may create their own negative life events and stress (for reviews, see Hammen, 2006; Liu & Alloy, 2010). For example, in a 1-year longitudinal study of depressed and nondepressed women, Hammen (1991) found that depressed women experienced more *dependent* negative life events, or negative events in which the depressed person was judged to have some contributory role. In particular, these dependent life events involved interpersonal conflict in which depressed women were thought to be partly responsible. Moreover, these women continued to generate negative events after their depression had remitted. Since this initial study, a number of researchers have replicated the *stress generation effect* with both adult and adolescent samples, including samples restricted to men (Hammen, 2006; Liu & Alloy, 2010).

Why do depressed individuals tend to create interpersonal conflicts and other "dependent" negative life events? Given that the depressed person continues to generate such events when the depression itself has remitted, the evidence suggests that the depressed person possesses enduring characteristics or that personality traits that are involved. Although this has been a more recent area of investigation, a number of more trait-like personality factors have been identified as capable of generating such negative dependent life events, including neuroticism (Kendler et al., 2003; Kercher et al., 2009), perfectionism or high self-criticism (Cox et al., 2009; Dunkley et al., 2003; Shahar et al., 2004), and poor interpersonal problem-solving (Davila et al., 1995).

In sum, the relationship between negative life events and depression is clear, although acute negative life events appear to have a stronger role in initial depressive episodes, while chronic events appear to be more involved with people who are experiencing recurrent depression. Increasingly, life event researchers have investigated the specific quality of negative life events, as well as matching and vulnerability characteristics of the individual. Moreover, risk factors such as short alleles on a gene involved serotonin functioning, poor social support, and low self-esteem have been identified in individuals who are most susceptible to the depressing influence of negative life events. Researchers have also begun to investigate how depressed individuals may generate their own negative life events and continue to do so even when the depressed state itself remits.

### Behavioral and Interpersonal Models BEHAVIORAL MODELS

Behavioral and interpersonal models have examined the behaviors, and especially the social behaviors, of the depressed individual. A notable early behavioral model was proposed by Lewinsohn (1974) and later reformulated (Lewinsohn et al., 1985). Lewinsohn (1974) argued that depression was due to a low rate of response-contingent positive reinforcement. When individuals fail to receive positive reinforcement that is dependent on the execution of some behavioral response (e.g., initiating a conversation), those behavioral responses become extinguished. This subsequent loss of response-based positive reinforcement deprives the individual of pleasure and leads to feelings of dysphoria. A recent review by Nusslock and Alloy (2017) underscores the relationship between depressive symptoms, reduced reward processing, and amotivation to pursue rewards. Moreover, downregulation of reward centers in the brain (e.g., frontostriatal neural circuits) that are involved in reward processing are shown to increase anhedonia symptoms (Nusslock & Allo, 2017).

Lewinsohn also emphasized the role of social skills and maintained that, as a result of poor social skills, the depressed individual is denied access to the reinforcing properties of social relationships. Segrin (2000) provides an elegant review of the relationship between social skills deficits and depression and notes that although it is limited, there is evidence that poor social skills appear to be an antecedent for depressive symptoms and not only a consequence of depressive symptoms. Other factors were posited that might lead to a low rate of response-contingent reinforcement. Specifically, the occurrence of negative life events-particularly events of loss, impoverishment, or excessive aversive events-diminish the supply of potential reinforcers in the individual's environment. Indeed, as previously reviewed, severe negative life events, particularly ones in which loss or interpersonal conflict is experienced, are associated with depression onset. Additionally, a decrease in the capacity to enjoy pleasant experiences and/ or an increase in sensitivity to negative life events were seen as contributing to lower rates of responsecontingent reinforcement.

To increase the predictive power of the theory, Lewinsohn et al. (1985) formulated a major revision that was intended to integrate existing knowledge about life events, cognitive processes, and interpersonal functioning. As such, this theory is no longer a distinctively "behavioral" model. In the revised theory, depression onset is caused by one or more stressful life events occurring in an individual who possesses inadequate coping skills or other risk factors. In these vulnerable individuals, events that disrupt major resources in life domains, such as personal relationships and job tasks, lead to an initial negative emotional response. Both life event disruptions and the experience of dysphoric mood lead to a decrease in response-contingent reinforcement, which has several cognitive and behavioral consequences. Cognitively, the individual becomes excessively self-focused, self-critical, pessimistic, and more aware of discrepancies between personal standards and actual accomplishments. Behaviorally, the person withdraws, has more social difficulties, and becomes less motivated. These cognitive and behavioral consequences combine to spiral the individual into an ever deepening state of depression.

Research has tended to support Lewinsohn et al.'s (1985) integrated model but has also forced the incorporation of additional cognitive constructs. Kanter and colleagues (2008) argue that modern behavioral models of depression should incorporate both environmental and interoceptive variables and incorporate the role of avoidance. Indeed, current behavioral activation models of depression, as well as Hayes and colleagues' (1999) model of experiential avoidance, argue that problematic avoidance in depression is a response to the core aversive experience of depressed mood, which is initially elicited from some environmental event(s). Thus, both models place an emphasis on the core affective experience, which may play an important role in maintaining or exacerbating symptoms of depression. Kanter et al. (2008) posit that while depressive affect in itself is not maladaptive, it becomes maladaptive through certain learned behavioral processes, particularly avoidance. Avoidance of unwanted private events (e.g., thoughts) and affective experiences may be negatively reinforced and exacerbate the avoidance behaviors that elicited them. This may initiate a cycle of unpleasant mood states and ineffective avoidance behaviors that may spiral into a depressive episode. Several studies have supported this proposed relationship. For instance, self-critical thoughts (an unwanted private event) were shown to increase experiential avoidance, which in turn predicted depressive symptoms among community adults (Moroz & Dunkley, 2019). And among women who disclosed a rape and experienced victim-blaming (negative environmental events), victim-blaming responses were associated with greater depressive symptoms, and this relationship was partially mediated by experiential avoidance (Bhuptani et al., 2019).

Kanter et al. (2008) also argue for the incorporation of "verbal behavioral processes" in modern behavioral models of depression. One such verbal behavior that has been implicated in depression is rumination (i.e., intrusive, repetitive, and negative thoughts), although it is important to note that rumination is featured in other models of depression as well (Ingram et al., 1998, 2011). Rumination has been associated with longer episodes of depression (Lavendar & Watkins, 2004), and studies have shown that rumination in the presence of depressed mood is characterized by a focus on personal problems (Lyubomirsky et al., 1999). Other studies have found that rumination about the occurrence of negative life events may have causal effects on depression (Arnow et al., 2004). These more recent studies suggest that depressed individuals who ruminate about failure experiences, poor interpersonal interactions, and other negatively toned events experience increased depressive symptoms and mood.

Rumination also has been observed in an interpersonal context. Rose (2002) defined the interpersonal use of rumination, or co-rumination, as a process wherein individuals mutually encourage extensively and repetitively discussing their problems and the associated negative affect while attempting to identify the cause of those problems. Co-rumination is associated with concurrent and prospective self-reports of depression (and anxiety) and is positively associated with the onset, severity, duration, and history of depressive episodes (Ames-Sikora et al., 2017; Bastin et al., 2015; Calmes & Roberts, 2008; Rose, 2002; Stone et al., 2010, 2011; Waller & Rose, 2010; White & Shih, 2012). Moreover, co-rumination has been shown to interact with negative life events to predict depressive symptoms over time (White & Shih, 2012).

### INTERPERSONAL MODELS

Although the roots of the interpersonal models of behavior can be traced back to Harry Stack Sullivan (1953), the contemporary interpersonal model of depression was articulated by Coyne in 1976. Coyne argued that the occurrence of stressful life events-especially loss of significant relationshipsleads to a display of depressive symptoms by the individual. These include expressions of helplessness and hopelessness, withdrawal from interactions, general slowing, and irritability and agitation. The depressed person's goal is to restore social support and gain reassurance regarding his or her self-worth and acceptance by others. Initially, the person gets what he or she wants: the social environment tends to respond with genuine concern and support, which functions to reinforce the depressed person's display of depressive symptoms.

The meaning of this social support, however, eventually becomes ambiguous. The depressed person may wonder: Are people responding with support and reassurance because they really believe that I am worthy, or are they doing so merely because I sought it? The depressed person, caught in this loop of uncertainty, continues to use depressive symptoms in an effort to be reassured. The persistence of such a depressive display, however, eventually becomes aversive to others, who then begin to withdraw. This leads to even further efforts by the depressed person to seek reassurance that he or she is worthwhile and is not being rejected by the person. In short, a cycle based on perceived or actual rejection by others is generated in the depressed person. This cycle is unpleasant to both the depressed person and to others who remain in the depressed person's social environment.

Coyne (1976) specifically predicted that it is excessive reassurance-seeking which culminates in feelings of hostility and aversion in others that then leads to rejection. Excessive reassurance-seeking is defined as "the relatively stable tendency to excessively and persistently seek assurances from others that one is lovable and worthy, regardless of whether such assurance has already been provided" (Joiner et al., 1999, p. 270). Empirical evidence supports the contention that there are significant relationships between reassurance-seeking and depression. For instance, Starr and Davila (2008) conducted a meta-analysis of 38 studies and found a medium effect size for depressive symptoms and reassuranceseeking, indicating that more depressive symptoms were related to higher levels of excessively seeking reassurance. Starr and Davila (2008) also found a significant, albeit small, effect size of .14 across 16 studies examining the positive correlation between reassurance-seeking and interpersonal rejection. It appears as though individuals engaging in excessive reassurance-seeking who also suffer from depression are at particular risk of being rejected (Pettit & Joiner, 2006). For example, those who report depressive symptoms but low levels of reassuranceseeking as well as anxious individuals with high levels of reassurance-seeking are not evaluated in the same negative light (Joiner & Metalsky, 1995; Pettit & Joiner, 2006). Furthermore, reassurance-seeking and depression may be more strongly linked in women. In support of this, Starr and Davila (2008) found stronger associations between reassuranceseeking and depression in samples with a higher percentage of female participants. Reassuranceseeking has also been found to interact with changes in perceived social support to predict the prospective development of depressive symptoms (Haeffel et al., 2007).

Integrating aspects of Coyne's interpersonal theory with social-cognitive work in self-enhancement and self-consistency theory, Joiner and colleagues (1992) proposed that when the mildly depressed reassurance-seeking is successfully person's rewarded by others, he or she is only temporarily satisfied. Specifically, the positive feedback elicited from others conflicts with negative self-beliefs, and consequently the depressed person doubts the validity of the feedback. This leads the depressed person to "flip flop" and seek negative feedback that is more consistent with current self-beliefs. More specifically, Evraire and Dozois (2011) propose that individuals with depression engage in excessive reassurance-seeking about their global, overall worth while engaging in negative feedbackseeking for more specific, concrete qualities. The combination of depression, excessive reassuranceseeking, and negative feedback-seeking then causes others to reject. Consistent with this view, Joiner and Metalsky (1995) found that undergraduate males who engaged in both negative feedbackseeking and reassurance-seeking were more likely to be rejected by their roommates. However, this social reaction may only occur with those closest to the depressed person; reassurance-seeking has been found to predict spouse- but not roommaterelated stress (Shahar et al., 2004; Stewart & Harkness, 2015).

Hence, individuals with depression try to both palliate their insecurities in relationships by engaging in reassurance-seeking and maintain a sense of consistency in self-schemas through their use of negative feedback-seeking. The individual suffering with depression who engages in these behaviors is at particularly high risk for rejection from close others (Joiner et al., 1993). Thus, something inherent to the disorder of depression is accounting for the social rejection experienced by these individuals. Evraire and Dozois (2011) suggest that it is the influence of entrenched core beliefs on the information-seeking behaviors of these individuals that explains why reassurance-seeking and negative feedback-seeking lead to rejection. In support of this, the reassurance-seeking literature suggests that it is not the reassurance-seeking behavior in itself that is related to depression and rejection, but rather the combined influence of negative core beliefs concerning interpersonal relationships and reassuranceseeking that creates aversive social consequences. Furthermore, it is the verification of negative selfviews that leads to a higher incidence of negative and emotionally distressing feedback for individuals

with depression compared to those without depression (Evraire & Dozois, 2011).

Other research has extended Coyne's original theory by integrating interpersonal and stressgeneration models of depression (Potthoff et al., 1995). As described previously, the stress-generation model argues that depressed individuals play a contributory role by generating their own negative life events and stress (Hammen, 2006). Researchers have found that reassurance-seeking predicts subsequent levels of interpersonal stress, which in turn predicts elevated levels of depressive symptoms (Joiner, 1994; Joiner et al. 1992; Potthoff et al., 1995). Birgenheir and colleagues (2010) conducted a more recent study and found that individuals who report high levels of sociotropy and reassuranceseeking demonstrate increased levels of negative interpersonal life events. Additionally, reassuranceseeking was found to mediate the relationship between sociotropy and negative interpersonal life events. Eberhart and Hammen (2010) tested a transactional model for depression on a sample of females involved in romantic relationships and found that romantic conflict stress mediated the effects of reassurance-seeking and anxious attachment on depressive symptoms. They also found that daily conflict stress mediated the effects of anxious and avoidant attachment styles, reassurance-seeking, and love dependency behaviors on daily depressive symptoms. Hudson and colleagues (2018) proposed that the relationship between stress generation and excessive reassurance-seeking in depression was attributable to difficulties with "theory of mind," or the ability to reason about what others are thinking. They found that, among depressed individuals, both very poor and very high accuracy on a theory of mind task was associated with increased excessive reassurance-seeking, which was associated with increased interpersonal stress. The authors propose that, among depressed individuals, difficulty understanding what others are thinking may lead to excessive reassurance-seeking, whereas interpersonal insecurity might increase motivations to understand what others are thinking, thereby increasing excessive reassurance-seeking. These findings support the contention that individuals' interpersonal style and their associated behaviors contribute to their depressive symptoms via their impact on stress generation.

Interpersonal models have thus focused researchers' efforts on the social consequences of depression, particularly of rejection. There remains some debate concerning the processes that lead the depressed person to be rejected. There is empirical evidence that social rejection is the result of the depressed individual's failure to meet the basic communication needs of others. Some researchers suggest that reassurance-seeking combined with social rejection, particularly in close and intimate relationships, leads to depression. Other work has integrated findings that reassurance-seeking interacts with generated life stress to predict depression.

### SOCIOEVOLUTIONARY MODELS

Since Coyne (1976) first proposed that depressed people act in ways that elicit rejection from others, conceptual models of depression have increasingly incorporated the role of social interactions. Evolutionary models of human psychological behavior are no exception, and they seek to identify characteristics and behaviors that demonstrate reproductive and survival advantages in human populations. As we have noted, depression confers major psychological, physical, and economic costs. From an evolutionary perspective, it is puzzling to consider the fact that depression remains so widespread despite the fact that several generations have had the chance to "select" it out (Steger, 2010). Socioevolutionary models of depression attempt to explain this phenomenon by proposing that mild to moderate depressive symptoms may have conferred survival and reproductive advantages via their social functions. According to the social risk hypothesis of depression (Allen & Badcock, 2003), depressed states evolved in order to stimulate low-risk responses when the possibility of social exclusion was perceived. Because social exclusion was a lifethreatening process throughout our evolutionary history, being sensitive to rejection cues and acting to reduce one's social burden to the group was a key survival function.

The social risk hypothesis makes three key predictions. First, people with depressive symptoms demonstrate social impairment, which triggers depressive symptoms via negative response from others. For example, depressed people elicit more negative affect in others through their interactions, which makes it more likely that other people will reject them (Steger, 2010; Joiner & Katz, 1999). For example, facial affect is emotionally evocative (Isaac, 2012), and research shows severely depressed individuals are more likely to exhibit negatively valenced facial expressions. Second, people with higher levels of depressive symptoms are more sensitive to negative social cues elicited from others. Biased information processing, such as a negative interpretation bias and attention allocation, has been shown to influence mood and contribute to depressive symptoms (Koster et al., 2009). Third, social subordinate behaviors are elicited in the depressed individual in order to reduce their burden in the group (e.g., submissiveness and reduced behavioral output). For example, those with greater depressive symptoms react to perceived dominance by others with exacerbated feelings of inferiority and submissiveness compared to those with fewer depressive symptoms (Zuroff et al., 2007).

Research stemming from the social risk hypothesis has supported the notion that depressive symptoms make people highly sensitive to cues that their social burden is increasing and, thus, the possibility of social exclusion. Steger and Kashdan (2009), however, have extended the socioevolutionary models of depression with their findings that depressed individuals are equally sensitive to evidence of rising social value. For example, through a daily process research method in which participants completed daily questionnaires for at least 3 weeks, they demonstrated that those who reported greater depressive symptoms were more likely to experience greater increases in feelings of well-being following a positive social interaction. Since depressed individuals are also more likely to overdetect and overreact to signs of rejection, this may lead to a pattern of more intense ups and downs following interpersonal interactions (Gable & Nezlek, 1998; Roberts & Monroe, 1994). Overall, socioevolutionary models suggest that mild to moderate dysphoric moods may have served to sensitize people to potential social rejection (and, more recently, rising social value) and elicit behaviors that prevented social exclusion.

### **Cognitive Models**

In the broadest sense, cognitive models of depression emphasize that people become depressed primarily because of the way they think. Beck's (1967, 1987) well-known model and related informationprocessing ideas are structured around this idea. Beck's model is discussed first, particularly in reference to the vulnerability aspects of this model as well as the diathesis-stress perspective in which this model is framed. Next reviewed are models that specify cognitively based subtypes of depression, including Abramson, Metalsky, and Alloy's (1989) hopelessness theory of depression, as well as cognitive self-regulatory approaches to depression. Before doing so, it is important to note that, similar to life event and behavioral-interpersonal models, cognitive models have become increasingly integrative and have emphasized the role of life events, genetics, and behavior.

# BECK'S COGNITIVE THEORY OF DEPRESSION

In Beck's (1967, 1987) model, nonendogenous depression results from the activation of a depressive self-schema. Self-schemas are organized mental structures that are representations of self-referent knowledge that guide appraisal and interact with information to influence selective attention, memory search, and cognitions (Ingram et al., 1998; Segal, 1988). The content of these schemas develops from interactions that occur during childhood development (Beck, 1967, 1987; Kovacs & Beck, 1978). For example, if childhood experiences are characterized by abuse, stress, or chronic negativity, schemas may arise that guide attention to negative events, lead to the enhanced recall of negative experiences, and distort information to fit the schema (Ingram et al., 1998). Although all persons evidence schemas, those of depressed individuals are considered dysfunctional because they represent a constellation of attitudes that lead to negative perspectives about oneself, the world, and the future, or what Beck has termed, the negative cognitive triad. Schemas also underlie tacit beliefs. For instance, a depressive self-schema might contain the belief "If I am not loved and accepted by all human beings then I am worthless." Such negative beliefs are not formed based on evidence and are often excessive, rigid, and inaccurate.

Depressive self-schemas also lead to negative biases or cognitive distortions, which lead to thinking errors. For instance, all-or-nothing thinking occurs when situations are viewed in only two categories instead of on a continuum (i.e., "If I am not a complete success, I'm a failure"). Mental filter is when negative details are focused on without taking into consideration the entire context. For instance, if conversing with a group of people, the depressed person might only notice the one person who yawned as opposed to the others who appeared interested. Overgeneralization refers to sweeping judgments or predictions based on a single incident (e.g., "Because last night's date did not go well, all women find me unattractive"). Emotional reasoning is thinking something must be true because one feels it to be so (e.g., "I feel ugly so I must look ugly"). Personalization occurs when the individual takes responsibility for a negative outcome without considering more plausible explanations, or, conversely, blaming others for something that is the individual's fault. Labeling occurs when the individual assigns a character trait onto themselves or other people (e.g., "I am stupid" or "I am worthless"). Jumping to conclusions is when an individual is mind-reading (e.g., "She is so bored listening to me talk") or fortunetelling (e.g., "If I go to the party, no one will talk to me"). Disqualifying the positive refers to instances where an individual is unable to acknowledge a positive thought, feeling, or behavior (e.g., "I only did my homework because I have nothing else to do"). Should/must thinking creates unhealthy expectations that are often unmet and can result in disappointment, guilt, and even shame (e.g., "I should go to the gym" or "I must study for 3 hours tonight"). Finally, catastrophizing occurs when the individual blows something out of proportion (e.g., "If I fail this test my life is over").

An original and fundamental aspect of Beck's model is the diathesis-stress context of negative cognition; depressive schemas lay dormant until activated by relevant stimuli: "Whether he will ever become depressed depends on whether the necessary conditions are present at a given time to activate the depressive constellation" (Beck, 1967, p. 278). Hence, stressful life events are necessary to activate negative schemas, and, once activated, schemas provide access to a complex system of negative personal themes that give rise to a corresponding pattern of negative information processing that leads to depression (Ingram, et al., 2011; Ingram et al., 1998; Segal & Shaw, 1986). Although Beck did not view all forms of depression to be solely caused by depressive self-schemas, he did view the cognitive triad and negative information processing bias to be intrinsic features of all forms of depression and to have causal significance.

As a diathesis factor, vulnerability is an important aspect of cognitive models because it clearly articulates hypotheses about causality. This idea suggests that negative cognitive factors emerge during stressful situations and that this cognitive reactivity makes the person more vulnerable to becoming depressed and is critical for the onset, course, relapse, and recurrence of depression. Therapeutic interventions which effectively alter vulnerability should also alter the individual's chance of relapses or recurrences. In fact, Hollon, Stewart, and Strunk (2006) have summarized data to suggest that, compared to pharmacotherapy for depression, cognitive therapy is more effective in preventing relapse and recurrence. Presumably this is the case because cognitive therapy changes negative thinking patterns that lead to depressed cognitive schemas. Breaking

this cycle by forming positive cognitive schemas not only brings about recovery from the disorder, but also modifies the underlying cognitive vulnerability (Garratt et al., 2007).

Since the appearance of Beck's cognitive theory, several cognitive models of depression have emerged that explicitly incorporate constructs from experimental cognitive psychology (Ingram, 1984; Teasdale, 1988; Teasdale & Barnard, 1993) to articulate the structure and function of schemas. For example, Ingram (1984) and Teasdale and Barnard (1993) conceptualized these structures as cognitiveaffective networks. Hence, in depression, an appraisal of loss results in the initiation of sad emotion and spreads activation throughout the associative linkages that make up the entire interconnected affective-cognitive network. The result of spreading activation is the heightened accessibility of the information embedded in the entire network, and the depressed individual thus becomes conscious of sad-valenced information (e.g., negative events, thoughts, and beliefs). As such, the depressed person exhibits superior attention to, encoding, and recall of negatively valenced self-referent information (for a review, see Gaddy & Ingram, 2014). This type of negative information processing continues to prime the depressogenic cognitive structure, resulting in a negative "cognitive loop" that both maintains and exacerbates the depressive state. This tendency of the depressed person to self-absorption (Ingram, 1990) leaves relatively minimal cognitive capacity available for attending to the external environment. Consequently, the individual's social interactions suffer, leading to social withdrawal. The subsequent loss of social contacts serves even further to prime the depressogenic cognitive-affective structures.

Support for many elements of Beck's model is considerable. For example, the descriptive aspects of depression noted by the model have been confirmed by numerous studies (Haaga et al., 1991; Ingram et al. 1998). In regard to thinking about the self, depressed people report more negative (Kendall et al., 1989) and less positive automatic self-referent thinking (Ingram et al., 1990). They are highly selfcritical (Cofer & Wittenborn, 1980; Hammen & Krantz, 1976) and are likely to negatively evaluate a variety of stimuli other than the self, including imagined activities (Grosscup & Lewinsohn, 1980) and other people (Hokanson et al., 1991; Siegel & Alloy, 1990). Depressed people are also pessimistic about the future (Alloy & Ahrens, 1987). This consistent support for the cognitive triad hypothesis has led some reviewers to argue for considering it as

a central descriptive feature of depression, equivalent to other such well-acknowledged facts about depression as highly recurrent and heritable (Haaga et al., 1991).

The evidence appears generally supportive of a systematic negative bias in information processing during depressive episodes (Haaga et al., 1991; Ingram & Holle, 1992). For example, depressed people display a tendency to direct their attention to internal, rather than external, information (Ingram, 1990), and they appear to selectively encode negative information (Ingram & Holle, 1992). Depressed individuals have also been found to recall considerably more negative information than positive (Matt et al., 1992).

The diathesis-stress perspective, and hence the vulnerability proposals of the model, have also been borne out by an accumulating body of data. There is evidence that dysfunctional schemas predict depression when activated by stressful life events (Dykman & Johll, 1998; Hankin et al., 2004). Furthermore, proposals regarding the emergence of a negative schema under stress have begun to receive consistent and considerable support (e.g., Segal & Ingram, 1994; Scher et al., 2005). For example, Ingram and Ritter (2000) found that when primed with a sad mood, formerly depressed individuals allocated their attentional resources toward negative stimuli, but nondepressed individuals did not. Such processes are not limited to formerly depressed adults. In a study of depressive schema activation processes in the offspring of depressed mothers, Taylor and Ingram (1999) found that these offspring evidenced significantly more negative information recall when they were primed with a sad mood than did the offspring of mothers who were not depressed.

Moreover, Segal et al. (1999) found that recovered patients who evidenced dysfunctional cognition in response to a negative mood experienced more relapse than equally recovered individuals who did not respond with heightened levels of dysfunctional cognition. These results have been replicated and extended by Segal et al. (2006). Finally, investigators have found that negative cognitive processes elicited during negative mood inductions interact with subsequent negative life events to predict depressive symptoms (Beevers & Carver, 2003; Segal et al., 1999). These findings suggest that those who are vulnerable to depression process information as hypothesized by cognitive-diathesisstress models and that this information processing predicts relapses. Indeed, in the data reported by Segal (Segal et al., 1999, 2006), cognitive responses

267

predicted relapse in some cases up to 2 years after the cognitive assessment. As such, these data provide support for the causal proposals of cognitive models.

There is some evidence that depressive cognition has a genetic basis. For example, Beevers and colleagues (2009) examined whether nondepressed individuals with one or two short alleles on the 5-HTTLPR gene would show greater negative cognitive reactivity in response to a negative mood manipulation. In short, a significant positive linear relationship between the number of short 5-HTTLPR alleles and a measure of the severity of negative thinking emerged, but only in the condition where participants were exposed to a sad mood video clip. These data suggest that genes involved in serotonergic functioning may play a role in the development of negative cognitive reactivity in response to dysphoric events. Furthermore, in a study investigating the brain regions of biased attention for both sad and happy stimuli, Beevers et al. (2010) found that volume of the lateral prefrontal cortex, an area involved in the cognitive regulation of emotion, was strongly associated with an attentional bias for emotional cues among carriers of the short 5-HTTLPR allele. Beck's model has thus received considerable support, with new information suggesting how the cognitive reactivity featured in the model is tied to neurobiological variables.

### ATTRIBUTION-BASED MODELS

One of the most widely known cognitive theories of depression was originally proposed by Seligman (1975). Seligman's model was based on an observation of apparent similarity between the responses of depressed people and the conditioned behavior of laboratory dogs who exhibited a lack of escape response after they had been unable to avoid intermittent painful electrical shocks. Seligman's theory focused on depressed persons' expectations that they are helpless to control aversive outcomes and the ensuing behavior consistent with these expectations.

Perhaps because of its simplicity, the learned helplessness theory quickly generated a tremendous amount of data (Abramson et al., 1978). Although much of this research supported the fundamental tenets of the model, other research revealed the model's deficiencies. Therefore, the theory was revised to focus on people's beliefs about the causes of events (Abramson et al., 1978). In this reformulated theory, an attributional style was proposed as the critical causal variable in depression. In particular, making specific, unstable, external attributions for positive events (e.g., "I succeeded because the test was really easy") and global, stable, and internal attributions for negative events (e.g., "I failed because I am stupid") was hypothesized to function as a cognitive vulnerability to depression.

Research on the various aspects of the reformulated helplessness/attributional theory of depression has provided substantial support: when individuals are depressed, cross-sectional studies show that they do tend to make the types of attributions hypothesized by the theory (Abramson et al., 2002). Additionally, some data show that the tendency to report some of these attributions predicts negative mood reactions in response to negative events (e.g., Metalsky et al., 1987, 1993). Moreover, a number of studies have supported the role of negative attributions in precipitating depression (Alloy et al., 2006; Rubenstein et al., 2016). For instance, the Temple-Wisconsin Cognitive Vulnerability to Depression Project has provided considerable evidence (Alloy & Abramson, 1999). In this project, nondepressed university freshmen were assessed on a number of cognitive measures, including measures of attributional style. These students were then followed for approximately 5 years, with frequent assessments of stressful life events, cognitions, and depressive symptoms and disorders. Results showed that negative attributional styles predicted both first and subsequent depressive episodes (Alloy et al., 1999, 2006). Likewise, Sturman and colleagues (2006) found that attributional styles for negative events significantly predicted symptoms of hopelessness depression when controlling for other factors. The results also indicate little correlation between attributional style and depressive symptoms that are not related to hopelessness depression, suggesting that attributional style is associated only with hopelessness depression symptoms.

# COGNITIVE SELF-REGULATORY APPROACHES TO DEPRESSION

Another useful approach to depression derives from models that attempt to identify how people regulate their behavior in the relative absence of external reinforcement (Bandura, 1977, 1986; Carver & Scheier, 1998). The ability to self-regulate is decidedly dependent on cognitive processes. For instance, people tend to adopt cognitive representations of desired future states that serve as guides and motives for action (e.g., Bandura, 1986). These *goal representations* serve as the benchmarks against which ongoing behavior is compared and evaluated. Variations in the representations of these goals are thought to influence motivation, performance, and affect (Caprara & Cervone, 2000). One proposed explanation is that, compared to healthy controls, individuals with depression create less specific goals and are more pessimistic about goal attainment, which hinders motivation (Dickson & Moberly, 2013). Thus, to understand the specific motivational and affective impact of the goal adopted, two additional cognitive self-regulatory variables must be considered: evaluative judgments and selfefficacy appraisals.

People make *evaluative judgments* in which they assess the relative successfulness of performance attainments. When performances fall short of standards, the effect can be motivating or disabling depending partly on the size of the discrepancy between standard and performance. Large discrepancies generally lead to feelings of futility, dysphoria, and low motivation, and small discrepancies spur positive affect, greater persistence, and eventual goal accomplishment (Locke & Latham, 1990). However, the precise motivational effect depends on a third variable: perceived self-efficacy for the goal-relevant behavior (Bandura, 1977, 1997). Self-efficacy appraisals refer to people's assessments of their abilities to organize and execute specific behavioral performances (Bandura, 1997). When people judge themselves capable of an adequate performance, they may persevere even when their initial performance was substandard and dissatisfying. When people appraise themselves as inefficacious, even small goal-performance discrepancies tend to promote dysphoria and lead to a slackening, or even to an abandoning of effort altogether (Cervone & Scott, 1995). According to Bandura (1997), a major pathway to depression occurs when individuals possess a low sense of self-efficacy for performing the actions required to realize valued goals.

There is a large literature linking individual differences in evaluative judgments (of the self and performances), goal representations, and self-efficacy judgments to depression. One of the most robust findings in the depression literature is that, while in an episode, depressed people are in fact particularly self-critical in evaluating performances (e.g., Blatt et al., 1982; Cofer & Wittenborn, 1980; Hammen & Krantz, 1976). Self-critical perfectionism was shown to predict greater depressive symptoms over time (Sherry et al., 2014). Furthermore, there is strong support for a relationship between efficacy judgments and depression in adults. For instance, self-efficacy for parenting (Olioff & Aboud, 1991), coping (Cozzarelli, 1993), social skills (Holahan & Holahan, 1987), and activities of personal importance (Olioff et al., 1989) have all been related, either directly or indirectly, to depressive symptoms (see Bandura, 1997).

Similar patterns have been discovered between efficacy judgments and depression for children and adolescents. For instance, a number of investigations have linked academic self-efficacy and depression in youth (Bandura et al., 1999; Scott et al., 2008; Tak et al., 2017). Furthermore, other studies have demonstrated how diverse efficacy beliefs, including those for forming and maintaining social relationships, managing relationships with parents, regulating mood, maintaining health, and resisting negative peer pressure, can directly or indirectly influence feelings of well-being, satisfaction, and depression (e.g., Bandura et al., 2003; Calandri et al., 2018; Caprara et al., 2005).

A number of goal characteristics have also been associated with depression, including level of abstractness (Emmons, 1992), intergoal conflict (Emmons & King, 1988), perceived stressfulness and level of difficulty (Lecci et al., 1994), and approach/promotion or avoidance/prevention focus (Higgins, 1997; Strauman, 2002). In terms of the approach/promotion or avoidance/prevention goal orientation, self-system therapy-a specific form of cognitive therapy that explicitly addresses deficits in approach/promotion goal orientation and goal pursuit—has shown superior treatment effects compared to cognitive therapy for depressed individuals evidencing deficits in approach/promotion goal processes (Strauman et al., 2006). Strauman and Eddington (2017) offer an in-depth review of self-system therapy and discuss several randomized control trials that suggest that self-system therapy is a valuable depression treatment approach. Last, other work has found that self-oriented goals, as opposed to other-driven goals, are associated with lower levels of depression (Ryan & Deci, 2000).

Many depression researchers have argued that depression can result from adopting goals that are excessively perfectionistic. Research employing attitudinal or trait-like measures of perfectionism has sometimes found that these characteristics are associated with dysphoric and depressive states (Ferrari et al., 2018; Flett et al., 1991; Hewitt & Dyck, 1986; Hewitt & Flett, 1991) and that they sometimes prospectively predict depressive symptoms (Brown et al., 1995; Flett et al., 1995). Across a number of studies, dysphoric and depressed individuals do appear to hold relatively stringent performance standards in that the goals adopted exceed the performance levels judged as accomplishable (Ahrens, 1987). Finally, the experience of negative affect can sometimes lead to the construction of more perfectionistic goal representations (Cervone et al., 1994; Scott & Cervone, 2002). When evaluating whether a given performance level would be satisfactory or not, people appear to consult their feeling states, in effect asking themselves: "How do I feel about it?" If they are in a negative mood, they are more apt to feel dissatisfied with the considered performance and adopt higher performance standards. Interestingly, dysphoric individuals appear particularly susceptible to this affect-driven process that culminates in the construction of more perfectionistic goals (Tillema et al., 2001).

Other research has focused on the quality of the goal adopted. Dykman (1998) argued that some people are prone to adopting a validation-seeking goal orientation, which involves goals that seek "to prove or establish . . . basic worth, competence, and likeability" (p. 141). As a result of having this type of goal orientation, these individuals "continually mine the world for information relevant to their worth, competence, and likeability" (p. 153). For such individuals, then, performance situations are loaded because self-esteem is always on the line, contingent on successful performance. Not succeeding translates into appraisals of low self-worth and increased depression. In contrast, other people tend to adopt growth-seeking goals and approach performance situations with a focus on developing potential and skill. For these individuals, poor performance does not call into question self-worth; rather, subpar performance is merely viewed as a learning experience that ultimately leads to selfbetterment. These growth-oriented individuals are viewed as more resilient and as less likely to develop depression in response to poor performance. Initial findings have generally supported the role of validation-seeking goal orientations in predicting changes in dysphoric symptoms, but only in the context of negative life events (Dykman, 1998; Lindsay & Scott, 2005).

### Conclusion

Depression is a concept with a long history, dating back to the earliest known writings. The phenomenon, however, no doubt existed before its features (and in some cases attendant superstitions) could be put into writing. As this history shows, ideas have also evolved considerably, to the point where the salient characteristics of depression have been codified in the official psychiatric nomenclature.

Using the currently accepted criteria, depression has a number of recognized subtypes. The type of depression that constituted the focus of this chapter, unipolar depression, occurs in all countries of the world and, depending on estimates, affects a large percentage of people throughout the world. Gender differences in the rate of depression are also found worldwide, with women being approximately twice as likely as men to report depression. Depression also tends to occur equally across various ethnic groups and subcultures.

Numerous psychological models of depression have been proposed. Many of the most widely accepted models are cognitive in nature, although not exclusively so. For instance, behavioral and interpersonal models have been proposed by several researchers, although even these have evolved to include key cognitive components as models have become more integrative over time. Models proposed by cognitive researchers tend to focus on information processing, negative thinking patterns such as cognitive distortions, and cognitive structures such as schemas. Social and cognitive models have contributed significantly to an understanding of several key aspects of depression, although they have not been without criticism. This is particularly true of the cognitive models. Coyne (1994), for instance, has detailed a number of criticisms of both the conceptual and empirical foundations of cognitive approaches to depression. Many of the criticisms have proved to be valuable in leading to theoretical refinements and new research paradigms. In addition, acknowledging the inability of existing cross-sectional and correlational research to allow for inferences about causality has been an important outgrowth of this criticism. In fact, such criticisms of the causal statements of cognitive models of depression have driven to a large degree the resurgence of interest in issues in such as diathesis-stress perspectives and vulnerability (Ingram et al., 1998).

Diathesis-stress perspectives form the core features of models of causality. Causality is a notoriously difficult construct to demonstrate, and although support has begun to build for various models' proposals for causality, one of the key tasks for depression researchers is to continue to move beyond descriptions of social and cognitive features to broaden an understanding of the causal pathways of these factors. Moreover, as paradigms in behavioral science become increasingly focused on translational work, it will be important to assess the linkages between the psychological variables commonly addressed in depression and biological pathways to affective disorders. This work is well under way, and although a comprehensive, integrated model of depression is in development, it must continue to be studied if we are to truly understand a disorder as complex as depression.

# CHAPTER 12

### Diagnosis, Comorbidity, and Psychopathology of Substance-Related Disorders

Ty Brumback and Sandra A. Brown

Substance use disorders (SUDs, including alcohol and other drug disorders) are among the most common psychiatric conditions in the United States, with more than 14% of individuals aged 12 or older meeting the DSM-5 criteria for any SUD in the past year (Substance Abuse and Mental Health Services Administration [SAMHSA], 2021). Of those, approximately 16% (6.5 million people) met criteria for both alcohol and another SUD. According to the findings of a nationally representative epidemiology study, the rates of illicit substance use from 2015 to 2019 increased among people aged 26 and older (14.6% to 18.3%), while rates in younger ranges remained stable or declined slightly. Cannabis remained the most common illicit substance used, with nearly 18% of people aged 12 and older reporting cannabis use in the past year. At the same time, binge drinking (i.e., drinking four or more drinks on an occasion for females or five or more drinks on an occasion for males), which puts individuals at higher risk for developing symptoms of alcohol use disorder (AUD), decreased slightly from 2015 (24.9%) to 2019 (23.9%). These trends in substance use highlight potential shifts in trajectories of risk for developing SUDs but also signify the persistence of substance use issues.

SUDs are problematic for society alone, but often are experienced along with a variety of psychiatric disorders that are highly comorbid with SUDs. In this chapter, we review the epidemiology, diagnostic criteria, related risk factors and problems, and comorbidities of SUDs. AUD is the most common SUD and, as such, will be a focal point of this chapter, though we will also describe the growing literature related to other SUDs and comorbidities.

#### **Evolution of the Diagnosis**

Diagnosis of SUDs was formalized with DSM-I in 1953, when SUDs were grouped under sociopathic personality disturbances, along with the paraphilias and antisocial personality disorder (ASPD; then known as "antisocial and dissocial reactions"). Categorization of SUDs with disorders associated with social deviance reflected the social climate. DSM-II made small changes to the SUD diagnosis, maintaining its consistency with personality disorders and sexual deviations and removing the sociopathic categorization. With the publication of the DSM-III in 1980, tobacco/nicotine dependence were added for the first time. Growing understanding of the etiology of psychopathology led to a revision, DSM-III-R, in 1987, in which diagnoses were refined to increase consistency and reflect empirically supported criteria. In this edition, SUDs were separated from personality disorders and paraphilias, and the categories of abuse versus dependence were added to reflect the concept of physiological dependence (i.e., withdrawal and tolerance). In 1994, the DSM-IV did not substantially change SUD diagnostic criteria but allowed

Abbre	eviations
ADHD	Attention deficit hyperactivity
	disorder
ASPD	Antisocial personality disorder
AUD	Alcohol use disorder
CD	Conduct disorder
CUD	Cannabis use disorder
ERP	Event-related potential
HRV	Heart rate variability
SUD	Substance use disorder

for listing specifiers (i.e., with or without physiological dependence) that appeared more relevant to some substances (e.g., alcohol, opiates) than others (e.g., hallucinogens, inhalants). Additionally, social consequences were moved from the dependence criteria to the abuse criteria.

#### DSM-5

In 2013, the fifth edition of the DSM was published nearly 20 years after the prior edition. The impetus to better reflect etiological understanding of disorders and the empirical basis of the clustering of diagnostic criteria led to several changes. Separate categories for abuse and dependence were removed, reflecting the research suggesting that the abuse category was less reliable than the dependence category (Langenbucher et al., 1996) and the dependence criteria did not necessarily reflect more serious, hierarchical progression of disorder than the abuse criteria (Schuckit et al., 2001, 2005). Instead, there is now a single SUD category with specifiers based on total symptom count of 11 possible symptoms. Two to three symptoms constitute a "mild" SUD, four to five symptoms suggest "moderate" severity, and six or more symptoms indicate a "severe" SUD. In the DSM-IV, a single symptom was needed for a substance abuse diagnosis, and three symptoms were needed for a substance dependence disorder. The new criteria are more consistent with other internationally accepted diagnostic systems (e.g., ICD-10). Finally, two criteria were changed: legal problems was removed and a symptom reflecting the presence of craving was added (Jones et al., 2012; see also Denis, Fatséas, & Auriacombe, 2012; Hasin et al., 2012; Saha et al., 2012, for analyses related to the development of DSM-5).

#### Clinical Subtyping

Clinicians and researchers have long recognized the heterogeneity of presentation of SUDs and have attempted to achieve a greater level of specificity by attempting to differentiate clinical subtypes (Epstein et al., 2002). The diagnostic system of the *DSM-5* does not seek to differentiate subtypes and allows for significant individual differences in the presentation of SUDs while also recognizing various etiological factors that contribute to the diagnosis. Creating specific subtypes of SUD could be beneficial in describing risk, providing prognosis, and tailoring treatments to target etiological factors to improve treatment outcomes. Clinical subtyping is not a new phenomenon, and clinical subtypes had been hypothesized and utilized well before the formal diagnostic system of the *DSM* was codified (Babor, 1996; Babor & Lauerman, 1986). Jellinek made one of the initial efforts to integrate various typologies based on causal features including exogenous (external causes) and endogenous (internal causes), with subtypes of steady and intermittent drinking within each category (Bowman & Jellinek, 1941).

Jellinek (1960) later refined these types into what he termed species: alpha, beta, gamma, delta, and epsilon, based on his clinical observation of motivational and behavioral characteristics. Of these, Jellinek focused primarily on two typologies that displayed physical dependence on alcohol. These two most common types were "delta alcoholics," whose drinking behavior was more socially and economically focused and who could not abstain from drinking, and "gamma alcoholics," who were more psychologically at risk and exhibited loss of control when drinking. While Jellinek's types were based on his clinical insights and his "species" typology gained popularity, the system lacked empirical validation and support (Babor, 1996). Jellinek's work later spurred others to seek typology systems based on empirical data. A common typological distinction utilized family history reflecting genetic contributions to SUDs. Individuals with a history of alcoholism in a first-degree relative generally have an earlier age of onset to drinking and a faster progression to alcoholism than individuals without a family history (e.g., Frances et al., 1980).

As empirical investigations progressed and a greater understanding of the neurobiological underpinnings of SUDs were identified, researchers began describing typologies reflecting this understanding (Leggio et al., 2009). Cloninger and colleagues developed a model based on data from Swedish sons of alcoholics and leveraged behavioral genetic contributions to the subtypes described (Cloninger et al., 1981). This first data-driven approach to developing subtypes of AUD yielded two typologies that differentiated both personality factors and behavioral tendencies. Type I alcoholics are characterized as having a later onset of alcoholrelated problems (after age 25) and more psychological (as opposed to physiological) dependence, and they tend to use alcohol to self-medicate psychological symptoms (Cloninger, 1987). Type II alcoholics, a more severe type reflecting of stronger family history of alcoholism, exhibit an earlier onset of alcohol-related problems and often have

more extensive behavioral problems associated with their use. Cloninger's subtypes were initially limited to male alcoholics, although they have been reasonably replicated in females (Glenn & Nixon, 1991). Cloninger's subtypes have been supported by elucidation of neurobiological underpinnings of SUDs, including the role of dopaminergic and serotonergic systems in Type I and Type II, respectively (Leggio et al., 2009; see Table 12.1 for comparison of several typologies).

Additional typologies have been developed using data-driven approaches seeking to substantiate the clinical utility of such models. For example, Babor, Hofmann, DelBoca, and Hesselbrock (1992) proposed Type A and Type B alcoholics that mimicked Cloninger's types, but that were based on clustering of 17 different characteristics of alcoholics, covering genetic, biological, psychological, and sociocultural aspects. These characteristics included family history of dependence, age of onset, and severity of dependence. Type A was similar to Cloninger's Type I, with a later onset of alcohol dependence, fewer problems in childhood, and less psychopathology. Type B was similar to Cloninger's Type II, with an earlier onset of alcohol dependence, more severe problems in childhood (particularly conduct disorder), greater levels of psychopathology, and a course that is more severe and associated with more chronic consequences and poor treatment outcomes. The Type A/B typology has been replicated in both male and female alcoholics as well as across cultural groups (e.g., Hesselbrock et al., 2000; Schuckit et al., 1995).

Using data from a large, nationally representative sample of more than 40,000 respondents, Moss, Chen, and Yi (2007) sought to empirically derive clinical subtypes of respondents with alcohol dependence. A latent class analysis identified five clusters. The clusters varied based on age at onset of AUD, family history of alcoholism, presence of antisocial personality traits, consumption patterns, and comorbidity of mood and anxiety disorders. In each of these classifications, it has been important to consider non-substance-related symptoms to further delineate subtypes. A recent attempt to use latent class analysis in a large sample of patients with AUD reflected the significant contributions that comorbidities make to the clinical presentation of AUD, likely reflecting etiological factors (Müller et al., 2020). Müller and colleagues (2020) reported that a three-class description of their sample accounted for the differences most efficiently, which included one group with low rates of comorbid symptoms, one class with higher rates of mood and anxiety disorders, and the third with high rates of other SUD and ASPD symptoms. The group without symptoms of

Table 12.1 Typolog	gies of alcohol use disorders

Delta • Socially influenced • Inability to abstain	<ul> <li>Type I</li> <li>Later onset</li> <li>Psychological dependence</li> <li>Self-medicate psychological symptoms</li> </ul>	<ul> <li>Type A</li> <li>Later onset</li> <li>Fewer early life problems</li> <li>Less stress</li> <li>Fewer negative social and physical effects</li> </ul>	<ul> <li>Class 3 (low comorbidity)</li> <li>Alcohol use problems without other psychopathology</li> </ul>
<ul> <li>Gamma</li> <li>Loss of control when drinking</li> <li>Psychological risk</li> </ul>	<ul> <li>Type II</li> <li>Earlier onset (&lt;25 years old)</li> <li>Higher family history of alcohol use problems</li> </ul>	<ul><li>Type B</li><li>Earlier onset</li><li>More early life problems</li><li>Higher psychopathology</li></ul>	<ul> <li>Class 1 (drug-dependent antisocial)</li> <li>High comorbidity of SUD</li> <li>Higher antisocial personality disorder</li> </ul>
			<ul> <li>Class 2 (depressed-anxious)</li> <li>Higher depression and anxiety comorbidity</li> <li>More prevalent in females</li> </ul>
Typology approach: clinical observation	Typology approach: clustering of symptoms in Swedish sons of alcoholics	Typology approach: clustering of 17 symptom types in US samples of men and women	Typology approach: latent class analysis in a French population-based cohort study

other comorbid disorders is purported to overlap in many ways with Cloninger's Type I and Babor's Type A, while the class with higher rates of mood and anxiety disorders included much higher rates of females. The third group reflects many aspects of the most severe types previously reported including Type II (Cloninger), Type B (Babor), and "young antisocial type" (Moss), which are associated with more persistent symptoms. This model further supports the notion that comorbid conditions are likely to affect progression of symptoms of AUD as well as prognosis and treatment outcomes (Müller et al., 2020).

Typology systems have been examined primarily within AUD, but some other researchers have attempted to create typologies of other SUDs. One widely accepted typology pertaining to cigarette smoking was proposed by Shiffman, Kassel, Paty, and Gnys (1994) and divided smokers into regular smokers versus "chippers." Shiffman's group highlighted the differences between the quantity and frequency of cigarette use as well as the identified motives for smoking. "Chippers" are distinct from regular smokers in that they typically smoke five or fewer cigarettes a day, do not meet criteria for nicotine dependence, and primarily report social motivation to smoke. Regular smokers report more frequent and habitual smoking marked by addictive motives and nicotine dependence. The distinction between regular users and "chippers" has been applied to several other SUDs including cannabis and cocaine, though it has primarily been used to describe patterns of use rather than as a systematically evaluated typology in most cases (e.g., Haney, 2009).

All the typologies described here are interesting from a clinical and research standpoint, and although no system yet developed has been refined enough to allow for true clinical or research utility, some research suggests that subtype is a moderator of pharmacological treatment of alcohol dependence (Kranzler et al., 2012; Pettinati et al., 2000). Heavy alcohol use is the most common feature of AUD, and personalizing interventions based on additional features remains a focus of research (Kranzler & Soyka, 2018). Personalized treatment options-based on specific subtypes of SUDs designed to intervene at different points in the progression of an SUD or geared toward more preventative measures in individuals who are not yet symptomatic but evidence various "characteristics" of a known subtype-remain an aspirational but as yet unattained goal (Witkiewitz et al., 2019).

#### Polysubstance Use Disorders

While much of the research literature on SUDs focuses on a single disorder, epidemiological data shows that many people have more than one SUD. For example, 16% of the total population with SUD in the past year in 2020 reported more than one SUD (SAMHSA, 2021). An examination of patients across the National Veterans Health Administration in the United States, revealed that nearly 27% of the population being treated for SUD reported more than one SUD (Bhalla et al., 2017). These polysubstance users may have elevated and unique risk factors for negative effects including increased incarceration and deviant behaviors (Hedden et al., 2010) and higher rates of lifetime suicide attempts (Smith et al., 2011). Use of other substances has been utilized in some of the prior efforts to create clinical subtypes of SUDs (e.g., Müller et al., 2020), and the clinical picture of those with more than one SUD is markedly more complex than single-SUD patients. Those with multiple SUDs tend to utilize more mental healthcare and medical care resources and show higher risk for liver disease, HIV, and comorbid psychiatric disorders (Bhalla et al., 2017).

While alcohol remains the most prevalent SUD, cannabis use disorder (CUD) is the second most prevalent, with past year estimates of 5% of individuals above age 12 exhibiting CUD in the United States (SAMHSA, 2021). CUD has been associated with increased risk for cocaine, stimulant, and club drugs use disorders, as well as 2-4 times the rate of other psychiatric disorders (Hayley et al., 2017). Polysubstance use and meeting criteria for multiple SUDs may reflect common neurobiological etiologies among the disorders and other comorbid conditions, as well as the social and behavioral effects of engaging in substance use (Crummy et al., 2020). Clearly, when characterizing the neuropathology of SUDs and considering diagnosis and treatment, multiple concurrent SUDs complicate the picture. Better delineating the risk factors and known etiological factors will help guide future research on polysubstance use and SUDs.

#### **Risk Factors for Substance Use Disorders** *Family History*

Researchers have examined the relationship between probands with SUDs and the incidence of these disorders in their relatives. The familial link for AUDs is widely established in the research literature (e.g., Merikangas, 1990; Prescott & Kendler, 1999), and several studies have found a potentially stronger heritability (i.e., greater genetic influence relative to environmental influence on outcomes) for illicit drug use than for alcohol (e.g., Jang et al., 1995). Disentangling environmental and genetic factors contributing to the heritability of SUDs remains a challenge. The genetic factors likely contribute to neurobiological, physiological, and behavioral tendencies that may make an individual susceptible to initiation and escalation of substance use, and environmental factors may exacerbate that susceptibility through specific (e.g., increased exposure to substances) or general (i.e., environment that creates global risk factors for psychiatric disorders) factors.

Researchers have determined via twin studies that the genetic risks for SUDs are largely nonspecific (Kendler et al., 2003). However, there are some unique family determinants that are critical in predicting adolescents who will develop SUDs, such as family environment and, in particular, exposure to parental SUDs (Biederman et al., 2000). Additionally, research suggests that family history of drug and alcohol dependence is associated with a more recurrent course of the respective disorders, greater impairment, and greater service utilization (Milne et al., 2009). Recently, some groups have focused on resilience despite family history of SUDs to elucidate mechanisms that contribute to the observed outcomes. For example, Martz and colleagues (2018) reported that greater inhibitory control as evidenced by dorsolateral prefrontal cortex activation during an inhibition task, was predictive of greater resilience among young adults with a family history of SUDs (Martz et al., 2018). Connecting neurobiological factors to related behaviors may prove a fruitful line of investigation to delineate the mechanisms by which family history contributes risk to offspring.

#### Level of Response to Alcohol

One mechanism by which heredity influences an individual's propensity to develop an AUD is by influencing the general level of response to alcohol, which encompasses both metabolic and behavioral effects. Responsivity has been evaluated by giving a challenge dose of alcohol and assessing body sway and subjective perception of alcohol effects, two correlated indicators of intoxication. Lower response to alcohol, or the need for a higher number of drinks for an effect, has been associated with family history of alcoholism (Schuckit, 1985; Schuckit & Gold, 1988), development of tolerance (the need for increased amounts to achieve the desired effect or a diminished effect in response to the same amounts) to alcohol (Lipscomb et al., 1979; Nathan & Lipscomb, 1979), and a fourfold greater likelihood of future alcohol dependence (Schuckit, 1994a). Level of response to alcohol appears to be a unique predictor of AUDs above and beyond a variety of other risk factors (Trim et al., Smith, 2009) and is a robust predictor in both young and middleaged groups (Schuckit et al. 2004, 2012). Level of response to alcohol also appears to be genetically mediated (Heath et al., 1999; Hinckers et al., 2006) and may reflect the heritability of multiple factors associated with increased risk for substance use.

#### Physiological Factors

Responses to external stimuli in the context of substance use have physiological effects in both the central and peripheral nervous systems. Some of these reactions appear to be closely tied to genetically heritable traits. For example, event-related potentials (ERPs) represent the neural responses to stimuli measured via scalp-recorded electrical signals of the electroencephalogram. The P300 ERP component is a positive-going wave that occurs between 300 and 600 ms after a stimulus is presented, commonly assessed utilizing an Oddball task, which simply requires the detection of infrequent stimuli in a series of regular stimuli (Kutas et al., 1977). Several studies have yielded evidence for heritability of the P300 ERP (e.g., Katsanis et al., 1997; O'Connor et al., 1994). Reduced amplitude and delayed latency for the P300 ERP have been detected in alcoholic individuals (Hansenne, 2006), as well as in cocaine- and opioid-dependent individuals (Moeller et al., 2004; Singh et al., 2009). Moreover, this pattern has also been demonstrated in non-alcohol-dependent children, adolescents, and adults with alcohol-dependent relatives (e.g., Polich et al., 1994; van der Stelt et al., 1998). These findings are generally interpreted as reflecting memory, attention, and inhibition disturbances. As a consequence of this body of research, reduced P300 amplitude has come to be considered a marker of heightened risk for the development of alcohol dependence as well as other externalizing disorders (Patrick et al., 2006).

In other physiological systems, heritability may also play a role in conveying risk for SUDs. For example, SUDs are associated with higher risk for cardiovascular disease, and substance use increases stress on the cardiovascular system and decreases the flexibility of the system (Ralevski et al., 2019). Heart rate variability (HRV), or the beat-to-beat intervals in heart rate, is an index of cardiovascular functioning that reflects the integration of both central and peripheral nervous system signals to the autonomic nervous system (Bates & Buckman, 2013). Chronic alcohol use decreases HRV, and, with abstinence, HRV tends to improve (Karpyak et al., 2014). The effects of alcohol use on HRV appear robust enough that multiple groups have proposed using it as a biomarker for AUD severity (Cheng, Huang, & Huang, 2019; Ralevski et al., 2019). HRV is particularly interesting because it reflects not only physiological effects of alcohol on the body, but also the motivational state of the individual (e.g., under conditions of craving), which have been predictive of relapse risk when measured in AUD patients undergoing treatment (Quintana et al., 2013).

#### Alcohol and Drug Expectancies

A highly productive area of research on risk factors for substance use has focused on expectancies, defined as beliefs about the anticipated effects of substance use. Individuals develop beliefs about the effects of substance use on social, affective, cognitive, and motor functioning, and self-report questionnaires are commonly used to assess these expectancies (e.g., Brown, Christiansen, & Goldman, 1987; Leigh & Stacy, 1993). Expectations about the effects of alcohol and other substances are learned in part from family, peer, and media influences (e.g., Brown, Creamer, & Stetson, 1987; Brown et al., 1999) even prior to personal use of a given substance. Alcohol expectancies have been shown to predict initiation, progression, and problem use, as well as posttreatment relapse (e.g., Brown et al., 1985; Connors et al., 1993; Smith et al., 1995), with expectations that alcohol use will yield positive effects predicting elevated risk. For example, heavier drinkers tend to endorse more positive and arousing expectancies compared to light drinkers, and expectancies measured in children prior to the onset of drinking behavior are prospectively associated with drinking behavior (Goldman, 2002; Dunn & Goldman, 1998). Furthermore, alcohol expectancies appear to mediate the relationship between a variety of risk factors (e.g., sensationseeking) and alcohol use (Darkes, Greenbaum, & Goldman, 2004). This has led some researchers to consider expectancies to be one of the primary systems that accounts for biopsychosocial risk for alcohol use (Goldman et al., 2006; Sher, Grekin, & Williams, 2005).

Although less extensively studied than alcohol, expectancy measures have also been developed for

other substances (Alfonso & Dunn, 2007; Jaffe & Kilbey, 1994; Schafer & Brown, 1991). Marijuana expectancies are similar to alcohol expectancies, with common domains (e.g., social and sexual facilitation, tension reduction, cognitive and behavioral impairment), and this may reflect both valence and arousal expectations that contribute to decisions to use marijuana (Luba et al., 2018; Waddell et al., 2021). Consistent with the different pharmacological effects of stimulants, cocaine expectancies include unique domains (e.g., anxiety, increased energy or arousal). Unlike many risk factors, expectancies may be modifiable, particularly in adolescence and young adulthood when these cognitive schemas are developed and convey strong propensity toward initiation of substance use (Montes et al., 2018). Interventions can utilize information about individual's expectancies (e.g., expectations of tension reduction or social facilitation) to challenge expectancies and develop alternative skills for achieving the desired effects.

#### Peer Influences

The influence of peers on substance use during adolescence is clear from decades of research (e.g., Newcomb & Bentler, 1986; Shoal et al., 2007; Wills et al., 2004); however, not all peer influences are equal because peers perceived as more similar exert a greater impact (Vik et al., 1992). Greater peer involvement with substances, higher perceptions of peer use, and greater perceived peer acceptance of substance use are risk factors for adolescent substance involvement (Epstein & Botvin, 2002). Additionally, peers may also influence expectancies about positive reinforcement from substance use, and perceptions of negative attitudes toward school by peers have been linked to earlier onset of cigarette and marijuana use among adolescents (Bryant & Zimmerman, 2002). Social context can exert powerful effects, with increased alcohol consumption occurring in adolescents in the presence of other adolescents who are drinking (Curran et al., 1997) and greater exposure to peer use leading to adoption of values and beliefs that foster a substance use lifestyle (Tapert et al., 1999). Socializing with substance-using peers provides greater access to substances and environments supportive of risky and deviant behaviors (Brown et al., 1989). The influence of peers has also been shown to differ based on race and sex, such that White females exhibited the strongest susceptibility to peer conformity to use marijuana and cigarettes compared to Black and Hispanic youth (Mason et al., 2014).

Peer connection mediates the influence of parental alcoholism, family conflict, and socioeconomic adversity on adolescent substance abuse (e.g., Fergusson & Horwood, 1999). More broadly, peer delinquency and positive attitudes about delinquency have also been associated with substance use in adolescent males in particular (e.g., Chassin et al., 1993) and increased exposure to stressful situations (Tate et al., 2007).

#### Sex Differences in Addictive Disorders

Although men and women share commonalities in substance use and SUDs, important differences exist. Men consume greater quantities and abuse substances at higher rates than do women, but this gender gap is narrowing for both alcohol and illicit drugs (e.g., Nelson et al., 1998). Several studies provide evidence of accelerated development of alcohol problems and dependence in women when compared to men, referred to as telescoping (e.g., Randall et al., 1999; Wojnar et al., 1997). Specifically, at similar levels of alcohol consumption, women experience problems faster, meet criteria for an AUD in a shorter time, and present for treatment earlier. Findings of accelerated progression for women for other substances are limited but have been documented for cannabis and opiates (Hernandez-Avila et al., 2004; Kosten et al., 1985).

Research shows that women are more vulnerable to many physical consequences of alcohol use and abuse. Higher blood alcohol concentrations occur in women after consumption of equivalent amounts of alcohol because of differences in metabolism of alcohol in both the stomach and liver and differences in body water. These differences in absorption and metabolism of alcohol have led to lower standards for the definition of moderate and heavy drinking for women compared to men. Women develop liver disease more quickly than men and have higher rates of liver-related mortality (Gavaler & Arria, 1995; Hall, 1995), and they may also experience more alcohol-induced brain damage (Hommer et al., 2001; Mann et al., 2005). Increased risk of breast cancer has also been associated with moderate to heavy alcohol consumption in numerous studies (Chen et al., 2011; Singletary & Gapstur, 2001).

In addition to physical effects, women with AUD experience more psychiatric comorbidity than men (Helzer et al., 1991). Women who abuse substances meet criteria for depression and anxiety disorders more frequently than their male counterparts, who are more likely to meet criteria for ASPD (Hesselbrock & Hesselbrock, 1993). Additionally, even after desistence of substance use, women tend to continue to exhibit higher rates of psychopathology and social impairment compared to men (Foster et al., 2014, 2018) and display more adverse consequences from SUDs relative to men (McHugh et al., 2018). Finally, relationships between victimization and substance use have been documented. Women with childhood histories of victimization (physical, sexual, or neglect) are more likely to develop alcohol and drug problems (Widom et al., 1995; Wilsnack et al., 1997; Zilberman et al., 2003).

#### **Risks Associated with Addictive Disorders** Interpersonal Aggression and Violence

Research has demonstrated a clear link between interpersonal aggression and substance use involvement: individuals who abuse a variety of intoxicating substances are more likely to perpetrate or be the victim of interpersonal aggression (e.g., Bushman & Cooper, 1990; Chermack & Giancola, 1997). Both alcohol use and aggression are influenced by executive functions, like inhibitory control, and may reflect developmental factors that put individuals at risk for various externalizing behaviors (Doran et al., 2012). Friedman, Kramer, Kreisher, and Granick (1996) termed substance use an "interactionist risk factor" in association with violence, such that substance use does not directly lead to violence or criminal behavior but may amplify a variety of other factors to create a high-risk situation for committing crimes or engaging in violent acts. Furthermore, it is unclear whether it is the acute or chronic effects of substance use that lead to aggressive behaviors. Giancola (2000) proffered a conceptual framework pointing to executive functioning as both a mediator and moderator of alcohol-related aggression. Specifically, alcohol interferes acutely with executive functioning, and drinking is more likely to lead to aggressive behaviors in individuals with low executive functioning.

Several substances have been associated with experiencing intimate partner violence in both men and women; those with the most evidence are alcohol, cocaine, and amphetamines (Kraanen et al., 2014; Smith et al., 2012). A large body of research has demonstrated an association between alcohol use and a variety of levels of aggressive behavior, including verbal aggression (e.g., O'Farrell et al., 2000), familial/marital aggression including child abuse (e.g., Caetano et al., 2001; Keller et al., 2009), sexual aggression (Davis et al., 2006; Ramisetty-Mikler et al., 2007; Stappenbeck & Fromme, 2010), homicide (Klatsky & Armstrong, 1993), and suicide (Brent et al., 1987; Kerr et al., 2011). Roizen (1993) demonstrated that perpetrators had consumed alcohol in 28–86% of homicide cases and 30–70% of suicide attempts. Experimental paradigms have also shown that acute alcohol administration leads to more aggressive behavior across a variety of situations (Giancola & Chermack, 1998; Hoaken et al., 1998).

Amphetamine and cocaine use are related to interpersonal aggression, although the hypothesized mechanisms differ. Acute amphetamine intoxication frequently leads to aggressive behavior, whereas prolonged amphetamine use results in a psychotic-like disorder, which in turn leads to aggressive behavior (Baker & Dawe, 2005). Cocaine intoxication is associated with increased paranoia and irritability, often leading to interpersonal aggression (Murray et al., 2003). In both cases, the potential for aggression seems mediated through cognitive functions interacting with contextual factors.

#### Sexual Behavior

Alcohol and drug use also have been shown to result in sexual dysfunction (O'Farrell et al., 1997; Simons & Carey, 2001). In a community epidemiological sample of more than 3,000 adults, Johnson, Phelps, and Cottler (2004) found that the most common sexual dysfunction associated with alcohol and marijuana use was anorgasmia, whereas other illicit drug use resulted in painful sex and reduced sexual pleasure. However, neither drugs nor alcohol was associated with reduced sex drive. The mechanism for the association between chronic substance use and sexual dysfunction is thought to be hormonal (Bannister & Lowosky, 1987; Van Thiel et al., 1980). These effects likely abate after prolonged periods of abstinence (Schiavi et al., 1995).

In addition to sexual dysfunction resulting from substance use, a common problem is the spread of sexually transmitted diseases resulting from increased sexual risk-taking, including but not limited to lack of condom use (Koopman et al., 1994; Leichliter et al., 2004). In contrast, one study using a diary method found that alcohol consumption prior to sex was not predictive of condom use; individuals followed their typical patterns of condom use or nonuse when intoxicated (Leigh et al., 2008). More recently, researchers have begun focusing on the disproportionate rates of SUDs among sexual minorities and have highlighted the increased risk for SUDs as well as negative sexual consequences (e.g., rates of risky sex and sexually transmitted infections/diseases) among sexual minorities (Schuler et al., 2018). Substance-related risky sexual behavior is particularly salient in adolescent populations, and substance use has been associated with an earlier onset of sexual activity (Bentler & Newcomb, 1986). The relationship between substance use and sexual risk-taking is appreciably stronger in White than in Black adolescents (Cooper et al., 1994).

#### Neurocognitive Impairment

Chronic, sustained substance use often results in significant cognitive impairment. The etiology of such impairment is thought to involve interactions among a variety of factors, including neurotoxicity, malnutrition, and trauma and varies depending on the substance abused (Lundqvist, 2005). Although impairments may remediate following cessation of use (Zinn et al., 2004), abstinence successfully diminishes the cognitive impairment in only a portion of the cases. Rourke and Løberg (1996) found that 45% of individuals with alcohol dependence still evidenced cognitive impairment after 3 weeks of sustained abstinence; 15% were still impaired at a year of abstinence. Methamphetamine-dependent individuals also demonstrated impairments during the first 3 weeks of abstinence (Kalechstein et al., 2003). A body of research supports that this may be a result of permanent frontal lobe damage (Dao-Castellana et al., 1998; Moselhy et al., 2001). Adolescent substance use is hypothesized to interfere with normal brain development, causing a variety of cognitive impairments (Hanson et al., 2011; Tapert & Brown, 1999); for example, one study found that during a 3-week period of abstinence from marijuana, adolescents' attention deficits persisted (Hanson et al., 2010).

Findings related to cocaine use are similar. O'Malley, Adamse, Heaton, and Gawin (1992) found that 50% of individuals with cocaine use disorder were cognitively impaired, compared to 15% of the control subjects, and severity of the impairment was associated with recency of cocaine use. Jovanovski, Erb, and Zakzanis (2005) conducted a meta-analysis of 15 studies and found that cocaine use had its most substantial cognitive effects on attention and visual and working memory. The results for executive functioning tests across studies were mixed, but, overall, researchers consistently found deficits in those areas of the brain (i.e., anterior cingulated gyrus and orbitofrontal cortex) that control both attention and executive functioning. Chronic cannabis use has a similar deleterious effect on both attentional processes and executive

functioning, whereas opiates may more specifically affect impulse control (Lundqvist, 2005).

#### Mental Health Comorbidity and Substance Use Disorders

Individuals with SUDs experience high levels of psychiatric comorbidity as documented by numerous large-scale epidemiological studies (Grant et al., 2004; Kessler et al., 1997). Explanations for the cooccurrence include (a) base rates of common psychiatric disorders naturally result in co-occurrence (Schuckit, 1994b), (b) comorbidity may increase the likelihood of seeking treatment or being referred to treatment (Schuckit, 1994b), (c) substance use may precipitate disorders directly (Sato, 1992) or exacerbate subthreshold symptoms to diagnostic levels (Negrete, 1989), (d) common genetic factors exist (e.g., Fu et al., 2002; Prescott et al., 2000), and (e) shared environmental risk factors exist (e.g., trauma; childhood abuse or neglect, life stress). Finally, substance intoxication and withdrawal states can resemble psychiatric symptoms, particularly depression, anxiety, and psychotic symptoms (Bacon et al., 1998; Schuckit, 1994b).

Comorbidity complicates diagnosis, treatment, and clinical course. Difficulties arise in differentiating psychiatric symptoms that are independent of substance use from those that are substanceinduced. Constructing a timeline for a patient's life that incorporates dates of abstinence and ages when substance use and other mental health symptoms occurred can clarify whether symptoms persist during periods of abstinence (Bacon et al., 1998; Schuckit, 1994b). In addition to diagnostic complications, substance use can diminish the effectiveness of treatment efforts. Pharmacotherapy for comorbid disorders can be compromised as substance use may decrease medication adherence, cause serious side effects, and potentiate some psychotropic medications, thus increasing potential for overdose (Catz et al., 2001; National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2005). Additionally, substance use is associated with increases in suicidal thoughts and attempts, necessitating a focus on crisis management rather than other therapeutic goals (e.g., Claassen et al., 2007; Goldstein & Levitt, 2006; Shen et al., 2006).

#### Mood Disorders

Symptoms of major depressive disorder, dysthymic disorder, and bipolar disorder frequently co-occur with SUDs (Hunt et al., 2020). The comorbidity of mood disorders and SUDs begins early among persons with SUDs who are aged 11-17 years, and increased risk of mood disorders has been documented across substance categories (alcohol, marijuana, other; Roberts et al., 2007). While the connection between SUDs and mood disorders is robust, the specific mechanisms across substances likely vary given the heterogeneity of mood and substance use symptoms (McHugh & Weiss, 2019). For example, cocaine and amphetamine withdrawal often include depression symptoms that persist beyond the acute withdrawal phase, and AUDs are commonly accompanied by depressive symptoms. Many adults with SUDs initiating addiction treatment report clinical levels of depression, although these symptoms remit for many following weeks or months of abstinence (Brown & Schuckit, 1988; Brown et al., 1998).

To ascertain the prevalence of comorbid alcohol dependence and major depression independent of alcohol effects, researchers using data from a national epidemiological survey compared the prevalence of a current major depression diagnosis (past year) among adults who were formerly alcohol dependent to that of those without a history of alcohol dependence. A history of alcohol dependence (more than a year prior) increased the risk of current major depressive disorder by 4.2 times (Hasin & Grant, 2002), supporting a strong association between these two disorders that is not solely a result of intoxication or withdrawal states. In the same national survey (undertaken in 2001-2002) assessing 12-month prevalence, the odds of having an independent mood disorder were increased over fourfold (odds ratio [OR] = 4.5) for adults with any substance-dependence diagnosis relative to adults without substance dependence (Grant et al., 2004). More recent evaluations have suggested the rates of comorbidity between SUDs and mood disorders have remained consistent over nearly 30 years of epidemiological data, indicating that between 20% and 25% of individuals with a mood disorder also meet criteria for a SUD (Hunt et al., 2020). Lifetime prevalence of depressive disorders among adults with cocaine use disorders in research treatment samples range up to 50% (e.g., Carroll et al., 1994). Similarly, among individuals with opiate use disorder, prevalence of comorbid mood disorder was 64% and comorbid severe mental illness was nearly 27% (Jones & McCance-Katz, 2019).

#### Anxiety Disorders

In contrast to the clear association between mood disorders and SUDs, the relationship is less clear

for anxiety disorders. Adding to the complexity of evaluating research findings, studies have differed with respect to the disorders that were included under the umbrella of anxiety. The tension reduction hypothesis proposed that alcohol is consumed for its ability to reduce tension and anxiety, suggesting an association between anxiety and AUDs that has intuitive anecdotal appeal. However, empirical studies with alcohol-dependent samples have not consistently supported this conceptualization (e.g., Langenbucher, & Nathan, 1990). In an extensive review of prevalence, family history, and disorder onset, Schuckit and Hesselbrock (1994) concluded that anxiety disorders (panic disorder, agoraphobia, obsessive-compulsive disorder, social phobia, and generalized anxiety disorder) did not occur at higher than general-population rates when substanceinduced anxiety syndromes were excluded. In a sample of youth aged 11–17 years, substance dependence was associated with increased likelihood of an anxiety disorder (OR = 2.2, 95% confidence interval [CI] = 1.2-4.3, but after controlling for other comorbid disorders, the relationship was not significant (OR = 1.0, 95% CI = 0.4-2.8; Roberts et al., 2007). In an adult sample, Schuckit and colleagues (1997) reported an increased risk of panic disorder and social phobia disorders (but not agoraphobia or obsessive-compulsive disorders) among alcohol-dependent adults compared to controls. The lifetime rate for independent anxiety disorders (agoraphobia, panic disorder, obsessive-compulsive disorder, and social phobia) was significantly higher for participants with alcohol dependence (9.4%) than for controls (3.7%). A nationally representative epidemiological study reported a lifetime prevalence of 19.4% for any anxiety disorder (agoraphobia, social phobia, simple phobia, panic disorder, obsessive-compulsive disorder) among adults with alcohol dependence and 28.3% among adults with other drug dependence compared to 14.6% in this combined community and institutional sample (Regier et al., 1990).

In a large study including data from Canada, Germany, Mexico, the Netherlands, and the United States, 32% of individuals with alcohol dependence and 35% of those with drug dependence met criteria for an anxiety disorder (generalized anxiety disorder, panic disorder, and phobic disorders were combined; Merikangas et al., 1998). Across countries, the onset of anxiety disorders preceded the onset of the AUD for the majority of participants. A large, nationally representative study reported increased odds of 2.8 for any independent anxiety disorder (panic disorder with and without agoraphobia, social phobia, specific phobia, generalized anxiety disorder) in adults with any substance dependence diagnosis (Grant et al., 2004). This finding was recently replicated and highlighted the increased odds for AUD and anxiety disorders (2.11) and SUD and anxiety disorders (2.91), which reflects a significant increase in comorbidity risk among substance users (Lai et al., 2015).

#### Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) has been a focus of substantial research focused primarily on veteran populations and female survivors of sexual assault and abuse. As many as 89% of patients with an SUD report they have experienced a traumatic event in their lifetime (Farley et al., 2004) and the rate of PTSD among individuals in addiction treatment has been reported to be 30-59% (Stewart et al., 2000). Studies document that among men with PTSD, AUDs are the most commonly occurring comorbid disorder, with other SUDs also being very prevalent. Among women with PTSD, depression and other anxiety disorders are most common, followed by AUDs (e.g., Kessler et al., 1995; Kulka et al., 1990). The associations between PTSD and SUD are difficult to disentangle, though it is broadly purported that individuals with PTSD may use substances as self-medication to relieve PTSD symptoms, and, over time, PTSD symptoms may come to trigger cravings for alcohol and drugs (Chilcoat & Breslau, 1998; Jacobsen et al., 2001). A study seeking to examine several competing hypotheses about the relationship between PTSD and substance use in a community sample suggested there is strongest support for the "self-medication" hypothesis that suggests the presence of PTSD symptoms increases substance use more so than hypotheses focused on shared vulnerability or early substance use contributing to higher rates of PTSD (Haller & Chassin, 2014). Research findings have been mixed on this conceptualization of the relations between substances and PTSD (e.g., Bremner et al., 1996; Freeman & Kimbrell, 2004), though systematic studies have led to more sophisticated hypotheses about the underlying neurobiological dysfunction associated with comorbid PTSD and SUD (María-Rios & Morrow, 2020). Additionally, treatment-focused studies indicate that the presence of SUDs decreases treatment adherence in PTSD (Bedard-Gilligan et al., 2018) and have supported the approach of treating comorbid PTSD and SUD concurrently due to the enmeshed nature of the

symptoms and behaviors that may share etiological factors (Flanagan et al., 2016; Roberts et al., 2016).

#### Schizophrenia and Other Psychoses

Among individuals with schizophrenia, between 40% and 50% also meet criteria for one or more SUDs (e.g., Blanchard et al., 2000; Hunt et al., 2018; Regier et al., 1990). Comorbidity rates are slightly lower for women but substantially higher (80-90%) in male homeless and incarcerated samples. A nationally representative epidemiological study sampling both community and institutional populations found individuals with schizophrenia had 4.6 times the odds of having an SUD compared to the general population (Regier et al., 1990). AUD and CUD appear to be most common among patients with schizophrenia (Hunt et al., 2018), and SUDs among those diagnosed with schizophrenia take a heavy toll, with higher rates of homelessness, criminal offenses, medical problems, suicide, poorer treatment compliance, and rehospitalization when compared to patients with schizophrenia without SUDs (Blanchard et al., 2000; Dixon, 1999). Furthermore, in a large epidemiological cohort study in Scandinavia, co-occurring SUD and schizophrenia was associated with 50-100% increase in hospitalizations and all-cause mortality rates (Lähteenvuo et al., 2021).

#### Eating Disorders

Co-occurrence of SUDs and eating disorders has been observed in both clinical and population samples (Holderness et al., 1994; Wolfe & Maisto, 2000). Generally, individuals who primarily restrict intake (anorexia nervosa, restricting type) have lower rates of SUDs than patients with other types of eating disorders (bulimia nervosa and anorexia nervosa, binge-eating/purging type); thus, the presence of binge-eating and purging may be considered a risk factor for development of SUDs among patients with eating disorders (Bahji et al., 2019). The prevalence of SUDs has been observed to be as high as 50% in treatment-seeking patients with eating disorders (Bulik et al., 2004) The co-occurrence of eating disorders and SUDs has been hypothesized to be multifaceted, encompassing biological, psychological, and social risk factors (Killeen et al., 2015). A review of mortality associated with psychiatric disorders observed the highest risk of premature death from both natural and unnatural causes in the SUDs and eating disorders (Harris & Barraclough, 1998), and co-occurrence of these disorders may place patients at even higher risk (Keel et al., 2003). One study sought to explain the relation between substance dependence and eating disorders and found that acting rashly when distressed (negative urgency) was more likely among a group of eating-disordered women than among control women. Additionally, individuals with comorbid SUD and eating disorders reported high levels of positive expectancies for both alcohol and eating/ dieting, and these findings have been replicated with young girls (Fischer et al., 2012).

#### Attention Deficit Hyperactivity Disorder

High rates of comorbidity for attention deficit hyperactivity disorder (ADHD) and SUDs have been documented in numerous studies (e.g., Clure et al., 1999; Ohlmeier et al., 2007); however, questions remain about the association between these disorders. Based on data from a survey of more than 4,000 youths aged 11-17, Roberts and colleagues (2007) found no increase in odds of ADHD among youth with SUDs. Findings were the same after adjusting for other comorbid non-substancerelated disorders. A recent study of childhood risk factors found that ADHD was predictive of earlier initiation of alcohol use but was not predictive of time from first drink to onset of alcohol dependence (Sartor et al., 2007). In contrast, Wilens, Biederman, Mick, Faraone, and Spencer (1997) found ADHD was associated with earlier onset of SUDs independent of other psychiatric disorders, and ADHD has been shown to increase the likelihood of nicotine dependence (Ohlmeier et al., 2007; Wilens, 2004). A recent meta-analysis examined longitudinal studies that followed children with and without ADHD into adolescence and adulthood, and children with ADHD were more likely to use and develop nicotine, alcohol, marijuana, and cocaine use disorders (Lee et al., 2011). Similarly, a recent study in a Swedish twin sample indicated ADHD increased the odds of experiencing any SUD; with AUD (OR = 3.58) and polysubstance use (OR = 2.54) the most significantly increased outcomes (Capusan et al., 2019). However, questions remain about whether it is ADHD specifically or the presence of other disorders that frequently accompany the diagnosis (mood, anxiety, externalizing disorders) that increases risk for development of SUDs. Recent research suggests that the hyperactivity and impulsivity components of ADHD pose more risk for substance use problems than does the inattention component (Elkins et al., 2007). Given that ADHD symptoms first appear during childhood, early identification and treatment for ADHD may

alter progression of substance use and problems that typically occur later.

#### Conduct Disorder and Antisocial Personality Disorder

Extensive research has verified a relationship between SUDs and conduct disorder (CD) and ASPD. A large prospective twin study assessed CD at age 11 and found an increased risk of initiating tobacco, alcohol, and illicit drug use by age 14 for adolescents with CD (Elkins et al., 2007). A diagnosis of CD by 14 years of age quadrupled the odds of nicotine dependence and more than quintupled the odds of alcohol or cannabis dependence by age 18 (Elkins et al., 2007). Other studies have found similar results, with CD predicting both early alcohol initiation and transition to alcohol dependence (e.g., Pardini et al., 2007; Sartor et al., 2007). The personality traits associated with CD appear to overlap with risk for SUDs, including higher neuroticism and lower conscientiousness and agreeableness, which may contribute to ongoing issues into young adulthood even if ASPD is not fully exhibited (Anderson et al., 2007). A large community sample of adolescents recruited from the juvenile correctional system and substance use treatment programs and siblings around age 16 and followed into their early 30s found that mortality hazard rates for probands and their siblings were nearly 500% higher than controls, and CD symptoms independently predicted mortality rates after controlling for SUD and family history (Border et al., 2018). ASPD is characterized by continuation into adulthood of CD problems, and high rates of comorbidity with SUDs have also been observed. Among adults with ASPD, 83.6% met criteria for an SUD (Regier et al., 1990). In a nationally representative epidemiological study, the lifetime prevalence of ASPD was 2.6% in the general sample, increasing to 14.3% among adults with AUD and 17.8% for adults with other SUD. Thus, substance use may be characterized as a symptom of CD and ASPD, though it appears that the underlying behavioral tendencies in these individuals increase the risk for negative outcomes beyond SUDs.

#### Conclusion

In this chapter, we reviewed the available information on diagnosis, risk factors, associated psychopathology, and comorbidities for substance-related disorders. SUDs are a significant public health problem because of the associated health, social, and legal consequences related to these disorders. The variety of risk factors and comorbid disorders make SUDs multifaceted and complex, and they require the implementation of efficacious prevention and intervention strategies that reflect the biopsychosocial conceptualization of these complex disorders. Regarding assessment of individuals with SUDs, close attention should be paid to other potentially dangerous behaviors or risk factors, such as risky sexual behavior and interpersonal aggression and violence. Given the high prevalence and frequent comorbidities, assessing for SUDs is paramount for treatment of any disorder. Developing a clear understanding of the relations between substance use and symptoms of other disorders is necessary for diagnosis and treatment planning. As SUDs are multiply determined, a careful assessment involving the aspects discussed in this chapter would enable more precise treatment recommendations.

## CHAPTER **I**3

## Substance Use and Substance Use Disorders

Kenneth J. Sher, W. E. Conlin, and R. O. Pihl

Substance use (SU) and various problems arising from it represent major public health and clinical problems and touch virtually every aspect of society. Recent estimates of the total costs (taking into account costs associated with healthcare, crime, and public safety) of SU including tobacco, alcohol, illicit drugs, and prescription opioids exceed \$740 billion a year, and this is likely an underestimate (National Institute on Drug Abuse, April 6, 2020; https://www.drugabuse.gov/drug-topics/trends-sta tistics/costs-substance-abuse).

The noted so-called Father of Modern Medicine, and one of the founding physicians at Johns Hopkins Medical School, Sir William Osler, wrote that "the only characteristic that distinguishes man from other animals is his propensity to take drugs" (in Bean, 1951). It is not without irony that one of the other famed founding physicians at Hopkins, William Halsted, "considered one of the greatest and most influential surgeons of all time" (Lathan, 2010, p. 31) fought cocaine and morphine addiction for most of his professional life.

Osler might well have added that there are exceptions to his statement and that the propensity to "do drugs" is as old as human behavior; its evolutionary roots date back to prehistory. Consider the fact that humans and many nonhuman animals, including invertebrates, curiously have enzymes for metabolizing alcohol. Why should this be? These enzymes are quite specific to alcohol. While evolutionary explanations are difficult to prove or disprove, it seems likely that the ability to digest ripening fruits that have started to "go bad" (i.e., ferment) extends the range of edible foods that may be necessary for survival. Moreover, detecting the scent of ethanol emanating from overripe fruit is an efficient strategy for food localization (Dudley, 2000, 2004).

In addition to localizing and extending food sources essential for survival, animal behaviorists have commonly observed various species ingesting substances for both medicinal and seemingly recreational purposes. The propensity to take drugs may not be as uniquely human as Osler believed, as intoxicated behavior is seen in nonhuman animals, from elephants to the catnip-consuming pet. Some consume hallucinogenic mushrooms—for example, Siberian deer—and then show incoordination and general intoxicated behavior (Cohen & Saavedra-Delgado, 1989).

Psychoactive substances have been part of human societies for at least several thousand years. References to poppy plants appear in Sumerian tablets dating back more than 4,000 years, and the word referring to them was synonymous with "to enjoy." Remnants of hemp plants dating back 6,000 years have been found in China (Escohotado, 1999). Archeological evidence suggests that alcoholic beverages were first produced 5,000–7,000 years ago (Crocq, 2007). While it appears that religious and medical use of most psychoactive substances were generally controlled and not associated with various harms, scholars have suggested that recreational use has often led to

#### Abbreviations

AUD	Alcohol use disorder
CD	Conduct disorder
DA	Dopamine
DUD	Drug use disorder
FASD(s)	) Fetal alcohol spectrum disorder(s)
NAc	Nucleus accumbens
NMDA	N-methyl-D-aspartate
OUD	Opioid use disorder
VTA	Ventral tegmental area

significant health and social problems, such as epidemics of alcohol use in England in the 1700s and opium use in eighteenth-century China (Heyman, 2009; Westermeyer, 2016). In modern times, psychoactive substances are likely to pose greater risks than they have historically owing to innovations in the manufacturing of drugs leading to increased potency, employment of efficient routes of administration, and geopolitical and social factors that facilitate the spread of substances (Vetulani, 2001; Westermeyer, 1988).

#### Substance-Related Phenotypes

Attitudes toward the use of psychoactive substances vary across cultures and religions, such that a given substance may be taboo in one culture, tolerated in another, and viewed as beneficial and as a valued source of pleasure in yet another (Hart, 2021). While some substances are associated with greater harm than others, psychopathologists distinguish between SU, per se, and substance use disorders (SUDs) including alcohol use disorders (AUDs), drug use disorders (DUDs), and tobacco use disorders.

Note that in contrast to most other forms of psychopathology, with the notable exception of posttraumatic stress disorder (PTSD), SUDs presume a necessary precondition: SU. In the case of PTSD, the precondition is presumed to be largely outside of the voluntary control of the individual. In contrast, SU initiation, regular use, and heavy use are, to varying degrees, operants in the service of some outcome, and SUDs are conceptualized to be consequences of SU. We can conceptualize etiology as a two-step process: (1) etiological factors related to SU and (2) etiological factors in SUDs, conditional upon SU. The two different "stages" can have both distinct and overlapping risk factors (e.g., Sartor et al., 2007), and, consequently, we should ensure the stages are viewed as distinct even if intimately intertwined. As noted by Saunders et al. (2019, p. 1624) in describing alcohol dependence in the ICD-11, "alcohol dependence is . . . understood as an adaptive response [i.e., a neurobiological adaptation or compensatory changes] following repeated use of alcohol, not as a primary biological disorder but an acquired one." Thus, in thinking about etiology we want to distinguish factors that lead to repeated use of the drug (and related, acute consequences) and those that relate to the development of the consequent adaptation/compensatory changes. This is a key distinction that is, unfortunately, often insufficiently resolved in much of the research on SUDs.

#### Substance Use

The use of a given substance can be described in a number of ways: whether the person has ever partaken (lifetime use), use in a given period of time (e.g., past 12 months), frequency of use (e.g., number of use occasions in the past month), routes of administration (e.g., oral, via injection), typical quantity of use on a given occasion (e.g., number of cigarettes in a day when one smokes), frequency of heavy use occasions (e.g., number of days marked by consumption of five or more drinks), maximum dose on a given occasion, or cumulative lifetime exposure to a substance. Assessment is rendered even more complex by (a) the fact that individuals may use more than one substance (simultaneously or not) and (b) the possibility of synergistic effects among substances. For example, the co-ingestion of cocaine and alcohol results in a unique, pharmacologically active metabolite (cocaethylene) with its own psychoactive effects that enhance the euphoric effect associated with cocaine (Jones, 2019). Interactions between alcohol and certain benzodiazepines pose a significant risk for fatal overdose, well above that associated with alcohol alone (the risk for fatal overdose with benzodiazepines alone is low; Koski et al., 2002). Additionally, both alcohol and benzodiazepine use are associated with fatal opiate overdoses (Tori et al., 2020).

Not all researchers view the use versus use disorder distinction as valuable. For example, Rehm et al. (2013) argue that virtually all social and medical problems associated with the use of that drug can be most parsimoniously explained by the simple concept of heavy use over time. They argue that other terms such as "addiction" or "substance dependence" are unnecessary and likely stigmatizing and could represent a barrier to treatment.

#### Substance Use Disorders

The cardinal diagnoses for SUDs in *DSM-III*, *III-R*, *IV*, and *IV-TR* were substance abuse and substance dependence, with abuse being diagnosed on the basis of hazardous behavior (e.g., driving while intoxicated) or social/interpersonal problems arising from SU, and dependence diagnosed on the basis of neuroadaptation to the substance (e.g., tolerance or withdrawal), preoccupation with the substance, and compulsion. In the latest revision of the *DSM*, *DSM-5*, the specific diagnoses of substance abuse and substance dependence were jettisoned in lieu of the single, superordinate category of SUD with 11 criteria and a gradient based on the number of criteria endorsed: mild (2–3), moderate (4–5), and

297

severe (6–11). The working group that developed the *DSM-5* SUD criteria set and diagnostic rules touted the changes as significant improvements over *DSM-IV* in several ways (Hasin et al., 2013). For example, the legal problems criterion was dropped due to lack of theoretical integration, poor diagnostic validity, and bias (i.e., differential item functioning) as a function of race/ethnicity. Furthermore, the addition of craving brought the *DSM* more into alignment with the *ICD*, which had included craving as part of its criteria set. Perhaps more importantly, craving is viewed as central to multiple theories of addiction and is the target of specific pharmacological interventions (Tiffany & Wray, 2012).

However, some of the ostensible improvements were more questionable. While the decision to abolish the abuse-dependence distinction was based on the failure of most factor analyses to identify more than a single dimension in SUD criteria sets, genetically informed factor analyses provide evidence for multiple factors (Kendler, Aggen et al., 2012) and most of the published work showing a unidimensional structure were based on limited numbers of indicators, likely precluding the ability to identify multiple, meaningful factors (Watts et al., 2021). Perhaps most critical for the purpose of this chapter, the genetically differentiable factors identified by Kendler, Aggen, and colleagues had different correlates, consistent with the idea of at least partially different etiologies for different phenotypic aspects of SUDs.

It is widely agreed that *DSM-IV*'s approach to criterion counts resulted in too many false-positive diagnoses, with only a single symptom required for an abuse diagnosis. However, the *DSM-5*'s requirement of *only* 2 criteria for diagnosis failed to address ongoing concerns about false positives and overdiagnosis (Martin et al., 2011). The very high rate of *DSM* diagnoses of AUDs in epidemiological surveys have led some to propose much stricter diagnostic criteria (Wakefield & Schmitz, 2014) which would produce dramatically lower prevalence rates from those based on current and past versions of the *DSM*.

In contrast to DSM versions III, III-R, IV, and IV-TR, the World Health Organization's ICD-10 never made the distinction between dependence and abuse, focusing primarily on the concept of dependence. (The ICD does have a separate category for "harmful use," but that is conceptually distinct from abuse and not considered further here.) While there are differences between ICD-11 and ICD-10 dependence as to how the diagnostic

features are combined into criteria, the essential character of the diagnosis is similar. In *ICD-11*, one must meet criteria in two of the following three areas: (1) impaired control over use, (2) the substance playing an increasingly important role in one's life, and (3) physiological features (e.g., tolerance or withdrawal). While the 11 SUD criteria in *DSM-5* (p. 483) can be summarized as covering the domains of impaired control, social impairment, hazardous use, and pharmacological criteria, a person can receive the diagnosis even if symptoms lie entirely in just one domain. Consequently, unlike *ICD-11, DSM-5* lacks the conceptual core of physiological dependence.

It is hard to pinpoint the exact phenotype being considered under *DSM-5* as there are more than 2,000 ways to meet diagnostic criteria and 55 ways to meet the lowest threshold of only two symptoms (Lane & Sher, 2015). It seems likely that the clinical heterogeneity of *DSM* reflects considerable etiological heterogeneity, and there could be considerable value in viewing SUDs as reflecting multiple constructs, each with somewhat distinct etiological features.

#### The Concept of "Addiction"

"Addiction" is not an official diagnostic term. Still, researchers and clinicians do use the term, increasingly so in recent years. Indeed, in the DSM-5, SUDs are described in the section entitled "Substance-Related and Addictive Disorders" and the home page of the National Institute of Drug Abuse's (NIDA) website (http:// https://www. drugabuse.gov/about-nida) states that NIDA's mission is "to advance science on the causes and consequences of drug use and *addiction* [emphasis added]." Although there is no official definition, the constructs that researchers discuss when studying "addiction" overlap the diagnostic criteria found in the DSM and ICD and include concepts such as compulsive use, neuroadaptation, craving, and a preference for the addictive substance over other reinforcers.

Table 13.1 outlines and tries to establish relations among *DSM-5* SUD criteria and the clinical constructs that are commonly equated with addiction, plus a few, selected addiction constructs that have been proposed by leading theorists. This latter group of constructs includes incentive sensitization (e.g., increased wanting and cue-elicited craving; Robinson et al., 2018), habit (use becomes automatized and difficult to unlearn and ultimately compulsive; Everitt & Robbins, 2016), allostasis

Table 13.1 Distinctions among DSM-5 substance	ce use disorder	diagnostic criteria, c	linical addic	tion concepts, and major	theoretical con	icepts		
Formal DSM-5 Criteria	Clinical Addic	tion Concepts			Selected Major	- Theoretic	al Concepts	
	Compulsive use	Neuroadaptation	Craving	Addictive Substance Preferred	Incentive Sensitization	Habit	Allostasis	Reinforcer pathology
				to other reinforcers

(change in the hedonic set point associated with adaptation to chronic drug use; Koob & Shulkin, 2019), reinforcer pathology ("the persistently high valuation of a reinforcer, broadly defined to include tangible commodities and experiences, and/or . . . the excessive preference for the immediate acquisition or consumption of a commodity despite longterm negative outcomes"; Bickel, Korrarnus et al., 2014). Note that this list is not exhaustive and there are other influential models that exist that overlap with these (e.g., multistep models that focus on how continued heavy use in concert with a vulnerable endophenotype conspire to bring about addictive behaviors; Piazza & Deroche-Gamonet, 2013).

However, as noted by Bickel et al. (2019, p. 8) and as illustrated in Table 13.1,

- 1. Theories of addiction vary with respect to the addiction constructs with which they are associated and the specific diagnostic criteria to which they relate.
- 2. A one-to-one correspondence does not exist between diagnostic criteria of, say, *DSM-5* and specific addiction constructs. For example, multiple criteria (e.g., psychological and health problems, interpersonal and social problems) could index the same addiction construct (e.g., compulsive use).
- 3. Some theories of addiction highlight features (e.g., negative affectivity) that are not part of our current diagnostic system for SUDs and overlap considerably with general psychopathology (e.g., Caspi et al., 2014).
- 4. Not all SUD criteria are fully consistent with clinical notions of addiction nor with specific theories of addiction that have been advanced.
- 5. Related to this last point, two individuals with the same number of SUD criteria may vary greatly in the extent to which they are "addicted" depending on the specific symptoms manifested (Lane & Sher, 2015), further highlighting the conceptual distinction between addiction and SUDs.

#### The Importance of Etiology

Understanding the etiology of SUDs is important for developing effective strategies for preventing and treating them. While there are a range of interventions designed to prevent the onset of SUDs (and other harms associated with SU) and to treat manifest disorder, the continuing persistence of both SU and SUDs indicates there is much more that can be done in this area.

Because use is a precondition for SUDs, many prevention approaches are at the policy level. This can involve national or local policies designed to restrict access to substances (e.g., prohibition), limit who can use them (e.g., age-related restrictions), make them difficult to use or obtain (e.g., via excise taxation), or minimize acute harm from use (e.g., impaired driving laws). Such prevention efforts are called "universal" in that they are meant to be applied to the total population. Such policy-driven prevention approaches don't rely on etiological knowledge and can be extremely effective since the entire population is targeted. Dramatic decreases in the incidence of lung cancer over the past 50 years (Meza et al., 2015) can be attributed, to a large degree, to decreases in smoking rates fueled by policy changes (including but not limited to restricted opportunities to smoke in public and workplace settings and taxation). In the United States, even more dramatic decreases in fatal alcohol-related motor vehicle crashes can be attributed to stricter drinking and driving laws initiated in the later part of the twentieth century (Voas et al., 2000). Other types of universal approaches include psychoeducational approaches in the schools (Foxcroft & Tsertsvadze, 2012), advertising bans (e.g., Saffer & Chaloupka, 2000), and public media campaigns (Allara et al., 2015). These public health approaches are obviously critical but, by themselves, don't totally eliminate the problem and, indeed, it's possible that some of these interventions can have adverse effects. As noted by Allara et al. (p. 9) with respect to public media campaigns, "Contrary to common belief, antidrug media campaigns may be damaging and their dissemination is ethically unacceptable without a prior assessment of their effects." Thus, all policies should be rigorously evaluated and not assumed to be useful on the basis of their rationale. This bears special emphasis with respect to alcohol control given alcohol's legal status, its high prevalence, and its extensive comorbidities with other SU.

While some of the heterogeneity among SUDs likely reflects mechanisms specific to SU, a complicating factor is that comorbidity, or the presence of another psychiatric diagnosis, is common (e.g., Bahji et al., 2019; Lai et al., 2015, Morisano et al., 2014). When two or more disorders co-occur, be it concurrently or longitudinally, a distinction is often made between primary and secondary disorders. This distinction reflects the degree to which one disorder is thought to be responsible for the development of the other, primarily based on the order of onset (e.g., Winokur et al., 1995). Although useful in principle, there are two reasons why this approach is more complex than might appear. First, SUDs and potential comorbid disorders have characteristic age-prevalence distributions with the modal age of, say, an SUD being younger than, say, the modal age of a co-occurring condition and so, a priori, SUDs will tend to be deemed primary or secondary based purely on their individual prototypic courses without clear implications for the presumed causal direction of influence from primary  $\rightarrow$  secondary. Much of the variance in the primary-secondary distinction is due to factors related to the normative age-incidence curves of each disorder, although there are individual differences in the relative ages of onset of the comorbid disorder (e.g., Fossey et al., 2006). That is, the degree to which order of onset itself is a meaningful index of presumed causality can always be questioned. Second, determining which disorder came first is always arguable. Should the onset of each disorder be dated to the time the pattern of symptoms reaches the diagnostic threshold, as is the usual practice? However, subthreshold symptomatology (or the processes causing it) in one disorder could conceivably influence subthreshold (or suprathreshold) symptomatology in the other disorder. One could look at the age of "first symptom" of each disorder to establish temporal precedence, but who's to say that that type of threshold captures the essence of the emergence of disorder? Moreover, dating age of onset at either the symptom or syndrome level presupposes that the underlying retrospection employed in most cross-sectional studies is accurate, a supposition not borne out by prospective studies that repeatedly query the age of onset of a particular problematic behavior (Parra et al., 2003). None of this is to say the primarysecondary distinction is not potentially useful, just that it is often hard to operationalize in a way that does justice to the concept and establish whether one disorder is predisposing or consequential.

The primary–secondary distinction should not be confused with a similar-sounding distinction between free-standing comorbid conditions and "substance-induced" mental disorders. The latter is applicable when a mental disorder develops within 1 month of a substance intoxication or withdrawal, and when it is known that the substance is capable of producing that disorder (*DSM-5*, p. 488). In most cases, the substance-induced mental illness should resolve over an extended period of abstinence. In any case, the primary–secondary distinction is deemphasized in the discussion of etiological factors that follows. What follows is a discussion of critical issues to consider when investigating current factors deemed etiologically significant for SUDs at multiple levels of analysis.

For any investigation of etiological underpinnings to prove meaningful, one needs to be mindful of several considerations. First, throughout different stages of substance involvement and psychosocial developmental, there is a dynamic interplay of risk factors over time. As such, the type and magnitude of the risk follows a temporally dynamic gradient. Both normative and deviant substance involvement are often age-graded, but stage of substance involvement must be distinguished from stage of general psychosocial development as the two may have different correlates and meanings (Sher et al., 2004).

Second, ascribing causative status to a risk factor is challenging, and often what one is dealing with is mere correlation rather than causation. Indeed, even assuming that an ostensible outcome is "substancerelated" can be difficult since it is often unclear if a seeming substance-related outcome (e.g., driving under the influence) reflects a complication of substance involvement or a generally heedless, risktaking disposition (Martin et al., 2014).

Third, what we might think of as a genetic risk factor might actually be environmental and vice versa. For example, in choosing one's peers, adolescents who are at-risk to develop conduct disorder (CD) and substance misuse problems are also genetically vulnerable to select/prefer affiliation with delinquent peers (Knafo & Jaffee, 2013). Another issue is assortative mating, where an individual with an SUD is more likely to partner with someone who also has such a disorder (e.g., Grant, Heath et al., 2007). In addition, depressed women, whose offspring are typically at-risk for conduct problems and/or substance misuse, often have a personal history of conduct problems and antisociality, and they also tend to marry and/or cohabitate with antisocial men (Moffitt, 2005).

Fourth, traditional categorical nosology as exemplified in the *DSM* and *ICD* arbitrarily delineates the boundaries of diagnostic categories, thereby implying that they are distinct taxa with distinct etiological mechanisms and obscuring the fact that comorbidity between mental disorders is typically the rule rather than the exception and likely, to varying degrees, reflective of hierarchical, dimensional traits affecting both (e.g., HiTOP; Kotov et al., 2017). A direct, logical implication of such a view is that comorbidity will increase along with the severity of the target diagnosis or comorbid condition, a prediction borne out by epidemiological data. As

noted by Helle et al. (2020, p. 632) with respect to AUD, "Greater AUD severity increases the likelihood of other psychopathology and, when present, 'more severe' presentations. That is, on average, a given disorder (e.g., depression) is more severe when co-presenting with an AUD, and increases in severity along with the AUD." While such a perspective is an implied corollary of hierarchical, dimensional models, this phenomenon is probably quite underappreciated.

Typically, the natural history of SUDs begins with experimentation, progresses to regular use, escalates to a pathological pattern of use with respect to the frequency and amount consumed, and may result in neuroadaptations (e.g., withdrawal, alteration of the hedonic set point; Koob & Schulkin, 2019) that motivate compulsive SU (i.e., use that persists in the face of aversive consequences; Lüscher et al., 2020). Along the way, the substance user may experience a range of negative consequences (e.g., social or occupational impairment); however, as noted above, it is often difficult, if not impossible, to ascribe various negative consequences to the substance itself since the users of substances may be prone to engage in a number of activities that have adverse consequences with or without the substance "on board" (for a detailed discussed, see Martin et al., 2014). As cogently observed when describing defining characteristics of psychopaths, Hervey Cleckley (1955) noted that the psychopathic personality is prone to exhibit "Fantastic and uninviting behavior with drink and sometimes without [emphasis added]" (pp. 406-410). That is, one could observe wildly disinhibited behavior under conditions of substance intoxication, but apportioning causality of the behavior to the substance versus the substance user is not straightforward, and ostensible SU consequences might not be consequences in a formal or meaningful sense.

In each of the stages of substance involvement, heterogeneous effects and mechanisms are likely. Moreover, the risk factors for one stage (e.g., initial use) aren't necessarily the same for another stage (e.g., SUD conditional upon use). As noted earlier, these different stages can have similar risk factors (e.g., conduct disorders) but risk factors for initiation can be different from risk factors for progression. When considering presumed etiological correlates of SUDs, the exact nature of risk is obscured if progression and stage of pathological substance use are not considered.

Consequently, although many cases of SUDs are superficially similar, there are likely different species of SUDs; that is, much of the similarity is only skin-deep. Stated more formally, the SUD phenotype can often be considered an instance of equifinality (Cicchetti & Rogosch, 1996), where the same end state may be reached "from a variety of different initial conditions and through different processes" (p. 597). Returning to the example of hazardous use, such a criterion could reflect generalized risktaking or heedlessness (i.e., not specific to the use of the substance), an indication of compulsive use, or both. Merely assessing the criterion without understanding its causes will fail to resolve what might be an important difference with respect to whether the symptom is best viewed as an indicator of an SUD or a noncausal correlate of an SUD.

#### At the Level of the Society

#### Culture

One's culture substantially contributes to initiating use, sculpting established patterns of drug use and possibly misuse. Which and how much of a substance is used and what the substance does, subjectively and objectively to and for individuals can strikingly be interculturally different (MacAndrew & Edgerton, 1969). This variation can determine how many individuals in each society use and misuse which forms of drugs and at which point of their life. Hence there is great relativity as to what is considered a harmful drug.

The relationships between cross-cultural differences and demographic variations within cultures are sometimes complex. For example, in the GENACIS project, a multinational study of gender-related and cultural influences on alcohol use and associated problems (Wilsnack, 2012) in 38 countries spread across all continents (except Antarctica), men were found to drink more than women. However, women in some cultures drink more than men in other cultures. That is, these demographic differences are conserved within cultures, but there is considerable variation in overall levels across cultures. Similarly, some correlates of alcohol excess (e.g., intimate partner violence) are similar across cultures.

However, some phenomena seen as "typical" in one culture may not appear in other cultures. For example, in North America, there is a strong age gradient in the prevalence of AUD (e.g., Vergés et al., 2012), with peak rates of onset and prevalence in late adolescence and young adulthood. The phenomenon is so strong that it has led to the conclusion that, on a population basis, AUDs can be considered a "developmental disorder of young adulthood" (Sher & Gotham, 1999). However, the notable age gradient, or any other demographic phenomenon observed in one culture, should not be assumed to be independent characteristics of the disorder itself outside of the culture it is observed in.

Moreover, these cross-cultural differences are not static. Distinctions between "wet" (heavy drinking) and "dry" cultures (both within and across nations) appear to be changing in the age of globalization. Historically, the Nordic and Anglo-Saxon cultures were characterized by high levels of what we'd today call binge drinking in contrast to the more moderate, wine-drinking Mediterranean culture. However, youth in the Mediterranean regions are now drinking more like their age peers to the North, such that historical drinking style differences have tended to erode (Room, 2010). In the United States, multiple epidemiological surveys have demonstrated major shifts in the prevalence of alcohol use over the past 20 years although these changes differ as a function of the age groups studied (Grucza et al., 2018).

Concerning alcohol, it has been shown that increases of price and taxes reduced alcohol consumption, morbidity, and mortality rates (Wagenaar et al., 2010). Furthermore, increasing the legal drinking age reduced teen DWIs and traffic deaths. Alcohol prices, nonetheless, remain quite low (Albers et al., 2013), likely reflecting the fact that price increases are typically not indexed to inflation (Jernigan & Trangerstein, 2020). While various alcohol control strategies (e.g., price increases, restrictions in availability with respect to time and place of sales, marketing bans) at the population level can be highly effective (Berdzuli et al., 2020), their effects could vary considerably due to sociodemographic characteristics of jurisdiction (Room et al., 2013). Additionally, as the COVID-19 pandemic has taught us, major restrictions in on-premise alcohol sales have been accompanied by increases in off-premise availability in many countries (Berdzuli et al., 2020) highlighting the complexities of designing alcohol control policies in the face of an ever-changing landscape.

Societal control of drug use is more readily achieved in isolated cultures, where it becomes interwoven into the basic fabric of life. The informational and commercial borderlessness of most Western societies predestines such control efforts to limited success, as witnessed by the failure of Prohibition, the war on drugs, and the fact that cigarettes and alcohol, although legally prohibited from sale to minors, are readily available to them. There are subcultures that promote and others that inhibit drug use and misuse. Drug subcultures emerge from common identities, such as age or perceived and real alienation, which in turn can promote group solidarity or result in group dysfunction. Central to each subculture is the development of a set of shared beliefs and practices. Normative beliefs, which are perceptions of the extent to which significant others approve or disapprove of or engage in a behavior themselves, have been shown to be important predictors of drug use, particularly in adolescents and young adults (Brooks-Russell et al., 2014). Conversely, the degree of spiritual/religious involvement has been shown in many studies to protect one against drug misuse (reviewed in Dick, 2011).

High levels of binge drinking with serious consequences by university students represent an illustrative example of the role of social networks within subcultures. Psychosocial predictors of drinking by undergraduates include overestimates of others' drinking behavior and attitudes (Woodyard et al., 2013), membership in a fraternity or sorority (Wechsler et al., 2009), binge drinking in high school (Wechsler & Nelson, 2008), family history for alcoholism (Dager et al., 2013), and nonreligiosity (Wichers, Gillespie et al., 2013). Despite changes over time, drinking levels and problem drinking by students remain high relative to other groups although these problems don't necessarily continue past college (e.g., Bartholow et al., 2003) and this generalization doesn't extend to other substances such as tobacco (Blanco et al., 2008).

#### Poverty and Related Variables

Although poverty per se is a weak predictor of drug misuse, poverty combined with other deleterious factors associated with impoverished areas (neighborhood deterioration, high crime) substantially increase risk for SU problems. The relationship between poverty, difficult living conditions, and drug misuse appears to be robust across many different cultures. The duration of time spent in poverty and the age of the individual moving into/ out of poverty also appear relevant. One Swedish population study found that, while economic instability in early childhood was a significant risk factor, instability during middle childhood or adolescence presented the greatest risk (Manhica et al., 2021). However, this increased risk is not specific to poverty in childhood, as an 18-year prospective study of adults found that living in a disorganized neighborhood was significantly associated with increased symptoms of AUD, with the link being mediated by psychological distress (Cambron et al., 2017).

Culture paints the drug-taking context and expectations of response, which can have significant influences on an individual's response to the drug. The notion that substances, in part, produce culturally prescribed effects has long been suggested by anthropologists who study drug use. There is substantial evidence, in crime and laboratory studies, that the use of alcohol increases the likelihood of aggression. Particular pharmacological effects on brain functioning that affect this behavior have been detailed (Parrot & Eckhardt, 2018). Yet there is considerable cross-cultural variation in the extent to which this effect occurs. MacAndrew and Edgerton (1969) suggested that alcohol-related violence was in part due to cultural norms in certain societies, specifically that cultural views of alcohol provide a "time out" from the normal behavior and an option to disclaim personal responsibility for deviant behavior committed while intoxicated.

Along with differences in individually experienced subjective effects, the cultural significance assigned to a drug has implications for SU. Cultural significance, in this case, refers to the aesthetic, historic, scientific, social, or spiritual emphasis that a given culture places on a particular substance (Durrant & Thakker, 2003). This significance can be broad, such as the significance of cannabis in Jamaican culture (Rubin & Comitas, 2019), or narrow, with specific preparations or methods of ingestion, such as the consumption of hallucinogen N,N-dimethyltryptamine via Ayahuasca in some Peruvian tribes (Labate & Canvar, 2014). Cultural significance can even vary within substances, such as the different cultural significance of consuming champagne versus beer versus liquor. This cultural significance shapes expectancies about the effects produced by the drug, the situations in which the drug is considered acceptable to use, and even the types of positive and negative outcomes predicted by using the substance. Within many cultures, psychotropic drugs are viewed in a spiritual rather than a hedonistic way, thus greatly coloring the response (De Rios & Smith, 1977). One particularly notable example of a culturally significant substance is alcohol. In many countries around the world, imbibing alcohol is a culturally constructed social practice, with alcohol consumption given social and emotional significance for various issues including (but not limited to) celebration, identity, recognition of achievement, hospitality, mourning, entertainment, and social solidarity (Copaceanu & Balaceanu-Stolnici, 2018).

Reflecting shifts in patterns of drug use, prescription drug use has recently surpassed traditional illicit drug misuse (cannabis excepted) by a considerable margin (Substance Abuse and Mental Health Services Administration, 2020). While there are growing concerns of prescription stimulants and benzodiazepine misuse among young adults, the most culturally significant trend of prescription drug misuse in the United States concerns opioid analgesics.

While opioids have a long and sordid history, the current "opioid epidemic" in the United States can be traced back to the mid-1990s, when attitudes in the medical field began to shift regarding the management and treatment of pain (e.g., "pain as the fifth vital sign"; American Pain Society, 1999). As pain management became a priority for medical providers, opioid prescriptions in the United States skyrocketed, with opioid consumption rising from 49,946 kg in 2000 to 165,525 kg in 2012. Although the initial response was positive, the cultural change had significant downstream consequences resulting in increased opioid misuse, addiction, and mortality. This sharp increase in prescription opioid use and misuse is also believed to be related to the recent increase in illicit opioid (e.g., heroin, fentanyl) use in the United States. While opioid use has risen worldwide, this "crisis" is uniquely American, with recent figures estimating that the United States consumes 80% of the opioids manufactured in the world each year (Shipton, 2018), and drug overdose is the leading cause of accidental death (Schiller et al., 2021).

Cultural examples adroitly illustrate that definitions of problems with drugs often depend on where one resides and who the user is: consequently, comprehensive models of causation must be multidimensional. Explanations that reside purely within the individual, either physiological or psychological, provide only a limited perspective, and models of etiology are, by necessity, contextually dependent on the environment and the inherent philosophies.

#### The Peer Group

If one's friends use and misuse drugs, the odds are much higher for oneself. Time spent with like friends that encourage and/or model deviancy, lack of achievement, and depressed mood are important factors in predicting problem SU (Castellanos-Ryan et al., 2013; Pei et al., 2020). Furthermore, CD is consistently found to be a strong predictor of drug use initiation, persistence of drug misuse into adulthood, and progression to addiction (Sartor et al., 2007). The relationship is so strong that precocious SU has been considered a possible diagnostic criterion for CD (Fairchild et al., 2019). This correlation between peer delinquency and SU and abuse could mirror a causal chain, wherein delinquent friends model and encourage SU among other problem behaviors or, conversely, a youth-governed phenomenon in which individuals at risk to use and misuse substances select and/or prefer friends who model and condone use (Schwartz et al., 2019).

While socializing with a deviant peer group is a robust predictor of SU, there is evidence that the "type" of socializing also plays a role in the relationship. One study found that unstructured socializing ("just hanging out," or spending time without any particular preplanned activity) can explain some of the within-individual patterns of SU. In other words, a person may be at increased risk of SU while spending unstructured time with a group of friends who primarily engage in SU, whereas they may be more at risk of engaging in vandalism when spending unstructured time with friends who engage primarily in vandalism (Hoeben et al., 2021). Whatever the mechanisms, a temporally dynamic action and interaction of these processes with one another is likely to be the case. One large-scale twin study showed that, along with the genetic susceptibility for externalizing disorders, peer delinquency was the strongest vulnerability for adverse drinking trajectories (Wichers, Gardner et al., 2013; Wichers, Gillespie et al., 2013). More recent research has found evidence for a gene-environment interaction wherein peer deviance moderates genetic influence for deviance. One longitudinal, nationally representative study found that genetic influences decreased and environmental influence increased as peer deviance increased (Schwartz et al., 2019).

Related to these phenomena is the so-called gateway model, which postulates that the transition from using one drug to another (more specifically from legal to illegal drugs) occurs sequentially. The order is generally hypothesized to lead from more recreational substances to "harder" drugs (substances that are less commonly used, more stigmatized, and present greater risk addiction, health consequences, and mortality). An approximation of this progression begins with cigarettes, alcohol, and marijuana; then moves to recreational stimulants, depressants, and hallucinogens; then finally leads to crack cocaine, methamphetamine, and heroin. Obviously, this progression is not inevitable, and the order is variable, but exposure to peers who engage in drug use a step beyond one's own is seen as an important determining factor, particularly if one is strongly identified with these peers.

This could in part be due to drug subcultures, as an individual may become exposed to new substances after associating with peer groups belonging to subcultures centered around particular substances ("stoners," "ravers," "psychonauts," etc.). This identification is seen as involving expectations regarding positive results from such drug use. Peer factors are thus central in three ways: first, in providing the drug; second, in developing attitudes about its use and effects; and third, in providing an exemplar. This peer cluster theory states not only that peers represent the most important predictor of use and progression to abuse but also that peers mediate the significance of other risk factors-for example, emotional problems and attitudes about oneself. Some research has confirmed these social learning interpretations, and the consequent argument has been made that interventions should be aimed at peers. However, while there is some support for the gateway theory, evidence that this effect is driven by peers or subcultures is mixed (Golub et al., 2005; Nkansah-Amankra, 2020), and the vast majority of individuals who use "softer" drugs do not progress into using harder drugs. Additionally, it is debated if subsequent drug use is actually caused by using the previous drug or if the apparent association is better explained by other factors (e.g., increased access to other substances, peer selection following drug use).

Part of the variability in characterizing peer and other factors in drug use arises from how use is defined. Studies that measure "ever used" may be selecting a suboptimal population for study since drug experimentation by adolescents, even with an illegal drug such as marijuana, appears to err on the side of normality as most adolescents have used the drug. A longitudinal study (Shedler & Block, 1990) found that adolescents who *never* experimented with drugs, particularly marijuana, showed indications of being more maladjusted than occasional experimenters. While experimenters do display some risk factors, heavy, escalating, and debilitating drug use should be the focus of concern.

#### The Family

Another area where modeling seems to play a role pertains to the behavior of one's parents and siblings. It has been known for many years that alcohol and substance use runs in families. Some of this behavior is directly heritable through genetic predispositions to SU and SU risk factors, while other influences come from the types of behavior modeled within the home and the family. Recent estimates suggest that roughly 50% of the variance of addictive behaviors is due to (epi)genetic effects (Friedel et al., 2021).

A large-scale investigation of a follow-up of nine large databases of adoptive children found that when either, versus neither, of the biological parents abused drugs, the offspring risk for drug abuse doubled, and when both did so, the risk tripled (Kendler, Sundquist et al., 2012). A slightly greater risk was found in offspring with paternal versus maternal drug abuse, and males seemed to be more genetically vulnerable than females. Furthermore, a biological family history of alcoholism, criminality, or other forms of psychopathology also elevated risk in adopted offspring (Kendler, Sundquist et al., 2012). Consistently, a subsequent analysis by the same group demonstrated that risk for SUDs was significantly greater when the age difference was smaller. Specifically, when both siblings were born on the same year, versus 10 years apart, the risk for a SUD in the unaffected sibling doubled. Risk also was substantially greater when the affected proband was older versus younger than the unaffected siblings, an effect that was much more pronounced in male versus female pairs (Kendler et al., 2013).

Children can also learn SU through the modeling of their parents' behavior. When parents provide their children with medication or use substances to relieve negative feelings, cope with stress, provide a social lubricant, etc., they are modeling both the behavior and the expectancies associated with the given drug. Drug and alcohol expectancies are learned, in part, from parents' attitudes and behaviors. Exposure to parental alcohol use models drinking behavior and expectancies for children/ adolescents, even if the parents experience negative consequences from alcohol use (e.g., Waddell et al., 2020). In addition to alcohol use, many studies have consistently supported parental drug use as a risk factor for adolescent initiation of use (Pentz & Riggs, 2013; Rusby et al., 2018). While there are specific genetic and environmental risk factors presented by the family, these risks are often correlated (i.e., families with genetic predisposition toward SU are also more likely to have deleterious environmental situations). Furthermore, research suggests that there is a cumulative risk, wherein exposure to multiple risks throughout development increasingly amplify one's risk. These factors, along with the interactions between environment and gene expression, create a complicated amalgam of familial risk that can be difficult to attribute to any specific cause (Stallings et al., 2016).

A recent study from a large-scale investigation of seven Norwegian twin birth cohorts yielded evidence that SU is highly heritable (Waaktaar et al., 2018). This genetic heritability was present for alcohol use, tobacco use, and illicit drug use and was present throughout adolescence and into early adulthood. Other recent work has found that both genetic and neighborhood factors predict SU, with a significant interaction between socioeconomic status (SES) and genetic risk for alcohol use (Pasman et al., 2020). Data from community-based samples show that more than half, and one-fifth of the offspring of alcoholics, become alcohol and illicit drug misusers, respectively, compared to one-fourth and one-tenth of matched controls (Hussong et al., 2012). Furthermore, after adjusting for comorbid parental psychopathology, environmental stressors, and familial dysfunction, parental alcoholism stands out as a unique predictor of drug use and misuse in adolescence and early adulthood.##

The simple availability of cigarettes, alcohol, marijuana, and prescription drugs within the family seems to be a contributing factor to SU. Drug availability plus permissive parental attitudes, low parental monitoring, and poor parental support further facilitate use (Maggs & Staff, 2018; Rusby et al., 2018). Even parental permissiveness toward legal substances (e.g., tobacco, alcohol) predict adolescent use of illicit drugs (Mehanović et al., 2021) As disordered conduct is a profound risk factor for substance misuse, family dynamics that increase risk of conduct problems also predict onset and progression of adolescent SU. These factors include maladaptive parenting; using harsh, coercive, and inconsistent discipline; and parent-child conflicts. Parental mistreatment is a particularly important risk factor in individuals at high genetic risk for CDs (Fairchild et al., 2019).

Stress is common in substance-abusing families. Stressors common in families with AUD include high conflict, poor communication, marital discord, coercive interactions, physical abuse and neglect, economic and social deprivation, and the extremes of parenting (i.e., too authoritarian or too lax; Velleman & Orford, 2013). Almost all (98%) of adolescents with drug abusing parents are beset by at least one other environmental adversity (McLaughlin et al., 2012). Considerable research has found that a history of childhood abuse is a strong predictor of adolescent SU, which in turn is a strong predictor of subsequent development of substance abuse or addiction. A recent study found that the relationship between childhood maltreatment and adolescent SU is not directly linked, but rather occurs through the development of posttraumatic stress symptoms and poor mother–child relationships (Yoon et al., 2017).

There is, of course, another side to this coin. There is evidence that positive family environments involving such things as religious involvement, positive marital relationships, distance from delinquent peers, and high parental warmth and monitoring reduce the likelihood of the development of SUDs (Dick & Kendler, 2012).

Positive family attributes may have effects that fluctuate and vary during the developmental process. For example, a longitudinal investigation following approximately 1,000 young adolescents for 11 years and assessing their drug consumption (specifically tobacco, alcohol, and cannabis) found that early adolescence use was predicted by lack of parental monitoring. However, as adolescents transitioned to high school and later adolescence, it was the quality of the family relationship (indexed by shared activities, mutual regard and positive affect between parents and adolescent offspring) that was most protective against SU. However, these family factors (parental monitoring, family relationship) did not appear to be relevant to drug use in young adulthood (Van Ryzin et al., 2012).

Seldom considered but potentially significant family factors in the etiology of SUDs are teratogenic effects. Drug use by parents can deleteriously affect intrauterine development. One widely accepted teratogenic effect that has received considerable mainstream attention is fetal alcohol syndrome (FAS) and its more broad designation of fetal alcohol spectrum disorders (FASD), involving low birth weight, prematurity, infant mortality, and physical anomalies in the central nervous system (CNS) development, maturation, and function (Norman et al., 2013). Similar deleterious phenomena have been observed in infants prenatally exposed to cocaine and cigarettes (Liu et al., 2013), methamphetamines (Twomey et al., 2013), opiates (Behnke et al., 2013), and many prescribed drugs, particularly barbiturates and other sedatives. In a birth cohort study (Alati et al., 2006), children of mothers who drank during pregnancy produced offspring who were 2.95

times more likely to later develop adolescent problem drinking when compared with controls. Another longitudinal study showed that the effect of maternal drinking during pregnancy bore a dose-response relationship with adult offspring self-reports of problematic behaviors (Day et al., 2013). While the link between ethanol exposure and FASD appears intuitive, some have argued for the importance of moderators or mitigators of the link between drinking during pregnancy and FASD, suggesting that the latter cannot be fully explained by the unconditional effects of ethanol exposure because an impoverished family environment also substantiates risk for FASD. It has been argued that FASDs are caused by nutritional deficiencies that ethanol exposure can exacerbate as opposed to their being a direct alcohol-induced neurotoxic effect (Ballard et al., 2012).

#### At the Level of the Individual

Given the same environmental context, not all individuals are equally likely to experiment with drugs, become regular users, or progress to heavy use with or without associated problems. A number of individual-level factors have been shown to be associated with risk for substance use and for SUD, and those that have received the most attention are highlighted below. Full description of individuallevel factors requires consideration of those that are both general and specific.

#### Stress and Affective Factors

When asked, people frequently report that they abuse substances to reduce stress. However, when subjective distress and stressor exposure are assessed, neither usually correlates very highly with degree of substance use (Sher & Grekin, 2007).

The relationship between SUDs and stress is theorized to occur for a number of reasons. SU may be a coping strategy, most typically a form of emotion-focused coping, as described in theories as self-medication (Khantzian, 1985, 1997), tension reduction (e.g., Greeley & Oei, 1999), or stress-response dampening (e.g., Sher, 1987). That is, individuals take psychoactive substances to directly reduce psychological distress (or avoid anticipated distress) via pharmacological mechanisms. For example, some drugs (especially benzodiazepines, which are prescribed clinically to reduce anxiety and panic, but also barbiturates and alcohol *in sufficient dosage*) have well-characterized anxiolytic properties, and users seek these out for their desired effects. While such effects are typically thought to be due to direct effects on neural systems involved in emotions, it is also possible that at moderate doses, certain drugs (e.g., alcohol) can facilitate emotion regulation by restricting attention to the most salient aspects of the surrounding environment. If these salient, environmental distractors are positive (or even neutral), attention is likely to be redeployed to them with less attention focused on distressing stimuli and/or thoughts, resulting in a distress-reducing effect (Fairbairn & Sayette, 2013; Josephs & Steele, 1990; Steele & Josephs, 1990).

It is possible that some users sometimes consume substances to avoid or minimize stress associated with anticipated or feared failure via "self-handicapping" (i.e., using a substance to provide an external attribution for failure; Jones & Berglas, 1978). In such cases, the neuropharmacological effect of the drug may be irrelevant or incidental because having an excuse (an attribution for one's shortcomings) is the operative mechanism.

The transition to SUD is also likely modulated by additional factors. For example, for Vietnam veterans who had drug abuse problems associated with PTSD, there was an average of 3 1/ 2 years between the onset of PTSD symptoms and the development of the SUD (Davidson et al., 1985). A meta-analysis of eight longitudinal studies showed that depression predicted alcohol consumption for women (Hartka et al., 1991). Consistent with the self-medication model, individuals with high levels of hopelessness report drinking to cope with depression, which can then lead to severe alcohol problems (Grant, Beck et al., 2007). In particular, women report problems with intimacy and interpersonal stress as the reasons for excessive drug consumption (Frank et al., 1990). However, given the importance of stress, anxiety, or depression as etiological factors, the fact that the majority of individuals who undergo these conditions do not turn to drugs for relief suggests that more than a single explanation is required. Additionally, negative emotions such as depression and anxiety often arise from chronic, heavy SU (e.g., DSM-5 substance-induced mood and anxiety disorders) and so disentangling the primacy of affective symptomatology and SU and SUDs can be quite challenging. However, whether negative affectivity is premorbid to or acquired through chronic, heavy SU, it is thought to play an important role in the maintenance and course of SUDs (Koob & Schulkin, 2019).

#### PERSONALITY

For much of the past century, problem drug behavior was typically ascribed to an addictive personality. Indeed, a plethora of studies yielded evidence supporting a wide range of personality profiles as etiologically significant. In an earlier review (Pihl & Spiers, 1978), it was determined that 93% of this research studied exclusively patients in treatment, thus likely reflecting the characteristics of individuals who seek or are mandated to treatment, or the concomitants of the problem rather than the cause of the problem. Barnes (1979, 1983) highlighted the differences between pre-alcoholic personality traits (i.e., those traits that prospectively predict the occurrence of an AUD) and clinical alcoholic personality traits (i.e., those traits that distinguish individuals with AUDs from those with other disorders or no disorder). Perhaps the biggest difference is that persons who eventually develop AUDs show less negative affectivity premorbidly than do those currently exhibiting clinical manifestations (Sher & Gotham, 1999).

Indeed, a prominent view of addiction, *allosta*sis theory (Koob & Schulkin, 2019), suggests that chronic adaptations to substance use lead to a change in the hedonic set point. There are progressive increases in negative affect, which then goad further consumption for transitory relief, thus setting up a vicious cycle (Sher et al., 2005).

From the perspective of the Five Factor Model (sometimes referred to as the "Big Five"), the traits that appear to be most important to risk for SU and SUDs are those associated with neuroticism, agreeableness, and conscientiousness (e.g., Malouff et al., 2007). Notably, specific facets of neuroticism (e.g., impulsiveness/negative urgency) and conscientiousness (lack of perseverance, lack of premeditation) may be particularly relevant to SUDs (Dick et al., 2010). In conceptualizing the way personality might be related to SU and SUDs, it is important to consider some less appreciated aspects of the relations between these two domains. First, personality changes developmentally, with individuals tending to become less neurotic, more conscientious, and more agreeable as they age, with these changes particularly evident in the third decade of life (Roberts et al., 2006). Coincidentally, this is the same period of time when individuals show decreasing rates of AUDs (Vergés et al., 2012) and other SUDs (Vergés et al., 2013). These two processes appear linked. As individuals "mature out" of their problematic SU they also show greater psychosocial maturation, as evidenced by decreased neuroticism

and increases in conscientiousness and agreeableness, and that part of desistance from problematic substance involvement reflects normative personality change (Lee & Sher, 2018). That is, the longitudinal association between personality and SUDs appears to be driven, in part, by psychosocial development.

While personality might be related to SU and SUDs either as a premorbid risk factor or as a complication of chronic use, an important issue largely overlooked in the research literature (but not among lay people or the recovery community) is the acute effects of a drug such as alcohol on personality expression, akin to a "Dr. Jekyll and Mr. Hyde" or "Nutty Professor" transformation. That is, intoxication might lead, in some, to state changes in personality; some people may be more agreeable and conscientious, others more antagonistic, and others more extraverted when "under the influence" (Winograd et al., 2016, 2017).

Although personality has typically been viewed as relatively stable cross-situationally, recent views of personality highlight the importance of situational determinants of personality expression (Fleeson, 2001). From this perspective, one important "situation" to consider is drug intoxication, which in some individuals occurs often and in important social contexts.

When discussing "why" might personality influence SU and SUDs more generally, it's important to note that multiple pathways of influence have been posited including (1) sensitivity to drug effects, (2) general deviance proneness, (3) trait emotionality, (4) emotional regulation, and (5) peer and environmental selection (Littlefield & Sher, 2016; Sher, 1991). That is, while personality in general and individual traits may play a critical role in the etiology of SUDs, it is not a single role and broadly encompasses most mechanisms that various theorists have proposed as central.

#### Cognitive and Motivational Processes

Dual-process models emphasize that drug use can be viewed as the outcome of two competing tendencies: (1) approach motivations toward using a substance and (2) restraint motivations to abstain or limit use. While such models are relevant to a wide range of behaviors (Strack & Deutsch, 2004), they are particularly relevant to conceptualizing addiction (Wiers & Gladwin, 2016; Wiers and Stacy, 2006). Such models provide the foundation of a general framework for integrating a diverse host of etiological factors, both internal and external, across multiple levels of biospsychosocial organization and stages of substance involvement.

#### EXPECTANCIES

Beliefs and expectancies regarding drug effects, reflecting both social learning and direct pharmacological experiences, are a critical part of the cognitive context and expectations of drug effects and predict drug use. The brain reacts to stimuli in terms of context (Luria, 1980), with one's culture, learning, and experience anchoring each new response. Regarding drugs, these factors coalesce in the form of expectancies. Generally, an individual frequently using a drug is more likely to perceive less risk and to approve more of the use of that drug. Among illicit substances, for example, marijuana is the most used (Substance Abuse and Mental Health Services Administration, 2020) and is perceived as least harmful, although in recent years the perceived harmfulness of marijuana has decreased without a concomitant increase in prevalence of use (Sarvet et al., 2018). Of course, one's attitudes toward a drug and beliefs about use are robustly associated with changing trends of drug use behaviors (Substance Abuse and Mental Health Services Administration, 2020).

The 1980s witnessed a decline in marijuana and cocaine use in the United States that was accompanied by greater perceived risk of use. Conversely, a drastic shift of these attitudes to the other direction during much of the 1990s seems to have accounted for the elevated use of many illicit substances, specifically marijuana. As well, ecstasy use in some of the early 2000s dramatically decreased as a result of greater perceived danger of its use (Droungas et al., 1995). Drug use is also affected by what one expects a drug to do to and for oneself, both objectively and subjectively. A large 9-year prospective study found that among males and females, consuming alcohol and marijuana could be predicted in adolescence and adulthood based on early expectations of the response of positive feelings to the drugs and the alleviation of negative feelings (Stacy et al., 1991).

Neural reflections of differential types of expectancies have been identified in the lab. In one functional magnetic resonance imaging (fMRI) study, participants were exposed to a noxious thermal stimulus after which they ingested a potent opioid receptor agonist. Those who had positive analgesia expectations showed double the benefit from the drug, which was associated with activation of the endogenous pain regulatory system. This benefit
was completely blunted among those with negative expectations, the latter of which correlated with decreased activation in brain regions involved in exacerbating pain via anxiety (Barrett et al., 2004). Some ostensible drug effects commonly associated with alcohol consumption (especially sexual arousal and aggression) have been found to be determined, to a nontrivial degree, by the belief one has consumed the substance (Crowe & George, 1989; Hull & Bond, 1986). However, such expectancy or placebo effects are not inevitable and may be highly conditional upon individual and situational factors. Moreover, some expectancy effects are in the opposite direction of alcohol effects, most likely reflecting compensatory strategies for managing intoxication (Testa et al., 2006).

Expectancies regarding drug effects are far more complex than simply positive (i.e., reinforcement) or negative (i.e., punishment). First, expectancies can vary as a function of the perceived dose of a substance (e.g., Wiers et al., 1997) or whether or not blood levels of the drug are increasing or decreasing (e.g., Morean et al., 2012). For example, someone may anticipate pleasurable arousal in ingesting a moderate amount of alcohol but also anticipate distress when the effects of the alcohol are wearing off, as occurs in hangover. How one weighs the costs and benefits of various substance effects and their immediacy interacts with individual differences in delay and probability discounting (Bickel, Koffarnus et al., 2014; Yi et al., 2010).

During adolescence, alcohol expectancies tend to become more positive (e.g., Sher et al., 1996) and then tend to decrease over adulthood (e.g., Nicolai et al., 2012). A recent study (Montes et al., 2019) found not only that baseline levels of positive expectancies predicted the onset of SU (specifically, alcohol, tobacco, and marijuana) but also that the rate of change was a significant predictor of onset for all substances. In addition to being of interest in their own right, expectancies appear to play an important mediating role for more distal risk factors such as personality (e.g., Mezquita et al., 2015). That is, personality tends to shape the types of expectancies that someone forms based on intraindividual factors, such as individual differences in pharmacological sensitivity to various drugs, proneness to negative emotional states, sensation seeking, and other mechanisms (Littlefield & Sher, 2016).

Such expectancies are intimately related to the stated reasons that individuals endorse about why they choose to consume a substance (Cooper et al., 2016). While there are similarities across different

psychoactive substances such as alcohol and marijuana in the various SU motives endorsed (e.g., enhancement or getting "high," coping with negative emotions, to conform with social norms, to heighten sociability), tobacco use motivations appear quite different and are characterized by automaticity/habit and responses to withdrawal cues. Note that someone can hold certain expectancies for a given SU effect but not necessarily use the substance for those anticipated outcomes. Thus, while intimately related to self-reported motivation, substance outcome expectancies are conceptually and empirically distinct.

### BASIC COGNITIVE FUNCTIONING

Variation in some aspects of cognitive functioning could put someone at risk for problematic use because they are associated with self-regulatory processes or substance-related reinforcement. To identify preexisting cognitive deficits that increase risk for substance use, as opposed to cognitive deficits that may have occurred as a result of using substances, researchers can examine characteristics of individuals who are at high risk for SU or SUDs (e.g., children of individuals with a SUD), but have not yet engaged in SU or developed an SUD. Such studies often find mild to moderate neuropsychological deficits present. These impairments have been found in five broad categories of cognitive performance: executive functions (which encompass abstracting, planning, and problem-solving abilities), language-based skills, attentional and memory processing, psychomotor integration, and visuoperceptual analysis and learning (Pihl et al., 1984).

Of central interest to understanding SU and SUDs is the role of executive function owing to its importance in decision-making and guiding selfdirected behavior. "Executive function" refers to a broad set of cognitive abilities including working memory updating, task switching, and response inhibition (Friedman & Miyake, 2017; Miyake et al., 2000) although various measures of response inhibition (e.g., Hamilton, Littlefield et al., 2015) appear to be associated with a broad common factor (Miyake & Friedman, 2012). Given its general association with a range of externalizing disorders as early as early childhood (Schoemaker et al., 2013), executive function (especially response inhibition) would appear to be an important endophenotype to consider when understanding cognitive risk factors for SU and SUDs. However, recent work (Gustavson et al., 2017) suggests that response inhibition is most strongly associated with SU in

adolescence but not in later life or with the transition to SUDs, again highlighting the importance of distinguishing factors associated with SU versus those associated with transition from SU to SUD.

Certain drugs (particularly alcohol) acutely impair these cognitive functions (Porjesz et al., 2005). This may be a central factor in explaining the high correlation between intoxicated behavior and aggression. For example, alcohol can disrupt executive functions necessary for restraint following provocation (Giancola, 2004). The notion that disinhibitory effects of alcohol are attributable to disruption of higher cortical functions is consistent with long-standing speculations on how drugs lead to disinhibition (McDougall, 1929).

Along with premorbid executive function deficits, chronic exposure to psychoactive substances can cause further impairment and thus can contribute to a worsening of substance-related problems. Fernandez-Serrano et al. (2010) showed a range of executive function deficits as a function of chronic use of different drugs of abuse and concluded that "alcohol abuse is negatively associated with fluency and decision-making deficits, whereas the different drugs motivating treatment have both generalized and specific deleterious effects on different executive components" (p. 317). There is also evidence that the neuroadaptations underlying addiction can also affect cognitive functions. For example, the development of incentive salience to drug cues is associated with impaired response inhibition (e.g., Lovic et al., 2011), potentially increasing addiction liability by both increasing approach and reducing restraining tendencies. Also, executive function and other higher intellectual functions appear to moderate other important cognitive risk factors for addiction such as delay discounting (Bailey et al., 2018; 2020).

At least for human males, the P300 wave of the visual event-related potential (ERP; a brainwave reflective of neural inhibition or attentional regulation and obtained via electroencephalography) exemplifies what is perhaps the best currently known endophenotypic marker for SUDs (Bingel et al., 2011; Euser et al., 2012; Singh & Basu, 2009). The P300 wave is evoked when a subject responds to a distinct stimulus presented among many similar ones and must make some type of decision or judgment (Metrik et al., 2009). The P300 amplitude has been shown to become attenuated in drugnaïve 11-year-old sons of alcoholic fathers, pointing to its heritability. This trait is also manifested in the full range of externalizing psychopathology as well as psychotic disorders, suggesting that the attenuated P300 amplitude is an endophenotypic marker for low-order disinhibitory externalizing disorders (Patrick et al., 2006; Volkow et al., 2003) or psychopathology more generally (Tang et al., 2020; Wada et al., 2019).

Anomalies in executive function and inhibitory control, added to augmented levels of anxiousdisinhibited traits, have been detected in both individuals addicted to psychostimulants and their unaffected siblings, but to a significantly greater extent in the former. This may point to both neurotoxic or other effects of persistent drug misuse (Miller & Rockstroh, 2013) and underlying vulnerability. These commonalities of reduced inhibitory control and increased anxious-disinhibition have thus been proposed as endophenotypic markers for the addiction to psychostimulants, reflected as a neurodevelopmental perturbation of prefrontal functioning (Iacono & Malone, 2011).

### ADDICTION-RELATED COGNITIVE CHANGES

While premorbid, individual differences in executive function and other cognitive functions put one at risk for SU and SUDs, both the direct neurotoxic effects of a drug on the brain and adaptive changes associated with prolonged heavy SU create further vulnerabilities for the development of severe SUDs and addiction.

Clearly the heavy consumption of most drugs is neurotoxic, and this is the case even for marijuana (Séguin et al., 1995). Cross-sectional studies tend to find small effects on neurocognition that are attenuated with abstinence (Scott et al., 2018). One longitudinal study found that deficits in short-term and working memory predicted an earlier age of onset of cannabis use, and cannabis use across adolescence was associated in declines in verbal intelligence and some executive tasks and reward processing (Castellanos-Ryan et al., 2017). The issue of distinguishing premorbid and acquired deficits in SUDs is always one that is hard to resolve in individual cases.

This is problematic for drawing etiological conclusions given the indisputable fact that drugs of abuse are neurotoxic. They hijack the CNS and remodel it, both functionally and structurally (Benningfield & Cowan, 2013; Volkow et al., 2016), effects only some of which are reversible (Meier et al., 2012). In the absence of a picture of the brain prior to drug use, it is hard to rely on a picture of the addicted brain if one wishes to distinguish aspects that triggered the drug use from aspects that reflect drug effects. Moreover, from a treatment perspective, uncertainty regarding the degree to which a given process or mechanism is likely premorbid or acquired in an individual patient makes it a challenge to set appropriate treatment targets.

As noted earlier, SUDs rarely appear in isolation and almost always co-occur in the context of externalizing (i.e., disruptive-disinhibitory) and/ or internalizing (i.e., anxious-depressive) attributes. To a considerable extent, the externalizing and internalizing factors are behaviorally and likely neurobiologically distinct, with the former corresponding to the reward cue system and the latter to the fear processing system which includes, among other regions, the amygdala, nucleus accumbens, and the hippocampus/parahippocampus (Li et al., 2013; Servaas et al., 2013). This last brain structure develops much earlier and faster than do those underlying higher cognitive functions, and it governs primitive fight-or-flight responses to actual or perceived threat.

Inefficient functioning at any point in the fear circuit can result in overresponsivity to events and an exaggerated secretion of stress hormones, which further deteriorates the functioning of this network. These disorders have been repeatedly correlated by evidence with exaggerated amygdalar activation associated with stimuli signaling threat. In a large study of adult female twins, where personality traits were related to drinking motives and symptoms of an AUD, a genetic relationship was found with coping (i.e., stress dampening) motives and AUDs symptoms (Littlefield et al., 2011). Conversely, in at-risk individuals whose response to drugs is mediated by the cue for reward system, at the core of their liability seems to reside a fundamental problem of impulse control. This problem can be analogized to stuck gas pedals and broken brakes, the latter being the prefrontal cortex and the former the limbic system. With the limbic system hyper- and the prefrontal cortex hypoactivated, the result is an impulsive response (Zucker et al., 2011). Generally, most brain imaging studies have found marked neural functional and anatomical aberration within the frontostriatal circuits in addicted individuals, which makes sense given that these circuits subserve the core clinical feature of many cases of SUDs: that is, the impulsive and compulsive seeking of the drug. These individuals tend to use and abuse psychostimulant drugs, including alcohol. Thus, understanding what leads an individual to express these differential traits and how they determine differential risk profiles associated with SUDs should have great explanatory power.

## Genetics

SUDs are at least moderately heritable. Since the 1980s, a number of adoption and twin studies have examined SUDs and found heritability estimates between 40% and 70% across the various drugs of abuse (Kendler et al., 2011; for a comprehensive review of the research on genetics of SU, see Lopez-Leon et al., 2021). Some studies (Korhonen et al., 2012; Stroud et al., 2009) have shown these heritability estimates to vary as a function of sex, while others have failed to find any sex differences (e.g., Baker et al., 2011). A study following more than 1,000 adolescent males and females aged 17-24 found that, while genetic effects became more relevant and important over time in men, environmental effects assumed more importance over time in women (Hicks et al., 2007). Given the well-established (but shrinking) sex differences in alcohol use, but the lack of evidence supporting the presence of sex differences in heritability of alcohol use, it has recently been suggested that researchers explore sex-specific gene-environment interactions (Salvatore et al., 2017). Furthermore, adolescence onset and adulthood onset of addictions have been associated with differential developmental etiologic underpinnings, with the former showing substantial evidence for shared environmental effects and little for genetic effects, and the opposite regarding adulthood-onset addiction (van Beek et al., 2012).

While many studies have focused on substancespecific heritability, polysubstance use appears to be the norm rather than the exception (Glantz & Leshner, 2000). Researchers have long hypothesized that a general liability of SU exists, with Young and colleagues (2006) suggesting that either AUD and DUD are different manifestations of a single underlying vulnerability or that the two are separate but highly correlated. Kendler and colleagues (2007) made similar conclusions, with two highly correlated genetic factors (one for legal and one for illegal substances). More recently, a large Norwegian twin study found heritability both common (acrosssubstance) and unique (substance-specific) heritability for substance use (Waaktaar et al., 2018). Moreover, at least with respect to alcohol dependence, there is evidence for multiple, heritable factors related to different forms of symptomatology (e.g., high consumption/tolerance, loss-of-control and preoccupation, and withdrawal/continued use despite problems). The overall picture to emerge from these studies is that there are multiple genetic factors contributing to SU and SUDs with some of these representing common liabilities and others that are substance-specific.

# CANDIDATE GENE STUDIES

The heritability estimates of addictions are analogous to those for the majority of illnesses widely prevalent in Western societies (Bienvenu et al., 2011). This high prevalence and heritability spurred a significant interest in identifying specific genetic variations that predispose one to SUDs. Two paradigms have been prominent: gene association studies, which investigate the allelic variation in specific genes believed to confer risk, and genome-wide association studies (GWAS), which investigate up to a million genetic variations across the entire genome for associations with the risk for drug addiction.

The currently best available specific genetic evidence of SUD risk involves cigarette addiction and implicates polymorphisms in the nicotinic acetylcholine receptors (Chang et al., 2009; Chen et al., 2009). These have been robustly associated with the number of cigarettes consumed daily (Lips et al., 2010) and with serum cotinine concentration (a long-lasting metabolite of nicotine; Munafo et al., 2012), which more objectively measures how much nicotine one inhales. Furthermore, individuals bearing a particular minor allele show a significantly decreased puff volume in response to smoking cigarettes (MacQueen et al., 2014). Notably, these previously mentioned genetic polymorphisms have also been linked to lung cancer (Hung et al., 2008) and respiratory health phenotypes, associations which appear to be mediated by the quantity of cigarettes one consumes (Saccone et al., 2010) and amount of smoke inhaled (MacQueen et al., 2014). This is a rather powerful example of an "outside-the-skin" genetic pathway for a cancer liability gene; the risk allele in a nicotinic receptor increases the propensity to more frequently purchase and smoke cigarettes, thereby augmenting lung cancer susceptibility (Kendler, Chen et al., 2012).

In line with research suggesting that initial low sensitivity to alcohol (i.e., low level of response to a given dose of alcohol) is a predictor of risk for AUD (Quinn & Fromme, 2011; Ray et al., 2016), there is genetic research pointing to some genes that might transmit this risk. The strongest evidence of genes affecting the sensitivity to alcohol have been variants that encode for activity of alcohol dehydrogenase and aldehyde dehydrogenase 2. These variations protect against the progression to alcoholism by contributing to an aversive response to ethanol. As such, the presence of certain genetic variance can indicate decreased vulnerability to the development of the problem. Many East Asians, but very few Caucasians, have this polymorphism, which affects a liver enzyme that protects sixfold against the disorder. Individuals with this genetic variant have high levels of acetaldehyde build up in the blood, resulting in aversive sensations and a visible flush. Variants of other aldehyde genes are actually thought to enhance risk of alcohol problems in individuals of European descent.

There was initially much excitement about the role of many various candidate genes associated with neuropharmacological systems related to basic motivational and reinforcement processes in the brain. This included genes related to catecholaminergic function (especially dopaminergic functioning), gamma-aminobutyric acid (GABA)-ergic functioning, serotoninergic functioning, and cannabinoid and opioid systems. For example, candidate gene studies have also identified specific genes related to general SU, with several being identified as increasing risk for two or more SU disorders, and the SLC6A4 gene being found to double an individual's odds of having an SUD (Lopez-Leon et al., 2021). However, despite a number of highprofile initial findings, frequent failures to replicate and achieve statistical significance in GWAS studies have caused the robustness of these findings to be questioned. With continued failures to replicate candidate gene findings and mounting research elucidating how small the effect sizes of individual genes truly are, it has become widely believed that a very large proportion (possibly most) of candidate gene hypotheses for psychiatric disorders were incorrect (Duncan, Ostacher et al., 2019). Furthermore, it is commonly accepted that GWAS studies and the use of polygenic risk scores (PRS) have effectively rendered traditional candidate gene studies obsolete (Duncan, Shen et al., 2019) although there may be some situations where they are useful to study specify mechanistic hypotheses as part of more focused investigations.

#### POLYGENIC RISK SCORES

Put simply, a PRS is computed to represent a person's overall genetic liability for a given trait, typically by calculating the weighted sum of their trait-associated alleles. Research using PRS for human traits has proliferated rapidly in the past decade, and polygenic risk is now being heavily researched in a wide variety of areas (Duncan, Shen et al., 2019), with SU and SUDs being no exception. As noted above, despite the high heritability of SU, the increase in SU risk associated with any individual gene is miniscule. Rather, it appears that SU and addiction heritability arises via small contributions from hundreds or even thousands of genetic variants. As such, GWAS studies and PRS have been primary avenues for further exploring the how of genetic risk for SU and addiction.

Studies using PRS have been conducted for many different substances. There is a considerable body of GWAS studies examining tobacco use and nicotine dependence. One study considered 1.2 million subjects and identified many significant risk loci; however, these mainly pertained to quantity and frequency of tobacco use rather than nicotine dependence (Liu et al., 2019). Largescale GWAS findings on alcohol use have had similar issues with finding risk loci for AUD, wherein the risk loci of quantity and frequency of drinking is not necessarily the same as the risk loci of AUD. As noted above, the diagnostic operationalization of AUD (and other SUDs) creates remarkable phenotypic heterogeneity, which reduces the power for GWAS studies to detect genetic effects. However, the increasingly large-scale GWAS studies being conducted continue to identify more risk loci. Recently, the largest AUD GWAS study ever conducted roughly tripled the number of risk loci identified for problematic alcohol use (Zhou, Sealock et al., 2020). While these PRS approaches (and GWAS approaches more generally) overcome some of the "missing heritability problem" (i.e., the large discrepancy between heritability estimates based on biometric models of twin data and the heritability estimates based on the additive effects of candidate genes; e.g., Génin, 2020; Manolio et al. 2009), the implicit heterogeneity of this approach (i.e., the collapsing of many different genetic variants into a single score) may be less well suited to studying specific genetic mechanisms.

In 2020, Zhou, Rentsch, and colleagues conducted the largest GWAS study to date on opioids and identified a significant association between an *OPRM1* variant and opioid use disorder (OUD). Other studies have identified possible variants associated with OUD risk, but replications will be necessary (Gelernter & Polimanti, 2021). A similar situation exists for stimulant dependence, with very few well-powered GWAS studies and only a single risk variant, *FAM53B*, currently identified as being associated with cocaine dependence (Gelernter et al., 2014).

## GENE-ENVIRONMENT INTERACTIONS

Further complicating these matters are the many possible interactions among variables (i.e., genes with environment) and with development (i.e., age of the individual), not to mention interactions among various genes and interactions among various environmental variables. A longitudinal large-scale Swedish twin study (Baker et al., 2011) suggested a shared vulnerability factor that mediated the association between the use of cigarettes, alcohol, and illicit substances at ages 13-14, 16-17, and 19-20. The effects of shared genetic and environmental factors were strikingly continuous, and while the genetic effects assumed more relevance and specificity with age, shared environmental factors became less important. Parental monitoring, for example, is tremendously important when children first embark into adolescence, at which stage drug use and experimentation often begins, yet genetic effects become increasingly important into young adulthood, where patterns of heavy use are often developed (Palmer et al., 2013)

Along with changes throughout development, there is also evidence that environmental circumstances (e.g., urbanicity, living in communities with greater migration, more interaction with older adolescents/young adults) can moderate genetic effects on alcohol use (Prom-Wormley et al., 2017). Twin studies have found that low parental monitoring increases genetic risk for smoking, while another variant was identified as having reduced expression in the presence of high parental monitoring and nonsmoking peers (Kaprio, 2009). Research found that genetic risk for smoking was also increased by traumatic life events and decreased by high social cohesion within one's community (Meyers et al., 2013). The role of trauma interacting with vulnerability genes has also been demonstrated with cannabis (Meyers et al., 2013). As with GWAS studies, gene-environment interactions for illicit drug use have received relatively less attention than their licit counterparts and will be an important avenue for future research.

Finally, even when genes are implicated, we remain a good distance from knowing what is

inherited and, most important, just what vulnerability is and how it is affected. For example, regarding alcoholism, Gordis (1996, p. 199) has listed some possibilities of what it is that is inherited: "differences in temperament, different initial sensitivity to the rewarding or aversive qualities of . . . [the substance], different rates and routes of [drug] metabolism, different taste preferences, different signaling from peripheral sites to the brain after . . . [consuming the substance] and different abilities to relate memories of . . . [drug] experiences to their consequences." Linking underlying genetic and nongenetic factors to underlying mechanisms remains one of the highest priorities of etiological research in this area.

## Biochemistry and Neuropharmacology

The neuropharmacology of drug effects represents key mechanisms for understanding both etiology and rational pharmacological treatment. The neuropharmacological systems most implicated in SUD etiology and maintenance involve the dopamine (DA), serotonin (5-HT), GABA, glutamate, endogenous opioid, and cannabinoid and nicotine systems. While these systems are responsible for a variety of different functions including (but not limited to) motivation, reward, reward prediction, energy, mood, sleep, and pain, they are of particular relevance to SU due to being the systems affected by commonly misused psychoactive drugs. Although discussed separately in what follows, these systems are intricately intertwined, continually acting and interacting with each other in facilitating and inhibitory fashions.

### THE DOPAMINERGIC SYSTEM

DA has a wide variety of physiological and psychological functions including reward, emotion, cognition, memory, and motor activity. Regarding SU, the importance of the DA system primarily stems from its association with motivation and activation of reward, but the system's function is much broader. The system is thought to signal the incentive salience of stimuli, be they rewarding, aversive, novel, or unexpected (Goodman, 2008; Pruessner et al., 2010).

DA has been hypothesized to be a critical neurotransmitter associated with addiction as virtually all drugs of abuse have been found to increase DA transmission in the limbic regions of the brain (Pierce & Kumaresan, 2006). A mainstream position holds that the dopaminergic projections from the ventral tegmental area (VTA) and the nucleus

accumbens (NAc) are required for most drugs to be reinforcing. For example, the rate of selfstimulation depends on the density of DA neurons (Jacobs et al., 2012). Studies of knockout mice in which genes expressing DA receptors have been disrupted have found reductions in the rewarding properties of ethanol and morphine (Sibley et al., 2017). Furthermore, prolonged elevation of mesolimbic DA results in sensitization to a given drug, meaning that the drug will produce an enhanced DA response in the future. This sensitization of the motivational salience of a drug has been hypothesized to be a major contributing factor in addiction, specifically the presence of a persistent motivational "wanting" even in absence of the "liking" typically associated with the DA system (Robinson et al., 2018).

Although all classes of substances appear to affect the dopaminergic system, each of them appears to do so through distinct biochemical mechanisms (Badiani et al., 2018). Recent research has found significantly less overlap in neuronal activations produced by separate injections of cocaine and heroin than two equally spaced injections of cocaine, indicating that the two drugs were activating different neuronal populations (Vassilev et al., 2020) As such, it is important not to assume that all drugs that act on a given neurotransmitter system work in the same way or that each "addicted brain" will have similar neuroadaptations. There is also research suggesting that not all classes of substances depend on the DA system to induce a reinforcing effect. Animal studies have shown that disrupting the NAc minimally affects seeking and/or consuming morphine (Sellings & Clarke, 2003), or heroin unless the animal has a preexisting heroin addiction (Nader et al., 1994).

In a process called *sensitization*, wherein the response to a stimulus is enhanced following repeated exposure to it, one drug may make another similar drug more reinforcing, a phenomenon termed cross-sensitization (Robinson et al., 2018). This also helps explain the high cooccurrence between certain forms of drug use as well as between SUDs and externalizing traits and disorders. For example, nearly half of individuals with an AUD have also had a lifetime SUD, and up to 30% of cigarette smokers met criteria for DSM-IV alcohol dependence (Castillo-Carniglia et al., 2019). Likewise, research has found a history of AUD in 77% of individuals diagnosed with antisocial personality disorder (Castillo-Carniglia et al., 2019).

### THE GABA AND GLUTAMATE SYSTEMS

GABA is the key inhibitory neurotransmitter in the CNS and the GABAergic neurons distributed throughout the brain (Ngo & Vo, 2019). Because of its high functional relevance, genes that play some role in modulating GABAergic signaling have become exceedingly popular in the study of addictions (Schuckit, 2018). Benzodiazepines, barbiturates, and alcohol are known to directly affect the GABAergic system (Costardi et al., 2015), with the extrasynaptic GABA-A receptors in the NAc being key neural substrates for the negatively reinforcing effects of alcohol (Cui et al., 2012).

Naturally occurring anxiolytic substances within the brain (Sangameswaran et al., 1986) and naturally occurring substances that heighten anxiety (Bodnoff et al., 1989) affect GABA transmission through their effects on structures of the antireward system like the amygdala (Savage et al., 2018). Thus, individuals affected by anxiety for whatever reason should find the use of alcohol, benzodiazepines, and barbiturates particularly reinforcing and such is seemingly the case; individuals who suffer from anxiety disorders and anxiety sensitivity show high comorbidity rates or risk for specific forms of SUDs. However, the GABA system is not wholly responsible for addiction to these substances, which may explain why pharmacological treatments for alcoholism that target GABA receptors have not received consistent support for their general effectiveness in treating withdrawal symptoms (Addolorato et al., 2012). One drug that has received considerable interest is acamprosate, which stimulates and attenuates the transmission of GABA and glutamate, respectively. Meta-analyses have found support for the efficacy of acamprosate (e.g., Cheng et al., 2020; Maisel et al., 2013), and current research focusing on precision medicine (finding which drug works best for which patients) is being conducted to identify specific indications for acamprosate and other AUD medications (Mann et al., 2018).

To explain withdrawal symptoms and druginduced changes in brain functioning, researchers also have examined glutamate, a membrane protein that is an excitatory amino acid and a primary neurotransmitter dealing with excitatory neurotransmission. There are a number of glutamate receptors, and they are widespread throughout the CNS; one glutamate receptor that may have specific relevance to the effects of alcohol and other drugs is N-methyl-D-aspartate (NMDA). It appears that alcohol has three effects on glutamatergic transmission, which occur through the NMDA receptor: interfering with excitatory neurotransmission, promoting excitotoxicity, and impairing neurodevelopment (as in FASD). Chronic ingestion of alcohol by experimental animals results in an increase in NMDA receptors in both limbic and cortical brain areas. This effect is transient, and during withdrawal these receptors actually increase and glutamate functioning in general is accelerated (Chandler et al., 2006). To a certain degree this specific action of alcohol on the NMDA receptor explains both the symptoms of drug withdrawal and the development of brain damage, which is a common concomitant of heavy alcohol consumption.

#### THE SEROTONERGIC SYSTEM

The neurotransmitter 5-HT is a critical regulator of human physiology and a wide spectrum of cognitive, affective, and sensory aspects of one's behavioral responses to environmental stimuli. With at least 16 receptor subtypes, this system also modulates circadian rhythms, food and water intake, sexual behavior, and response to pain (Sibley et al., 2017). Structural and/or functional aberrations in this system appear to generate disinhibited behaviors in addition to exaggerated sensitivity to stress as a result of perceived or actual threat, likely via disturbing one's learning of fear associations (Hartley et al., 2012). Indeed, disinhibition is a cardinal risk factor for many SUDs (Joyner et al., 2019), and a hypersensitivity to stress and threat is at the core of vulnerability for affective disorders.

Almost all commonly abused drugs acutely increase 5-HT activity throughout the brain. Following chronic SU, 5-HT tissue levels, basal extracellular activity, and the sensitivity of the serotonergic system is significantly altered. Given the role of 5-HT in sensory processing, learning, and memory, these acute increases and chronic alterations may be involved in the development of drug use behaviors and addiction (Müller & Homberg, 2015). While the serotonergic system also contributes to addiction indirectly through its influences on the DA and glutamatergic systems, there is evidence that the serotonergic system also makes distinct contributions to the development of drug intake behavior (Müller & Homberg, 2015).

Drugs of abuse also affect 5-HT systems in various ways. Some hallucinogens, lysergic acid diethylamide (LSD), dimethyltryptamine (DMT), psilocybin, and the phenethylamines (mescaline, MDMA) have an affinity for 5-HT<sub>2</sub> receptors (Titeler et al., 1988), and blocking the latter abolishes the effects of these drugs. Conversely, acute use of cocaine blocks 5-HT reuptake in the short term, while chronic use likely attenuates serotonergic signaling. MDMA has been repeatedly shown to increase extracellular 5-HT activity in a large number of brain regions including the NAc, striatum, and VTA. Although drugs have considerably different effects on the serotonergic system, the general trend is an acute increase in 5-HT during drug use and an overall reduction in 5-HT after prolonged use (Müller & Homberg, 2015).

### ENDOGENOUS OPIOID SYSTEM

The opioid system regulates the extracellular drug-induced DA release. For example, individuals addicted to cocaine show remarkable elevations in mu-opioid receptor availability, likely mirroring attenuated secretion of endogenous opioids (Goodman, 2008). The ingestion of opiate drugs results in direct stimulation of opioid receptors in the brain. The consumption of any other substance of abuse, palatable or sweet food, and engaging in gambling or sexual behavior are all correlated with the secretion of endogenous opioids (Emery & Akil, 2020). This system is widespread throughout the body, with at least three types of receptors and three groups of known transmitters. Opioid receptors in the NAc appear to affect this system through the neurotransmitter DA. Stimulation appears reinforcing, as animals will self-administer opioids.

The endogenous opioid system is involved in the rewarding properties of heroin and other commonly abused narcotics. Long-acting drugs aimed at occupying opioid receptors (e.g., methadone, buprenorphine) are effective in attenuating some aspects of craving. Drugs that block these receptors, such as naltrexone, naloxone (commonly known as Narcan), and nalmefene, diminish heroin-induced positive psychoactive effects in detoxed individuals and can be administered to rapidly reverse symptoms of heroin overdose (Robinson & Wermeling, 2014).

Naltrexone is a nonselective opiate antagonist that at least partially acts on the midbrain by inhibiting the mu-opioid receptors, thereby decreasing alcohol-induced DA secretion in the NAc (Goodman, 2008). Approved to treat alcoholism in 1995, the support for effectiveness of this drug has been mixed, with emerging evidence indicating sex differences in effectiveness (Canidate et al., 2017). Clinical studies have shown that naltrexone diminishes the high from alcohol and reduces craving (Boutrel, 2008). To the extent that this notion is correct, it is reasonable to conclude that naltrexone should (assuming compliance) be selectively therapeutic with this particular at-risk population.

### CANNABINOID AND NICOTINE SYSTEMS

Cannabinoid receptors are distributed throughout the brain but are particularly prominent in the cerebellum, prefrontal cortex, hippocampus, and basal ganglia (Glass et al., 1997). Endocannabinoids are involved in a negative feedback loop in which they bind to presynaptic neurons and dampen their activity. Because they exist throughout the brain, the specific function of a given signal is highly dependent on which neural circuits are involved. Research has indicated that cannabinoids have pleiotropic signaling functions that can help restore homeostasis after neurological disruption; this has raised considerable interest in the development of therapeutic interventions based on the endocannabinoid system (Cristino et al., 2020). There is also evidence that the endocannabinoid system is involved in the rewarding effects of many commonly abused substances, and it has been implicated in the process of addiction (Maldonado et al., 2006). Rats exposed to THC in early life have blunted dopaminergic responses to naturally rewarding stimuli later in life (Bloomfield et al., 2016).

Nicotine has been, and still is, commonly thought to be the psychoactive substance that renders cigarettes addictive (Prochaska & Benowitz, 2019). Sorge and Clarke (2011) and others have suggested that rats, if left in full control, selfadminister doses of nicotine that are much lower than expected and do so at a slower rate. Along with other ingredients, nonchemical factors (e.g., sensory effects, habit, social aspects) have been found to significantly contribute to cigarette addiction (Rose, 2006). Furthermore, there is a growing body of evidence that the cognitive enhancement (improved attention, focus, working memory) produced by nicotine may also significantly contribute to tobacco use, especially in individuals with cognitive deficits (Valentine & Sofuoglu, 2018).

The effects of nicotine can be complex and unpredictable due to the combination of neural stimulation and desensitization that nicotine can produce (Hibbs & Zambon, 2017). The mesolimbic reward system is activated, and the DA, endogenous opioid, and glucocorticoid systems are affected, among others. These reinforcing effects

317

produced by nicotine are strong enough to support reward-based conditioning (Winters et al., 2012), and tolerance and withdrawal develop.

Nicotine is highly addictive, with more than 90% of smokers making attempts to quit; while about half do eventually achieve abstinence, less than 4% of yearly quit attempts are sustained long term (Prochaska & Benowitz, 2019). This observation, however, should not be construed as suggesting that inhaled nicotine products instigate greater levels of physiological dependence than do other substances of abuse. There appears to be a variety of risk factors that predispose smokers to becoming addicted, including age of first cigarette, other SU, other psychiatric disorders, and genetic vulnerability. Additionally, in recent decades social constraints have reduced the prevalence of smoking and have led to a shift from dependence to intermittent use among those who do smoke (American Lung Association, 2020, https://www.lung.org/research/trends-in-lungdisease/tobacco-trends-brief/overall-tobacco-tre nds). Such intermittent smokers may still exhibit significant dependence symptomatology, especially if they were once daily smokers (Shiffman et al., 2012).

# Conclusion

DSM-5 diagnoses were designed to maximize diagnostic agreement, and they rely on behavioral definitions, greatly reducing their explanatory relevance with respect to understanding the nature of the underlying condition. As discussed in this chapter, understanding SUDs requires a multidisciplinary perspective that spans multiple levels of analysis; from the cultural to psychological to genetic to neuropharmacological. Marrying the multiple levels of analysis to produce a cohesive and coherent conceptual framework is clearly a major challenge, but one worth taking on.

In recent years, the value of adopting a more etiological, mechanistic framework for psychopathology has been embraced by initiatives like the Research Domains Criteria (RDoC; Insel et al., 2010). Although RDoC was not initially oriented to SU and SUDs, efforts have recently been launched to fill this hole. These include the Alcohol Addiction RDoC (AARDoC; Litten et al., 2015), the related Addiction Neuroclinical Assessment (ANA; Kwako et al., 2016), and the NIDA Phenotyping Assessment Battery (PhAB; e.g, Keyser-Marcus et al., 2021). Related to these efforts is the Etiologic, Theory-Based, Ontogenetic Hierarchical (ETOH) Framework of AUD (Boness et al., in 2021). As illustrated in Figure 13.1, this framework was derived from Boness et al.'s "systematic review of reviews" of models of addiction. Borrowing from RDoC and HiTOP, the ETOH framework is structured around higher-order superdomains (reward, cognitive control, negative emotionality), which in turn encompass narrower domains and subdomains and would appear to provide a more comprehensive set of constructs than ANA/AARDoC, PhAB, RDoC, and HiTOP (see table 3 in Boness et al., 2021).

Note that the superdomains and subdomains are all somewhat transdiagnostic in the sense that these same constructs are relevant to other forms of psychopathology (and, by extension, comorbidity of other forms of psychopathology with SUDs). However, the manifestation of certain subdomains or components is likely to be highly specific to a given substance (e.g., specific positive and negative expectancies, incentive salience, and habit). In addition, some components such as trait negative and positive emotionality are viewed as premorbid characteristics, whereas other components (e.g., incentive salience, withdrawal) are viewed as consequential, and still others are a mix of both. The value in this and other similar frameworks is that they provide a conceptual structure for seemingly disparate concepts and hold the potential for developing personalized interventions targeting those components likely to be important in a given person.

While such frameworks would appear to hold great promise for both guiding basic and applied research on SUDs and for developing personalized interventions, their clinical utility has yet to be adequately tested. This is not a trivial issue as the challenges of validly assessing these constructs in a way that does justice to them and is psychometrically sound, coupled with pragmatic concerns about their norming and interpretation, are considerable. Additionally, as alluded to earlier, such implicitly endophenotypic approaches need to be carefully considered in the context of cultural and societal differences regarding how substances are controlled (both formally and informally) and viewed more generally. The integration of these endophenotypic perspectives with environment, broadly conceived, represents an important priority for future research.

CHAPTER 14

# Schizophrenia: Presentation, Affect and Cognition, Pathophysiology and Etiology

Angus MacDonald III and Caroline Demro

For Susan, a young graduate student, undergoing a psychotic break was "like turning on a faucet to a torrent of details" (Weiner, 2003). Strange questions arose, like what lay beneath superficial appearances? What did that person intend by saying "Hello"? What was the secret meaning of the ad on that passing bus, or even the significance of a falling leaf? According to Susan, the world had become suffused with new meanings like light, in this case an overwhelming, sinister, and saturating light. She no longer attended classes or met with friends. She changed her name, broke off contacts with her family, gave away her things, and disguised her identity. After 6 months-terrified, alone, and exhausted-she gave up her efforts to resist what she now understood as a US Central Intelligence Agency plot. She began a sequence of ever-more harrowing suicide attempts that eventually brought her to the attention of police and then psychiatrists. For Susan and her family, this would become a lifelong struggle with schizophrenia, one of the most disruptive and distressing illnesses of any kind.

Unfortunately, Susan's story is not rare. Still, it is important to bear in mind that people with schizophrenia have many different symptoms. What they have in common is lives interrupted, and often hopes, dreams, and plans irrevocably changed. This chapter will discuss the affective and cognitive impairments, pathophysiology, and etiology of schizophrenia. Chapter 15 of this volume further addresses the social aspects of this disorder including psychosocial treatments, whereas Chapter 16 of this volume discusses other conditions along the schizophrenia spectrum. First, we will unpack the symptoms of the disorder and its prevalence.

### Nosology

Schizophrenia is a syndrome that involves a collection of symptoms that appear unrelated but cooccur in many patients. In *DSM-5*, the diagnosis of schizophrenia requires two or more of the following symptoms: delusions (believing something that most people don't and despite evidence to the contrary), hallucinations (perceiving something that is not present), disorganized speech, disorganized or catatonic behavior, or negative symptoms (lacking normal emotional responses to events, reduced levels of motivation, or a disrupted flow of speech). To increase the consistency of course and outcome for people diagnosed with the disorder, the criteria also include a minimum duration and rule-outs for other conditions.

These criteria are not without controversy. In authoring the *DSM-5* criteria there was discussion about including cognitive impairment as a criterion for schizophrenia (Keefe & Fenton, 2007), which was ultimately set aside because it is not specific to this disorder. There were questions about using or

Abbreviations	
COMT	Catechol-methyltransferase
GABA	Gamma-aminobutyric acid
GADI	Glutamic acid decarboxylase I
MRI	Magnetic resonance imaging
NMDA	N-methyl-d-aspartate (receptors)
PCP	Phencyclidine
PD	Personality disorder

investigating the use of a more dimensional organization scheme for what have been classified as different psychotic disorders thought to exist along a spectrum (for review, see Krueger & MacDonald, 2005; Van Os & Tamminga, 2007). However, any such changes will have to wait to be incorporated at a later date, if ever (Heckers et al., 2013). Therefore, the diagnostic criteria that remain in place today largely derive from those put forward in the Research Diagnostic Criteria (Spitzer et al., 1975), a forerunner to DSM-III, which was published in 1979. The DSM-III criteria supplanted more vague descriptions of schizophrenia that existed in DSM-II and harmonized practice in the United States with psychiatric practices in Europe, which had maintained the more rigorous, descriptive traditions of German psychiatrist Emil Kraepelin (1856-1926), a man frequently recognized as the founder of modern psychiatry.

### History of the Clinical Disorder

Allusions to psychoses can be found in many cultures the world over. For example, psychotic symptoms are mentioned in classical Greek, Roman (Evans et al., 2003), and Chinese works (Nei et al., 1975). However, in these sources, there does not appear to be any conceptualization of schizophrenia as a coherent disease per se. The construct of schizophrenia that we use today derives largely from the work of Emil Kraepelin. By all accounts, Kraepelin was an active physician with training in experimental psychology and a keen appreciation for the importance of collecting data. Beginning in 1886, while practicing in Estonia, and soon afterward while leading the Psychiatry Departments at the University of Heidelberg and then Munich, he compiled detailed clinical histories with a particularly keen ear for his patients' experiences of their illness over time. These accounts led him to differentiate schizophrenia, which he called *dementia* praecox (literally premature madness), from manicdepressive insanity. This aspect of the description remains a fundamental organizing principle of the DSM-5 to this day. Even so, the validity of this

distinction—now referred to as the *Kraepelinian dichotomy*—has never been fully embraced for reasons we consider later. Kraepelin had a tremendous influence on twentieth-century psychiatry through his prolific students and through his frequently revised *Textbook on Psychiatry* (German *Lehrbuch der Psychiatrie*; see Heckers & Kendler, 2020, for an analysis of the various editions of his classifications). A pattern of psychotic symptoms over time, rather than any particular cluster of symptoms, was the hallmark of *dementia praecox*, and he believed it was progressive and largely untreatable (Kraepelin & Barclay, 1971).<sup>1</sup>

A contemporary of Kraepelin, Swiss psychiatrist Eugene Bleuler (1857–1939), coined the term schizophrenia. He argued vehemently against the Kraepelinian view of inevitable deterioration and felt the term dementia praecox misled trainees to focus on the wrong aspect of the disorder. He used the term schizophrenia to delineate a "'splitting' of the different psychic functions" of the mind (Bleuler & Zinkin, 1911/1950, p. 8). One unanticipated side effect of this new word has been a fusing, now common in public discourse, between schizophrenia and multiple personalities (or dissociative identity disorder, DID). Students of psychiatry and clinical psychology grind their teeth when they hear references to schizophrenia as a "split personality." But the confusion is illuminating if it reminds us about an essential, phenomenological aspect of schizophrenia. Consider the experience of a woman named Clara:

Despite the "usual" voices, alien thoughts and paranoia, what scared me the most was a sense that I had lost myself, a constant feeling that my self no longer belonged to me. What made such an existential orientation even more intolerable is the voices incessantly telling me that the only way to reunite with my real self is to commit suicide. So I tried. Still, nothing had happened. I was simply sectioned again, detached from my real self, observing what was being done to me in a thirdperson perspective. . . . Even though I am now stabilized on a new medication, I still cannot accept

<sup>&</sup>lt;sup>1</sup> A tragic consequence of Kreapelin's prognosis for schizophrenia would soon play itself out as eugenic doctrines became popular. In an era when gene expression was only beginning to be understood, eugenics held that population health would improve if so-called unhealthy genotypes did not reproduce. In this context, Kraepelin became an active proponent of eugenics and "mental hygiene." Interested readers are referred to Shepherd's (1995) treatment of this aspect of early psychiatry. This history plays an often unspoken role in the late adoption in America of theories of schizophrenia that emphasized the importance of genetic liability because many recoiled from this eugenic interpretation.

the diagnosis. The medication helps the observing self dominate over the suffering self, but the real "me" is not here anymore. I am disconnected, disintegrated, diminished. (Kean, 2009)

Clara's distress is clear, and this vivid description captures a splitting of the mind and that fractured sense of self that Bleuler took to be a core feature of schizophrenia. Though there are elements of dissociation here, it is not a description of separate personalities as in DID.

# **Epidemiology and Course of Illness**

Based on accepted definitions, schizophrenia occurs in all populations studied. This was the prominent conclusion of the World Health Organization (WHO)'s 10-country study of schizophrenia around the world (Jablensky et al., 1992) which was conducted in the context of the Cold War and a vocal antipsychiatry movement. Sites were chosen in developing and developed nations, East and West, and in urban and rural districts. The rate of people who fulfilled these harmonized criteria for schizophrenia over their lifetime (called *lifetime morbid risk*) was similar across sites and approximately 1%. This may be a slight overestimate, with more recent reviews estimating the median lifetime morbid risk across 27 studies to be 72% (McGrath et al., 2008). In contrast to the WHO's epidemiological study there seems to be variation across locations such that prevalence is greater in more developed economies. Also, there did not appear to be changes in these rates over time.

According to population-based epidemiological studies, the highest incidence, or first episode, of schizophrenia is age 20-24 for men and 25-29 for women (Kirkbride et al., 2006), although the first symptoms of psychosis might appear several years beforehand (Häfner et al., 1994). While men have an earlier onset and a more severe course, there is no difference between men and women in the median estimates of lifetime morbid risk for the disorder (McGrath et al., 2008). Thus, women gradually "catch up" to men with more later-onset cases. Formerly, there was some thought that, by the age of 40 or 50, people exited the risk period for schizophrenia, but more recently it has been suggested that this is an arbitrary distinction and that cases of schizophrenia in older, and even elderly, patients may occur, although these cases may have a different symptom profile (Howard et

al., 2000). While rare cases of schizophrenia and schizophrenia-like symptoms in early childhood have been reported, the earliest onset of schizophrenia cases is early puberty (Remschmidt & Theisen, 2012). Thus, while the traditional view of schizophrenia as a disorder of late adolescence and young adulthood is still accurate for most cases, our understanding must incorporate a wider risk period, including a period during which an *attenu-ated psychosis syndrome* may emerge.

The attenuated psychosis syndrome, now included in DSM-5, is characterized by symptoms that, notably, do not quite reach the threshold for psychotic intensity and duration. Syndromes are a way to systematize the symptoms and other measurable signs of an illness that often, but do not necessarily, co-occur. This syndrome is also referred to as clinical high risk or ultra high risk and is typically characterized by relatively intact insight. Outcomes vary for people who meet criteria for attenuated psychosis syndrome, making the term "prodromal" inappropriate because only approximately 36% go on to develop a full psychotic disorder within 3 years (Fusar-Poli et al., 2012). However, the syndrome is distressing and impairing in its own right and is often accompanied by comorbid mental health issues. Efforts to improve outcome prediction have led to risk calculators such as one by the North American Prodrome Longitudinal Study, which found specific symptoms (e.g., unusual thoughts, suspiciousness, lower cognitive performance), a decline in social functioning, and an earlier onset to be particularly predictive of conversion to a psychotic disorder (Cannon et al., 2016). Importantly, the course of psychotic disorders is episodic in nature, with periods of recovery and recurrence for most patients (Jobe & Harrow, 2010), though there is a good deal of variation in people's experiences with the illness over time (Tandon et al., 2009).

Given the varied course of schizophrenia and the diverse outcomes of individuals who experience an attenuated psychosis syndrome, additional epidemiological research is needed to understand risk factors for illness and prognosis. The WHO epidemiological study has been corrected with regard to risk factors that are now accepted, such as whether or not one is an immigrant (McGrath et al., 2008). We will address other risk factors, such as father's age at conception, cannabis use in adolescence, and season of birth in higher latitudes, when we examine the etiology of schizophrenia. However, it is one thing to locate where and when schizophrenia happens and quite another to locate the construct of schizophrenia amid the broader symptoms of psychopathology.

# Locating the Constructs of Schizophrenia and Psychosis

## DEFINITIONS AND RELATED CLINICAL CONSTRUCTS

A perennial discussion exists about how to think about schizophrenia. On the one hand, it is a diagnosis. As a diagnosis it is a closed construct we can use to define who has it and who does not. On the other hand, schizophrenia is just as much a syndrome as the attenuated psychosis syndrome. Unlike diagnoses, syndromes are open concepts without necessary and sufficient conditions for membership. For some, this argument over whether the construct of schizophrenia is a diagnosis or a syndrome is a silly semantic distraction that detracts from the work of solving the problem. For others this is a debate about the very nature of the disorder itself, without which the problem cannot be solved. To start, it will be useful to agree on several distinctions that might otherwise be confusing based on their use.

"Psychosis," originally from the Greek psyche (mind or soul) and -osis (an abnormality or derangement) is a broad term for describing the state of "losing touch with reality." Thus psychosis describes the current symptoms. In DSM-5, psychotic symptoms include delusions, hallucinations, and formal thought disorder consisting of disorganized thinking and speaking. Psychotic symptoms are present in many psychiatric illnesses other than schizophrenia, including bipolar disorder, dementia, drug-induced psychosis, and also a number of physiological conditions such as delirium. Because of this, the term "psychosis" tracks with a patients' state without making any assumptions about any enduring traits. For example, it is common for symptoms to ebb and flow among patients who warrant a diagnosis of schizophrenia. What fluctuates is how psychotic they are, not how schizophrenic.

The "schizophrenia spectrum" is a term first used in the late 1960s by several authors to refer to the marginal conditions of schizophrenia (Erlenmeyer-Kimling & Nicol, 1969; Kety et al., 1971). Its early use was in the context of partial penetrance of genes associated with genetic liability, and it served as shorthand for describing someone who appeared to have a genetic liability to schizophrenia; that is, someone with schizotaxia, but who had yet to fully decompensate (Meehl, 1962). The schizophrenia spectrum is now often used in a manner that is almost synonymous with a dimensional approach to psychosis-that is, a continuum of symptom expression, including a range of clinical and subclinical symptoms including odd behavior that may or may not ever manifest as a clear case. It may also refer to diagnostic entities similar to schizophrenia, including the attenuated psychosis syndromes described above as well as schizophreniform disorder, schizotypal, schizoid, paranoid and avoidant personality disorders, and, of course, schizophrenia. Following Kraepelin, authors generally do not include affective disorders, such as bipolar disorder, as part of the schizophrenia spectrum though these can be accompanied by psychotic features. Schizoaffective disorder, the construct to which we now turn, is included in the spectrum.

One thing that discussions of schizophrenia singular, plural, or in spectrum-rarely clarify is whether the fundamental Kraepelinian distinction between dementia praecox and manic-depressive insanity exists in nature. Although not the first to observe the phenomenon (Kraepelin himself was apparently aware of such cases), Kasanin (1933) receives credit, or blame, for coining the term "schizoaffective" to describe patients with features of both schizophrenia and mania or depression. Thus the very construct of schizoaffective disorder presents a grave challenge to the original dichotomy of dementia praecox and manic-depressive insanity. The construct was originally incorporated into DSM-I as a subtype, eventually gaining the status of a separate disease entity.<sup>2</sup> This disorder survives despite a lack of evidence for any differences in etiology, in pathophysiology, in cognitive or affective functioning, and only occasional differences in treatment outcome between patients with schizophrenia and schizoaffective disorder. Thus, while the schizoaffective diagnosis appears to occupy an intermediate place between schizophrenia and the

<sup>&</sup>lt;sup>2</sup> Another "intermediate" diagnosis whose origin is relevant to schizophrenia is *borderline personality disorder*. The borderline here was that between psychosis and neurosis. In current practice, borderline personality disorder is rarely conceptualized as part of the psychotic spectrum although antipsychotic medicines may be prescribed.

Figure 14.1 Psychosis symptoms illustrated as part of the Hierarchical Taxonomy of Psychopathology (HiTOP) psychosis superspectrum. PD, personality disorder.

Adapted from Kotov et al. (2020), reprinted with permission).

mood disorders based on symptoms (Laursen et al., 2009), there does not appear to be anything unique in terms of underlying features. As of now the schizoaffective construct remains in the lexicon because it has become a convenient way to describe patients with a mixed presentation.

### STATISTICAL ANALYSES AND EMPIRICAL CONSTRUCTS

In the absence of a definitive test to distinguish psychiatric conditions, clinicians and researchers group patients much like Kraepelin and Bleuler did, by their history and observable symptoms. The diagnoses then applied to those groups implies that distinct latent constructs exist. But are the distinctions between psychiatric conditions, like the distinction between schizophrenia and bipolar disorder, real? An increasing number of scientific, and particularly statistical, tools have been turned toward the question of whether schizophrenia exists in nature distinct from other entities. This work, using the kind of large databases that would make Kraepelin proud, examines the meta-structure of psychopathology. This meta-structure describes the relationships between various observed symptoms. The evidence for this, discussed in Chapter 3 of this volume, suggests that in many cases clean distinctions between clinical constructs do not really exist. This finding is largely borne out in the context of psychotic disorders as well.

As part of the statistical examinations of the relationships between symptoms, the Utility Work Group of Hierarchical Taxonomy of Psychopathology (HiTOP) derived the model for psychotic disorders illustrated in Figure 14.1 based on many studies (Kotov et al., 2020). What does it mean to specify a spectrum of thought disorder composed of reality distortions, disorganization, dissociation, and mania? It means those symptoms tend to co-occur, such that an elevation in one is somewhat predictive of elevations in others. We discuss these relationships more in the next section on Clinical Presentation. Similarly, what it means to have a spectrum of detachment is that symptoms like inexpressivity and avolition, commonly called negative symptoms, tend to co-occur. What does it mean to specify a superspectrum of psychosis? It means that thought disorder and detachment are themselves more related to each other than they are to other symptoms, like anxiety. Importantly, the symptoms themselves relate to a number of different DSM-5 diagnoses on the psychosis spectrum, as indicated by the ovals underneath the observable symptoms. Across a number of studies using a variety of modeling approaches and populations,

evidence is weak that a nosological, or symptombased, categorical distinction can be made between schizophrenia, bipolar affective disorder, and other entities on the psychosis spectrum. Instead, there appears to be a pattern of covariation in the symptoms in these disorders that suggests common elements of impaired cognitive and affective processing.

### CONCEPTUALIZING SCHIZOPHRENIA

A theme of this chapter will be that schizophrenia is neither a disease entity, nor a group of disease entities (for additional, convergent evidence, see MacDonald, 2013). For most purposes, it is useful to understand schizophrenia as an open concept. As a syndrome, schizophrenia is a collection of symptoms that may appear to be superficially unrelated but whose co-occurrence in many patients suggests a shared etiology of some kind. Open concepts frustrate precise definitions. While one can impose definitions, they remain artificial because there are no necessary or sufficient conditions for membership in a class described by an open concept. Any boundary for the class should be taken with a grain of salt. Members of an open concept have a "family resemblance," one to the next, and we recognize members of the class because they are similar to this or that exemplar.

Understanding schizophrenia as an open concept is not to deny its existence or to suggest the construct is useless or even harmful. In fact, *most concepts are open concepts*, and we build up our understanding of the concept through experience rather than through definitions. In natural language, concepts with natural boundaries are the exception rather than the rule. Thus while natural boundaries between schizophrenia and other disorders may not exist, open concepts like schizophrenia or the schizophrenia spectrum are useful for guiding the study of the causes and treatment of an illness. We can now turn to its internal structure and the challenge of understanding the differences among patients with schizophrenia.

# Clinical Presentation and Structure of Symptoms

If we have located the construct of schizophrenia as a delineated space on a schizophrenia spectrum with a certain level of symptom severity and no clear boundaries that exist in nature, there still remains a high level of heterogeneity among patients diagnosed with the illness in terms of its presenting symptoms and its prognosis. This

is another kind of challenge to the construct of schizophrenia because it suggests that there may be different kinds of schizophrenia. Indeed, as early as 1911, Bleuler and others were concerned about this level of heterogeneity and sought out meaningful subgroups of patients within the larger diagnosis (e.g., Bleuler & Zinkin, 1911/1950). Bleuler wrote of different schizophrenias, as one might discuss different cancers. These different schizophrenias, or subtypes as they came to be known, included paranoid patients, whose presentation was dominated by preoccupation with delusions or auditory hallucinations; catatonic patients, who were immobile or, in improved cases, showed flat affect and little motivation; and undifferentiated (or, in Bleuler, hebephrenic) patients, who did not fall conveniently into either of those categories but also did not have a milder form of the illness (referred to as simple schizophrenia). While subtypes of schizophrenia are still used in the popular press, they were inconsistent over time, did not appear to track familial risk, provided little guidance for differential treatment, and were retired from DSM-5.

Another way to cope with heterogeneity is to examine the important axes, or dimensions, along which patients vary, similar to the strategies used in HiTOP's work, described above. Although the use of this approach can be dated to the mid-twentieth century (Wittenborn & Holzberg, 1951), the most influential schemes that guide thinking today date from the 1980s and delineate two factors: positive and negative symptoms. Subsequent schemes have added more dimensions such as disorganization, excitement, and depression (for review, and three further dimensions, see Peralta & Cuesta, 2001).

*Positive symptoms*, situated within HiTOP's thought disorder spectrum, are so called because they can be thought of as additional capacities patients develop. These include persecutory ideation, other sorts of delusions, and hallucinations that can involve various senses although auditory hallucinations are the most common. Consider the experience of one student.

(Rats) gnawed relentlessly on my neurons, causing massive degeneration. This was particularly upsetting to me, as I depended on a sharp mind for my work in neuroscience. The rats spent significant periods of time consuming brain matter in the occipital lobe of my brain. . . . So I sought means of ridding my body of them. I bled them out through self-cutting and banging my head until the skin broke, bloody. Continually, I kept my brain active, electrocuting the rats that happened to be feasting on the activated neurons.

"As a neuroscientist, how can you believe all this?" the doctors queried.

"Because it is all of the Deep Meaning. . . . The Deep Meaning transcends scientific logic." (Stefanidis, 2006)

These are the kinds of symptoms that feature most prominently in the press and film. Ted Kaczynski, the so-called Unabomber, published a persecutory diatribe arguing that his assassinations were a reasonable response to the threat to human freedom from technology. Nobel Prize winner John Nash's delusions that he was helping hunt down communists were featured in the Hollywood film *Beautiful Mind*.

To say that positive symptoms constitute a dimension is to make at least two assertions. First, that if someone has one of these symptoms, they are at increased risk for the others, perhaps because they share a common causal factor. Second, that in the great variety of experiences patients report, there is a continuum from those with many of these symptoms and those who suffer from none of them. As in the above example, most delusions and hallucinations have a negative valence: they are frequently disturbing, they are sometimes positive (generally grandiose), and are almost never emotionally neutral. Thus, they can be quite intrusive, although many chronic patients somehow learn to adapt.

*Negative symptoms*, similar to HiTOP's detachment spectrum, are so called because they can be thought of as lost capacities. Negative symptoms include blunted affect, emotional withdrawal, motor retardation, and anhedonia, which is the inability to experience pleasure. It is ironic that positive symptoms are frequently scary, whereas this other aspect of the disorder is marked by abnormally reduced emotion. Consider this patient's report of her inability to experience pleasure:

[T]his nothingness of the self is permanently there. Not a single drug or therapy has ever helped with such nothingness. By nothingness, I mean a sense of emptiness, a painful void of existence that only I can feel. My thoughts, my emotions, and my actions, none of them belong to me anymore. This omnipotent and omnipresent emptiness has taken control of everything. I am an automaton, but nothing is working inside me. (Kean, 2009)

The motivations of wanting and fearing are fundamental to living organisms, and these seem to be strongly affected by negative symptoms. Many patients with negative symptoms also report reduced desires and aversions, but their experiences of pleasure and perhaps pain are unaffected (Gard et al., 2007), which could be what this example is describing. Of note, antipsychotic medications typically do not improve negative symptoms, as we discuss in the later section on neuropsychopharmacology.

Disorganization symptoms are the dimension of inattention and formal thought disorder and are also situated with the HiTOP thought disorder spectrum. One prominent example of this is incoherence, also known as word salad. When asked the question "Why do people comb their hair?" one patient responded, "Because it makes a twirl in life, my box is broken help me blue elephant. Isn't lettuce brave? I like electrons, hello please!" (Videbeck, 2010). While incoherence is an extreme form of disorganization, more common forms include distractible speech; when asked, "Do you have problems keeping your attention on things?" the patient responds, "I don't know. . . . What was that again?" Sometimes patients experience thought blocking, in which the patient stops in the middle of a thought and cannot finish the sentence. There are a number of problems patients experience in communicating, such as illogicality and a tendency to lose one's train of thought, known as *derailment*. This dimension also includes inappropriate affect, such as when a patient giggles while describing their suicide attempt (Peralta & Cuesta, 1999).

Two other symptoms dimensions that frequently emerge from factor analyses are excitement (sometimes called mania) and depression (Peralta & Cuesta, 2001). Obviously, these two factors are not specific to schizophrenia. Our consideration of models of personality and psychopathology described above might even suggest that these two factors are manifestations of positive and negative emotionality (or extraversion and neuroticism) and are prominent dimensions of normal personality variation (e.g., Markon, 2010; Wright et al., 2012). Also within that context of the meta-structure of psychopathology and our conclusion that schizophrenia is an open concept, one might well wonder whether the positive, negative, and disorganization dimensions are dimensions of schizophrenia or dimensions of psychosis more broadly.

Other sources of variability between patients may require clinical attention, such as cognitive impairments and suicidality. The lifetime risk of suicide among people with schizophrenia is about 6.6%, which is much higher than in the general population and is indistinguishable from the rate (about 6.7%) among people with unipolar depression, a condition for which suicidal ideation constitutes an actual symptom (Nordentoft et al., 2011). Of course the number of suicide attempts is far higher still. Importantly, the risk for suicide attempts is highest among people early in the course of their psychotic illness (Sher & Kahn, 2019).

Symptoms can be thought of as retrospective and global descriptions of patients' experiences and reactions to those experiences. One way to understand these phenomena more objectively may be to examine the cognitive and affective mechanisms that lead to the experiences that are later reported as symptoms.

### **Cognition and Affect in Schizophrenia**

Two traditions, from clinical science and experimental psychology, have been used to evaluate cognition and affect in schizophrenia, in part to understand the relationships between thought and emotion and in part to provide a link across levels of analysis between symptoms and the biological mechanisms involved in the disorder. We will start with findings from the clinical neuropsychological tradition.

# Neuropsychological Approach to Deficits in Schizophrenia

The neuropsychological approach to schizophrenia is characterized by the use of standardized behavioral tests. The goal of this approach is to compare the pattern of performance in schizophrenia patients to patterns in patients with a variety of brain injuries to determine, by analogy, the brain abnormalities that might relate to schizophrenia.

By the turn of the twenty-first century, R. Walter Heinrichs and his students had built up a large database of neuropsychological studies published on schizophrenia. They coded the studies in a manner that allowed them to calculate each task's effect size, which is the difference between the means of the patient and control groups measured in standard deviation units (Heinrichs, 2001, 2005). This work showed that across a wide range of tests, in every category of thinking they examined-including verbal memory, nonverbal memory, attention, general intelligence, spatial ability, executive functioning and language functioning-patients on average performed worse than controls. Patients performed the worst on global verbal memory (Cohen's effect size = -1.41) like the WAIS Logical Memory subtest, and they performed the least badly on tasks like the WAIS block design subtest (Cohen's effect size = -.46, Heinrichs & Zakzanis, 1998). Between these two extremes, there was little systematic sense to patients' behavioral impairments. For example, nonverbal domains other than block design-from simple motor skills, like the Grooved Pegboard test, to other measures of performance IQ-were also among the most impaired (with effect sizes of -1.30 and -1.26, respectively). The average effect size across this assortment of neuropsychological tests was -.92, meaning patients on average performed about a standard deviation below controls (Heinrichs, 2005). This deficiency was larger than in other domains studied with quantitative metrics, such as patients' impairments in neuroimaging, electrophysiology, and even the molecular biological studies Heinrichs also examined. This pattern of widespread behavioral impairments in patients with schizophrenia can be thought of as a generalized deficit (Chapman & Chapman, 1973). Despite medication, and despite improvements in measurement of more specific domains of dysfunction, this generalized deficit still remains the most prominent feature of behavior on neuropsychological tests in patients with schizophrenia.

Does the generalized deficit relate to patients' symptom expression? Dominguez and colleagues (2009) reviewed this literature by dividing neuropsychological tasks into nine domains of performance (executive control, speed of processing, verbal working memory, etc.) and comparing their relationship with positive, negative, disorganized, and depressed symptoms across 58 studies. In this light, positive and depressive symptoms showed few systematic relationships with performance across cognitive domains, whereas negative symptoms were correlated with the cognitive domains (r =-.08 to -.25) and disorganization symptoms were correlated (r = -.12 to -.29). Thus, these off-theshelf tests suggest that performance across domains, perhaps corresponding to the generalized deficit, is most closely linked to negative and disorganization symptoms, whereas they do not provide very much insight into the nature of delusions, hallucinations, and other positive symptoms. Let us then consider an alternative approach that may provide a complementary set of tools.

# Cognitive-Experimental Approach to Deficits in Schizophrenia

The pattern of finding a generalized deficit across a broad swathe of neuropsychological tests presents a challenge to behavioral researchers. Logically, the domain or domains with the largest effect sizes should provide guidance for choosing processes to be examined in detail. This examination might then isolate the brain networks and predisposing cognitive processes that underlie symptoms. However, when so many facets of behavioral performance are impaired, and suspicion falls on nearly every brain region thought to support those processes according to clinical neuropsychological lore, there is no clear path to follow.

A different approach that also emphasizes behavioral performance is called the cognitiveexperimental approach. Instead of using a broad battery of well-standardized tests to find group differences, this approach is hypothesis-driven. That is, it tests theories about mechanisms underlying the various symptoms of schizophrenia by comparing performance across closely matched conditions which are a kind of experimental manipulation. While experimental studies of schizophrenia patients have been conducted since the outset-indeed, Kraepelin trained in the laboratory of the founder of experimental psychology, Wilhelm Wundt-the modern tradition of cognitive-experimental psychopathology grows from the work of pioneers like David Shakow and Saul Mednick (1958) who applied new theories of information processing and learning, respectively, to the study of schizophrenia.

To follow one such pioneer, Shakow examined a phenomenon that came to be called reaction time crossover (Rodnick & Shakow, 1940). This meant patients responded faster to a probe following an irregular delay compared to a consistent delay. Patients' performance was therefore relatively spared following an irregular delay, the condition that is harder for controls. Shakow conceptualized reaction time crossover as a failure to maintain alertness, or maintain set over time, and found it was related to patients' level of disorganization symptoms (Rosenthal et al., 1960). As cognitive theory continued to develop, the construct of maintaining set fell out of favor and became subsumed within other psychological constructs; one such generalization was context processing. Context processing was introduced by Jonathan Cohen and colleagues to bring into a single framework the extant literatures on executive control, attention, and working memory (Cohen & Servan-Schreiber, 1992; Servan-Schreiber et al., 1996). This posited that context processing was the goal-dependent modulation of brain activity to support "nondominant" or underlearned responses. For example, patients'

performance on a modified continuous performance task was impaired on a condition that required extra context processing relative to the condition that did not. Reminiscent of Shakow, patients' impairments correlated with disorganization symptoms, although not more so than for neuropsychological tasks (see MacDonald, 2008, for further discussion).

Positive symptoms may relate to another psychological mechanism, predictive processes. A fundamental role of the mind is to predict because an organism's survival depends on understanding how its actions impact itself and the world around it (Friston, 2009). When we are conscious of these predictions, they can even be expressed as beliefs. For example, part of the brain called the ventral tegmental area activates when an unexpected reward occurs, like a frosty milkshake on a hot day. Like Pavlov's dogs (Pavlov, 1927), after predictors for the reward are learned this area fires when the predictor occurs, such as the appearance of the neon milkshake sign, before the actual reward (Schultz, 2007). This learning mechanism may be a general principle of thought and has been called the "Bayesian brain" after the eighteenth-century developer of probabilistic inference (see Corlett et al., 2020, for further discussion). A number of investigators have speculated that impairments in these fundamental inferential mechanisms, related to the salience network in the brain which evaluates rewards and threats, might lead to psychotic symptoms (Feeney et al., 2017; Kapur, 2003). Whether conscious or not, if the process of belief formation becomes untethered from events in the world, then uncomfortable and uncanny feelings are inevitable. People seek explanations or interpretations for those feelings. When they do, they will be seen as delusional if they cannot be convinced by alternative explanations. There is growing evidence that such processes are involved in positive symptoms, although this mechanism may not account for all such symptoms (Donaldson et al., 2020).

Negative symptoms may relate to a distinct but related aspect of learning, *insensitivity to rewards*. As with predictive processing, there is a literature stretching back decades that examines processes of valuation, motivation, and emotional expressiveness. The notion that these mechanisms relate to negative symptoms has a great deal of appeal, although it has been noted that these impairments are not particularly specific to schizophrenia (Strauss & Cohen, 2017). Gold and colleagues (2008) examined the extent to which measures of these processes related to symptom ratings. In one task, participants pressed a button quickly to indicate whether or not to see the current picture again later in the experiment. Controls pressed more to see pleasant and avoid unpleasant pictures, but not neutral pictures. Similarly, controls were willing to wait longer for larger rewards.

A common problem here, as with other symptoms domains examined using the cognitiveexperimental approach, is their moderate correlation with symptoms among patients. For example, Gold and colleagues (2008) report that performance on their motivation and valuation tasks was occasionally correlated with symptom ratings at a moderate level but was more commonly quite a bit lower and therefore indistinguishable from correlations with general neuropsychological tasks. Therefore, it is important to note that other cognitive-experimental approaches are continuing to develop, and these theories are naturally broadening to incorporate the methods and theories of cognitive neuroscience, which we will address subsequently. In many respects, the cognitive-experimental approach to the behavioral level of analysis is the natural domain for demonstrating the relationship between the psychological mechanisms underlying momentto-moment experiences and the global, frequently retrospective reports of symptoms. The approach incorporates and modifies tools to examine specific hypotheses as opposed to using well-standardized testing batteries. This flexibility presents a challenge because many paradigms will not perform in the manner expected, and even here it can be difficult to distinguish between specific deficits in a hypothesized mechanism and the generalized deficit (see Chapman & Chapman, 1973). Despite these challenges, one measure of the success of the experimental cognitive approach is that it has become an integral component of cognitive neuroscientific studies that use such tasks to challenge specific brain regions and networks during imaging. As such, we now turn our attention to the important findings from this level of analysis.

# Cognitive Neuroscience and Systems Neuroscience of Schizophrenia

A widely accepted view is that schizophrenia is a disease of the brain. However, since all mental disorders involve neuronal functions, this is not a particularly helpful revelation. Furthermore, it is not yet clear what kind of brain disease it might be. There is no single insult to the brain or any single structure or neurotransmitter that is uniquely responsible. Therefore, one challenge is to link the symptoms of schizophrenia and the problems in cognition and affect to particular facets of brain functioning.

It would be helpful to know that a handful of regions show slowed responses, relative decreases or increases in activation, or weaker connectivity in schizophrenia. Unfortunately, and despite a great deal of effort, this kind of pithy conclusion is not yet possible from the fragmented literature arising from the various methods used to study the neural processes in people with schizophrenia.

# Electroencephalography

Scalp electrodes can reveal a number of different aspects of the timing of brain functions. One method, called electroencephalography (EEG), focuses on the frequencies of different brain waves. Findings based on this technique have indicated that schizophrenia involves a reduction of the power of brain waves across a broad spectrum, but impairments in the gamma spectrum (which has a frequency of electrical brainwaves in the 30-80 Hz range) may be particularly telling (Gandal et al., 2012). This frequency is responsible for cognitive coordination (Phillips & Silverstein, 2003) and for binding thoughts from different parts of the brain together into a coherent percept (Gonzalez-Burgos & Lewis, 2008). Another way of using scalp electrodes is to examine event-related potentials, which speak to the timing of brain responses to stimuli. Unsurprisingly, this technique has shown that many waveforms have a reduced magnitude in patients. The stand-outs in this crowd, either due to popularity of study or ease of reliable measurement, are reductions in the P1, MMN, and P300 wave forms (for review, see Ford et al., 2012): the P1 is a very early component associated with the perception of a stimulus; the MMN, which stand for mismatch negativity, is an early waveform interpreted as showing an impairment in the early, nonvolitional capacity to redirect attention; the P300 is a component interpreted as indicating a capacity for attentional orientation. Thus there is ample evidence that schizophrenia affects the timing of a number of important processes in the brain, some of which dovetails with evidence of early perceptual impairments and some of which suggests top-down failures of cognitive control processes.

# Structure and Connectivity

If there are timing dysfunctions in the brain, what brain *regions* are most affected? Magnetic resonance imaging (MRI) has been the tool of choice for addressing this kind of question in recent years

341

because MRI machines can be tuned to examine several aspects of brain anatomy: structure and structural connectivity and function and functional connectivity. Beginning with structure, a highly replicated and completely unspecific finding is that patients have reductions in intracranial, wholebrain, and total gray and white matter volumes and increases in ventricular volumes (De Peri et al., 2012). Early efforts to show more specific abnormalities showed a consistent loss of gray matter in the superior temporal lobes, a region implicated in auditory sensory processing (Shenton et al., 2001). Inevitably, methods have evolved and there are now several quantitative reviews of the literature using whole-brain, voxel-by-voxel analyses, called voxelbased morphometry (Chan et al., 2011; Ellison-Wright et al., 2008). These reviews, reporting on two to three dozen studies, have found consistent reductions in gray matter in thalamus and limbic regions such as insula, anterior cingulate, uncus, and amygdala. While thalamus is an essential cortico-cortico relay network, these limbic regions are thought to work together in a salience network responsible for evaluating stimuli for rewards and threats in the environment. Of course the picture is not entirely consistent, and there are other regions where even these reviews differ, such as whether reductions in left inferior frontal gyrus or the cerebellum are reliably reduced in first-episode patients. The impact of chronicity has also been examined, with chronic patients continuing to show gray matter loss in some of these same limbic regions, such as the insula, but also starting to show gray matter compromised in executive control regions such as the inferior and dorsolateral prefrontal cortex, and in a region that becomes more active during rest, the medial prefrontal gyrus. Although far fewer studies have directly compared people with schizophrenia and bipolar disorder, they do appear to be similar in showing reductions in whole-brain volume and a number of other features compared to controls (De Peri et al., 2012). Schizophrenia patients may show more gray matter volume reduction, whereas bipolar patients may have more white matter reduction, which may suggest some specificity.

White matter is composed of myelinated axons carrying information across the brain. An imaging technique known as *diffusion tensor imaging* can be used to quantify the extent to which these axon fiber tracts are organized coherently, like rope, or incoherently, like lint. Unsurprisingly, the vast majority of this literature has found evidence for less coherence in the axon fiber tracts of patients with schizophrenia, with some evidence suggesting that the connections between frontal lobe regions are particularly compromised (Pettersson-Yeo et al., 2011). A shortcoming of both this structural connectivity literature and the structural abnormalities described above is that very few studies have reported how differences among schizophrenia patients relate to their symptom presentations, therefore making it difficult to tell a more refined story about the relationship between structure and symptoms. Nevertheless, we will try to rectify this when we turn to functional neuroimaging.

### Function and Functional Networks

Functional imaging of the brain began in the 1970s (Ingvar & Franzen, 1974), with a marked increase in interest following the advent of functional MRI (fMRI) in the early 1990s. However, a concern soon arose as to whether differences in brain activity between patients and controls caused differences in performance or whether differences in performance, strategy, or motivation reduced the demands on regions that healthy participants used to perform tasks (e.g., Ebmeier et al., 1995). This causality confound still bedevils the field, increasing the challenge of extracting a coherent meaning from the literally thousands of fMRI studies that have been published to date.

Despite this confound there are a number of conclusions from studies that have begun to link the heterogeneity in patients' symptoms to differences in functioning across the brain (for review of symptom-activation relationships, see Goghari et al., 2010). For example, the occurrence of auditory hallucinations corresponds to activity in the superior temporal gyrus, an area which we also noted had structural abnormalities. Thus, one of the most common symptoms in schizophrenia may reflect processing at the earliest sensory inputs into the brain. Positive symptoms more generally also appear to be related to abnormalities in the medial prefrontal cortex, a region associated with self-awareness and ideas about others' state of mind. Reduced activation in ventral striatum, a region associated with reward processing, appears to correlate with the extent to which negative symptoms are expressed. Negative symptoms have also been associated with blunted amygdalar responses. Both of these regions are involved in the salience network described earlier. Consistent with behavioral work, disorganization has been related to impairments of activation of the prefrontal cortex, a region of the brain implicated in executive functioning.

While these findings begin to fit within our picture of schizophrenia, they also highlight a major flaw in this literature, which, due in part to small sample sizes, has largely neglected: the need to examine the relationships between brain activity and patient heterogeneity in symptoms and functioning. This situation is beginning to improve, and several large data sets are currently being collected to allow more definitive tests of these relationships. In the meantime, our next step is to go below the level of systems and look more closely at molecular neurobiology.

# Cellular Pathophysiology and Neuropsychopharmacology of Schizophrenia

A growing literature has examined the brain's structure at a still more molecular level, scrutinizing which neurons and glia are present and how patients' neuronal cells may differ from healthy controls. This work has relied on brain tissues from people who have donated this organ upon their death, and it reminds us of the importance of this kind of generosity for solving important mental health challenges. Since people live with schizophrenia for many years before dying, patients' brains not only reflect the causes of the disorder, but also the sequelae of chronic illness and the use of medication. These caveats notwithstanding, a number of telling findings have emerged. Complementing this work, neuropharmacology addresses the chemical compounds that affect neurotransmission, including but not limited to neurotransmitters. There are a number of candidates for study, with no reason to think that any one neurotransmitter can account for patients' heterogeneity or is more fundamental to the disorder. This has not always been the case; for many years, schizophrenia was thought to be an illness uniquely associated with problems in the transmission of dopamine (DA).

The origin of the *DA hypothesis* of schizophrenia is useful to relay because it provides a nutmeg of consolation for students of psychopathology frustrated by how much we still have to discover after a century of schizophrenia studies. In the mid-twentieth century, psychiatry had to be content with many vagaries and empirical observations, which is a polite way of saying experiments guided by chance and providence. There was plenty of incentive and opportunity for experimentation: thousands and thousands of schizophrenia patients were permanently housed on the sprawling, overcrowded campuses of state hospitals. In

this atmosphere, a class of compounds that had originally been developed for the textile industry in the nineteenth century and tested for possible antimalarial and anesthetic properties during World War I eventually came to the attention of a team of French psychiatrists (cf. López-Muñoz et al., 2005). After some tinkering, the compound that would be known as chlorpromazine proved to be surprisingly good at reducing patients' concerns about, and the occurrence of, delusions and hallucinations. Though it was hailed as a wonder drug, soon its side effects began to overshadow its successes. This, in turn, led to attempts to find compounds similar to chlorpromazine, without such severe side effects, that would come to be known as typical antipsychotics. Interestingly, these were used in the treatment of schizophrenia starting in the mid-1950s, long before it was understood how they worked. The definitive result underpinning the first dopamine hypotheses of schizophrenia was not published until the mid-1970s, when it was demonstrated that clinical effects of the various antipsychotic drugs available at that time strongly correlated with the extent to which they blocked DA receptors (Seeman & Lee, 1975). This illustrates that treatments can be viable even if the cause of the condition is unknown or even misunderstood. While the DA hypothesis accounted for a number of observations about psychosis at the time, the façade of this simple explanation would not stand indefinitely, despite several revisions (for a review of various DA hypotheses as well as a modern rendering of the hypotheses, see Howes & Kapur, 2009; for another perspective, see Kendler & Schaffner, 2011).

A challenge to the reigning hypothesis built around the therapeutic effects of DA antagonists came from the *psychomimetic* (psychosis-inducing) effects of another drug known as phencyclidine (PCP, "angel dust"). Phencyclidine was originally developed as a tranquilizer; however, people who used the drug showed transient schizophrenia-like symptoms, and patients who were given the drug showed long-lasting symptom exacerbations even at very low doses (Luby et al., 1962). When evidence emerged that phencyclidine and similar compounds such as ketamine ("special K") increased the activity of the N-methyl-D-aspartate (NMDA) receptors on glutamatergic pyramidal neurons (Vincent et al., 1979), it brought into focus an alternative glutamate hypothesis (Javitt & Zukin, 1991). Pyramidal neurons are pervasive and can be thought of as the primary working neurons and connections of the cortex. This glutamate hypothesis was parsimonious

insofar as it explained how a single dysfunction might result in numerous, correlated impairments in different brain systems and relate to the degradation of white matter tracts described above. Reinforcing this theory, postmortem studies began to show that pyramidal neurons in patients' brains had shorter axons, tighter cell packing, and fewer NMDA receptors on their dendrites (see Lin et al., 2012, for review). It then became necessary to explain away the primary basis of the DA hypothesis, which could be done if the effectiveness of typical dopaminergic antipsychotic drugs was simply the result of dopaminergic modulation of glutamate or even secondary to their sedative effects. As a result only a few new pharmaceuticals have been developed based on these findings. For example, drugs targeting glutamate receptors have been tested for and shown to be effective at reducing ketamine-induced psychotic symptoms and normalizing related brain activity in healthy volunteers (Kantrowitz et al., 2020). This low yield is in no small part due to the difficulty of safely modulating the activity of one of the most fundamental cell types of the brain.

A third pathophysiological and neuropharmacological hypothesis is largely built on postmortem brain tissue observations but also incorporates gene expression and brain network connectivity data. In this case, the abnormalities of interest are in the gamma-aminobutyric acid (GABA) interneurons that inhibit activity in other neurons, primarily pyramidal neurons. This is therefore known as the GABA hypothesis. These neurons, and in particular a subset of them known as basket and chandelier cells, contain parvalbumin. Parvalbumin maintains the tone of pyramidal neurons that is needed to resonate appropriately in the gamma frequency. This frequency, it will be recalled, underlies cognitive coordination and binding. Originally based on postmortem studies of patients, the GABA hypothesis incorporates the roles of DA and glutamate, proposing that perturbations of these neurotransmitter systems are downstream from the dysconnectivity that results from a failure to maintain the tone of pyramidal neurons (see Gonzalez-Burgos & Lewis, 2008, for review). Thus, parvalbumin neurons are thought to be impaired in producing and releasing GABA, which results in the cognitive deficits of schizophrenia (Lewis, 2014). While this hypothesis suggests a new neurotransmitter system to target with pharmaceuticals, this promise has yet to be realized. In the meantime, it provides an elegant example of how multiple methods and data from many levels of analysis can be synthesized into a comprehensive account of a mental illness.

Taken together, this work suggests an imbalance between excitatory and inhibitory neurotransmission related to psychosis. Concentrations of glutamate and GABA, representing the primary excitatory and inhibitory neurotransmitters, respectively, are dysregulated in schizophrenia. Elevations of glutamate concentration are consistently documented in schizophrenia spectrum disorders (Merritt et al., 2016) and partly explained by genetic influences (Legind et al., 2019) while dysregulated GABA has met mixed findings in schizophrenia (Egerton et al., 2017) and also bipolar disorder (Schür et al., 2016). Both glutamate and GABA concentrations are related to functional connectivity problems between brain regions in schizophrenia (Shukla et al., 2019) as well as cognitive functions such as working memory (Bojesen et al., 2020). Some evidence for drug treatments targeting the glutamatergic and GABA balance have also emerged but await replication.

This section provides only a taste of an extensive literature on the neuroscience, pathophysiology, and pharmacology of schizophrenia. Before moving on to explore causes of these neural abnormalities, it will be useful to make two general observations. The first is that while the hypotheses are competing in the scientific community, they need not actually compete in the brain. That is, the hypotheses may all contain a non-mutually exclusive portion of the truth, and other mechanisms may be in play. While it is parsimonious to think that the neural basis of schizophrenia is simple, nature frustrates this hope. Research can be hypothesis-driven without making the naïve assumption that there is, at the core, a single abnormality. The second is that, due to evidence of the kind described here, schizophrenia is often considered more organic, or biological, than many other disorders described in this text. This classification brings along many implicit assumptions about the condition and those who suffer from it. For example, it suggests that the true pathology of schizophrenia is to be found in neurons and that treatments for schizophrenia will require medicine to change those neurons. The distinction between psychological and organic causes for a disorder may be appealing, but it is increasingly untenable given our understanding of the tight relationships between the software and hardware of the brain. The brain limits the cognitive mechanisms that can be implemented, but those same neurons also reflect the

traces of the cognitive mechanisms that have been required of them. In fact, all disorders addressed in this textbook have or will have neural correlates; all symptoms will respond to medicine, either real or hypothetical. Sometimes the symptoms of schizophrenia appear to be more biologically based, but this is simply because new biological methods are often brought to bear here first, before expanding to other diagnoses. In the final analysis, schizophrenia is unlikely to prove a special case of mental illness in this regard.

### **Etiology of Schizophrenia**

In reviewing findings on the causes of schizophrenia, we will follow the simplified scheme of classifying causes as either genetic or environmental.

### Genetic Risks for Schizophrenia

Some of the first examinations of the etiology of schizophrenia were family studies conducted by the protégées of Emil Kraepelin in the 1910s (see Kendler & Zerbin-Rüdin, 1996). Family studies allow inferences through the use of quantitative genetics, based on the association between degree of genetic relatedness and level of risk. These earliest studies showed patients' siblings were at a markedly increased risk of illness relative to the general population, but the work was largely neglected until the 1960s when a new generation of scholars began to examine whether genes might play a role in the etiology of schizophrenia. Gottesman (1991) combined these data across studies to show a compelling relationship: thirddegree relatives such as patients' first cousins, who share about 12.5% of their genes, show a 2% risk of developing the disorder (compared to .7% in the general population). Second-degree relatives, such as uncles and nieces, share about 25% of their genes and have a 2-6% risk, whereas first-degree relatives such as siblings, including fraternal twins, have a 6-17% risk. Patients' monozygotic twins, who share 100% of their genes, have nearly a 50% risk of developing the illness. These data are interpreted in the parlance of quantitative genetics as indicating the heritability of the liability to schizophrenia. Liability can be thought of as the diathesis to schizophrenia (i.e., it is necessary but not sufficient for developing the illness). These data, along with information about the prevalence of schizophrenia in the general population, show that the liability is 80% heritable in most populations, which is to say 80% of the variance in liability

in that population is associated with variance in genes across the whole genome.

The data do not tell us how heritable schizophrenia is. As noted, the likelihood that you will develop schizophrenia if your monozygotic co-twin has the illness is 50%. These findings suggest a phenomenon called reduced penetrance. Simply inheriting the genetic liability for the illness is, on average, insufficient to cause the illness. Something additional is needed. Thus, the diathesis-stress model suggests some kind of environmental stressor might be required in addition to the diathesis to make the disorder become manifested. We will review a number of such proposed stressors below, but it is worth noting that luck-the chance factors that govern whether or not this or that gene is expressed in the body's cells-also counts as an "environmental" contribution within this model.

Quantitative genetic studies provide the impetus for *molecular genetic research*, and this has now become one of the fastest developing domains of the schizophrenia literature. Rather than asking *whether* genes contribute to the illness, this research asks *which* genes contribute. The hope is not simply that identifying these genes will be interesting, but that the functions of those genes will suggest treatments, or even a cure. The thrust of the story of the molecular genetics of schizophrenia is threefold: identifying genes involved in the illness requires very large samples of patients and controls and more markers across the genome because there are likely to be many, many genes that convey a tiny bit of risk.

In the 1990s, the molecular genetics of schizophrenia consisted largely of linkage studies that used measures of recombination frequency, rather than a specific physical distance along each chromosome, to detect regions of various chromosomes that might be associated with risk for schizophrenia. By the end of this era, there were a number of promising findings, such as a portion of chromosome 2p12–q22.1 that was consistently linked to the illness (Lewis et al., 2003). However, the method precluded identifying specific genes and therefore precluded understanding the specific pathways to illness.

In the 2000s, attention turned to specific genetic markers known as *single-nucleotide polymorphisms* (SNPs), which formed the basis of the candidate gene approach. In this method, SNPs on a number of candidate genes were selected for closer scrutiny because they were thought to be involved in a putative neural mechanism. SNP markers on a number of genes came to light, including genes relevant to
DA (e.g., catechol-O-methyltransferase [COMT]), glutamate (e.g., neuregulin [NRG1]), GABA (e.g., glutamic acid decarboxylase 1 [GAD1]), and neurodevelopment (e.g., disrupted in schizophrenia 1 [DISC1]), among others. While a number of early studies using this method provided excited results, researchers became concerned about the low level of replicability of many findings, particularly those derived from small sample sizes (Ns < 1,000).

A series of new findings shook up this a priori approach to gene discovery when genotyping technology advanced and genome-wide association studies (GWAS) became practical. GWASs do not examine a few markers in selected genes. Instead, they look at markers across all chromosomes to determine any gene with a strong association to an illness. Armed with immense samples sizes, GWAS studies have discovered that many genes-likely numbering in the thousands-are statistically associated with the illness and that many of these genes are quite common in the general population as well. In addition, all the genes that have so far been associated with schizophrenia together account for a very small proportion of the variance in schizophrenia in the population, suggesting that more complicated interactions and pathways will have to be taken into account. As opposed to implicating a specific genetic or molecular mechanism of risk, these studies so far suggest that a number of mechanisms may be relevant to the diathesis for schizophrenia and psychosis more broadly. Recently, efforts to quantify an individual's overall genetic liability for schizophrenia have calculated a "polygenic risk score" that sums one's risk alleles weighted by their respective effect sizes from GWAS (Choi et al., 2020). This polygenic risk score can be combined with functional neuroimaging to explain variance in brain function (Cao et al., 2020) and perhaps yield information relevant for tailored treatment. Additionally, polygenic risk scores for schizophrenia have been used to predict other mental health concerns (e.g., anxiety, depression) and environmental conditions (e.g., nicotine use, trauma), though this work has yet to be extended to individuals of non-European descent (Docherty et al., 2018). The job of untangling these genetic findings enough to turn them into treatment options remains a daunting task.

#### Environmental and Other Risks for Schizophrenia

In the decades following World War II, clinical practice in the United States was dominated by psychodynamic—and therefore primarily environmental—explanations of psychosis. One tragic consequence of this bias was the growth of a myth of a *schizophrenogenic mother*. The schizophrenogenic mother was said to have defective interactions with her children and a number of other vague and at times conflicting shortcomings as a parent that led the future patient to learn something that eventually manifested as the illness. The unintended result of these strongly environmental theories of schizophrenia was that the parents of patients, already struggling with the day-to-day difficulties of supporting their ill son or daughter, were further saddled by the guilt of having caused the illness itself. This is the cautionary environmentalists' tale much as the history of eugenics cautions against overinterpreting genetic causal factors.

The fundamental observation that still requires an environmental, or nongenetic, account of the etiology of schizophrenia is that the concordance between monozygotic twins is about 50%. Since this is less than 100%, it is thought that there must be some nongenetic cause that leads to the ultimate manifestation. Table 14.1 lists eight additional risk factors that have been established through large meta-analyses. None of these risk factors implicates defective parenting, and most of them implicate either pre- or perinatal events (older fathers, prenatal famine, maternal influenza, obstetrical complications, winter or spring birth) or other biological risk factors (Toxoplasmosis gondii exposure, lifetime cannabis use). That is, they are unlikely to affect one's learning regimen.

Of note, given recent efforts to legalize marijuana across the world, cannabis use as a risk factor for schizophrenia carries a dose-response relationship

 Table 14.1
 Nongenetic risk factors associated with

schizophrenia		
Risk factor	Odds ratio	
Migrant status	4.6	
Older fathers	3.8	
Toxoplasmosis gondii exposure	2.7	
Prenatal famine	2.3	
Lifetime cannabis use	2.1	
Obstetrical complications	1.8	
Urban rearing	1.7	
Winter or spring birth	1.1	

Note: For full citations, see MacDonald & Schulz (2009). Odds ratios are calculated as the increased odds of someone with the risk factor developing the condition, where 1.0 is the general population risk. such that patients who used cannabis more than 50 times in their lifetime have a significantly higher rate of developing schizophrenia, especially if use began at a younger age (Ortiz-Medina et al., 2018). Of the two others, migrant status and urban rearing, it is unclear what aspect of these very general risk factors convey risk at this time, although an argument can be made for stress or anxiety. Importantly, even the most reliably potent risk factors-such as migrant status or older fathers-only moderately increases risk; most patients are not migrants or the offspring of older fathers. Furthermore, migrant status or urban rearing represent only a fraction of one's environment, and recent research has attempted to examine broader contexts that reflect the interdependence of environmental risk factors (e.g., ethnic density, presence of pollution and infectious agents; Plana-Ripoll et al., 2018). This type of work has been termed "exposome" research because it aims to examine the environmental exposures more comprehensively, similar to genome-wide analyses (Guloksuz, van Os et al., 2018). Exposome research, in attempting to capture the entirety of environmental exposures, has an admirable goal of identifying modifiable risk factors for schizophrenia, though not without encountering unique challenges (see Guloksuz, Rutten et al., 2018).

Another question that arises with a great deal of regularity is whether brain injuries cause schizophrenia. Many researchers who use neuroimaging and therefore screen patients for head injuries have observed that patients with schizophrenia are far more likely than controls to report an errant baseball bat or harrowing bicycle accident that left them with a concussion. According to published case studies, head injuries can only in rare instances lead to psychosis, and these patients generally have few negative symptoms (Fujii & Fujii, 2012). These findings would seem to suggest that a schizophrenia patient with few negative symptoms would be indistinguishable from a head-injury-induced psychosis patient. However, this kind of question is tricky to study rigorously in sufficiently large samples for definitive conclusions.

Finally, careful readers will note that our classification of genetic and environmental causation is, like other convenient distinctions raised in this chapter, to be taken with a grain of salt. For example, evidence for these risk factors does not rule out the possibility that a great deal of the reduced concordance between monozygotic twins is simply due to chance; such twins may have inherited differences in the strength of expressing certain genes, a phenomenon known as *methylation*. Thus, even nongenetic causes may involve the genome in some ways. Another way in which the genetic/ environmental distinction may be misleading is in the context of gene-environment correlations and gene-environment interactions. For example, cannabis use may only be a risk factor for people with a particular diathesis, such that people with a family history of schizophrenia are more susceptible to the psychosis-inducing effects of cannabis (Ortiz-Medina et al., 2018). Thus, the reader should be prepared to critique such simplistic classifications. More often than not, etiological explanations of schizophrenia involve both genetic and environmental components. For instance, a growing literature exploring the connection between schizophrenia and immune functioning points to formative environmental risk factors (e.g., maternal influenza, autoimmune disorders) that activate and prime immune reactivity, as well as schizophrenia risk genes that promote inflammation (Müller, 2018). This vulnerability-stress-inflammation model is yet another theory that emphasizes the complexity of schizophrenia.

#### Conclusion

The symptoms of schizophrenia constitute a devastating, serious, and persistent syndrome that affects a remarkably high proportion of the human race. It can affect all aspects of life, indeed shortening life itself through increased suicidality and other health consequences. Numerous theories of the nature of the illness have arisen and fallen in the 100 years since its description and coinage by Kraepelin and Bleuler. Were these progenitors alive today, they would survey the legacy of their work with a mixture of pride and disappointment.

There is much to be proud of in the century of work that has expanded our knowledge of how different symptom dimensions relate to each other and to other disorders, how these relate to cognitive functions and brain networks, and how these brain networks are in turn influenced by biochemical processes. The fact that these processes may not be specific to schizophrenia per se but may be relevant to disorders beyond that strict definition does not detract from those accomplishments. It is ironic, however, that much of the progress in treating the illness has proceeded entirely independent from the psychopathological science of it. Pharmacological treatment discoveries, although never coincidences, have only in recent years built on our understanding of the causes of the disorder. It is also ironic

that psychosocial treatments, used rarely in the past, have become increasingly acceptable within this new zeitgeist of nonspecificity of symptoms and broad sources of causation. Thus, while the construct introduced to psychiatry 100 years ago is certainly showing signs of ageing, it is sure to provide a reference point for thinking about psychosis far into the future.

## Social Functioning and Schizophrenia

Jill M. Hooley and Stephanie N. DeCross

Impaired social functioning is a fundamental feature of schizophrenia. Recognized in the early clinical descriptions of the disorder, social dysfunction remains one of the defining characteristics of the syndrome. A century ago, Emil Kraepelin noted the lack of concern for social convention that characterized the patient with schizophrenia, remarking that

[t]he patients no longer have any regard for their surroundings; they do not suit their behavior to the situation in which they are, they conduct themselves in a free and easy way, laugh on serious occasions, are rude and impertinent towards their superiors, challenge them to duels, lose their deportment and personal dignity; they go about in untidy and dirty clothes, unwashed, unkempt, go with a lighted cigar into church, speak familiarly with strangers, decorate themselves with gay ribbons. (Kraepelin, 1919/1989, p. 34)

Though contemporary writers might describe these social difficulties less vividly, it is acknowledged that everyday social encounters often present considerable challenges to those with schizophrenia. Of course, schizophrenia clinical profiles are heterogenous in presentation. Nonetheless, withdrawal and social isolation are often primary components. Impairment in social or occupational functioning is also necessary for the diagnosis to be made in *DSM-5*.

In this chapter we provide an overview of the literature concerning social functioning in schizophrenia. This is a broad topic that covers a range of different research areas. Because of this, our review must necessarily be more selective than exhaustive. We are often unable to consider many interesting and important aspects of the topics that are discussed. What we hope to do is to trace the arc of research work in this area, highlighting the progression of knowledge over time. Wherever possible, we also draw readers' attention to articles that provide more detailed consideration of specific issues.

# Interpersonal Adjustment and Schizophrenia

The subjective reports of people with schizophrenia are full of references to the difficulties they experience during ordinary social interactions. These difficulties are also mirrored in the comments of their family members. The ex-wife of "Jon," who was diagnosed with schizophrenia, described it in this way:

Some aspects of Jon's illness were particularly puzzling. I knew he was highly intelligent and perfectly at ease when it came to discussing complicated philosophical issues or analyzing the works of sophisticated artists. Why then was he at a loss when it came to dealing with everyday human relationships? He didn't seem to be able to get the feel

of people, to interpret their gestures correctly. Instead of relying on that intuitive understanding we usually have of what other people are trying to convey, he built up intricate theories that often led him to erroneous interpretations. It took me a long time to understand that this continuous theorizing might be his way of grappling with his own uncertainty and bewilderment. It was as though some strange deficiency prevented him from understanding some things that seem perfectly obvious to most people. (Anonymous, 1994, p. 228)

Relationships have been classified as a function of the interpersonal needs that they serve. Instrumental relationships are task-oriented and goal-driven. Work and service relationships, such as purchasing an item in a store, asking for directions, giving appropriate information in a job interview, or dealing with those responsible for processing disability benefits, primarily subserve instrumental role needs (see Liberman, 1982).

People with schizophrenia show significant impairment in their instrumental relationships (see Wallace, 1984, for a review of the early literature). For example, those with the illness are frequently unable to finish school or to achieve the level of education they desire.

After graduation I enrolled at a college near home. I stayed only 2 years. It was difficult for me to deal with ordinary situations, such as a problem with a teacher. (Herrig, 1995, p. 339)

Many individuals with schizophrenia are also unable to hold a job for sustained periods of time. Only about 10–20% of patients are employed (Marwaha & Johnson, 2004), and when they do work, it is often at an employment level that is lower than that of their parents. Jon, the patient described earlier, had his first breakdown when he was in the army. He left the army and later found part-time work. Finding that too much, he subsequently gave up work entirely and stayed at home reading, writing, and doing household chores while his wife went out to work (Anonymous, 1994).

Deficits are also apparent in the social-emotional domain. In contrast to the task-oriented or goaldirected nature of instrumental interpersonal relationships, social-emotional aspects of relationships are driven more by the needs of the relationship itself. Social-emotional exchanges might include such things as asking how a spouse or partner feels, greeting a relative, going to an event with a friend, or chatting at a party (Liberman, 1982). Although these sorts of transactions are everyday occurrences for most of us, they are not routine for the person with schizophrenia.

I wanted to blend in in the classroom as though I were a desk. I never spoke. I didn't participate in any extracurricular activities or have any close friends. (Herrig, 1995, p. 339)

Traditionally, marriage has been regarded as indicative of a person's ability to develop and sustain a close interpersonal relationship. Although marriage is far from a perfect indicator of social competence, compared to people in the general population, people with schizophrenia are six times less likely to marry (MacCabe et al., 2009). Rates of marriage are also much lower in patients with schizophrenia than they are in those with other severe forms of mental illness such as bipolar disorder (Mueser et al., 2010). Notably, males with the disorder are particularly unlikely to marry. Although precise rates vary across studies, schizophrenia severely reduces the probability of marriage for men, although it compromises it less for women (Häfner, 2003).

General descriptions of the problems experienced by patients with schizophrenia are important and informative. However, they tell us little about what these patients actually do (or fail to do) in social situations. Fortunately, researchers have explored the interpersonal problems associated with schizophrenia to better understand their nature and possible origins. It is to this literature that we now turn.

## **Measuring Social Behavior**

#### Social Competence

Social competence is "a context-related and more or less subjective judgment or evaluation of observed behavior or social role performance" (Appelo et al., 1992, p. 419). In general, it reflects how well we consider people to be doing in everyday social situations. Often used interchangeably with terms such as "social role functioning" or "social role adjustment," it is the most global level of analysis. As we have already seen, subjective accounts and clinical observations highlight the problems in social competence that are so typical of schizophrenia. Studies that have examined social competence more formally have also reached similar conclusions.

Early work in this area assessed patients using the Social Competence Scale (Zigler & Phillips, 1961). This rather heterogeneous measure considers age of onset, education, marital status, occupation, and employment history to yield a composite social functioning score. As might be expected, schizophrenia patients typically score lower on the Social Competence Scale than do psychiatric patients with other disorders (e.g., Schwartz, 1967). Adolescents at risk for schizophrenia also score more poorly on this instrument, both relative to nonpsychiatric controls and to adolescents at risk for mood disorders (Dworkin et al., 1990).

Other measures of global social functioning (see Yager & Ehmann, 2006, for a review) include the Social Adjustment Scale (SAS-II; Schooler et al., 1986) and the Quality of Life Scale (QLS; Heinrichs et al., 1984). The SAS measures interpersonal performance in work, relationships with household members, relationships with other relatives, leisure and recreational activities, and personal well-being. The QLS has four dimensions and provides ratings on interpersonal relations, instrumental role functioning (primarily occupational, student, or homemaker roles), intrapsychic functioning (i.e., cognitive, affective, and motivational functioning) and common objects and activities (which assesses whether the patient reads newspapers, possesses a wallet, or is otherwise involved with the objects and activities of everyday life). On both measures, patients with schizophrenia score worse than either nonpatient controls or patients diagnosed with mood disorders (see Bellack, Morrison et al., 1990). Moreover, impaired social functioning relative to controls on the SAS-II is found even in patients who are experiencing their first episodes of illness (Ballon et al., 2007). Global difficulties in social competence thus seem to be characteristic of those diagnosed with schizophrenia at all stages of the illness.

## Social Skills

354

Social skills represent a level of social functioning that is more molecular than the broad concept of social competence. They have been described as the "specific verbal, nonverbal and paralinguistic (e.g., voice tone) behavioral components that together form the basis for effective communication" (Mueser et al., 1990, p. 138). Social skills include the ability to give and obtain information and to express and exchange attitudes, opinions, and feelings. These skills, which are apparent in the everyday conversations, encounters, and relationships that people have with each other, are thought to be foundational for social competence.

MAJOR CLINICAL SYNDROMES

In the research lab, one way to assess social skills is through role-play techniques. In role-playing, the patient interacts with a confederate in a prescribed situation (such as an exchange with a sales associate or a staged argument with a loved one). Various components of social skill, such as the appropriateness of gaze, duration of speech, meshing (e.g., the smoothness of turn-taking and pauses in the conversation), or the expressiveness and congruence of facial expression (see Mueser, Bellack, Douglas, & Morrison, 1991), can then be assessed. Verbal skills, which are evaluated in the context of the social situation being enacted, are also considered.

Although best viewed as a measure of response capabilities rather than as a reflection of behavior occurring in the natural environment, role-play nevertheless appears to be a valid method for the study of interpersonal behavior (see Mueser & Bellack, 1998). Behavior during role-play is strongly correlated with more global measures of social competence. Judges' ratings of verbal and nonverbal behavior also differentiate patients with schizophrenia from people with mood disorders or healthy controls (Bellack, Morrison, Mueser et al., 1990).

Social skills research, relying heavily on roleplaying tasks, has provided useful information about more specific social difficulties associated with schizophrenia. For example, in conversation, patients with schizophrenia show weaker verbal (e.g., clarity, negotiation, and persistence) and nonverbal skills (e.g., interest, fluency, and affect) than do non-patient controls (Bellack et al., 1994). Compared with patients diagnosed with mood disorders or with non-patient controls, they also tend to be less assertive when challenged. Moreover, although in the face of criticism psychiatric and nonpsychiatric controls tend to apologize or explain, schizophrenia patients tend to deny making errors or to simply lie (Bellack et al., 1992). It is important to note, however, that overall social performance in patients with schizophrenia tends to involve mild impairments across a range of component skill areas rather than marked problems in any one domain (see Mueser, Bellack, Douglas, & Morrison, 1991).

## Social Problem-Solving

The ability to successfully recognize an interpersonal problem, formulate a solution, and take action is fundamental to social success. Social problem-solving, another element of social competence, can be examined in a variety of ways. The Means-Ends Problem Solving (MEPS) procedure presents research participants with hypothetical interpersonal problem situations and measures how well they can conceptualize and generate effective solutions to resolve each problem. In an early series of studies, Platt and Spivak (1972, 1974) reported that, compared with a control sample of hospital employees, patients with schizophrenia were less able to provide appropriate and potentially effective solutions to the problems under consideration.

Patients diagnosed more using more current (post-DSM-III) diagnostic criteria for schizophrenia also demonstrate problems with interpersonal problem-solving and perform worse than controls. This is apparent using measures such as the Assessment of Interpersonal Problem-Solving Skills (AIPSS; Donahoe et al., 1990; Bowen et al., 1994). Bellack and his colleagues (1994) have also reported that inpatients with schizophrenia show deficits on other social problem-solving tasks. More specifically, relative to controls, the schizophrenia patients generated solutions that were rated by judges as being less appropriate and less likely to be able to be implemented. The patients were also generally less assertive and less able to recognize poor problem solutions that were unlikely to work. Nonetheless, it warrants mention that these difficulties also characterized patients with bipolar disorder. Both patient groups performed less well than controls, and no significant differences between the patient groups were found.

Considered together, there appears to be ample evidence demonstrating that schizophrenia patients exhibit a wide range of problems across a diverse array of social domains when compared with control participants. There is also evidence that, even when compared to patients with other forms of psychiatric disorders (such as mood disorders), patients with schizophrenia still show more impairments (Bellack, Morrison, Wixted et al., 1990; Bellack et al., 1992; Mueser et al., 2010), though this is not always the case (e.g., Bellack et al., 1994). It is quite likely that the factors that underlie poor social problem-solving in patients with chronic schizophrenia (e.g., cognitive impairments) are not the same as the factors associated with poor social functioning in patients with bipolar disorder (e.g., acute symptoms). More data on the extent to which problems remain when patients show clinical improvement would be informative. Although social impairments appear to be stable over time in people with schizophrenia (Cornblatt et al., 2007; Mueser, Bellack, Douglas, & Morrison, 1991), less is known about the long-term stability of skill deficits in other diagnostic groups. However, even in older patient samples (age 50 years or older) social functioning deficits are still more marked in schizophrenia patients than they are in those with major mood disorders (Mueser et al., 2010).

#### Gender and Interpersonal Functioning

A sizeable literature suggests that the course of the illness is more benign in women than in men. For example, female patients have a characteristically later age of onset of the illness (Häfner et al., 1993; Abel et al., 2010). Men show a peak in the incidence of schizophrenia between 20 and 24 years of age. For women, the peak in the number of new cases during these ages is less marked, and the onset of schizophrenia is instead more broadly distributed throughout the 20s and early 30s. Females also have shorter and less frequent psychotic episodes and show a better response to treatment than do their male counterparts (see Leung & Chue, 2000).

Gender differences are also apparent in the interpersonal realm. Compared with males, female patients have a milder range of interpersonal problems and are characterized by better social functioning. Both Dworkin (1990) and Perry, Moore, and Braff (1995) have reported that females with schizophrenia, as a group, scored significantly better than males with schizophrenia on the Social Competency Index (Zigler & Phillips, 1961). Andia and her colleagues (1995) also found that women with schizophrenia were more likely than men with the disorder to live independently, be employed, and have been married despite having similar symptom profiles. Moreover, females in this last study had higher levels of social functioning even though they were being maintained on lower doses of antipsychotic medication than the male patients.

Similar gender differences have been reported by other research groups. Using a role-play test, Mueser and his colleagues (1990) reported a clear gender difference across a range of different measures. Although they did not differ from male patients with respect to their symptoms, females with schizophrenia were more skilled than males in the appropriateness of the duration of their speech (very short or very long responses were rated less favorably), their meshing or turn-taking abilities during conversations, aspects of their verbal content in specific role-play scenarios, and their overall social skills. There is also evidence that the relationship between gender and social skill may be specific to schizophrenia. In the study just described, gender was unrelated to social skill in either the mood disorder or the non-psychiatric control groups.

Gender differences are not universally documented. Indeed, in the study just described, no differences were found between the male and female patients with schizophrenia on measures of social adjustment such as the SAS-II and the QLS. More global measures of social adjustment may simply be less sensitive to gender differences than laboratorybased assessments are. Overall, however, when gender differences are found, the results typically point toward better interpersonal functioning in females with schizophrenia.

Why do women score better on measures of social functioning? Differences in the age of onset of the illness may provide a partial explanation. As we have noted, more men than women develop schizophrenia in their late teens or early 20s, with a later average age of onset for women (Abel et al., 2010). During adolescence and young adulthood, social relationships typically become a major focus of interest and there is a rapid acquisition of social skills. An earlier age of onset in men may disrupt developmental processes supporting social functioning to a greater extent than is the case for women, who develop the disorder later. Women may also be more likely to marry and have children in part because these life changes may occur before the development of the disorder.

The increased levels of social functioning apparent in female patients may simply reflect the fact that women, for reasons that are not fully clear, tend to have a somewhat milder form of illness. Related to this, some authors have speculated about the neuroprotective properties of estrogen (Rao & Kőlsch, 2003). Because of its ability to reduce the sensitivity of D<sub>2</sub> dopamine receptors, estrogen may exert a weak neuroleptic-like effect on symptoms (Kulkarni et al., 2008). Females may also be less susceptible than males to structural brain abnormalities that could lead to developmental problems and greater impairment in functioning (Abel et al., 2010). Interestingly, the social functioning advantages apparent in women with schizophrenia are not seen in older patients (Mueser et al., 2010). This may be because of reduced estrogen production in older women.

## Social Functioning and Clinical Symptoms

Schizophrenia is characterized by symptoms such as hallucinations, delusions, affective flattening, and anhedonia. Each or all of these might be expected to be associated with interpersonal difficulties. In this section we examine the evidence as a function of two major symptom groupings: positive and negative.

Developed in an effort to explain the heterogeneity in schizophrenia, the division between positive and negative symptoms (Andreasen & Olsen, 1982) is based on whether the symptoms of the disorder are florid (or in excess of "normal") or instead represent the absence of the typical (i.e., a "defect" or failure to display a "normal" behavior). Symptoms such as delusions, hallucinations, formal thought disorder, or bizarre behavior are thus regarded as positive symptoms, while alogia (greatly reduced speech or speech conveying very little information), affective flattening, avolition (apathy), and anhedonia are characteristic negative symptoms (Kirkpatrick et al., 2006). Negative symptoms that are enduring and that do not reflect efforts to cope with positive symptoms are also termed deficit symptoms (Carpenter et al., 1988).

Positive symptoms in general do not appear to be particularly related to social adjustment (Bellack, Morrison, Wixted et al., 1990; Bora et al., 2006; Perry et al., 1995; see also Dworkin, 1990). However, reports of associations between positive symptoms (more or more severe symptoms) and impaired social competency can be found (Appelo et al., 1992; Corrigan & Toomey, 1995). This suggests that intact thought processes may be necessary for effective social functioning. Precisely which symptoms might compromise which domains of interpersonal functioning and under what circumstances, however, are questions in need of further investigation.

Examining the association between negative symptoms and social functioning is not as straightforward as it might first appear. As Dworkin (1992) has noted, many ratings on the Scale for the Assessment of Negative Symptoms (SANS; Andreasen, 1982) are based on the patient's behavior during an interview. Yet an interview is an interpersonal situation. Moreover, the ratings that are made are based on behavioral indicators such as unchanging facial expression, decreased spontaneous movements, and poor eye contact. But these behavioral indicators of negative symptoms could be the result of social skills deficits.

Recognizing this problem, what do we know about the association between negative symptoms and social functioning or social skills? Perhaps not surprisingly, negative symptoms have been linked to poorer social functioning, particularly when more global measures of social adjustment are used (e.g., Appelo et al., 1992; Blanchard et al., 1998; Bora et al., 2006; Pinkham & Penn, 2006). Moreover, even in first-episode patients, the presence of more severe negative symptoms is associated with having a smaller social network with fewer friends (Thorup et al., 2006).

In a focused examination of the role of negative symptoms, Bellack and his colleagues (Bellack et al., 1989; see also Bellack, Morrison, Wixted et al., 1990) administered the SANS to a sample of inpatients with schizophrenia. These patients were then further divided into a group that had more severe negative symptoms and a group that had less severe negative symptoms (i.e., positive symptom and mixed symptom patients; see Andreasen & Olsen, 1982). Consistent with prediction, the negativesymptom patients were found to be significantly more impaired on the SAS-II and the QLS than were the other schizophrenia patients or the control patients with schizoaffective disorder or bipolar disorder.

Less compelling, however, are the data linking negative symptoms with more specific social deficits. Jackson et al. (1989) reported impressive associations between negative symptoms and social skills during a role-play task. Corrigan and his colleagues (Corrigan, Green, & Toomey, 1994) also found that patients' scores on a scale assessing blunted affect, emotional withdrawal, and motor retardation were negatively correlated with their performance on a social cue recognition task. However, Appelo et al. (1992) concluded that negative symptoms did not explain specific skill deficits in their sample of schizophrenia patients, and no compelling links between negative symptoms and problem-solving ability were reported by Bellack et al. (1994). Finally, using the Physical Anhedonia Scale and the Social Anhedonia Scale (see Chapman et al., 1976), Blanchard, Bellack, and Mueser (1994) found no relationship between either of these two anhedonia scales and measures of social skill in their patient samples.

Overall, the findings suggest that, although negative symptoms may not be particularly associated with any specific social skill deficit, they do predict unemployment (Marwaha & Johnson, 2004), reduced social network size (Thorup et al., 2006), and diminished social competence more broadly. This raises the question of whether the social deficits of schizophrenia patients can be explained solely by negative symptoms.

The answer is "probably not." Although schizophrenia patients with negative symptoms generally perform less well than non-negative symptom schizophrenia patients on measures of interpersonal skill, the latter still perform less well than affectively ill or community control groups (Bellack et al., 1989; Bellack, Morrison, Wixted, & Mueser, 1990; Dworkin, 1990; Dworkin et al., 1991). This suggests that social impairments are associated with schizophrenia in general and are not linked only to the negative symptoms of the disorder.

Moreover, in Dworkin's (1990) study of twins with schizophrenia, male patients showed greater asociality and withdrawn behavior, as well as poorer premorbid social competence than did females. This, as we have seen, is in keeping with the generally better social functioning of female versus male patients. However, Dworkin found no significant differences between the sexes with respect to the symptoms that they exhibited. The differences in social functioning found in this sample are therefore not easily explained simply by differences in symptoms (see also Andia et al., 1995).

In summary, these results suggest that negative symptoms and social functioning may reflect different processes in the development and manifestation of schizophrenia. Negative symptoms may exacerbate the poor interpersonal abilities of those with schizophrenia. However, negative symptoms alone do not provide a full explanation for the interpersonal deficits that characterize the disorder. Rather, the data point to the likely existence of some more focal deficit that is related to social functioning.

## Are Social Deficits Apparent Before the Onset of Schizophrenia?

If the social deficits that characterize people with schizophrenia are simply a consequence of the symptoms of disorder (or are secondary to the effects of medications and hospitalization) we would not expect them to be observable prior to the onset of the illness. However, evidence suggests that interpersonal difficulties often appear long before any psychiatric illness is diagnosed.

One way to examine this issue is to explore the premorbid adjustment of currently diagnosed patients using retrospective reports. Cannon and colleagues (Cannon et al., 1997) interviewed the mothers of 70 patients with schizophrenia, 28 patients with bipolar disorder, and 100 healthy controls. Mothers were asked to report on their children's adjustment in several areas, including social functioning. Compared with the mothers of both the healthy controls and the patients with bipolar disorder, mothers of patients with schizophrenia reported that their children were significantly less sociable and more withdrawn in their childhood and adolescent social relationships. Differences in the premorbid social adjustment of the patients with bipolar disorder were also apparent when compared to the healthy controls. However, overall, they were less impaired than the schizophrenia group, and they continued to do quite well in school despite their social problems.

Of course, retrospective investigations are not without methodological problems. One concern is the accuracy of the historical reports. In a creative series of studies Walker and her colleagues (e.g., Walker & Lewine, 1990) circumvented this problem by examining the home movies of people diagnosed with schizophrenia. These home movies featured the patients and their healthy siblings interacting during childhood, years before any psychiatric difficulties became apparent in one of the children. Despite this, independent raters, who did not know which child later developed schizophrenia, were able to successfully identify the vulnerable child. This was the case even though the sample was selected to include patients whose parents reported that their children showed no unusual behavior or signs of illness when they were growing up. Although raters were given no specific instructions about how to evaluate the children in the home movies, they indicated that their decisions were frequently guided by interpersonal aspects of the children's behavior. Behaviors such as decreased social responsiveness, reduced eye contact, and lack of positive affect were mentioned, although other factors, such as motor behavior, also influenced the decisions.

Other evidence of premorbid social deficits in schizophrenia comes from examinations of high-risk populations. In the classic form of high-risk investigation, the offspring of parents with diagnosed schizophrenia are recruited in childhood and then studied prospectively. These children, who are at genetically heightened risk for psychiatric disorder themselves, can be followed closely as they mature. Using data from the New York High-Risk Project, Dworkin and his colleagues reported that adolescents at risk for schizophrenia were rated as being less socially competent than adolescents who were at risk for affective illness (Dworkin et al., 1990, 1991; Dworkin et al., 1994). These evaluations, made by trained raters, were based on information from interviews conducted with the adolescents themselves as well as from interviews with their parents. The adolescents at risk for schizophrenia also reported significantly poorer peer relationships and decreased hobbies and interests relative to the adolescents at risk for mood disorders. In other words, among high-risk adolescents, those who were later diagnosed with schizophrenia had poorer peer relationships even before they became ill.

More recent work has introduced other approaches in the service of earlier identification and intervention for risk states. One option is to select subjects who score high on measures known to be predictive of later schizophrenia. Such people are considered at behavioral high risk. Another approach involves studying people who are thought to be at high risk for developing schizophrenia because they are already showing some of the prodromal (early clinical) signs of the disorder along with functional decline, commonly known as clinical high-risk or ultra high-risk states (Keshavan et al., 2011).

In an example of the former approach, Zborowski and Garske (1993) selected male subjects who scored high on a self-report measure of schizotypic traits involving perceptual aberrations and magical ideation (the Per-Mag Scale; see Chapman et al., 1982, 1994). These males were then compared to control male undergraduates who had low scores on the same self-report scale. Although the two groups were comparable with respect to their age and class rank, the groups differed in important ways when they interacted with a female research assistant in a videotaped interview. Males high on the Per-Mag scale showed more odd behavior during the interview. They were also rated as being more avoidant. Interestingly, the female interviewers reported that, when interacting with the hypothetically schizophrenia-prone males, they felt more anxious, angrier, and less curious than when interacting with the control males. These data suggest that undergraduate males who are not psychiatrically ill but who are at statistically higher risk for the development of schizophrenia show interpersonal anomalies during social interactions. Importantly, their odd and avoidant behavior also appears to create social discomfort for those with whom they interact.

Given that social impairments are associated with both genetic and behavioral high risk for the development of schizophrenia, it should come as little surprise that social difficulties also characterize those who have prodromal positive symptoms but who are not psychotic (Ballon et al., 2007; Cornblatt et al., 2007). Moreover, these social deficits may be an omen for what is to come. Cornblatt and colleagues (2007) reported that social impairments measured in the prodrome predicted the presence of psychosis 1 year later. This raises the possibility that impaired social functioning could be an early marker for schizophrenia. Of course, whether social functioning deficits reflect a vulnerability to the disorder or simply create the kinds of stressful circumstances that might trigger the onset of schizophrenia is not resolved. Social difficulties may be a manifestation of an underlying diathesis, a behavioral marker that engenders increased social stress (perhaps from irritated peers or family), or both.

Regardless, research has identified poor premorbid social functioning as a negative prognostic sign. Retrospective studies have linked poorer premorbid social functioning to a more chronic clinical course and more frequent hospitalizations (Cannon-Spoor et al., 1982). In contrast, good premorbid functioning has been shown to be predictive of more complete remissions after an episode of illness (Amminger & Mutschlechner, 1994). Premorbid functioning is also predictive of the level of community functioning and adjustment that can be attained once the illness has developed (Childers & Harding, 1990). Simply put, social difficulties, whether indexed via measures of premorbid adjustment or through other global assessments, appear to signal serious clinical problems in the future.

## Exploring the Role of Cognition in Social Dysfunction

So far, we have described how social behavior is altered in schizophrenia. But what are the building blocks of typical social functioning, and how might compromise in these domains affect social behavior? One potential factor here is cognition, defined as "the ability to accurately perceive, attend to, and remember information" (Green, 2016, p. 9). An extensive literature documents the difficulties that schizophrenia patients experience in aspects of their neurocognitive functioning relative to healthy controls (see Heinrichs, 2005). Given this, it is reasonable to ask if problems with cognition might serve as "rate limiters" (see Bellack, 1992) for how well patients can function in a social domain. Certainly, the interpersonal skills that most of us take for granted depend on a wide range of cognitive operations. They are also much more complex than we typically appreciate. For example, entering into a conversation requires us to selectively focus our attention on the appropriate stimulus (our conversational partner) while at the same time filtering out the rest of the background noise that is around us. In addition, to respond appropriately we need to remember what our partner has said and generate a comment of our own that is related and on-topic. This places obvious demands on our memory systems and on higher-level information processing and executive skills. Moreover, all of this must be done while simultaneously processing the multiple verbal and nonverbal cues that our partner generates.

The conversational abilities of even healthy subjects can be easily disrupted. Barch and Berenbaum (1994) asked college students to complete a complex processing task while at the same time talking to an interviewer. The students' performance under this condition was then compared to their performance during a control interview that did not have a concurrent task. Under the condition of reduced processing capacity, the students' conversational skills showed marked impairment. More specifically, they spoke less, showed less syntactic complexity in their language, and said "um" and "ah" significantly more than they did during the control interview. This experimental manipulation reveals just how important certain facets of information processing are likely to be to smooth social performance. They also suggest that those who more ordinarily lack sufficient cognitive resources to meet competing demands might well be expected to experience difficulties making sense of and navigating the interpersonal world. A personal comment from a schizophrenia patient highlights this struggle.

I have trouble concentrating and keeping my mind on one thing at a time, especially when I'm with people. I can hear what they're saying, but I can't keep up with them and make sense of the conversation. I lose my grip on being part of the conversation and drift off. It's not so bad when I'm talking with just one other person, but if I'm trying to tune in to a conversation with several people, things come in too fast and I get lost. It's hard for me to contribute to a conversation when the ideas get blurred. (Liberman, 1982, p. 78)

### **Neurocognition and Social Functioning**

Neurocognition and social functioning are clearly linked. A patient's ability to function in the community, for example, is related to the kind of executive functioning skills that are assessed by tasks such as the Wisconsin Card Sort Test (WCST; Heaton, 1981). In this task the subject is presented with four key cards that show different shapes, colors, and quantities (e.g., a red triangle, three blue squares, two yellow circles). The subject is presented with a card from a deck and asked to match it to a key card according to a matching principle that is not revealed by the tester (e.g., color, number, shape). The only feedback the subject receives is whether the match they have made is correct or incorrect. After the subject has been successful over several trials, the matching principle is abruptly changed, and a formerly correct response is now incorrect. The subject is required to discover the new matching principle and sort the cards according to that until it changes again.

The WCST involves abstract conceptual learning and problem-solving. Although healthy controls can complete the WCST without much problem, patients with schizophrenia often experience difficulties. Moreover, how well patients perform on the WCST is predictive of their functioning in the community. In a meta-analytic review, Green and colleagues (Green et al., 2000) reported a modest relation (r = .23) between card-sorting performance and global social functioning. This association suggests that the kinds of skills tapped by the WCST (executive functioning, concept formation, and cognitive flexibility) are also necessary for good social competence (see also Lysaker et al., 1995; Jaeger & Douglas, 1992).

Memory skills are important, not only for social competence in general (e.g., Goldman et al., 1993), but also for social problem-solving. Poor memory has been related to greater social skill impairments in patients with schizophrenia and schizoaffective disorder but not in patients with mood disorders (Mueser, Bellack, Douglas, & Wade, 1991). Memory has also been found to be linked to the ability to implement solutions in a role-play task (Bellack et al., 1994).

Consistent with these observations, Green et al.'s (2000) review highlighted the role of memory in the functional outcome of patients with schizophrenia. The ability to learn new psychosocial skills (such as might be taught in a rehabilitation program) is predicted by immediate verbal memory. This concerns the ability to acquire, store, and retrieve information for more than a few minutes, as might be required to remember items to purchase on a trip to the supermarket. Secondary verbal memory, which involves the ability to acquire and recall information after a longer delay (e.g., lists of words, stories), is also important. Secondary verbal memory predicts community functioning at the global level; it also predicts both performance on social problem-solving tasks and psychosocial skill acquisition. Overall, however, immediate verbal memory appears to be a little more strongly associated with functional outcome in schizophrenia (r = .40) than is secondary verbal memory is (r = .29).

Another neurocognitive domain that emerges with some frequency in the functional outcome literature concerns *vigilance*. Vigilance, or sustained attention, is a process required to read a book or focus attention while receiving instructions. Green and colleagues (2000) have reported an effect size of r = .20 between vigilance and functional outcome and provided solid support for the association between vigilance and social problem-solving as measured by the AIPSS.

The link between attentional dysfunction and interpersonal deficits is further suggested by results of one of the high-risk projects described earlier. As part of a comprehensive assessment battery, subjects from the New York High Risk Project were tested on a wide array of attentional measures, allowing a single "attentional index" score to be assigned. Consistent with findings discussed earlier for diagnosed patients, children's attention scores were found to be highly correlated with two factors derived from the Personality Disorders Examination (PDE; Loranger et al., 1987) and measured in adulthood. These factors reflected a relative insensitivity to other individuals coupled with an indifference to their feelings, and an avoidance of interpersonal interactions whenever possible (see Cornblatt, et al., 1992). Thus, children who exhibited deficits in their attentional skills were, as adults, less socially sensitive, more socially indifferent, and more socially avoidant. Using data from a second sample in this same project, Dworkin et al. (1993) were further able to demonstrate that childhood attentional dysfunction was predictive of significantly poorer social competence when the children reached adolescence. Thus, even in those simply at high risk for schizophrenia, the link between attention and interpersonal performance is apparent. In children at risk as well as in adults with schizophrenia, deficits in attention are associated with deficits in social competence and social skills.

To summarize, research findings implicate cardsorting performance, immediate memory, secondary verbal memory, and sustained attention/ vigilance in the functional outcomes of patients with schizophrenia. These functional outcomes include global functioning in the community, social problem-solving, and psychosocial skill acquisition. Yet traditional measures of neurocognition leave much of the variability in social functioning unaccounted for (Penn et al., 1997). This has prompted the search for other factors that might lead to greater understanding of the cognitive underpinnings of impaired social functioning in schizophrenia. Of central importance here has been the study of social cognition.

### Social Cognition in Schizophrenia

Social cognition is concerned with the mental operations that underlie the capacity to perceive, interpret, and process social information (Green et al., 2019). It is a broad construct that includes many different abilities. Unlike nonsocial cognition, it concerns stimuli that are personally relevant. Moreover, although social cognition obviously requires nonsocial neurocognitive skills, it also involves other skills (see Couture et al., 2006). These include the ability to perceive and make correct inferences about the emotions of others (emotion processing), the ability to pick up social cues (social knowledge), the ability to understand that others have mental states that differ from one's own and make correct inferences about another person's intentions or beliefs (mentalizing and theory of mind [ToM]), and the ability to use causal attributions to draw conclusions about social events that occur (attributional style). Skills in these domains are considered more proximal to social behavior than the skills traditionally assessed in neurocognitive paradigms. They may also prove to be more amenable to intervention than basic cognitive processes.

#### Emotion Perception

People who have schizophrenia struggle with the kinds of social processing tasks that most of us perform with relative ease. A case in point is emotion perception (see Edwards et al., 2002). Those with the disorder have problems identifying specific emotions in faces. They also have difficulties making judgments about differences in emotional expressiveness-again typically in faces. Compared to controls, the effect sizes associated with these performance deficits in patients with schizophrenia are large in magnitude (d = -0.89 for facial emotion identification; d = -1.09 for differentiation; see Kohler et al., 2010). A subsequent meta-analysis conducted by Savla and colleagues (2013) reported comparable effect sizes of g = 0.89 for emotion perception and g = .89 for emotion processing, which involves understanding emotions, discriminating between different emotions, and managing emotions and emotional reactions.

Patients with schizophrenia are also impaired relative to healthy controls in their ability to recognize emotion being conveyed in speech (e.g., Hooker & Park, 2002). In some instances, they may fail to comment on emotional expression at all (e.g., Cramer et al., 1992; Hellewell, Connell, & Deakin, 1994). Face perception and face affect recognition deficits have also been demonstrated in psychosis-prone, schizotypic individuals (e.g., Poreh et al., 1994). Differences in facial affect recognition between controls and individuals at clinical high risk for psychosis have also been noted, although Barbato et al. (2015) reported that this difference was no longer significant after controlling for age and IQ. This is interesting because several other studies have reported impairments in facial emotion processing in clinical high-risk individuals (e.g., Amminger et al., 2011; Kohler et al., 2014). Going forward, the role of IQ in particular warrants additional consideration in studies of this type.

In clinical high-risk samples, problems with recognizing emotion in faces do not appear to be related to the presence of positive or negative symptoms (Barbato et al., 2015). However, problems with emotion recognition have been linked to both negative symptoms (e.g., Mueser et al., 1996) and positive symptoms (Poole et al., 2000) in patients with the full illness. Nonetheless, in a large sample of patients with schizophrenia (N = 521), the correlations between ability to recognize facial emotions and positive and negative symptoms, although significant, were very small in magnitude (around r =.1; see Maat et al., 2015). Moreover, even when in remission, schizophrenia patients performed worse than healthy controls. Although more remains to be learned, symptoms do not appear to provide a full explanation for the emotion perception difficulties characteristic of schizophrenia.

Finally, as might be expected, there is a link between emotion recognition problems and interpersonal functioning. Mueser et al. (1996) noted strong associations between schizophrenia patients' abilities to identify facial emotions from photographs and nurses' ratings of those patients' social skills in a hospital setting. A similar correlation between better performance on tasks of emotion recognition and better social functioning has also been reported by other researchers (e.g., Hooker & Park, 2002; Ihnen et al., 1998; Poole et al., 2000). Such findings highlight how integral the ability to identify and distinguish different emotions is for successful social adjustment.

#### Social Perception and Knowledge

Being successful in interpersonal situations requires social knowledge. It is difficult to imagine

361

how a person lacking a basic understanding of the structure and rules of social interactions could participate fluidly and competently in social exchange. Given the interpersonal difficulties that are associated with schizophrenia, it is not surprising that people with this disorder often perform poorly on tests that measure social perception or social knowledge.

In an interesting early study, Cutting and Murphy (1990) gave patients multiple choice questions that were designed to tap two knowledge domains. The first concerned practical knowledge (e.g., "Why is it not safe to drink tap water in some countries?"). The second assessed knowledge in a more social domain (e.g., "How would you tell a friend politely that they had stayed too long?"). For this latter question, the answer choices included "There's no more coffee left," or "You'd better go. I'm fed up with you staying too long," or (correct answer) "Excuse me. I've got an appointment with a friend." Compared with those diagnosed with bipolar disorder or major depression, the patients with schizophrenia showed significant impairment on the social knowledge test. Interestingly, the nonsocial knowledge test did not discriminate between the patients with schizophrenia and bipolar disorder, although both patient groups scored significantly worse than the depressed patients.

Social knowledge can also be assessed in other ways. The Schema Component Sequencing Task (SCST; Corrigan & Addis, 1995) contains 12 sets of cards. Each set contains 5-8 cards that describe the component actions involved in different social situations (e.g., going shopping, getting a job). The person completing the test is presented with the cards in a mixed-up order and then asked to arrange the cards in the order that makes sense for the successful completion of the social task. Compared to nonclinical controls, patients with schizophrenia take longer to sort the cards and are less likely to put them in the correct order (Pinkham & Penn, 2006). Moreover, in the study just described, sorting time and accuracy on the SCST were highly correlated with interpersonal skill measured during a conversational role play. As Pinkham and Penn (2006) noted, "to interact effectively, one needs to know the rules that govern social settings" (p. 176).

Meta-analysis suggests that the mean effect size for problems with social perception and social knowledge in those with schizophrenia is large for social perception (g = 1.04) and medium (g = .54) for social knowledge (Savla et al., 2013). Social perception is also compromised in those at clinical high risk and is unrelated to symptoms and IQ (Barbato et al., 2015; Piskulic et al., 2016). This suggests that problems understanding social rules and social relationships may be a key feature of vulnerability to psychosis.

### Theory of Mind and Mentalization

Frith (1992) was the first to suggest that people with schizophrenia might have difficulties understanding the mental states of others, a skill that he referred to as "theory of mind." Research since then has confirmed that schizophrenia patients do indeed experience problems with metacognition. This is apparent on tasks that require an understanding of the beliefs or intentions of others (ToM tasks) as well as on tasks that require evaluations of the affective states of others (often referred to as mentalization).

In an early study, Corcoran, Mercer and Frith (1995) explored how well schizophrenia patients and patients with other psychiatric conditions were able to pick up hints made by others. Patients with schizophrenia, depressed or anxious psychiatric controls, and psychiatrically healthy controls were given brief scenarios that featured interactions between two characters. At the end of each scenario, one of the characters dropped a very obvious hint (e.g., "I want to wear that blue shirt but it's creased"). Subjects were then asked to say what the character meant and what he or she was hinting at. If the subject failed to get the hint, an even more obvious cue was given (e.g., "It's in the ironing basket"). Consistent with a problem in metacognition, the schizophrenia patients did poorly on this task, scoring significantly lower than those in the two control groups. Findings such as this again bring to mind the earlier comment from the exwife of "Jon": "It was as though some strange deficiency prevented him from understanding some things that seem perfectly obvious to most people" (Anonymous, 1994).

A more advanced metacognitive test is the Faux Pas Recognition test (Baron-Cohen et al., 1999). Developed for use in autism research, this test requires the experimenter to read stories to the research participant and then ask that person whether someone in the story said something that they should not have said. The research participant is also asked additional questions so that the experimenter can confirm that they understand why the faux pas comment should not have been made and why the person who made the faux pas comment might have said it. Compared to healthy controls, patients with schizophrenia perform poorly on the Faux Pas test (Hooker et al., 2011; Zhu et al., 2007). Moreover, although impaired performance on this test is correlated with worse social functioning, faux pas recognition appears to be unrelated to the presence of clinical symptoms.

In addition to being characteristic of patients with chronic schizophrenia, ToM and mentalization deficits can also be seen in first-episode patients (see Bora & Pantelis, 2013; Bora, Yücel & Pantelis, 2009a, for meta-analyses). In each case the effect sizes are large relative to healthy controls. The effect sizes associated with impairments in metacognition are also remarkably similar across the first episode (d = -1.0) and chronic (d = -1.1) patient groups. These findings suggest that such difficulties probably do not result from factors such as illness progression or long-term medication use. It is also unlikely that problems in metacognition result from the presence of severe symptoms because they have been noted in remitted patients (Herold et al., 2002). Although the effect sizes are much smaller, impairments in metacognition can even be detected in first-degree relatives of patients with schizophrenia as well as in people at clinical high risk for the disorder (Bora & Pantelis, 2013; Janssen et al., 2003). For example, Barbato et al. (2015) observed problems detecting sarcasm in a large sample of clinical high-risk individuals-problems that were independent of age or IQ. Taken together, these findings provide further support for the independence of metacognition impairments and clinical state and again suggest that difficulties in this domain of social cognition may be a vulnerability marker.

It warrants mention that ToM difficulties and problems with mentalization are not specific to schizophrenia. They are also found in patients with autism and those with bipolar disorder (Bora, Yücel & Pantelis, 2009b). For example, Donahoe and colleagues (2012) reported that, relative to healthy controls, patients with bipolar disorder and patients with schizophrenia performed equally poorly on the Reading the Mind in the Eyes test (Baron-Cohen et al., 2001). This requires participants to identify the emotion being depicted when only the eye region of a given face is shown. However, on another ToM task (hinting task), the performance of the patients with bipolar disorder was intermediate between the performance of the controls and the performance of the patients with schizophrenia. In other words, the patients with bipolar disorder were much less impaired. The differences just reported also remained when IQ and symptom severity were statistically controlled. Findings such as these suggest that the decoding of mental state (eyes task) is impaired in both bipolar disorder and schizophrenia, although the former group of patients may have more mild impairments in the area of mental state reasoning (hinting task). They are also consistent with the idea that, rather than being entirely distinct disorders, schizophrenia and bipolar disorder may lie on a spectrum of neurodevelopmental/affective pathology, with bipolar disorder involving less cognitive impairment and schizophrenia reflecting more neurodevelopmental compromise and more cognitive difficulties (Craddock & Owen, 2010).

### Attributional Style

Another domain of social cognition concerns how people tend to explain the causes of events that happen in their lives. This is referred to as attributional style (AS). Within schizophrenia, it has been demonstrated that patients who have persecutory delusions or paranoid ideation tend to blame other people, rather than the situation itself, when there is a negative circumstance that demands an explanation (see Bentall et al., 2001). For example, if we encounter a person who acts in an unfriendly way toward us, we might make an attribution that they are rude. On the other hand, if we subsequently learn that they received bad news just before we met them, we would likely correct our initial impression. People with persecutory delusions, however, typically fail to update or modify their initial impressions, retaining the blaming attribution. A strong need for early closure, impairments in cognitive flexibility, and deficits in mentalizing and ToM are possible factors that could prevent people with schizophrenia from countering natural biases in attribution style (see Couture et al., 2006).

Attributional bias is the least well studied domain of social cognition. However, meta-analysis suggests that the differences between patients with schizophrenia and healthy comparison samples are very small (Savla et al., 2013). As such, this aspect of cognition may play a less prominent role in our understanding of social adjustment in schizophrenia.

In summary, across a wide range of socialcognitive tasks, schizophrenia patients appear to perform poorly. Not only do they have difficulties with respect to reading emotional cues, but they also appear to be less socially facile. They fail to spot the kinds of subtle (or not so subtle) social hints that most of us detect without difficulty. Compounding these problems, they also have impairments in gaze perception, perceiving a face with an averted gaze as making eye contact with them (Tso et al., 2012; Hooker & Park, 2005). Since the days of Kraepelin we have known that navigating the social world presents serious challenges for those with schizophrenia. As a result of research efforts spanning several decades, we now know much more about the behavioral components of social functioning that are most severely compromised.

## Is Social Cognition a Better Predictor of Social Behavior Than Neurocognition?

A considerable proportion of the variance in social cognition is explained by nonsocial cognition (Vauth et al., 2004); intact cognitive functions are clearly required for a person to perform well on tests of social cognition. Yet evidence suggests that neurocognition and social cognition are largely distinct constructs (Allen et al., 2007; Sergi et al., 2007). This has prompted researchers to examine how well measure of neurocognition and social cognition predict overall social functioning.

In an early consideration of this issue Corrigan and Toomey (1995) administered a battery of nonsocial cognition measures to a sample of patients with schizophrenia and schizoaffective disorder. The measures of nonsocial cognition included a measure of vigilance (the degraded stimulus form of the Continuous Performance Test), a measure of immediate memory (Digit Span Distractibility Task), a measure of secondary memory (the Rey Auditory Learning Test), and a measure of conceptual flexibility (the WCST). In addition, a measure of social cognition, the Social Cue Recognition Test (SCRT), was also administered. The SCRT consisted of eight videotaped vignettes that featured two or three people interacting in a social situation. After viewing the vignettes, subjects were asked to answer a series of true-false questions about the interpersonal cues they saw in the interactions. The measures of nonsocial and social cognition were then correlated with performance on a measure of interpersonal problem-solving, the AIPSS. Social cue sensitivity was found to be related to receiving (detecting a problem), processing (coming up with a solution), and sending (role-playing the solution) skills. In contrast, none of the nonsocial cognitive variables predicted performance on the AIPSS. These findings suggested that measures of social cognition were more strongly associated with interpersonal problem-solving skills than were measures of nonsocial cognition.

364 | MAJOR CLINICAL SYNDROMES

In a subsequent study Pinkham and Penn (2006) administered several tests of neurocognition (assessing overall intellectual functioning, immediate memory, and executive functioning) and several tests of social cognition (assessing emotion recognition, social knowledge, and ToM) to outpatients with schizophrenia as well as to nonclinical controls. These variables were then used to predict interpersonal skill as measured in a role-play test that involved talking to a confederate. For the patients with schizophrenia, the measures of social cognition accounted for almost twice as much variance in interpersonal skill as did the measures of neurocognition.

As this and other studies illustrate, measures of social cognition contribute additional variance to functional outcome in schizophrenia over that contributed by measures of neurocognition (see also Brekke et al., 2005; Sergi et al., 2006). Further support for this conclusion comes from two recent meta-analyses (Fett et al., 2011; Halverson et al., 2019). Using data from 166 studies involving 12,868 participants with nonaffective psychosis, Halverson and colleagues (2019) reported a sampleweighted average effect size of 0.21 between neurocognition and measures of functional outcome, with the largest effect size (.33) being seen for the relationship between neurocognition and social skills. For social cognition (considered as an overall summary variable), the effect size was slightly higher (.24) with the largest effect being noted for the relationship between ToM and social skills (effect size = .38). Consistent with this, Maat, Fett, and Derks (2012) have observed that performance on the hinting task (also a ToM measure) was the best predictor of quality of life in a large sample of patients with schizophrenia. Overall, there is good support for the idea that social cognition is a critical mediator in the link between neurocognition and social functioning in schizophrenia (see Schmidt et al., 2011; Halverson et al., 2019). Neurocognitive impairments may lead to problems with social cognition which in turn exert a negative influence on social functioning.

More recently, researchers have begun to consider whether the negative symptoms so closely linked with social impairment represent a behavioral manifestation of social cognition. Some data suggest that certain facets of social cognition are associated with specific negative symptoms; other data suggest that fundamental abnormalities may affect social cognition broadly and result in negative symptoms. Reflecting this, an integrated model has now been proposed to capture how these associations may emerge (Pelletier-Baldelli & Holt, 2020). Work of this kind demonstrates how social cognition, compared to neurocognition, is increasingly becoming a primary area of focus in the investigation of social deficits in schizophrenia.

## Neural Basis of Altered Social Cognition in Schizophrenia

Neuroscientific methods are now being used to illuminate how neural alterations relate to impairments in social cognition. Here, we consider some representative studies and discuss findings across various stages of illness.

One active area of interest concerns the neurobiological basis of ToM, or mentalization. As we noted earlier, ToM involves the ability to perspective-take, make inferences about, and attribute mental states to the self and to others. In healthy controls, brain regions such as the temporal pole, temporoparietal junction, precuneus, and medial prefrontal cortex are involved in these tasks. People with schizophrenia generally show aberrant patterns of activation in these regions when engaged in ToM tasks, although such differences are not always consistent across studies. Most studies report hypoactivation within mentalization systems, with hypoactivation being related to poor task performance. However, other studies report hyperactivity of these regions in schizophrenia and comparable task performance between groups. Quite possibly, individuals with schizophrenia require higher levels of activation to achieve the same mentalization proficiency (Green et al., 2015). This interpretation is complemented by structural findings of ventromedial prefrontal cortex gray matter reduction in schizophrenia, which has been found to be associated with poorer performance on task-based, self-reported, and interview-rated ToM assessments (Hooker et al., 2011). Aberrant structure and function in these regions related to impaired mentalization likely contributes to the social difficulties experienced by people with schizophrenia.

It should be noted that not all processes may be impacted. Affect-sharing is a process that describes the functional correspondence between an individual observing another person with an emotional expression and the activation of the observer's own emotion-related brain regions, including dorsal anterior cingulate cortex and anterior insula. This aspect of social cognition appears to be intact in schizophrenia (Horan et al., 2014). Aspects of ToM like self-reflection have also been investigated in relatives of patients with schizophrenia, providing insights into potential biological vulnerabilities. In a study of self-reflection, compared to controls, first-degree relatives of patients with schizophrenia showed less activation in posterior cingulate cortex and superior temporal gyrus—regions known to be involved in self and other processing (Brent et al., 2014). Furthermore, reduced activation was associated with higher levels of subclinical delusional ideation. This suggests that functional alterations in this circuitry are associated with genetic liability for schizophrenia and may also confer vulnerability to delusional thinking.

Many domains of social cognition are often at least partially dependent on higher level knowledge-knowledge that may itself be impaired in schizophrenia. Another approach is studying lower level, nonverbal processes that may underlie social cognitive processes and support social behavior. Certain perceptual social cue processes, like affective face perception and affective vocal prosody, are prime examples. People with schizophrenia generally demonstrate hypoactivation of relevant regions during such processing, showing reduced activation in the fusiform face area and amygdala during affective face processing and reduced activation in superior temporal gyrus and inferior frontal gyrus during affective voice processing. In contrast, patients also show hyperactivation in regions not typically associated with face perception during affective face processing (Green et al., 2015). Relatedly, a meta-analysis demonstrated that patients with schizophrenia exhibit increased amygdala activation in response to neutral, rather than aversive emotional stimuli (Anticevic et al., 2012). This may have important implications for the perception of neutral social cues.

Another example of a crucial lower-level process is "personal space," or the preferred distance an individual maintains when interacting with another individual (Hayduk, 1983). Personal space is an important communicative tool; greater proximity promotes social affiliation (Kahn & McGaughey, 1977), and greater distancing, while offering more protection against physical threat, can also convey mistrust (Lourenco et al., 2011). Personal space has long been known to be larger and more inflexible in schizophrenia (Horowitz et al., 1964), and recent work has investigated the possibility that neural alterations might be implicated in this. Holt and colleagues (2015) focused on a region of a frontoparietal network involved in the sensory monitoring and guiding of behaviors occurring in personal space. In schizophrenia patients, one region of this network, called the dorsal intraparietal sulcus, was found to be hyperresponsive to social stimuli appearing to intrude on personal space. Patients showed the expected finding of larger personal space sizes. Larger personal space sizes were also associated with neural hyperresponsivity as well as being correlated with more negative symptoms. Alterations of neural circuitry involved in preferred social spacing may contribute to changes in low-level behavioral social communication that exacerbate interpersonal difficulties in schizophrenia.

The default mode network is a large-scale brain network known to be broadly involved in selfreferential thinking and self and other processing, in addition to more specific processes such as ToM, mentalization, emotion recognition, and autobiographical memory. Adults with schizophrenia show increased connectivity within the default mode network, although there are mixed findings of increased and decreased connectivity between the default mode network and other networks. These disruptions in adults are associated with poorer cognitive and social functioning (Hu et al., 2017). There is also evidence for neural alterations in the resting-state functional connectivity of the default mode network in adolescents with early-onset psychosis (Nair et al., 2020). Moreover, these neural alterations are generally consistent with the overall pattern found in adults. This suggests that similar changes may characterize the brain at the onset of illness, regardless of age.

Social deficits are often early warning signs of schizophrenia even before onset of illness (Kimoto et al., 2019), suggesting that neural changes likely precede the onset of full-blown psychotic symptoms. As we have noted earlier, research with samples of individuals at clinical high risk for psychosis can be informative here. For example, in the schizophrenia literature, patients show gray matter volume reductions in neural regions supporting cognition, and this reduction in gray matter volume predicts worse social functioning (Hooker et al., 2011). Other work has reported similar, albeit less severe gray matter volume reductions in clinical high-risk samples (Fusar-Poli et al., 2012). Compared to healthy controls, clinical high-risk individuals show reduced gray matter volume in parahippocampal gyrus, postcentral gyrus, and anterior cingulate cortex (Lincoln & Hooker, 2014). Volume reductions in these latter two regions were also associated with self-reported social impairment. The finding that

structural abnormalities in regions associated with social and emotional processing were related to social functioning deficits is interesting, given that the majority of clinical high-risk individuals do not convert to psychotic illness. It suggests that findings such as these are but one element of a broader constellation of evolving neural, psychological, and functional declines on the trajectory toward psychosis.

Relevant to this point, other social cognitive processes such as mental simulation appear to be intact in clinical high-risk samples. Mental simulation is the process of generating internal representations of another's thoughts and feelings, a part of ToM. Lincoln and colleagues (2020) examined neural correlates of mental simulation of pain, asking individuals to watch videos of another person experiencing pain and then to simulate the observed situation on themselves. Across clinical high-risk individuals and healthy controls, greater activation in somatosensory cortex was associated with greater rates of positive social experiences and affective empathy. Not only was this process not compromised in clinical highrisk individuals (at least in somatosensory cortex), but these findings also suggest that the neural mechanisms underlying simulation are important for social behavior and can help explain individual variability. Such work with at-risk individuals highlights how including clinical high-risk populations in research expands our knowledge across stages of illness.

## Motivational Processes and Social Functioning

To this point we have described some of the social difficulties characteristic of people with schizophrenia (or those at increased risk of developing schizophrenia) and considered the neural systems that may support effective social competence. Unaddressed thus far, however, is the role of social motivation-the internal drive to connect with others and form meaningful relationships. Initially, it was believed that diminished interest or pleasure in social interactions (the negative symptom known as social anhedonia) accounted for the social isolation and poorer social functioning characteristic of schizophrenia (Kwapil, 1998). However, people with schizophrenia express a need for connection through their choices of activities (Gard et al., 2014). They also regard improved social functioning as an important treatment goal (Shumway et al., 2003). This suggests that something other than reduced interest in social engagement may be playing a role, leading to a focus more specifically on motivation.

At a general and global level, motivation has been shown to mediate the link between neurocognition, social cognition, and functional outcome including social behavior (Gard et al., 2009). Yet motivation is a multifaceted construct that comprises several distinct processes. These include hedonic experience (the ability of a person to like or enjoy something they experience), incentive salience (how rewarding the event is expected to be and how much the person wants the experience), and effort computation and expenditure (which involves integrating information about the costs and benefits of seeking a potentially rewarding outcome; see Barch & Dowd, 2010). Difficulties in any or all of these domains are likely to compromise social behavior and impair social functioning.

Basic behavioral neuroscience has distinguished between two components of pleasure: "liking" versus "wanting." "Liking" describes reactive feelings of pleasure to a stimulus in the moment. It is often referred to as hedonic experience. "Wanting," on the other hand, refers to the anticipation of pleasure that could be obtained from a stimulus in the future. Because such a stimulus is marked as relevant, or salient to the individual, "wanting" is otherwise referred to as incentive salience. These processes are supported by different neural pathways in the brain, where "liking" is associated with distributed hotspot patterns of activation across the brain and the serotonin and opioid systems, whereas "wanting" is associated with neural structures such as the striatum and the dopamine system (Berridge & Robinson, 1998, 2016).

People with schizophrenia demonstrate intact hedonics. In other words, they report similar levels of pleasure in the moment (consummatory pleasure, "liking") from daily activities as do healthy controls. On the other hand, people with schizophrenia report less expected pleasure from future activities (anticipatory pleasure, "wanting"). What this suggests is that the deficit may be specific to incentive salience (Gard et al., 2007).

Incentive salience is a core mechanism in reward learning whereby individuals learn to predict which stimuli are associated with rewards and respond behaviorally to obtain those rewards. Dopamine plays a mediating role in this. Reward learning deficits have been demonstrated in schizophrenia, with impairments in learning associated with the receiving but not the removal of reward; these alterations are also correlated with negative symptom severity (Reinen et al., 2014).

The assessment of the effort involved to obtain rewards and the cost-benefit analysis of that effort

expenditure are another set of related processes modulated by dopamine (Salamone et al., 2007) and altered in schizophrenia. At a behavioral level, people with schizophrenia show less of an increase in effort when higher magnitude or higher probability rewards are available. This is suggestive of abnormalities in effort-cost computations. These impairments are correlated with negative symptom severity and with community as well as work functioning (Barch et al., 2014; Gold et al., 2013). Patients also show inaccuracies in estimating the effort required to obtain goals and report engaging in less effortful activities and setting less effortful goals; this is again related to functioning (Gard et al., 2014).

Effort-based decision-making involves dopamine and brain regions such as the anterior cingulate cortex, ventral striatum, and amygdala (Culbreth et al., 2018; Treadway & Zald, 2011). Neurobiological differences in these regions may contribute to impaired effort computation and expenditure. Work examining this question in schizophrenia is still preliminary. However, altered functioning in the cingulate gyrus, ventral striatum, and dorsolateral prefrontal cortex appears to be implicated (Culbreth et al., 2018, 2020; Huang et al., 2016).

## Social Motivation: An Emerging Research Direction

Research is providing us with increased knowledge of the components involved in global motivation. However, social interactions are qualitatively unique. Not only do they present opportunities for social reward (i.e., acceptance, connection) but they also bring with them the possibility of social punishment (i.e., rejection). Emerging work in these areas has the potential to deepen our understanding of factors involved in social motivation more specifically.

In healthy controls, the neurobiological representations may differ across social (i.e., faces) versus nonsocial (i.e., monetary) rewards and punishments, across social rewards versus social punishments more generally, and for anticipation versus consummation of rewards and punishments (Fulford et al., 2018). Neural regions associated with reward/ affective, mentalizing, and mirror neuron systems have all been shown to be involved in social reward and punishment processing and have recently been proposed as a "social interaction network" (Redcay & Schilbach, 2019). A recent systematic review of the small number of studies on social reward and punishment in schizophrenia-spectrum disorders has highlighted weaker modulation of brain activity of regions within this social interaction network, including amygdala, insula, and prefrontal, cingulate, and striatal regions (Mow et al., 2020).

Effective social functioning involves the simultaneous avoidance of social punishment and pursual of social reward in an optimal way; relative sensitivity to different aspects of social reward is likely to modulate social motivation. As we have already noted, one factor contributing to decreased social motivation in schizophrenia may be reduced sensitivity to reward. While playing a cooperative social game, male patients with nonaffective psychosis showed blunted reward-related activation in the caudate nucleus relative to healthy control males (Gromann et al., 2013). Relatedly, despite showing no impairment in the recognition of emotion, patients with schizophrenia show decreased tendencies to approach happy faces (Radke et al., 2015). Other work has found that patients with schizophrenia are faster to avoid happy faces (de la Asuncion et al., 2015). Reduced reward sensitivity and heightened rejection sensitivity may be playing key roles here.

Unlike the specific deficit in general anticipatory pleasure, people with schizophrenia may show diminished anticipatory as well as consummatory pleasure in the social domain. Compared to healthy controls, patients report less anticipated pleasure about participating in social interactions (Engel et al., 2016). They also report less pleasure after engaging with smiling conversational partners (Campellone & Kring, 2018). Importantly, no work has yet examined the impact of social punishment on subsequent social reward anticipation in schizophrenia. Also currently lacking is a consideration of how people with schizophrenia make decisions about social engagement. Social interactions require effort. Although they have the potential to be rewarding, they can also involve social costs including the risk of rejection. Social decisionmaking thus involves weighing the potential for both social reward and social punishment; altered sensitivity to either or both of these aspects of social interactions may differentially impact effort calculations and behavioral choices.

Social interactions are dynamic and complex and are often ambiguous in terms of the potential for rewarding versus punishing outcomes (FeldmanHall & Shenhay, 2019). Research thus far has largely neglected the dynamic, interactive nature of reward and punishment in a social setting and how this interplay may influence social motivational processes and shape social behavior. This paves the way for a new frontier of research moving forward, especially work that examines such questions in ecologically valid, creative ways. Ecological momentary assessment (EMA) is emerging as one approach for collecting data in real time, permitting investigations of the time course of real-world social interactions (Fulford et al., 2018). Elucidating such nuances holds great promise in addressing the complexities of social motivation alterations and their impact on social functioning in schizophrenia.

# The Social Consequences of Schizophrenia Patients' Social Difficulties

Our focus so far has been on the interpersonal functioning of patients diagnosed with schizophrenia. Although the nature of the social difficulties observed tends to vary from study to study, one conclusion can be safely drawn. Schizophrenia patients are less skilled and less fluid in complex interpersonal situations than are people in the general population. In many cases, they are also more impaired than are patients with other severe psychiatric conditions.

Blanchard and Panzarella (1998) have speculated on how affective flattening, one characteristic symptom of schizophrenia, may disrupt interpersonal functioning. They hypothesized that diminished emotional expressiveness in the person with schizophrenia may be interpreted by others as a lack of feeling. In other words, family, friends, and coworkers may interpret blunted affect as apathy or insensitivity. To the extent that this is true, it might be expected to damage interpersonal relations. Indeed, Blanchard and Panzarella (1998) reported findings that highlight how readily observers misinterpret the feelings of someone with schizophrenia based on facial cues.

Misinterpretation does, in fact, appear to be the most accurate description of what happens. There is no evidence that the affective flattening that we see in schizophrenia patients represents a lack of true emotional experiences. Patients with schizophrenia are less expressive facially than are controls when they view emotional film clips or engage in social role-play. However, they report experiencing emotion at equal or greater levels (Aghevli et al., 2003; Berenbaum & Oltmans, 1992; Kring et al., 1993). Indeed, in some studies, schizophrenia patients appear to be more aroused (as measured by skin conductance) by emotional stimuli than are healthy controls (Kring & Neale, 1996). Thus, there appears to be a lack of congruence between the expressive and the subjective experience response systems of emotion in schizophrenia. The lack of affective expression among schizophrenic patients may not be due to an underlying experiential deficiency, but rather may represent a failure to express the emotions being experienced in a manner detectable by others.

This may be one reason why interacting with a person with schizophrenia does not seem to be easy for the average person. Earlier, we described the results of a study in which female interviewers interacted with male college students who scored high on two scales associated with increased risk for schizophrenia (Zborowski & Garske, 1993). Even though the male students only showed schizotypic traits, interacting with them resulted in more anger, increased anxiety, and less interest on the part of the female interviewers than did interactions with males who did not exhibit these schizotypic traits.

In another study, Nisenson, Berenbaum, and Good (2001) had student research assistants form brief friendships with schizophrenia patients at a local inpatient psychiatric facility. Although the students were specifically selected because of their congenial dispositions, over the course of the 2 weeks of the study, the amount of negativity that the students expressed toward the patients increased significantly. Findings such as these lend credence to the idea that interacting with patients with schizophrenia may present a considerable social challenge. This is especially unfortunate because many individuals, even those in the early stage of the illness, report feelings of loneliness.

#### Interpersonal Stress and the Onset of Schizophrenia

Social interaction is a two-way street. People with schizophrenia have social problems that tend to make those with whom they interact feel uncomfortable. However, in the other direction, schizophrenia patients are also sensitive to the social environments in which they live.

It is widely accepted that problems in the family environment do not cause schizophrenia in the absence of any genetic diathesis for the disorder. However, people at high genetic risk for schizophrenia may be especially sensitive to high levels of family disorganization compared to those at low genetic risk. Over the course of a longitudinal study, Tienari and his colleagues (2004) collected data on the psychiatric outcomes of children born to mothers with schizophrenia but adopted at an early age. A comparison sample consisted of children who were adopted early in life but who had no specific genetic risk for schizophrenia. After observing, testing, and interviewing the adoptive parents of the children, the researchers made ratings of the family environment. They then looked at the number of children who went on to develop schizophrenia or schizophrenia spectrum disorders (less severe psychotic disorders that are thought to be related to schizophrenia) in adulthood.

The results were quite striking. For the children at low genetic risk, being raised in a healthy or disorganized family environment made little difference to their eventual psychiatric outcomes. In both cases, about 4% of the children went on to develop schizophrenia or schizophrenia spectrum disorders. For the children who were at high genetic risk for schizophrenia, however, this was not the case. When they were raised in a healthy family environment, the rates of schizophrenia in the high genetic risk group were comparable to those of the low risk group (4.4%). However, when they were raised in an aversive family environment, 18.6% of the highrisk children went on the develop schizophrenia or schizophrenia-related illnesses as adults.

Tienari et al.'s findings highlight the importance of gene–environment interaction in the development of schizophrenia. More specifically, they suggest that genetic factors may play a role in determining how susceptible to the possible adverse effects of dysfunctional family environments each of us may be. Perhaps most importantly, however, these findings illustrate the protective effects that can result from living in a healthy family environment, even for those at high genetic risk.

The family environment can also play a powerful role for individuals at clinical high risk for psychosis. Thompson and colleagues (2019) found that family functioning (family communication, cohesion, problem-solving, and support) moderated the association between positive symptoms and social and role functioning in a clinical high-risk sample, such that this relationship held for those with low family functioning. In other words, family environments characterized by greater levels of communication, cohesion, problem-solving, and support may serve as a buffer against the link between positive symptoms and poorer social and role functioning in this population.

#### Interpersonal Stress and Relapse

Decades ago, Brown and his colleagues noticed that the social environment into which patients

with schizophrenia were discharged after they left the hospital was significantly associated with how well they fared psychiatrically over the next several months (Brown et al., 1962). In later work, Brown and his co-workers attempted to quantify the aspects of the family environment that were associated with patients relapsing or remaining well after a hospital stay. The result of these efforts was the construct of *expressed emotion* (EE).

EE reflects the extent to which the relatives of a psychiatric patient talk about that patient in a critical, hostile, or emotionally overinvolved way during an interview conducted in the patient's absence. This interview, which is termed the Camberwell Family Interview (CFI), asks the relative a series of semi-structured, open-ended questions about the patient's previous and current psychiatric difficulties. Most important, it provides the family member with an opportunity to talk about the index patient's functioning in the months prior to the hospitalization.

A series of studies conducted all over the world have established that high EE (especially high criticism) is a robust and reliable predictor of early relapse in schizophrenia (see Butzlaff & Hooley, 1998). Patients who return home to live with relatives who are rated as being high in EE have relapse rates that are more than double those of patients who return home to live with low EE relatives (e.g., 50–60% vs. 20–30%). Interestingly, this association is not unique to schizophrenia. EE has also been shown to predict poor outcome in patients with mood disorders, anxiety disorders, eating disorders, and substance abuse disorders (see Hooley, 2007, for a review).

Although the prevalence of high EE in families varies across cultures (Jenkins & Karno, 1992), high EE tends to be normative in Europe and the United States. It has been measured not only in the relatives of psychiatric patients but also in psychiatric staff involved in supervising and treating patients (Berry et al., 2011). In many cases, high levels of EE may be a natural response to the stress of prolonged caretaking and continued exposure to psychopathology. EE levels do seem to increase in families where patients have been ill for longer periods of time (Hooley & Richters, 1995). Nisenson et al.'s (2001) findings of increased negativity in the students who visited schizophrenia inpatients also lends credence to this notion that criticism and hostility might develop as a consequence of continued interaction with a challenging patient.

High EE may also be a reaction to the symptoms (or to the social or behavioral disturbances) of the patients themselves. For example, spouses of psychiatric patients who have more negative symptoms are less happy with their relationships than are spouses who are married to patients with more positive symptoms (Hooley et al., 1987). This may be because negative symptoms, as we have discussed earlier, are associated with more interpersonal deficits on the part of patients, and these interpersonal difficulties may generate tension within a marital relationship. Another possibility is that spouses who live with patients who have more pronounced positive symptoms are, because of the unusual nature of the symptoms, more likely to view such patients as being psychiatrically ill and thus remain more sympathetic and understanding (Hooley & Gotlib, 2000). In contrast, one unfortunate consequence of many negative symptoms (e.g., apathy or poor self-care) is that they may not readily be attributed to severe mental illness. Families may thus be more likely to blame patients for negative symptoms in a way that they would not blame them for positive symptoms. Several empirical studies have now provided data consistent with this attributional model (see Barrowclough & Hooley, 2003, for a review). Moreover, experience suggests that family members are much more likely to complain about patients' generally low levels of activity and lack of cleanliness than they are to complain about delusions or hallucinations.

Finally, characteristics of the relatives themselves may also be important. Hooley (1998) has shown that relatives who have a more internally based locus of control make more critical remarks about patients than do relatives with a more external locus of control. Personality characteristics such as flexibility and tolerance also appear to be negatively related to high EE attitudes (Hooley & Hiller, 2000). Certain personality characteristics may thus render relatives more or less likely to become high EE when challenged by the stress of coping with psychopathology in a loved one.

How might these observations be integrated? Taken together, these findings are consistent with the notion that high EE relatives are people who (not unreasonably) find atypical behavior difficult to accept. Perhaps because they believe that patients are capable of controlling certain aspects of their symptoms or problem behaviors, these relatives then make efforts to encourage patients to behave differently. These efforts may be well-intentioned and designed to help patients function at a higher level. In some cases, these interventions may be helpful and well-received by patients. In other cases, patients may be unable (or possibly unwilling) to change in the way that the relative wants. The relative's level of frustration may rise, tolerance may decrease, and, over time, critical attitudes (and later, hostility) may be the inevitable result. According to this formulation, relatives' characteristics and patient factors interact over time to produce high levels of tension in the household and create stress for relative and patient alike.

Precisely why patients are more likely to relapse in the face of high EE is still an unanswered question. However, within a diathesis-stress framework, EE is generally assumed to be a form of psychosocial stress. In a series of studies Hooley and colleagues have used functional magnetic resonance imaging (fMRI) to explore what happens in the brains of people who are emotionally healthy and people who are vulnerable to psychopathology when they are directly exposed to personal criticisms (Hooley et al., 2005, 2009, 2012). Overall, the findings suggest that, compared to healthy controls, those with a vulnerability to psychopathology show less engagement of prefrontal areas (e.g., dorsolateral prefrontal cortex) and more activation in limbic regions (e.g., amygdala) during exposure to criticism. Both of these are key brain regions with regard to emotion processing. They are also brain areas implicated in many forms of psychopathology. Current thinking is that criticism from family members may be problematic because it challenges some of the neural circuitry involved in the regulation of emotions.

#### Psychosocial Approaches to Treatment

Schizophrenia is a disorder with strong biological underpinnings. Yet even when medications result in symptomatic improvement, social deficits remain (Bellack et al., 2004). This speaks to the importance of psychosocial treatments (Mueser et al., 2013). Although no strategy alone is sufficient to treat schizophrenia, as Bellack and Mueser (1993) have noted, "psychosocial interventions can play a critical role in a comprehensive intervention program and are probably necessary components if treatment is to improve the patient's overall level of functioning, quality of life, and compliance with prescribed treatments" (p. 318).

Developed in the 1970s, one of the most frequently used treatments aimed at the correction of interpersonal deficits in schizophrenia involves *social skills training* (SST). SST programs are designed to teach patients a wide variety of interpersonal skills. These may range from very basic behavioral skills (e.g., eye contact or turn-taking) to more elaborate sequences of behaviors such as those involved in being assertive. In SST, complex sequences of social behaviors, like making friends or interviewing for a job, are broken down into their component parts. These parts are then further reduced to more basic elements. After being first taught by instruction and modeling to perform the component elements, patients then learn to combine them in a more fluid manner through further instruction coupled with reinforcement and feedback.

Meta-analytic reviews support the efficacy of social skills training for improving social competence. Pfammatter, Junghan, and Brenner (2006) reported that social skills training resulted in posttreatment improvements in social skill acquisition (d= .77) and assertiveness (d = .43) as well as in social functioning (d = .39). Improvements in skill acquisition (d = .52) and social functioning (d = .32) were also apparent in follow-up studies. Importantly, rates of rehospitalization were reduced (d = .48). A later review of 23 randomized controlled trials by Kurtz and Mueser (2008) also showed that skills training had beneficial effects on social and daily living skills (d = .52) as well as community functioning (d = 0.52). Benefits to negative symptoms (d = .40)and on relapse rates (d = .23) were also apparent. The benefits of social skills training for negative symptoms were further highlighted in the meta-analysis conducted by Turner and colleagues (2018).

Given the neurocognitive deficits associated with schizophrenia, cognitive remediation therapy is also an appealing intervention strategy. Studies in this area often involve repeated practice on cognitive tasks, or the learning of compensatory strategies (e.g., Wykes et al., 2007). The results overall appear to be positive. Cognitive remediation is associated with post-treatment improvements in attention (d= .32), memory (d = .36), and executive functioning (d = .28); social cognition (d = .20) and social functioning (d = .49) also improve (see Pfammatter et al., 2006). A more recent meta-analysis of 40 randomized controlled trials involving 2,104 participants reported significant effect sizes for cognitive remediation for improving global cognitive functioning (d = .45), social cognition (d = .65), and psychosocial functioning (d = .42) as well as smaller and less durable effects on reducing symptoms (d =.18; see Wykes et al., 2011). Unfortunately, having more symptoms is associated with smaller benefits overall (Wykes et al., 2011). The benefits of cognitive remediation for older patients ( $\geq 40$  years) also appear to be much more limited (Kontis et al., 2013). Cognitive remediation has also been shown

371

to be beneficial for patients in the early stages of illness, although the effect sizes overall tend to be smaller than they are for patients with more established illness (Revell et al., 2015).

Although cognitive remediation therapy sometimes leads to improvements in social cognition, this is not always the case (Horan et al., 2011; Wolwer et al., 2005). This suggests that neurocognitive changes may not be necessary for social cognitive improvement. It also highlights the need to target social cognition more directly.

In general, efforts to ameliorate social cognition deficits in schizophrenia take one of two forms. Some interventions are highly specific and target a single domain, such as facial affect recognition (see Wolwer et al., 2005). Other treatment programs are much more broad-based and target multiple domains. An example here would be Social Cognition and Interaction Training (SCIT; Penn et al., 2007). This is an 18- to 24-week group-based intervention designed to improve emotion perception, attributional bias, and ToM abilities (see Combs et al., 2007, 2009).

To date, relatively few studies have been conducted, and the number of patients involved in each study is generally quite small. More randomized controlled trials with adequate follow-up assessments are still needed (see Horan & Green, 2019). Nonetheless, there is cause for cautious optimism. Results of an effect-size analysis that included 16 studies (with 313 participants) showed that social cognitive training produced significant improvements in facial affect identification (d = 0.84) and social perception (d = 1.29) as well as enhancing ToM skills (d = 0.70). Improvements on measures of executive functioning (d = 1.70) were also noted. However, at least as currently delivered, social cognitive training does not seem to produce significant changes in positive symptoms (d=.27) and only has a small effect (d = .32) on negative symptoms (Kurtz et al., 2016).

Importantly, psychosocial interventions targeting neurocognition and social cognition have been shown to be effective in populations at clinical high risk for psychosis. In a randomized controlled trial, participants were measured at baseline, after treatment, and at 3-month follow-up (Friedman-Yakoobian et al., 2020). Compared to those who received an active control intervention, participants who received an integrated neurocognitive and social cognitive remediation intervention showed significantly greater improvements in social functioning and social cognition (ToM and managing emotions), both after treatment and at 3-month follow-up. These types of interventions therefore show promise for populations at different points along the trajectory toward psychotic illness

Finally, it warrants mention that psychosocial interventions targeted at helping families cope with schizophrenia also provide clinical benefits. Typically, family-based interventions begin by educating relatives about the symptoms, etiology, treatment, and prognosis of schizophrenia. Families are then provided with family-based therapy, in either an individual family context (e.g., Leff et al., 1982, Tarrier et al., 1988) or in a group containing patients and relatives from several families (e.g., McFarlane et al., 1995). Meta-analyses (e.g., Pfammatter et al., 2006) indicate that such approaches improve relatives' knowledge about the disorder (r = .39), reduce levels of EE (r = .59), improve patients' social functioning (r = .38), and result in decreased rates of relapse (r = .42) at 6- to 12-month follow-up.

Most recently, family-based interventions have been used to help youth at clinical high risk for developing psychosis. Interventions like Family-Focused Therapy (FFT) combine psychoeducation with other topics such as stress management, communication enhancement, and problem-solving skills training in the family context (Miklowitz et al., 2014). Results of these family-based interventions are promising, often resulting in a return to higher levels of functioning and avoidance of conversion to psychosis altogether (McFarlane, 2016). Although much remains to be learned about how such interventions work, such findings highlight the key role that family can play in altering the trajectory toward and clinical course of schizophrenia.

## Conclusion

Difficulties in the interpersonal domain characterize schizophrenia patients at all stages of the illness. Although the extent and nature of social difficulties varies considerably from one individual to another, males appear to be particularly likely to experience difficulties in their social relationships. Social difficulties also frequently predate the illness, are found in those who are at risk for schizophrenia, and remain present even during periods of symptom remission.

Although the symptoms of schizophrenia compromise social functioning to some degree, there is reason to believe that the social difficulties experienced by many schizophrenia patients are important in their own right. Precisely why they are such a central feature of the illness is not clear. Interpersonal impairments seem, at least to some degree, to be related to neurocognitive deficits, particularly those involving attention/vigilance and aspects of memory. Difficulties in these areas may also underlie some problems in more social areas of cognition. However, social cognition is distinct from neurocognition. Importantly, it appears to serve as a mediator between neurocognition and functional outcome. Altered processes related to social motivation serve as additional factors contributing to social difficulties in schizophrenia.

It is likely that schizophrenia patients' difficulties in relating to and understanding the social world seriously limit the extent to which they can develop supportive interpersonal relationships. This is unfortunate because schizophrenia patients, like many other patients, appear to be at higher risk of relapse when they live in emotionally stressful home environments. Helping patients improve their social skills and helping families cope with the stress of a schizophrenic relative is important for many reasons.

Understanding the nature and origins of social functioning impairments in schizophrenia is hindered by the variability in social functioning measures used in different studies. Social adjustment is a broad concept that encompasses performance on lab-based tasks of social skill as well as global functioning in the community. As noted by others (Cohen et al., 2006; Green et al., 2000), different types of cognitive deficits are associated with different domains of social functioning. Unfortunately, most research investigations do not involve both lab-based and community-based assessments (but see Addington & Addington, 1999; Addington et al., 1998, for exceptions).

The extent to which particular social difficulties are specific to schizophrenia is also not always clear. This speaks to the need for appropriate psychiatric control samples. More information about the stability of interpersonal functioning in general and skill deficits in particular is also needed. Longitudinal investigations are the exception rather than the rule in this research area. Perhaps most important, however, is the question of *why* social deficits are so characteristic of patients with schizophrenia.

Going forward, some of the most exciting directions will be those that continue to build on existing neurobiological evidence for alterations in brain structure and function in schizophrenia. Social motivation is one area particularly ripe for investigation, with a need to study the interaction of social reward and social punishment processing and how that relates to anticipation of and effortbased decision-making regarding social interactions. Continued investigations of neural correlates of social cognition and social motivation that link neurobiology with real-world social behaviors, particularly across various stages of illness including clinical high-risk populations, will no doubt shed light on how neurobiological, psychological, and behavioral changes conspire to result in impaired social functioning in schizophrenia. They may also give us new insights about how to enhance current remediation efforts and reduce the social disability that is, sadly, so characteristic of this disorder.

## Paranoia and Paranoid Beliefs

Richard P. Bentall

## A Conceptual History

As a review in an earlier edition of this volume pointed out, the terms "delusion" and "paranoia" often appear together in the psychiatric literature, reflecting the development of modern clinical terminology which employs both words to refer to abnormal forms of belief (Blaney, 2015). However, both terms have also found a place in everyday language, reflecting the complex interplay in the way that concepts are employed by mental health professionals and ordinary people. This interplay, and the shifting ways in which these terms have been defined in textbooks of psychiatry and abnormal psychology, have presented opportunities for confusion that should be addressed at the outset.

In the case of *delusion*, common language usage preceded the technical, clinical application of the term. The earliest English uses of the word to describe "a fixed false opinion or belief with regard to objective things," listed in the Oxford English Dictionary, date from the sixteenth century (e.g., Abraham Fraunce's The Lawiers Logike, published in 1588: "For that thereby men fell headlong into divers delusions and erronious conceiptes"). The words paranoia and paranoid, by contrast, were first established in the clinical literature and only found their way into everyday language in the second half of the twentieth century. Derived from the Greek words para (beyond, beside) and nous (mind, intellect), the OED dates the earliest nonmedical use to Samuel Beckett's 1938 novel Murphy, although the context is a description of psychotic patients in a psychiatric ward ("Paranoids, feverishly covering sheets of paper with complaints against their treatment or verbatim reports of their inner voices"). How paranoia subsequently became part of common English remains murky. In a celebrated essay, the historian Richard Hofstadter (1964) talked about the paranoid style in American politics, explicitly drawing parallels between what he understood to be the characteristics of certain psychiatric patients and political attitudes and movements that have become manifest at various points in US history. But popular culture has no doubt also played a role; Black Sabbath's second studio album (1970) was named *Paranoid* and Douglas Adam's radio comedy series (later a series of books), *The Hitchhiker's Guide to the Galaxy* (1978) had a character called Marvin the Paranoid Android (although, in the clinical sense, Marvin was more neurotic than paranoid, and the term was no doubt chosen for its alliteration).

The clinical use of both concepts dates from the nineteenth century, when French and German psychiatrists, for example Jean-Étienne Esquirol (1772–1840) and Karl Kahlbaum (1828–1899), identified groups of patients who appeared to present with a limited form of insanity in which abnormal beliefs affected only circumscribed areas of functioning, leaving intact other domains of reasoning and judgment (Kendler, 1995). By the end of this period, the concept of delusion as a particular kind of false belief that was a symptom of mental illness was widely accepted (Berrios, 1991) although, as we will see, the criteria for distinguishing delusions from nonpathological beliefs remains contested.

The German psychiatrist Emil Kraepelin (1856– 1927) was particularly influential in the development

of psychiatric classification in general (Bentall, 2003) and shaping the modern concept of paranoia specifically. Over the course of his career, he proposed many clinical concepts that remain important today, gradually refining his diagnostic criteria over iterations of his textbook of psychiatry, which went through nine editions between 1883 and 1927. In this way, he introduced the concept of dementia praecox (the precursor of the modern concept of schizophrenia), which he defined as a chronic, nonsenile, deteriorating condition that affected all of the psychic functions and that could present in various forms, including a form in which persecutory delusions were prominent, paranoide formen dementia praecox (Kendler, 2020). However, in his later work, Kraepelin distinguished patients who had this disorder from those he described as suffering from paranoia, whose delusions formed gradually, without any evidence of intellectual deterioration, and were based on the misinterpretation of events, often against a background of adverse life experiences (Kendler, 2018).

In the years following Kraepelin, paranoia was used in a bewildering variety of ways in different countries, as nosological categories expanded and collapsed in a process that has been likened to the "endless shuffling of the same old cards" (Hoenig, 1980). Debates during this period concerned whether paranoia was a type of schizophrenia, a stage in the progression to severe psychosis, or a separate diagnostic entity with symptoms that can occur in mild forms that sometimes evade psychiatric intervention (Dowbiggin, 2000). In the middle years of the twentieth century, the concept fell out of favor in clinical usage, particularly in the United States, where the diagnosis of schizophrenia was increasingly employed to cover a wide range of mental and social pathologies, provoking concerns about the cross-cultural validity of the concept (Cooper et al., 1972) and about the reliability of psychiatric diagnoses in general (Spitzer & Fliess, 1974). These concerns eventually provoked the neo-Kraepelinian revolution in psychiatry, which sought to return the discipline to the firm foundations established by Kraepelin (Blashfield, 1984).

The neo-Kraepelinian's greatest achievement was the publication of *DSM-III* in 1980, which sought to provide unambiguous diagnostic criteria for psychiatric disorders. This edition of the American Psychiatric Association's manual included the diagnosis *paranoid disorder*, which encompassed only persecutory delusions; in addition, the diagnosis was not to be applied when a diagnosis of schizophrenia was warranted (an exclusion criterion that has been retained ever since). However, at about the same time, some US psychiatrists, notably George Winokur (1977) and Kenneth Kendler (1980), were making efforts to characterize patients whom they believed merited the diagnosis and argued that the concept should be broadened. Their views were influential when later editions of the manual were published so that, when DSM-III-R was published in 1987, the concept of paranoia was side-lined in favor of a broader concept of delusional disorder. This condition is described in DSM-5 as a disorder in which disorganized speech and negative symptoms are absent, hallucinations are rare, and in which the pathognomic symptom is nonbizarre delusions (Kendler, 2017). The manual lists seven subtypes: erotomanic (characterized by the delusion that someone is in love with the individual), grandiose (having great but unrecognized talent or having made some important discovery), jealous (the delusion that a spouse is being unfaithful), persecutory, somatic (delusions about bodily functions or sensations), mixed and unspecified (used when the dominant delusional theme cannot be specified).

A notable deviation from this historical process of nosological reification was made by Ernst Kretschmer (1888–1964), who rejected a disease model of paranoia and claimed that some delusional states occurred when people with vulnerable personalities responded to stressful events.

He found that this clinical syndrome is caused by a triad of factors. There is a special personality factor characterized by hypersensitivity, exhaustibility, psychosexual inhibitions, and lack of normal intuitive erotic under-standing. Partial immaturities and familial psychopathology are frequently found. The second factor is an embarrassing or hurtful experience brought about when these usually quiet people are driven by their normal sexuality or the requirements of their daily lives into intense interaction with others. If the third factor, their social environment, does not allow any escape, the stage is set for the formation of paranoid reactions which can grow into true delusions. While the full-blown psychiatric picture is not very common, abortive or transient variations are quite frequent. (Hoehne, 1988)

The idea that some individuals have persistent paranoid traits in the absence of delusions has been represented in all editions of the *DSM* as *paranoid personality disorder*, characterized by suspicions of being deceived, doubts about the trustworthiness of others, reluctance to confide in others, the
inference of threatening or demeaning meanings in benign remarks, the bearing of grudges, unfounded perceptions of attacks on character or reputation, and suspiciousness about the fidelity of a spouse. However, following extensive disagreements about the nature of personality disorders during the writing of the most recent edition of the manual (Widiger, 2011; Krueger, 2013), an alternative classification system is included in DSM-5, in a final section on emergent models of psychopathology. This section contains a general definition of personality disorder and then further definitions of six different types-antisocial, avoidant, borderline, narcissistic, obsessive-compulsive, and schizotypal-which are all described as disorders of identity (how the individual thinks of him or herself), self-direction (goals), empathy, and intimacy (ability to form close relationships with others). The absence of a paranoid type should be noted. A parallel although less fractious process (Mulder, 2021; Reed, 2018) led to a fundamental revision of the ICD classification so that, in ICD-11, eight different types have been replaced with a single classification of personality disorder which can be supplemented with descriptions of specific personality traits shown by the patient; again, no paranoid type is specified.

These persisting debates suggest that there is no settled agreement about the usefulness of the concept of paranoid personality disorder. As a consequence, only limited research has been conducted on the topic (Lee, 2017). Moreover, researchers who have attempted to study the condition have continued to disagree about whether it is related to either schizophrenia or delusional disorder (Triebwasser et al., 2013). However, as we will see, there is a rich literature on paranoia in nonclinical populations that has been conducted outside the framework of diagnostic psychiatry.

# **Case Study**

Diagnostic categories do little justice to the wide variety of paranoid beliefs and presentations encountered in clinical practice. Although each individual psychiatric patient presents unique complexities that are difficult to capture in biographical sketches, a case vignette reported by British psychiatrists Dimech, Kingdon, and Swelam (2009), which was subjected to review and commentary by three independent clinicians, illustrates the different ways in which paranoid beliefs are approached by mental health experts with different theoretical orientations. Dimech et al.'s account concerned a young man called Zeppi, a 29-year-old migrant to the United Kingdom from Malta, arrested for the possession of offensive weapons (a machete and a dagger) after he had threatened his cousin, who owned the takeaway restaurant where he worked. When interviewed at a police station in London, Zeppi was guarded but at the same time relieved because he had felt in danger of being attacked for more than a year and had sought police protection on a number of occasions.

Zeppi's difficulties had become apparent when he had begun to feel vulnerable when working late shifts at the restaurant. His cousin had been forced to take on another member of staff as a consequence, but Zeppi had accused the new employee of trying to kill him by using a high-tech electronic device to fire magnetic waves at his body, causing him to feel palpitations. When Zeppi's cousin expressed skepticism about his complaints, Zeppi concluded that he, too, was part of a conspiracy, which involved an international criminal organization under the control of his former parish priest in Malta. Zeppi believed that the priest wished him to die a slow and painful death and that his cousin, who he referred to as "the traitor," had informed the priest of his whereabouts.

The three independent experts who reviewed Zeppi's case brought different training and conceptual tools to the task. Casey (2009), a psychiatrist, referred to the then current edition of the DSM, DSM-IV, and diagnosed Zeppi as suffering from schizophrenia, chronic paranoid type. Wilder (2009), a psychologist schooled in the behavior analytic approach, drew attention to the fact that Zeppi had been raised by his maternal grandmother during his first years of life but had largely been ignored by her. He had experienced only 7 years of schooling, with few opportunities to acquire social skills. In London, he was friendless and isolated. These observations led Wilder to suggest that a simple reinforcement approach might be effective, with a therapist systematically providing attention when Zeppi discussed mundane topics but ignoring him when he began talking about his delusions.

The present author, a clinical psychologist schooled in cognitive-behavior therapy and who had participated in clinical trials of psychological treatments for psychosis, drew attention to the wider psychological literature on the psychology of paranoia (Bentall, 2009). It is fair to describe Zeppi's family as highly dysfunctional. He had been the product of an incestuous relationship between

his mother and her grandfather. The pregnancy was concealed by his mother and only became known to the rest of the family when she went into labor. Because of the family's deep shame about these events, Zeppi was not baptized, his birth was never registered, and he was made to hide away whenever the local priest visited. He spent the first 8 years of his life living on his maternal grandparents' farm without attending school, but, after his grandfather died, he moved to live with a kindly aunt on the nearby island of Gozo. There, he began to attend school but was badly bullied by the other schoolchildren. He had a very close relationship with his younger cousin, but his older cousin was hostile toward him and, on one occasion, sexually abused him. At the age of 15 years, he began working with his younger cousin in a local bakery but became severely depressed when the cousin moved abroad, resulting in a period of inpatient psychiatric treatment. When his younger cousin visited from London, he suggested that Zeppi should follow him to the UK to work for him.

There are several aspects of this biography that are consonant with the research literature on paranoia, which will be discussed later, notably the importance of the attachment process and experiences of victimization in the development of paranoid symptoms. A striking aspect of the story is that Zeppi's beliefs, although apparently incomprehensible when considered out of context, appear to be much more comprehensible—although still very strange—once his life story is known.

# **Modern Definitions**

# Delusions

In DSM-5, delusions are defined as

fixed beliefs that are not amenable to change in light of conflicting evidence. Their content may include a variety of themes (e.g., persecutory, referential, somatic, religious, grandiose). . . . Delusions are deemed bizarre if they are clearly implausible and not understandable to same-culture peers and do not derive from ordinary life experiences.

The definition contained in the current edition of the World Health Organization's diagnostic manual, *ICD-11* is similar to that in previous editions of the *DSM*, which described delusions as false beliefs.

A belief that is demonstrably untrue or not shared by others, usually based on incorrect inference about external reality. The belief is firmly held with conviction and is not, or is only briefly, susceptible to modification by experience or evidence that contradicts it. The belief is not ordinarily accepted by other members or the person's culture or subculture (i.e., it is not an article of religious faith).

However, each of these definitions, and many others that have been suggested, creates numerous conceptual problems, particularly when attempting to distinguish between the pathological beliefs of psychiatric patients and nonpathological but extreme beliefs such as violent political and religious ideologies and conspiracy theories (Bentall, 2018). For example, the criterion that a belief is false might also be thought to apply to the conspiracy theory that the 2020 US presidential election was rigged, although this belief is not usually considered delusional (at least in the technical sense). This criterion is also difficult to apply in cases where a belief is pathological but coincidentally true (it has been observed that the spouses of patients with delusional jealousy, when their patience wears thin, often desert them for new partners; Enoch & Trethowan, 1979), or when delusions have religious content, or when they seem implausible but not impossible (as in the case of a patient who claims to be the subject of surveillance by the intelligence services) (Cermolacce et al., 2010).

The criterion that beliefs should be held rigidly in the face of evidence that would refute them is similarly problematic if used to distinguish between delusions and other kinds of beliefs. On the one hand, there is evidence that some deluded patients are able to consider the possibility that their beliefs are mistaken, adjust their beliefs in the face of hypothetical contradictions, and generate alternative explanations for their experiences (e.g., Buchanan et al., 1993); this observation is supported by the modest success of cognitive-behavioral interventions (which encourage patients to evaluate their own beliefs) for people with delusions (Mehl et al., 2015) with better outcomes in the most recent studies (Sitko et al., 2020).

On the other hand, a considerable number of studies, for example using interview methods (e.g., So et al., 2012) or by asking people to assess conflicting information (e.g., Woodward et al., 2008) (see later section on cognitive impairments) have shown that belief inflexibility (the unwillingness to change beliefs in the light of updated information) is associated with delusional conviction (the individual's certainty that the belief is true) and also, to a lesser extent, with the distress associated with a delusional belief and the individual's preoccupation with it (Zhu et al., 2018). However, a general problem in interpreting these findings is the failure to consider the inflexibility of the personally important beliefs (e.g., religious beliefs and political convictions) of nondeluded people. For example, a considerable literature has demonstrated motivated reasoning and resistance to attitude change in people with strongly held political ideologies (Taber & Lodge, 2013; Westen et al., 2006). When Colbert et al. (2010) asked people with delusions, people who had recovered from delusions, and healthy controls whether they were willing to consider whether their delusional (patients) or idiosyncratic but meaningful (controls) beliefs were mistaken, personally meaningful beliefs were held with equal conviction, and equally inflexibly, in all three groups.

A feature of delusions that was emphasized by Kraepelin, although he did not believe it applied to all cases, was that they are nonsensical. Subsequent commentators have defined delusions as bizarre if they violate agreed ideas about what is possible (Mullen, 2003) or deviate from "culturally determined consensual reality" (Kendler et al., 1983), and this concept is included in DSM-5, which advises clinicians to note whether delusions are bizarre ("clearly implausible, not understandable, and not derived from ordinary life experiences") when diagnosing disorders such as schizophrenia and delusional disorder. However, although studies show that clinicians can generally agree on which beliefs are delusional, the reliability of the distinction between bizarre and nonbizarre delusions has been consistently reported as poor (Bell et al., 2006).

Other investigators have focused on subtle aspects of experience associated with beliefs. Those working in this tradition, mostly from continental Europe, have been inspired by philosophers such as Franz Brentano (1838–1917), Edmund Husserl (1859–1938), and Martin Heidegger (1889–1976) (see Broome et al., 2012) and have argued that the psychotic disorders are, in general, disturbances of the way that the individual experiences being in the world, which can only be revealed by subtle engagement with the patient and interrogation about his or her symptoms (Bovet & Parnas, 1993).

A pioneer in this approach to psychopathology was the German psychiatrist and philosopher Karl Jaspers (1913–1959). Jaspers (1912/1968, 1913/1963) argued that the first task of the clinician is to employ empathy to understand the unique meaningful connections that compose the patient's psychic life. These connections, he argued, are quite

different from the kind of causal relations usually studied in the natural sciences:

In the natural sciences we find causal connections only but in psychology our bent for knowledge is satisfied with the comprehension of a quite different sort of connection. Psychic events "emerge" out of each other in a way which we understand. Attacked people become angry and spring to the defence, cheated persons grow suspicious. The way in which such an emergence takes place is understood by us, our understanding is genetic. . . . We can have no psychological understanding without empathy into the content (symbols, forms, images, ideas) and without seeing the expression and sharing the experienced phenomena. All these spheres of meaningful objective and subjective experience form the matter for understanding. Only in so far as they exist can understanding take place. (Jaspers, 1913/1963, pp. 302-303)

In Jasper's view, empathy with the patient is not possible in the case of true delusions. The patient's statements are therefore *ununderstandable* and can only be "explained" as manifestations of illness. Later commentators elaborated this idea into the distinction between the *form* and *content* of a disorder. For example, Kurt Schneider (1887–1967) argued that diagnosticians should be concerned with how a symptom occurs and is experienced, rather than its content. The latter, he argued, can best be interpreted in terms of the patient's biography and is less relevant to diagnostic issues (Hoenig, 1982).

Phenomenological investigators have therefore argued that the abnormal form of delusions is revealed by subtle changes in mental state, some of which precede the onset of the fully developed delusional system. For example, in detailed studies of more than a hundred psychotic patients-mostly soldiers with paranoid symptoms-conducted in a military hospital during World War II, Klaus Conrad (1905–1961), claimed to identify a series of stages through which their paranoid ideas evolved (see Bovet & Parnas, 1993; Mishara, 2009). First, according to Conrad (1958/2012), there was an initial phase of das Trema (derived from Greek, colloquial for stage fright) or delusional mood, which may last for a few days or much longer, in which the patient feels a sense of tension, that there is something in the air but is unable to say what has changed. At first, this applies only to certain events and objects, but it gradually spreads to encompass everything in the patient's world, creating suspiciousness, fear, and a sense of separation from

others. This leads to a state of *apophany* (revelation) in which the delusion appears suddenly, as an "ah-ha!" experience, often bringing about a sense of relief. Finally, in the *anastrophe* (turning back) phase the patient feels him- or herself to be the passive center around which the delusional business of the world is revolving. These ideas have been influential when some modern researchers have tried to identify very early prodromal or basic symptoms of psychopathology (e.g., Klosterkotter et al., 2001) but there has been a dearth of empirical studies to determine whether these kinds of stages are typical in patients with paranoid beliefs.

Two important limitations of the phenomenological approach should be noted. First, as acknowledged by many in the field, the ability to describe the form of others' experiences is limited by language, not only of the interviewer but also of the person attempting to describe his or her own mental states. Second, and less often acknowledged, by focusing exclusively on the experiences of patients with pathological mental states, phenomenologists have not been sufficiently cognizant of the phenomenologyindeed, sometimes frank weirdness-of ordinary human experiences (Bentall, in press). This becomes evident when, instead of thinking about mundane beliefs, we consider more emotionally charged but nonetheless widely accepted experiences and beliefs. For example, the zoologist Sir Alister Hardy (1896-1985) collected accounts of religious experience from more than 6,000 people in which many reported experiences that were strikingly similar to the unusual phenomenological characteristics of delusions described by Conrad (Hardy, 1979). Twenty-nine percent of these accounts included, "A patterning of events in a person's life that convinces him or her that in some strange way they were meant to happen." A detailed analysis of a small number cases of people who had made themselves known to Hardy's research unit found that these types of experiences could not be distinguished from psychotic experiences either in terms of form or content (Jackson & Fulford, 1997).

### Paranoid Beliefs

Today the terms *paranoid* and *persecutory* tend to be used interchangeably to describe delusions in which the individual believes he or she is the victim of some kind of persecution. Nearly every scholar who has studied severe mental illness since the earliest days of psychiatry has noted that these kinds of beliefs are particularly common among psychiatric patients. In the Schedules for Clinical Assessment **Box 16.1** Freeman and Garety's (2000) Criteria for Classifying a Delusion as Persecutory

- A. The individual believes that harm is occurring, or is going to occur, to him or her.
- B. The individual believes that the persecutor has the intention to cause harm.

There are a number of points of clarification:

- I. Harm concerns any action that leads to the individual experiencing distress.
- II. Harm only to friends or relatives does not count as a persecutory belief, unless the persecutor also intends this to have a negative effect upon the individual.
- III. The individual must believe that the persecutor at present or in the future will attempt to harm him or her.
- IV. Delusions of reference do not count within the category of persecutory beliefs. A delusion of reference involves the belief that innocuous events (e.g., a casual glance from a stranger in the street or a news bulletin on the radio) have special significance for the individual.

of Neuropsychiatry (World Health Organisation, 1997), this type of delusion is defined as the patient's belief "that someone, or some organization, or some force or power, is trying to harm them in some way; to damage their reputation, to cause them bodily injury, to drive them mad or to bring about their death." In a detailed consideration of this and other proposed definitions, Freeman and Garety (2000) suggested the more precise definition given in Box 16.1.
