Preface

Purpose

The purpose of *The VLSI Handbook* is to provide in a single volume a comprehensive reference work covering the broad spectrum of VLSI technology. It is written and developed for the practicing electrical and computer engineers in industry, government, and academia. The goal is to provide the most up-to-date information in IC technology, devices and their models, circuit simulations, amplifiers, logic design, memory, registers and system timing, microprocessor and ASIC, test and testability, design automation, and design languages. The handbook is not an all-encompassing digest of everything taught within an electrical and computer engineering curriculum on VLSI technology. Rather, it is the engineer's first choice in looking for a solution. Therefore, full references to other sources of contributions are provided. The ideal reader is a B.S.-level engineer with a need for a one-source reference to keep abreast of new techniques and procedures as well as review standard practices.

Background

The handbook stresses fundamental theory behind professional applications. In order to do so, it is reinforced with frequent examples. Extensive development of theory and details of proofs have been omitted. The reader is assumed to have a certain degree of sophistication and experience. However, brief reviews of theories, principles and mathematics of some subject areas are given. These reviews have been done concisely with perception. The handbook is not a textbook replacement, but rather a reinforcement and reminder of material learned as a student. Therefore, important advancement and traditional as well as innovative practices are included.

Since the majority of professional electrical engineers graduated before powerful personal computers were widely available, many computational and design methods may be new to them. Therefore, computers and software use are thoroughly covered. Not only does the handbook use traditional references to cite sources for the contributions, it also contains all *relevant* sources of information and tools that would assist the engineer in performing his/her job. This may include sources of software, databases, standards, seminars, conferences, etc.

Organization

Over the years, the fundamentals of VLSI technology have evolved to include a wide range of topics and a broad range of practice. To encompass such a wide range of knowledge, the handbook focuses on the key concepts, models, and equations that enable the electrical or computer engineer to analyze, design and predict the behavior of very large-scale integrated circuits. While design formulas and tables are listed, emphasis is placed on the key concepts and theories underlying the applications.

The information is organized into 13 major sections, which encompass the field of VLSI technology. Each section is divided into chapters, each of which was written by a leading expert in the field to enlighten and refresh knowledge of the mature engineer, and to educate the novice. Each chapter contains introductory material, leading to the appropriate applications, and references. The *references* provide a list of useful books and articles for following reading.

Locating Your Topic

Numerous avenues of access to information contained in the handbook are provided. A complete table of contents is presented at the front of the book. In addition, an individual table of contents precedes each of the thirteen sections. Finally, each chapter begins with its own table of contents. The reader is urged to look over these tables of contents to become familiar with the structure, organization, and content of the book. For example, see Section VIII: Microprocessor and ASIC, then Chapter 61: Microprocessor Design Verification, and then Section 61.8: Emulation. This tree-like structure enables the reader to move up the tree to locate information on the topic of interest.

A combined subject and author index has been compiled to provide means of accessing information. It can also be used to locate definitions; the page on which the definition appears for each key defining term is given in this index.

The VLSI Handbook is designed to provide answers to most inquiries and direct inquirers to further sources and references. We trust that it will meet your needs.

Acknowledgments

The compilation of this book would not have been possible without the dedication and efforts of the Editorial Board of Advisors, the section editors, the publishers, and most of all the contributing authors. I wish to thank them all and also my wife, Shiao-Ling, for her patience and understanding.

Wai-Kai Chen
Editor-in-Chief

Editor-in-Chief

Wai-Kai Chen, Professor and Head of the Department of Electrical Engineering and Computer Science at the University of Illinois at Chicago, teaches graduate and undergraduate courses in electrical engineering in the fields of circuits and systems. He received his B.S. and M.S. in electrical engineering at Ohio University where he was later recognized as a Distinguished Professor. He earned his Ph.D. in electrical engineering at the University of Illinois at Urbana-Champaign.

Professor Chen has extensive experience in education and industry and is very active professionally in the fields of circuits and systems. He has served as a visiting professor at Purdue University and the University of Hawaii at Manoa. He was Editor of the *IEEE Transactions on Circuits and Systems,* both *Series I and II* and President of the IEEE Circuits and Systems Society. Currently, he is Editor-in-Chief of the *Journal of Circuits, Systems and Computers* and Editor of the *Advanced Series in Electrical and Computer Engineering*, Imperial College Press. He received the *Lester R. Ford Award* from the Mathematical Association of America, the *Alexander von Humboldt Award* from Germany, the *Ohio University Alumni Medal of Merit for Distinguished Achievement in Engineering Education*, the *Senior University Scholar Award* from University of Illinois at Chicago, the *Distinguished Alumnus Award* from the University Illinois at Urbana-Champaign, and the *Society Meritorious Service Award* and the *Education Award* from IEEE Circuits and Systems Society. He also received more than a dozen honorary professor awards from major institutions in China.

A Fellow of the Institute of Electrical and Electronics Engineers and the American Association for the Advancement of Science, Professor Chen is widely known in the profession for his *Applied Graph Theory* (North-Holland*), Theory and Design of Broadband Matching Networks* (Pergamon Press*), Active Network and Feedback Amplifier Theory* (McGraw-Hill), *Linear Networks and Systems* (Brooks/Cole*), Passive and Active Filters: Theory and Implementations* (John Wiley), *Theory of Nets* (John Wiley), and *The Circuits and Filters Handbook* (Editor-in-Chief, CRC Press).

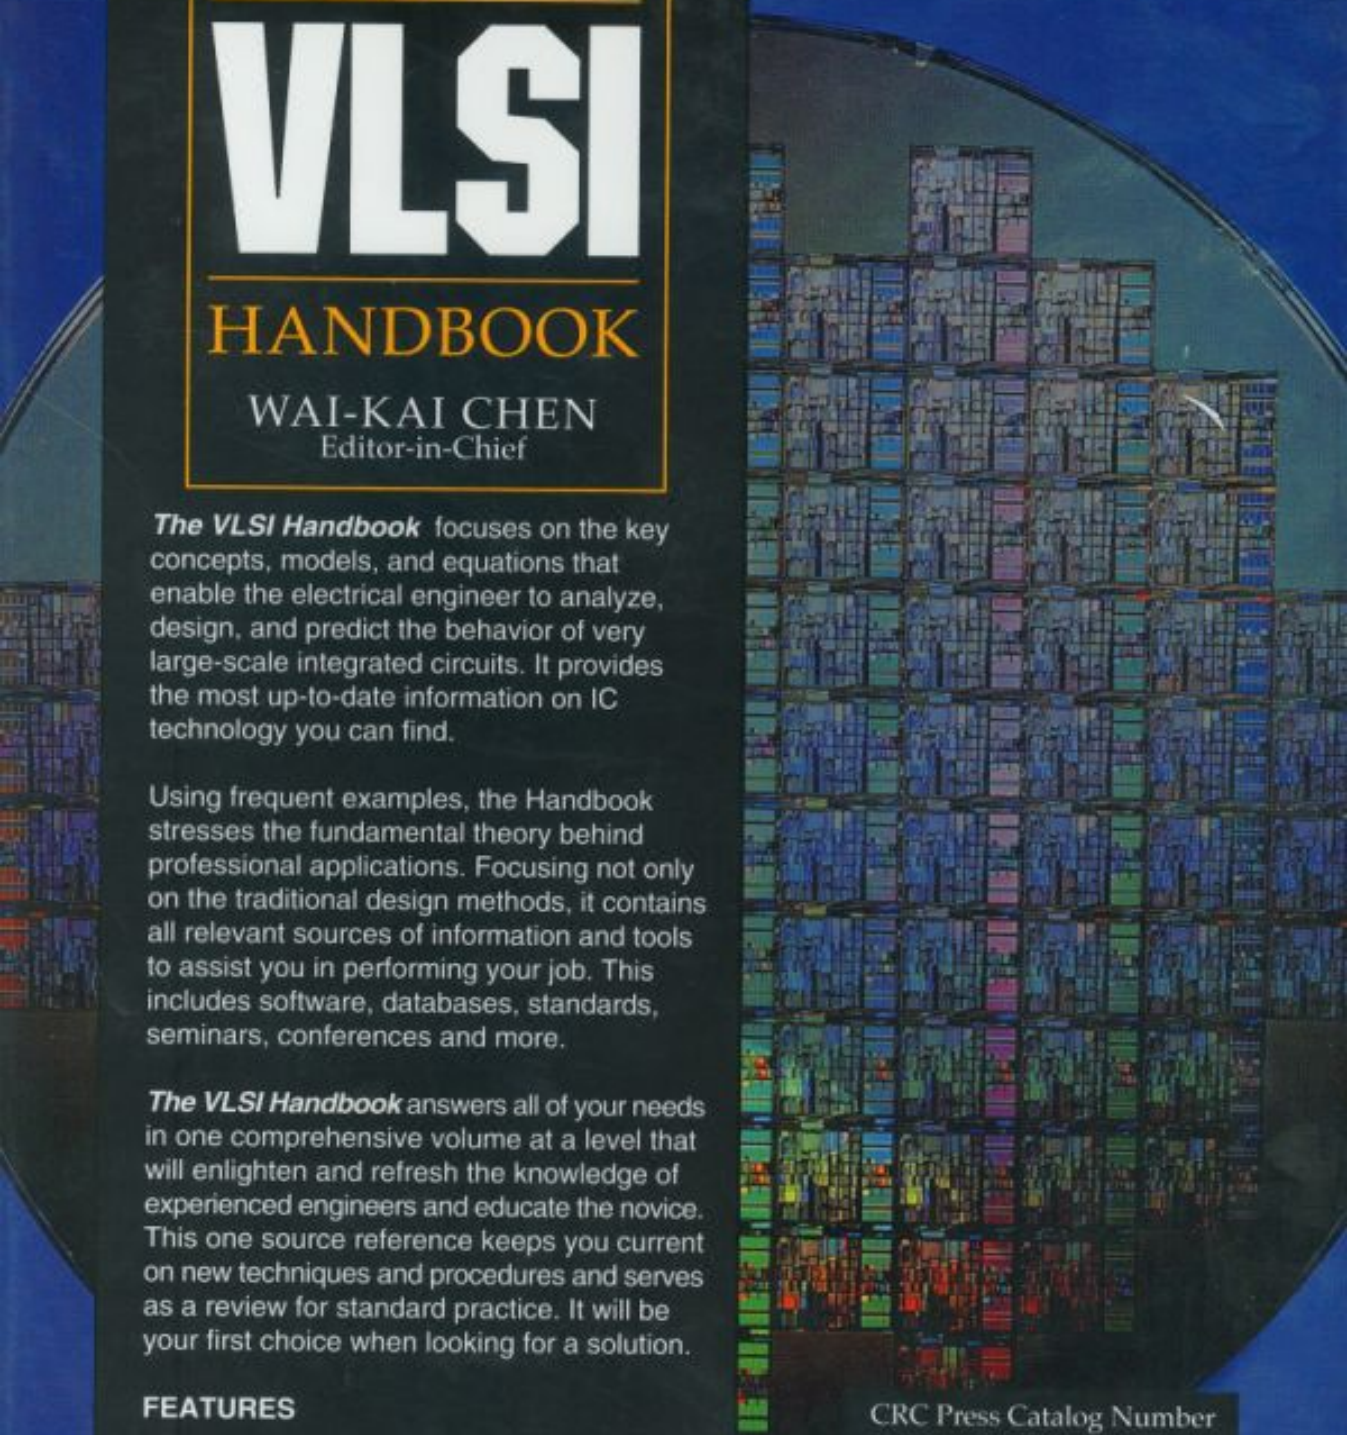
THE VLSI HANDBOOK

WAI-KAI CHEN
Editor-in-Chief



The VLSI Handbook focuses on the key concepts, models, and equations that enable the electrical engineer to analyze, design, and predict the behavior of very large-scale integrated circuits. It provides the most up-to-date information on IC technology you can find.

Using frequent examples, the Handbook stresses the fundamental theory behind professional applications. Focusing not only on the traditional design methods, it contains all relevant sources of information and tools to assist you in performing your job. This includes software, databases, standards, seminars, conferences and more.

The VLSI Handbook answers all of your needs in one comprehensive volume at a level that will enlighten and refresh the knowledge of experienced engineers and educate the novice. This one source reference keeps you current on new techniques and procedures and serves as a review for standard practice. It will be your first choice when looking for a solution.

FEATURES

- Covers the latest technologies in VLSI circuit design, fabrication, and testing
- Provides articles on research and applied technology
- Focuses on key issues facing the integrated circuit industry including the scaling of circuits, fabrication process, materials, and CAD simulation tools for design and testing
- Discusses automating the design process

VLSI Technology: A System Perspective

Krishna Shenai
Erik A. McShane
University of Illinois at Chicago

1.1 Introduction

The development of VLSI systems has historically progressed hand-in-hand with technology innovations. Often, fresh achievements in lithography, or semiconductor devices, or metallization have led to the introduction of new products. Conversely, market demand for particular products or specifications has greatly influenced focused research into the technology capabilities necessary to deliver the product. Many conventional VLSI systems as a result have engendered highly specialized technologies for their support.

In contrast, a characteristic of emerging VLSI products is the integration of diverse systems, each of which previously required a unique technology, into a single technology platform. The driving force behind this trend is the demand in consumer and noncommercial sectors for compact, portable, wireless electronics products — the nascent "system-on-a-chip" era.[1–4] Figure 1.1 illustrates some of the system components playing a role in this development.

Most of the achievements in dense systems integration have derived from scaling in silicon VLSI processes.[5] As manufacturing has improved, it has become more cost-effective in many applications to replace a chip set with a monolithic IC: packaging costs are decreased, interconnect paths shrink, and power loss in I/O drivers is reduced. Further scaling to deep submicron dimensions will continue to widen the applications of VLSI system integration, but also will lead to additional complexities in reliability, interconnect, and lithography.[6] This evolution is raising questions over the optimal level of integration: package level or chip level. Each has distinct advantages and some critical deficiencies for cost, reliability, and performance.

Board-level interconnection of chip sets, although a mainstay of low-cost, high-volume manufacturing, cannot provide a suitably dense integration of high-performance, core VLSI systems. Package- and chip-level integration are more practical contenders for VLSI systems implementation because of their compact dimensions and short signal interconnects. They also offer a tradeoff between dense monolithic integration and application-specific technology optimization. It is unclear at this time of the pace in the further

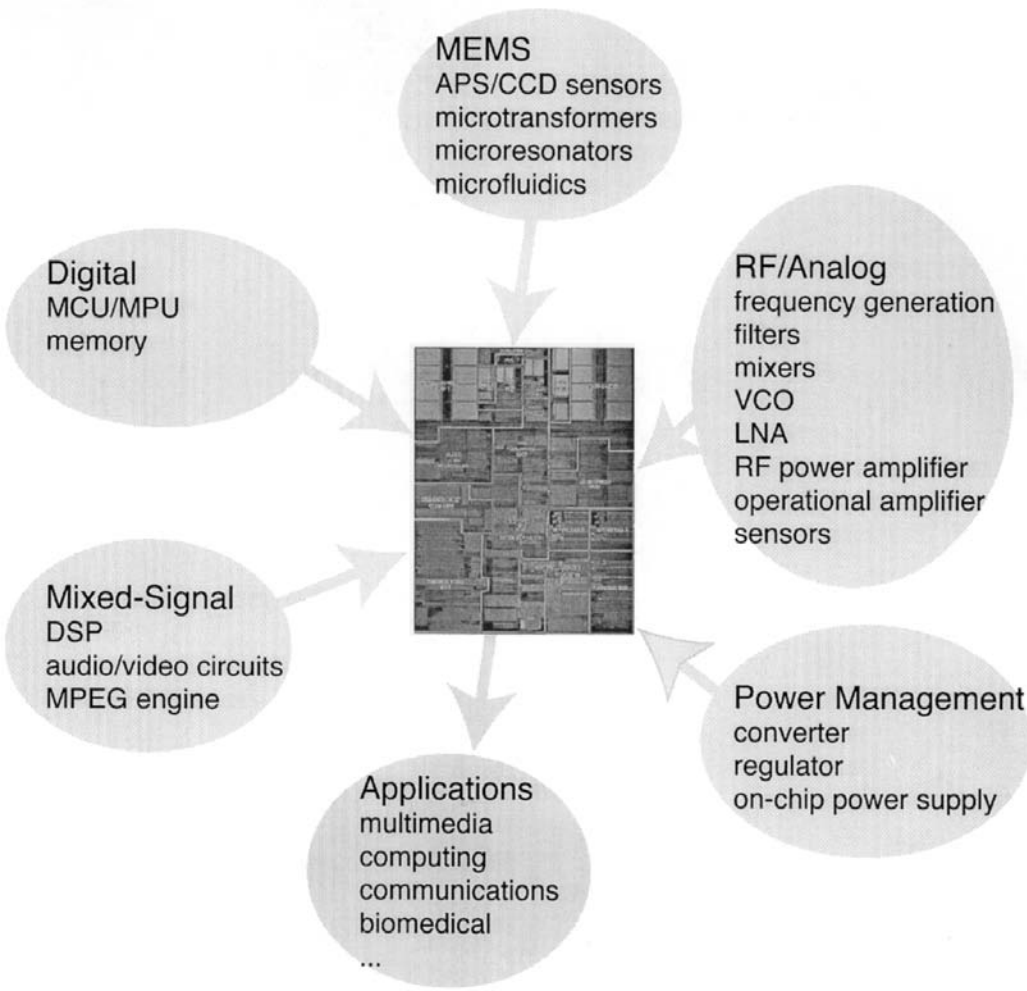

FIGURE 1.1 These system components are representative of the essential building blocks in VLSI "systems-on-a-chip."

evolution of VLSI systems, although systems integration will continue to influence and be influenced by technology development.

The remainder of this chapter will trace the inter-relationship of technology and systems to date and then outline emerging and future VLSI systems and their technology requisites. Alternative technologies will also be introduced with a presentation of their potential impact on VLSI systems. Focused discussion of the specific VLSI technologies introduced will follow in later chapters.

Given the level of systems integration afforded by available technology and the diverse signal-processing capabilities and applications supported, in this chapter a "VLSI system" is loosely defined as any complex system, primarily electronic in nature, based on semiconductor manufacturing with an extremely dense integration of minimal processing elements (e.g., transistors) and packaged as a single- or multi-chip module.

1.2 Contemporary VLSI Systems

VLSI systems can be crudely categorized by the nature of the signal processing they perform: analog, digital, or power. Included in analog are high-frequency systems, but they can be distinguished both by

design methodology and their sensitivity to frequency-dependent characteristics in biasing and operation. Digital systems consist of logic circuits and memory, although it should be noted that most "digital" systems now also contain significant analog subsystems for data conversion and signal integrity. Power semiconductor devices have previously afforded only very low levels of integration considering their extreme current- and voltage-handling requirements (up to 1000 A and 10 kV) and resulting high temperatures. However, with the advent of hybrid technologies (integrating different materials on a single silicon substrate), partial insulating substrates (with dielectrically isolated regions for power semiconductor devices), and MCM packaging, integrated "smart" power electronics are appearing for medium power (up to 1 kW) applications. A relative newcomer to the VLSI arena is microelectromechanical systems (MEMS). As the name states, MEMS is not purely electronic in nature and is now frequently extended to also label systems that are based on optoelectronics, biochemistry, and electromagnetics.

Digital Systems

Introduction

The digital systems category comprises microprocessors, microcontrollers, specialized digital signal processors, and solid-state memory. As mentioned previously, these systems may also contain analog, power, RF, and MEMS subsystems; but in this section, discussion is restricted to digital electronics.

Beginning with the introduction in 1971 of the first true microprocessor — the Intel 4004 — digital logic ICs have offered increasing functionality afforded by a number of technology factors. Transistor miniaturization from the 10-micron dimensions common 30 years ago to state-of-the-art 0.25-micron lithography has boosted IC device counts to over 10 million transistors. To support subsystem interconnection, multilevel metallization stacks have evolved. And, to reduce static and switching power losses, low-power/low-voltage technologies have become standard. The following discussion of VLSI technology pertains to the key metrics in digital systems: power dissipation, signal delay, signal integrity, and memory integration.

Power Dissipation

The premier technology today for digital systems is CMOS, owing to its inherent low-power attributes and excellent scaling to deep submicron dimensions. Total power dissipation is expressed as

$$\begin{aligned} P &= P_{dynamic} + P_{static} \\ &= (P_{switching} + P_{short\text{-}circuit} + P_{leakage}) \\ &= V_{DD}^2 f \sum_n a_n c_n + V_{DD} \sum_n i_{sc_n} + V_{DD} \sum_n (1 - a_n) i_{leak_n} \end{aligned} \tag{1.1}$$

where V_{DD} is the operating supply; f is the clock frequency; and per node a_n is the switching activity, c_n is the switching capacitance, i_{scn} is the short-circuit current, and i_{leakn} is the leakage current (subthreshold conduction and junction leakage). From this expression it is apparent that the most significant reduction in power dissipation can be accomplished by scaling the operating supply. However, as V_{DD} is reduced to 1 V, the contribution of leakage current to overall power dissipation increases if transistor V_T is scaled proportionally to V_{DD}. Subthreshold current in bulk CMOS, neglecting junction leakage and body effects, can be expressed as[7]

$$I_{sub} = \frac{W}{L} I_0 e^{\frac{V_{GS} - V_T}{n\phi_t}} \left(1 - e^{\frac{-V_{DS}}{\phi_t}}\right) \tag{1.2}$$

where

$$I_0 = k'(n-1)\phi_t^2 \tag{1.3}$$

$$n = 1 + \frac{\gamma}{2\sqrt{\phi_t}} \tag{1.4}$$

$$k' = \mu C'_{ox} \tag{1.5}$$

$$\gamma = \frac{\sqrt{2q\varepsilon_S N_B}}{C'_{ox}} \tag{1.6}$$

$$C'_{ox} = \frac{\varepsilon_{ox}}{t_{ox}} \tag{1.7}$$

W and L are channel width and length, respectively; ϕ_t is thermal voltage (approximately 0.259 V at 300 K); μ is carrier mobility in the channel; ε_{ox} is gate dielectric permittivity (3.45×10^{-13} F/cm for SiO_2); ε_S is semiconductor permittivity (1.04×10^{-12} F/cm for Si); N_B is bulk doping; and t_{ox} is gate dielectric thickness. This trend is exacerbated if minimal-switching circuit techniques are employed or if sleep modes place the logic into idle states for long periods. Device scaling thus must consider the architecture and performance requirements.

Figures 1.2 and 1.3 show the inverse normalized energy-delay product (EDP) contours for a hypothetical 0.25-micron device.[8] The energy required per operation is

$$E = \frac{P}{f} \tag{1.8}$$

Normalization is performed relative to the best obtained EDP for this technology. Fig. 1.2 shows data for an ideal device and Fig. 1.3 adds non-idealities by considering velocity saturation effects and uncertainty in V_{DD}, V_T, and temperature T. In the ideal device, the dashed lines indicate vectors of normalized constant performance relative to the performance obtained at the optimal EDP point. The switching frequency can be approximated by

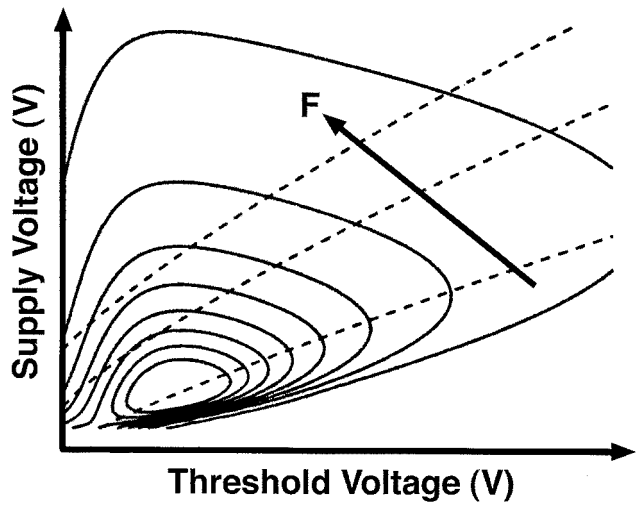

FIGURE 1.2 Inverse normalized EDP contours for an ideal device (after Ref. 8). Dashed lines indicate vectors of constant performance. Arrow *F* shows direction of increasing performance.

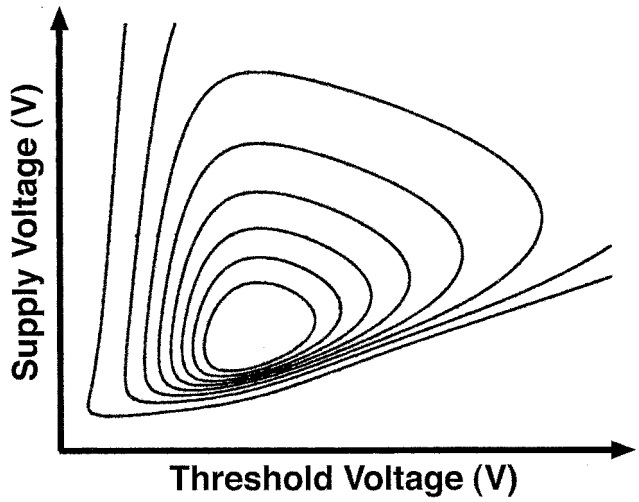

FIGURE 1.3 Inverse normalized EDP contours for a non-ideal device considering velocity saturation and uncertainty in V_{DD}, V_T, and temperature T (after Ref. 8).

$$f = \frac{1}{t_{rise}} = \frac{1}{t_{fall}} = \frac{I_{Dsat}}{CV_{DD}} \tag{1.9}$$

and the performance, F, when considered as proportional to f, can be expressed as

$$f = \alpha \frac{(V_{DD} - V_T)^2}{V_{DD}} \tag{1.10}$$

where scaling factor α is applied to normalize performance. These plots illustrate the tradeoffs in optimizing system performance for low-power requirements and highest performance. Frequency can also be scaled to reduce power dissipation, but this is not considered here as it generally also degrades performance.

Considering purely dynamic power losses (CV^2f), scaling the operating supply again yields the most significant reduction; but this scaling also affects the subthreshold leakage since V_T must be scaled similarly to maintain comparable performance levels (see Eq. 1.10). In this respect, fully depleted SOI CMOS offers improved low-voltage, low-power characteristics as it has a steeper subthreshold slope than bulk CMOS. Subthreshold slope, S, is defined as

$$S = \frac{dV_G}{d(\log I_D)} \tag{1.11}$$

This can be expressed (from Ref. 9) for bulk CMOS as

$$S = \frac{\hat{k}T}{q} \ln(10) \left(1 + \frac{C_D}{C_{ox}}\right) \tag{1.12}$$

and for fully depleted SOI CMOS (assuming negligible interface states and buried-oxide capacitance) as

$$S = \frac{\hat{k}T}{q}\ln(10) \tag{1.13}$$

where $\hat{k}$ is Boltzmann's constant (1.38×10^{-23} V·C/K), C_D is depletion capacitance, and C_{ox} is gate dielectric capacitance. Hence, for the same weak inversion gate bias, SOI CMOS can yield a leakage current several orders of magnitude less than in bulk CMOS.

Additional power dissipation occurs in the extrinsic parasitics of the active devices and the interconnect. This contribution can be minimized by salicide (self-aligned silicide) processes that deposit a low sheet resistance layer on the source, drain, and gate surfaces.

Switching Frequency and Signal Integrity

After power dissipation, the signal delay (or maximum switching frequency) of a system is the most important figure-of-merit. This characteristic, as mentioned previously, provides a first-order approximation of system performance. It also affects the short-circuit contribution to power loss since a dc path between the supply rails exists during a switching event. Also, signal delay and slope determine the deviation of a logic signal pulse from an ideal step transition.

Digital systems based on silicon bipolar and BiCMOS technologies still appear for high-speed applications, exploiting the higher small-signal gain and greater current drive of bipolar transistors over MOSFETs; but given the stringent power requirements of portable electronics, non-CMOS implementations are impractical. Emerging technologies such as silicon heterojunction bipolar and field-effect transistors (HBTs and HFETs) hold some promise of fast switching with reduced power dissipation, but the technology is too immature to be evaluated as yet.

The switching rate of a capacitively loaded node in a logic circuit can be approximated by the time required for the capacitor to be fully charged or discharged, assuming that a constant current is available for charge transport (see Eq. 1.9). Neglecting channel-length modulation effects on saturation current, the switching frequency can be written as

$$\begin{aligned} f &= \frac{I_{Dsat}}{CV_{DD}} \\ &= \frac{\frac{k'}{2}\frac{W}{L}(V_{GS} - V_T)^2}{CV_{DD}} \\ &\propto \frac{(V_{DD} - V_T)^2}{CV_{DD}} \end{aligned} \tag{1.14}$$

Voltage scaling and its effects on power dissipation have already been discussed. Considering the capacitive contribution, a linear improvement to switching speed can be obtained by scaling node capacitance. Referring to Fig. 1.4 and neglecting interconnect capacitance, the node capacitance, of a MOSFET can be expressed as

$$C_{OUT} = C_{GD} + \kappa(V_{OL}, V_{OH})(C_{db}) \tag{1.15}$$

$$C_{GD} = x_{jl}C_{ox}W + \frac{1}{2}C_{ox}WL_{eff} \tag{1.16}$$

$$C_{db} = C_{j0}WY + 2C_{jsw}(W + Y) \tag{1.17}$$

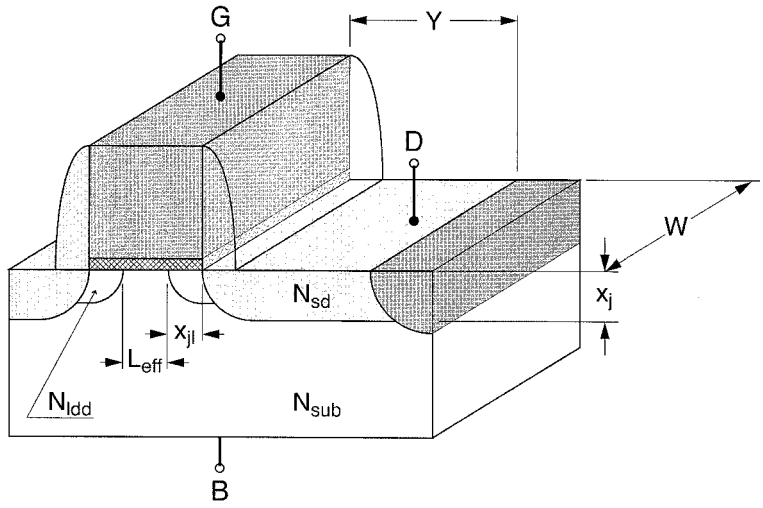

FIGURE 1.4 A MOSFET isometric cross-sectional view with critical dimensions identified.

$$C_{j0} = \sqrt{\frac{q\varepsilon_{Si}}{2\left(\frac{1}{N_{sd}} + \frac{1}{N_{sub}}\right)\phi}} \tag{1.18}$$

$$C_{jsw} \approx C_{j0} x_j \tag{1.19}$$

The drain-to-body junction capacitance C_{db} is bias dependent, and the scaling factor κ is included to determine an average value of output voltage level. Source/drain diffusion capacitance has two components: the bottom areal capacitance C_{j0} and the sidewall perimeter capacitance C_{jsw}. Although C_{jsw} is a complex function of doping profile and should account for high-concentration channel-stop implants, an approximation is made to equate C_{jsw} and C_{j0}. From Fig. 1.5, it is clear that SOI CMOS has greatly reduced device capacitances compared to bulk CMOS by the elimination junction areal and perimeter capacitances. Another technique in SOI CMOS for improving switching delay involves dynamic threshold voltage control (DTMOS) by taking advantage of the parasitic lateral bipolar transistor inherent in the device structure.[10]

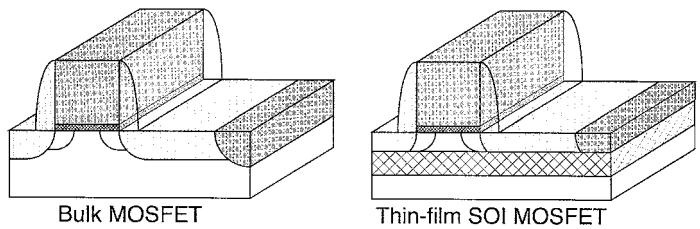

FIGURE 1.5 Cross-sectional views of a MOSFET: bulk and thin-film SOI.

To reduce interconnect resistance, copper interconnect has been introduced to replace traditional aluminum wires.[11] Table 1.1 compares two critical parameters. The higher melting point of copper also reduces long-term interconnect degradation from electromigration, in which energetic carriers dislodge

metal atoms creating voids or nonuniformities. Interconnect capacitance relative to the substrate is determined by the dielectric constant, ε_r, and the signal velocity can be defined as

$$v = \frac{c}{\sqrt{\varepsilon_r}} \tag{1.20}$$

Low-ε_r interlevel dielectrics are appearing to reduce this parasitic effect.

TABLE 1.1 Comparison of Interconnect Characteristics for Al and Cu

Material	Specific Resistance (μΩ-cm)	Melting Point (°C)
Al	2.66	660
Cu	1.68	1073

Memory Scaling

The two most critical factors determining the commercial viability of RAM products are the total power dissipation and the chip area. For implementations in battery-operated portable electronics, the goal is a 0.9-V operating supply — the minimum voltage of a NiCd cell. RAM designs are addressing these objectives architecturally and technologically. SRAMs and DRAMs share many architectural features, including memory array partitioning, reduced voltage internal logic, and dynamic threshold voltage control. DRAM, with its higher memory density, is more attractive for embedded memory applications despite its higher power dissipation.

Figure 1.6 shows a RAM block diagram that identifies the sources of power dissipation. The power equation as given by Itoh et al.[12] is

$$P = I_{DD}V_{DD} \tag{1.21}$$

$$I_{DD} = mi_{act} + m(n-1)i_{hld} + (n+m)C_{DE}V_{INT}f + C_{PT}V_{INT}f + I_{DCP} \tag{1.22}$$

where i_{act} is the effective current in active cells, i_{hld} is the holding current in inactive cells, C_{DE} is the decoder output capacitance, C_{PT} is the peripheral circuit capacitance, V_{INT} is the internal voltage level, I_{DCP} is the static current in the peripheral circuits, and n and m define the memory array dimensions.

In present DRAMs, power loss is dominated by i_{act}, the charging current of an active subarray; but as V_T is scaled along with the operating voltage, the subthreshold current begins to dominate. The trend in DRAM ICs (see Fig. 1.7) shows that the dc current will begin to dominate the total active current at about the 1-Gb range. Limiting this and other short-channel effects is necessary then to improve power efficiency.

Figure 1.8 shows trends in device parameters. A substrate doping of over 10^{18} cm^{-3} is necessary to reduce SCE, but this has the disadvantage of also increasing junction leakage currents. To achieve reduced SCE at lower substrate dopings, shallow junctions (as thin as 15 nm) are formed.[13]

Bit storage capacitors must also be scaled to match device miniaturization but still retain adequate noise tolerance. Alpha-particle irradiation becomes less significant as devices are scaled, due to the reduced depletion region; but leakage currents still place a minimum requirement on bit charge. Figure 1.9 shows that required signal charge, Q_S, has reduced only slightly with increased memory capacity, but cell areas have shrunk considerably. High-permittivity (high-ε_r) dielectrics such as Ta_2O_5 and BST ($Ba_xSr_{1-x}TiO_3$) are required to provide these greater areal capacitances at reduced dimensions.[14] Table 1.2 lists material properties for some of the common and emerging dielectrics. In addition to scaling the cell area, the capacitor aspect ratio also affects manufacturing: larger aspect ratios result in non-planar interlevel dielectric and large step height variation between memory arrays and peripheral circuitry.

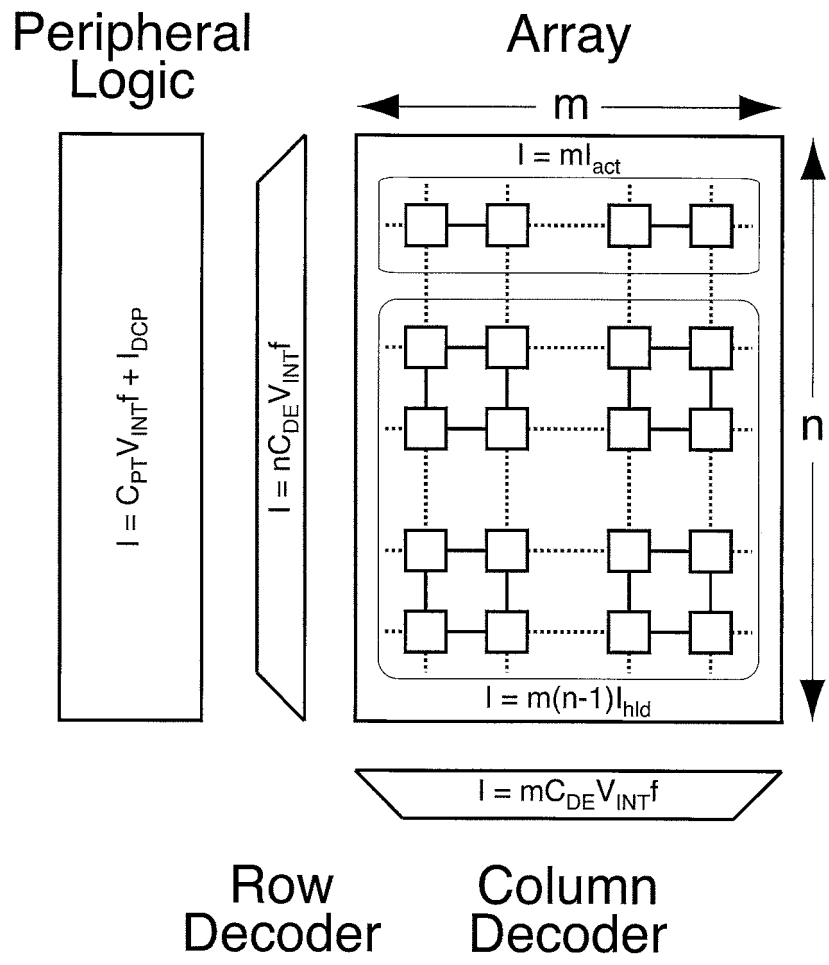

FIGURE 1.6 RAM block diagram indicating effective currents within each subsystem.

Analog Systems

Introduction

An analog system is any system that processes a signal's magnitude and phase information by a linearized response of an active device to a small-signal input. Unlike digital signals, which exhibit a large output signal swing, analog systems rely on a sufficiently small signal gain that the linear approximation holds true across the entire spectrum of expected input signal frequencies. Errors in the linear model are introduced by random process variation, intrinsic device noise, ambient noise, and non-idealities in active and passive electronics. Minimizing the cumulative effects of these "noise" contributions is the fundamental objective of analog and RF design.

Reflecting the multitude of permutations in input/output specifications and operating conditions, analog/RF design is supported by numerous VLSI technologies. Key among these are silicon MOST, BJT, and BiCMOS for low-frequency applications; silicon BJT for high-frequency, low-noise applications; and GaAs MESFET for high-frequency, high-efficiency amplifiers. Newcomers to the field include GaAs and SiGe heterojunction bipolar junction transistors (HBTs). The bandgap engineering employed in their fabrication results in devices with significantly higher f_T and f_{max} than in conventional devices, often at lower voltages.[15–17] Finally, MEMS resonators and mechanical switches offer an alternative to active device implementations.

TABLE 1.2 Comparison of High-Permittivity Constant Materials for DRAM Cell Capacitors

Material	Dielectric Constant	Minimum Equivalent Oxide Thickness (nm)
NO	7	3.5 to 4
Ta_2O_5	20–25	2 to 3
BST	200–400	?

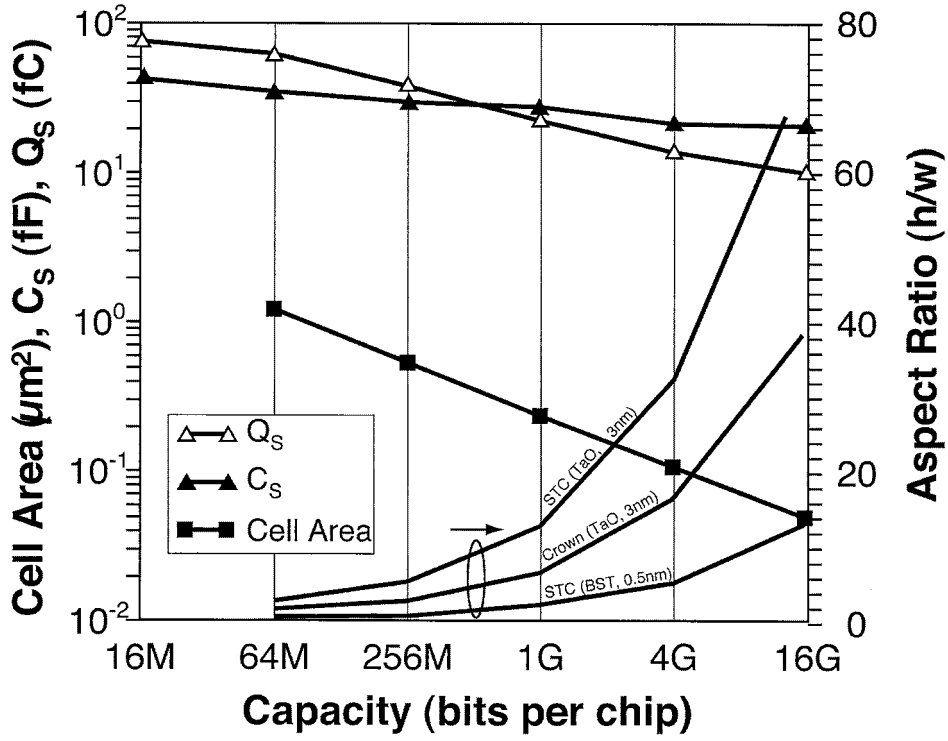

FIGURE 1.9 Trends in DRAM cell characteristics (after Ref. 13).

The most familiar application of a high-frequency system is in wireless communications, in which a translation is performed between the high-frequency modulated carrier (RF signal) used for broadcasting and the low-frequency demodulated signal (baseband) suitable for audio or machine interpretation. Wireless ICs long relied on package-level integration and scaling to deliver compact size and improved efficiency. Also, low-cost commercial IC technologies previously could not deliver the necessary frequency range and noise characteristics. This capability is now changing with several candidate technologies at hand for monolithic IC integration. CMOS has the attractive advantage of being optimal for integration of low-power baseband processing.

Amplifiers

Amplifiers boost the amplitude or power of an analog signal to suppress noise or overcome losses and enable further processing. Typical characteristics include a low noise figure (NF), large (selectable) gain (G), good linearity, and high power-added efficiency (PAE). To accommodate the variety of signal frequencies and performance requirements, several amplifier categories have evolved. These include conventional single-ended, differential, and operational amplifiers at lower frequencies and, at higher frequencies, low-noise and RF power amplifiers.

A challenge in technology scaling is providing a suitable signal-to-noise ratio and adequate biasing at a reduced operating supply. For a fixed gain, reducing the operating supply implies a similar scaling of the input signal level, ultimately approaching the noise floor of the system and leading to greater susceptibility to internal and external noise sources. Large-signal amplifiers (e.g., RF power amplifiers) that exhibit a wide output swing face similar problems with linearity at a lower operating supply.

A low-noise amplifier (LNA) is the first active circuit in a receiver. A common-source configuration of a MOSFET LNA is shown in Fig. 1.10. The input network is typically matched for lowest NF, and the output network is matched for maximum power transfer. Input impedance is matched to the source resistance, R_s, when[18]

$$\omega_0^2(L_1 + L_2)C_{gs} = 1 \tag{1.23}$$

$$\frac{g_m L_1}{C_{gs}} = R_s \tag{1.24}$$

The gain from the input matching network to the transistor gate-source voltage is equal to Q, the quality factor

$$Q = \frac{1}{g_m \omega_0 L_1} \tag{1.25}$$

where ω_0 is the RF frequency. If only the device current noise is considered, then the LNA noise figure can be expressed as

$$NF = 1 + \frac{2}{3}\frac{\omega_0 L_1}{QR_s} \tag{1.26}$$

It is observed that a larger quality factor yields a lower noise figure, but current industry practice selects an LNA Q of 2 to 3 since increasing Q also increases the sensitivity of the LNA gain to

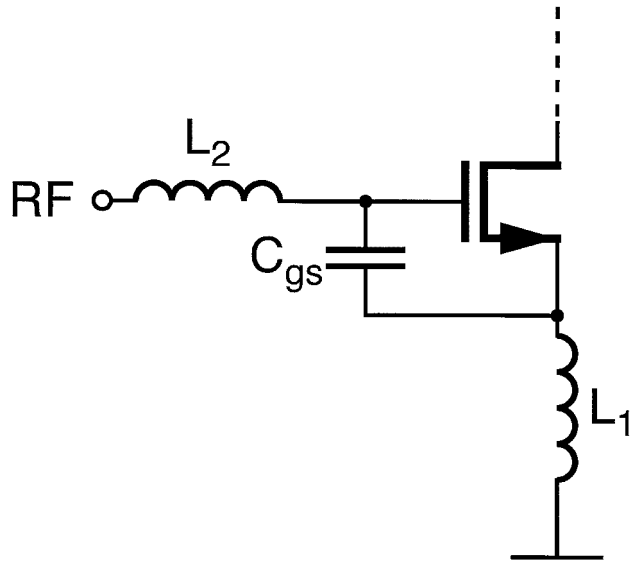

FIGURE 1.10 Common-source LNA circuit schematic.

tolerances in the passive components. By combining Eqs. 24 and 25, the device input capacitance C_{gs} can be defined

$$C_{gs} = \frac{1}{R_S Q \omega_0} \tag{1.27}$$

Assuming that the transistor is in the saturation region and that Miller feedback gain is –1, the contributions to the input capacitance are

$$C = \left(\frac{2}{3} C'_{ox} L_{eff} + C_{gso} + 2 C_{gdo}\right) W \tag{1.28}$$

where C_{gso} and C_{gdo} are, respectively, the gate-source and gate-drain overlap capacitances. The bias current (assuming a reasonable value for g_m) can then be obtained from

$$I_{Dsat} = \left(\frac{g_m^2}{2W}\right)\frac{L_{eff}}{k'} \tag{1.29}$$

As device dimensions are reduced, the required biasing current drops. Since cutoff frequency, f_T, also improves with smaller device dimensions, MOSFET performance in RF applications will continue to improve.

Power amplifiers, the last active circuit in a transmitter, have less stringent noise figure requirements than an LNA since the input signal is generated locally in the transmitter chain. Instead, linearity and PAE are more critical, particularly for variable-envelope communications protocols. RF amplifiers typically operate in class AB mode to compromise between efficiency and linearity.[19] Power-added efficiency is defined as

$$PAE = \frac{\eta}{1 - \frac{1}{G}} \tag{1.30}$$

where η is the drain (collector) efficiency (usually about 40 to 75%) and G is the amplifier power gain. This balance is highly sensitive to the precision of matching networks. Technologies such as GaAs, with its high-resistivity substrate, and SOI, with its insulating buried oxide, are best suited for integrated RF power amplifiers since they permit fabrication of low-loss, on-chip matching networks.

Interconnects and Passive Components

Passive components in analog and RF design have the essential role of providing biasing, energy storage, and signal level translation. As device technology has permitted a greater monolithic integration of active devices, a similar trend has appeared in passive components. The quality of on-chip passives, however, has lagged behind that of high-precision discrete components. Two characteristics are required of VLSI interconnects for RFICs: low-loss and integration of high-quality factor passives (capacitors and inductors). As discussed previously, resistive losses increase the overall noise figure, lead to decreased efficiency, and degrade the performance of on-chip passive components. Interconnect and device resistance are minimized by saliciding the gate and source/drain surfaces and appropriately scaling the metallization dimensions. Substrate coupling losses, which also degrade quality factors of integrated passives and can introduce substrate noise, are controlled by selecting a high-resistivity substrate such as GaAs or shielding the substrate with an insulating layer such as in SOI.

In forming capacitors on-chip, two structures are available, using either interconnect layers or the MOS gate capacitance. Metal-insulator-metal (MIM) and dual-poly capacitors both derive a capacitance from a thin interlevel dielectric (ILD) layer deposited between the conducting plates. MIM capacitors

offer a higher Q than dual-poly capacitors since, even with silicidation, resistance of poly layers is higher than in metal. Both types can suffer from imprecision caused by non-planarity in the ILD thickness caused by process non-uniformity across the wafer.

MOS gate capacitance is less subject to variation caused by dielectric non-uniformity since the gate oxide formation is tightly controlled and occurs before any back-end processing. MOS capacitors, however, are usually dismissed for high-Q applications out of concern for the highly resistive well forming the bottom plate electrode. Recent work, however, has shown that salicided MOS capacitors biased into strong inversion will achieve a Q of over 100 for applications in the range 900 MHz to 2 GHz.[20]

Inductors are essential elements of RFICs for biasing and matching, and on-chip integration translates to lower system cost and reduced effects from package parasitics. However, inductors also require a large die area and exhibit significant coupling losses with the substrate. In addition to degrading the inductor Q, substrate coupling results in the inductor becoming a source of substrate noise. The Q of an inductor can be defined[21] as

$$Q = \frac{\omega L_s}{R_s}. \text{ Substate loss factor} \cdot \text{Self-resonance factor} \tag{1.31}$$

where L_s is the nominal inductance and R_s is the series resistance. The substrate loss factor approaches unity as the substrate resistance goes to either zero or infinity. This implies that the Q factor is improved if the substrate is either short- or open-circuited. Suspended inductors achieve an open-circuited substrate by etching the bulk silicon from under the inductor structure.[22] Another approach has been to short-circuit the substrate by inserting grounding planes (ground shields).[21]

Power Systems

Introduction

Power processing systems are those devoted to the conditioning, regulation, conversion, and distribution of electrical power. Voltage and current are considered the inputs, and the system transforms the input characteristics to the form required by the load. The distinguishing feature of these systems is the specialized active device structure (e.g., rectifier, thyristor, power bipolar or MOS transistor, IGBT) required to withstand the electrothermal stresses imposed by the system. The label power integrated circuits (PICs) refers to the monolithic fabrication of a power semiconductor device along with standard VLSI electronics. At the system level, this integration has been made possible by digital control techniques and the development of mixed-signal ICs comprising analog sensing and digital logic. On the technology side, development of the power MOSFET and IGBT led to greatly simplified drive circuits and decreased complexity in the on-chip electronics.

Three types of PIC are identified: smart power, high-voltage ICs (HVICs), and discrete modules. Discrete modules are those in which individual ICs for power devices and control are packaged in a single carrier. Integration is at the package level rather than at the IC. Smart power adds a monolithic integration of analog protection circuitry to a standard power semiconductor device. The level of integration is quite low, but the power semiconductor device ratings are not disturbed by the other electronics.

HVICs are different in that they begin from a standard VLSI process and accommodate the power semiconductor device by manufacturing changes. HVICs are singled out for further discussion as they are the most suitable for VLSI integration. Although the power semiconductor device ratings cannot achieve the levels of a discrete device, HVICs are available for ratings with currents of 50 to 100 A and voltages up to 1000 V.

Two critical technical issues faced in developing HVICs are the electrical isolation of high-power and low-voltage electronics, and the development of high-Q passive components (e.g., capacitors, inductors, transformers). In the following discussion, the characteristics of power semiconductor devices will not be considered, only the issues relating to HVIC integration.

Electrical Isolation

Three types of electrical isolation are available as illustrated in Fig. 1.11.[23] In junction isolation, a p^+ implant is added to form protective diodes with the n^- epitaxial regions. The diodes are reverse-biased by applying a large negative voltage (~ –1000 V) to the substrate. Problems with this isolation include temperature-dependent diode leakage currents and the possibility of a dynamic turn-on of the diode. Additional stress to the isolation regions and interlevel dielectric is introduced when high-voltage interconnect crosses the isolation implants. The applied electric field in this situation can result in premature failure of the device.

A self-isolation technique can be chosen if all the devices are MOSFETs. When all devices are placed in individual wells (a twin-tub process), all channel regions are naturally isolated since current flow is near the oxide–semiconductor interface. The power semiconductor device and signal transistors are

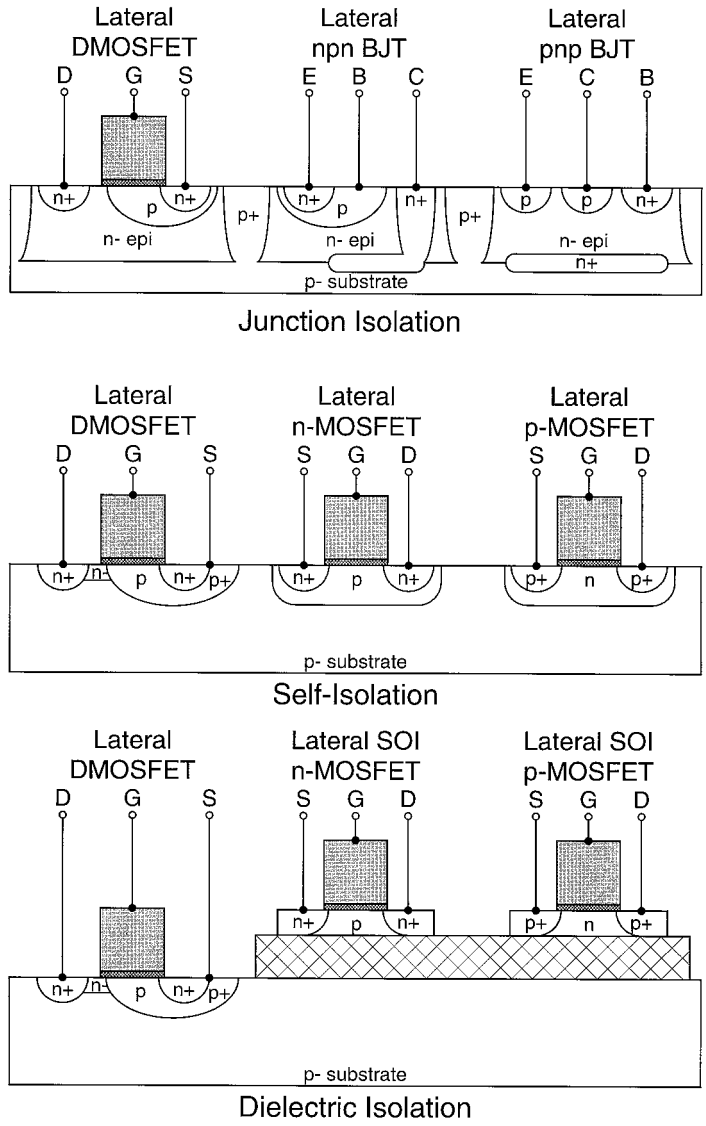

FIGURE 1.11 High-voltage IC isolation technologies: junction, self-, and dielectric-isolation.

fabricated simultaneously in junction and self-isolation, resulting in a compromise in performance.[24] In practice, bulk isolation techniques are a combination of junction and self-isolation since many HVICs exhibit dynamic surges in substrate carriers, corresponding to power device switching, that may result in latchup of low-voltage devices.[25]

Dielectric isolation decouples the fabrication of power and signal devices by reserving the bulk semiconductor for high-voltage transistors and introducing an epitaxial semiconductor layer for low-voltage devices on a dielectric surface. Formation of the buried oxide can be accomplished either by partially etching an SOI wafer to yield an intermittent SOI substrate or by selectively growing oxide on regions intended for low-voltage devices, followed by epitaxial deposition of a silicon film. In addition to providing improved isolation of power semiconductor devices, the buried oxide enhances the performance of signal transistors by reducing parasitic capacitances and chip area.[26]

Interconnects and Passive Components

A key objective in applying VLSI technology to power electronics is the reduction in system mass and volume. Current device technologies adequately provide the monolithic cofabrication of low-voltage and high-voltage electronics, and capacitors and inductors of sufficiently high Q are available to integrate substantial peripheral circuitry. As switching frequencies are increased in switching converters, passive component values are reduced, further improving the integration of power electronics. These integration capabilities have resulted from similar requirements in digital and analog/RF electronics. Conventional VLSI technologies, however, have yet to reproduce the same integration of magnetic materials needed for transformers.

Magnetics integration is hindered by the incompatibility of magnetic materials with standard VLSI processes and concerns over contamination of devices. A transformer cross-section is shown in Fig. 1.12 where the primary and secondary are wound as lateral coils with connections between the upper and lower conductors provided by vias.[27]

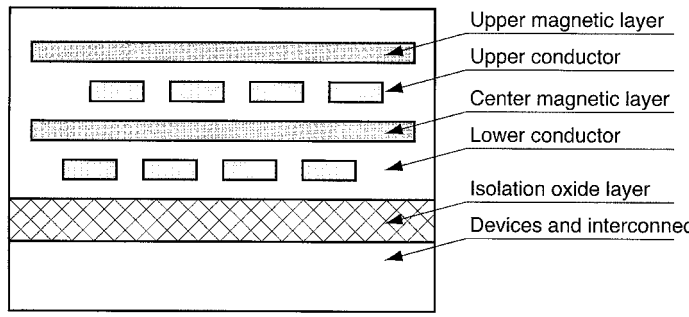

FIGURE 1.12 Cross-sectional view of a VLSI process showing integration of magnetic layers for coil transformers.

1.3 Emerging VLSI Systems

Building on the successes in integrating comprehensive systems from the individual signal processing domains, many next-generation hybrid systems are appearing that integrate systems in a cross-platform manner. The feasibility of these systems depends on the ability of technology to either combine monolithically the unique elements of each system or to introduce a single technology standard that can support broad systems.

Embedded Memory

Computer processors today are bandwidth limited with the memory interface between high-capacity external storage and the processing units unable to meet access rates. Multimedia applications such as

3-D graphics rendering and broadcast rate video will demand bandwidths from 1 to 10 GB/s. A conventional 4-Mb DRAM with 4096 sense amplifiers, a 150-ns cycle time, and a configuration of 1-M × 4-b achieves an internal bandwidth of 3.4 GB/s; however, as this data can be accessed at the I/O pins only in 4-bit segments, external bandwidth is reduced to 0.1% of available bandwidth.

Although complex cache (SRAM) hierarchies have been devised to mask this latency, each additional cache level introduces additional complexity and has an asymptotic performance limit. Since the bandwidth bottleneck is introduced by off-chip (multiplexed) routing of signals, embedded memories are appearing to provide full-bandwidth memory accesses by eliminating I/O multiplexing.

Integration of DRAM and logic is non-trivial as the technology optimization of the former favors minimal bit area, a compact capacitor structure, and low leakage, but in the latter favors device performance. Embedded DRAM therefore permits two implementations: logic fabricated in a DRAM process or DRAM fabricated as a macro in an ASIC process.

Logic in DRAM Process

DRAM technologies do not require multilevel interconnect since their regular array structure translates to very uniform routing. Introducing logic to a DRAM process has been accomplished by merging DRAM front-end fabrication (to capture optimized capacitor and well structures) with an ASIC back-end process (to introduce triple- or quad-level metallization).

Example systems include a 576-Kb DRAM and 8-way hypercube processor[28] and a 1-Mb DRAM and 4-element pixel processor.[29]

DRAM Macro in ASIC Process

DRAM macros currently developed for instantiation in an ASIC process implement a substrate-plate-trench-capacitor (SPT) by modifying deep trench isolation (DTI). Access transistor isolation is accomplished with a triple-well process to extract stray carriers injected as substrate noise.

Fabrication of the stacked-capacitor (STC) structures typical of high-capacity DRAMs cannot be performed in standard ASIC processes without significant modification; this limitation forces additional tradeoffs in the optimal balance of embedded memory capacity and fabrication cost. Example systems include an 8-Mb DRAM and 70-K gate sea-of-gates IC.[30]

Monolithic RFICs

Technologies for monolithic RFICs are proceeding in two directions: all-CMOS and silicon bipolar. All-CMOS has the attractive advantages of ready integration of baseband analog and digital signal processing, compatibility with standard analog/RF CMOS processes, and better characteristics for low-power/low-voltage operation.[31] CMOS is predicted to continue to offer suitable RF performance at operating supplies below 1 V as long as the threshold voltage is scaled accordingly. Silicon bipolar implementations, however, outperform CMOS in several key areas, particularly that of the receiver LNA.

A frequency-hopped spread-spectrum transceiver has been designed in a 1-micron CMOS process with applications to low-power microcell communications.[32,33] A microcell application was chosen since the maximum output power of 20 mW limits the transmission range.

RFICs in bipolar and BiCMOS typically focus on the specific receiver components most improved by non-CMOS implementations. A common RFIC architecture is an LNA front-end followed by a down-mixer. Interstage filtering and matching, if required, are provided off-chip. In CMOS, a 1-GHz RFIC achieved a conversion gain of 20 dB, an NF of 3.2 dB, an IP3 of 8 dBm, with a current drain of 9 mA from a 3-V supply.[34] A similar architecture in BiCMOS at 1 GHz achieved a conversion gain of 16 dB, an NF of 2.2 dB, an IP3 of –10 dBm, with a current drain of 13 mA from a 5-V supply.[35]

Single-Chip Sensors and Detectors

One of the most active areas of system development is in the field of "camera-on-a-chip" in which VLSI-compatible photodetector arrays are monolithically fabricated with digital and analog peripheral circuitry.

The older charge-coupled device (CCD) technology is being replaced by active-pixel sensing (APS) technologies in new systems since CCD has a higher per-cell capacitance.[36] APS also offers a monolithic integration of analog-to-digital converters and digital control logic. On-chip digitization of the sensor outputs eliminates the additional power loss and noise contributions incurred in buffering an analog signal for off-chip processing.

Conventional CMOS technology is expected to permit co-fabrication of APS sensors down to feature dimensions as small as 0.25 microns,[37] although leakage currents will become a concern for low-power operation. Other low-power techniques that degrade APS performance such as silicidation and thin-film devices can be controlled by slight process modifications. Silicide blocks eliminate the opaque, low-resistance layer; and thin-film devices, such as those found in fully depleted SOI, can be avoided by opening windows through the SOI-buried oxide to the bulk silicon.

MEMS

Electrothermal properties of MEMS suspended or cantilevered layers are finding applications in a variety of electromechanical systems. For example, suspended layers have been developed for a number of purposes, including microphones,[38] accelerometers, and pressure sensors. By sealing a fluid within a MEMS cavity, pressure sensors can also serve as infrared detectors and temperature sensors. Analog feedback electronics monitor the deflection of a MEMS layer caused by the influence of external stresses. The applied control voltage provides an analog readout of the relative magnitude of the external stresses.

MEMS micropumps have been developed which have potential applications in medical products (e.g., drug delivery) and automotive systems (e.g., fuel injection).[39] Flow rates of about 50 μl/min at 1-Hz cycling have been achieved, but the overall area required is still large (approximately 1 cm^2), presently limiting integration. Beyond macro applications, microfluidics has been proposed as a technique for integrated cooling of high-power and high-temperature ICs in which coolant is circulated within the substrate mass.

1.4 Alternative Technologies

The discussion so far has assumed a VLSI system to be comprised primarily of transistors, with the exception of non-electronic MEMS. Although this implementation has evolved unchallenged for nearly 50 years, several innovative technologies have progressed to the state that they are attracting serious attention as future competitors. Some, such as quantum computing, are still fundamentally electronic in nature. Others, like biological, DNA, and molecular computing, use living cells as elemental functional units.

The chief advantage of these technologies is the extreme power efficiency of a computation. Quantum computing achieves ultra-low-power operation by reducing logic operations to the change in an electron spin or an atomic ionization state. Biological and DNA computing exploit the energy efficiency of living cells, the product of a billion years of evolution. A second attribute is extremely fast computation owing to greatly reduced signal path lengths (to a molecular or atomic scale) and massively parallel (MP) simultaneous operations.

Quantum Computing

Quantum computing (QC) is concerned with the probabilistic nature of quantum states, by which a single atom can be used to "store" and "compare" multiple values simultaneously. QC has two distinct implementations: an electronic one based on the wave-function interaction of fixed adjacent atoms[40] and a biochemical one based on mobile molecular interactions within a fluid medium.[41] In fixed systems, atom placement and stimulation are accomplished with atomic force microscopy (AFM) and nuclear magnetic resonance (NMR), but performance as a system also requires the ability to

individually select and operate on an atom.[42] Molecular systems avoid this issue by using a fluid medium as a method of introducing initial conditions and isolating the computation from the measurement. Computational redundancy then statistically removes measurement error and incorrect results generated at the fluid boundaries.

Recent work in algorithms has demonstrated that QC can solve two categories of problems more efficiently than with a classical computer science method by taking advantage of wave function indeterminate states. In search and factorization problems (involving a random search of N items), a classical solution requires $O(N)$ steps, but a QC algorithm requires only $O(\sqrt{N})$; and binary parity computations can be improved from $O(N)$ to $O(N/2)$ in a QC algorithm.[43]

Practical implementation of QC algorithms to very large data sets is currently limited by instrumentation. For example, a biochemical QC system using NMR to change spin polarity has signal frequencies of less than 1 kHz. Despite this low frequency, the available parallelism is expected to factor (with the $O(\sqrt{N})$ algorithm) a 400-digit number in one year: greater than 3×10^{186} MOPS (mega-operations per second).[44]

DNA Computing

In DNA computing, a problem set is encoded into DNA strands which then, by nucleotide matching properties, perform MP search and comparison operations. Most comparison techniques to date rely on conformal mapping, but some reports appearing in the literature indicate that more powerful DNA algorithms are possible with non-conformal mapping and secondary protein interaction.[45] The challenge is in developing a formal language to describe DNA computing compounded by accounting for these secondary and tertiary effects, including protein structure and amino acid chemical properties.[46] Initial work in formal language theory has shown that DNA computers can be made equivalent to a Turing machine.[47]

DNA can also provide extremely dense data storage, requiring about a trillionth of the volume required for an equivalent electronic memory: 10^{12} DNA strands, each 1000 units long, is equal to 1000 T bits.[48] DNA computations employ up to 10^{20} DNA strands (over 11 million TB), well beyond the capacity of any conventional data storage.

Molecular Computing

Molecular computers are a mixed-signal system for performing logic functions (with possible subpicosecond switching) and signal detection with an ability to evolve and adapt to new conditions. Possible implementations include modulation of electron, proton, or photon mobility; electronic-conformation interactions; and tissue membrane interactions.[49] Table 1.3 lists some of the architectures and applications.

"Digital" cell interactions, such as found in quantum or DNA computing, provide the logic implementation. Analog processing is introduced by the nonlinear characteristics of the cell interaction with respect to light, electricity, magnetism, chemistry, or other external stimulus. Molecular systems are also thought to emulate a neural network that can be capable of signal enhancement and noise removal.[50]

TABLE 1.3 Summary of Some Architectures and Applications Possible from a Molecular Computing System

Mechanisms and Architectures	Applications
Light-energy transducing proteins	Biosensors
Light-energy transducing proteins (with controlled switching)	Organic memory storage
Optoelectronic transducing	Pattern recognition and processing
Evolutionary structures	Adaptive control

2.1 Introduction

Silicon LSIs (large-scale integrated circuits) have progressed remarkably in the past 25 years. In particular, complementary metal-oxide-semiconductor (CMOS) technology has played a great role in the progress of LSIs. By downsizing[2] MOS field-effect-transistors (FETs), the number of transistors in a chip increases, and the functionality of LSIs is improved. At the same time, the switching speed of MOSFETs and circuits increases and operation speed of LSIs is improved.

On the other hand, system-on-chip technology has come into widespread use and, as a result, the LSI system requires several functions, such as logic, memory, and analog functions. Moreover, the LSI system sometimes needs an ultra-high-speed logic or an ultra-high-frequency analog function. In some cases, bipolar-CMOS (BiCMOS) technology is very useful.

The first part of this chapter focuses on CMOS technology as the major LSI process technology, including embedded memory technology. The second part, describes BiCMOS technology; and finally, future process technology is introduced.

2.2 CMOS Technology

Device Structure and Basic Fabrication Process Steps

Complementary MOS (CMOS) was first proposed by Wanlass and Sah in 1963.[1] Although the CMOS process is more complex than the NMOS process, it provides both n-channel (NMOS) and p-channel (PMOS) transistors on the same chip, and CMOS circuits can achieve lower power consumption. Consequently, the CMOS process has been widely used as an LSI fabrication process.

Figure 2.1 shows the structure of a CMOS device. Each FET consists of a gate electrode, source, drain, and channel, and gate bias controls carrier flow from source to drain through the channel layer.

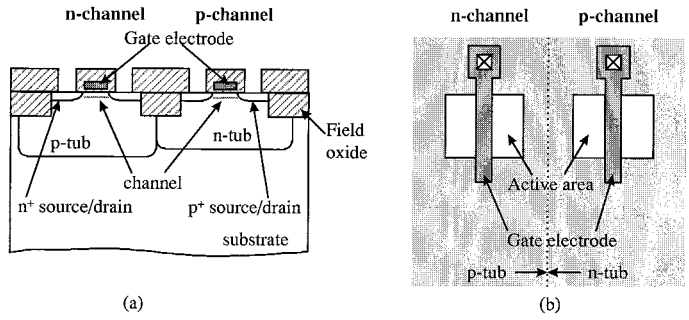

FIGURE 2.1 Structure of CMOS device: (a) cross-sectional view of CMOS, (b) plain view of CMOS.

Figure 2.2 shows the basic fabrication process flow. The first process step is the formation of p tub and n tub (twin tub) in silicon substrate. Because CMOS has two types of FETs, NMOS is formed in p tub and PMOS in n tub.

The isolation process is the formation of field oxide in order to separate each MOSFET active area in the same tub. After that, impurity is doped into channel region in order to adjust the threshold voltage, V_{th}, for each type of FET. The gate insulator layer, usually silicon dioxide (SiO_2), is grown by thermal oxidation, because the interstate density between SiO_2 and silicon substrate is small. Polysilicon is deposited as gate electrode material and gate electrode is patterned by reactive ion etching (RIE).

The gate length, L_g, is the critical dimension because L_g determines the performance of MOSFETs and it should be small in order to improve device performance. Impurity is doped in the source and drain regions of MOSFETs by ion implantation. In this process step, gate electrodes act as a self-aligned mask to cover channel layers. After that, thermal annealing is carried out in order to activate the impurity of diffused layers.

In the case of high-speed LSI, the self-aligned silicide (salicide) process is applied for the gate electrode and source and drain diffused layers in order to reduce parasitic resistance. Finally, the metallization process is carried out in order to form interconnect layers.

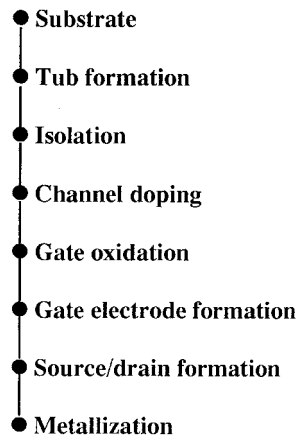

FIGURE 2.2 Basic process flow of CMOS.

Key Process Steps in Device Fabrication

Starting Material

Almost all silicon crystals for LSI applications are prepared by the Czochralski crystal growth method,[2] because it is advantageous for the formation of large wafers. (100) orientation wafers are usually used

for MOS devices because their interstate trap density is smaller than those of (111) and (110) orientations.[3] The light doping in the substrate is convenient for the diffusion of tub and reduces the parasitic capacitance between silicon substrate and tub region. As a starting material, lightly doped (~10^{15} atoms/cm^3) p-type substrate is generally used.

Tub Formation

Figure 2.3 shows the tub structures, which are classified into 6 types: p tub, n tub, twin tub,[4] triple tub, twin tub with buried p^+ and n^+ layers, and twin tub on p-epi/p^+ substrate. In the case of the p tub process, NMOS is formed in p diffusion (p tub) in the n substrate, as shown in Fig. 2.3(a). The p tub is formed by implantation and diffusion into the n substrate at a concentration that is high enough to overcompensate the n substrate.

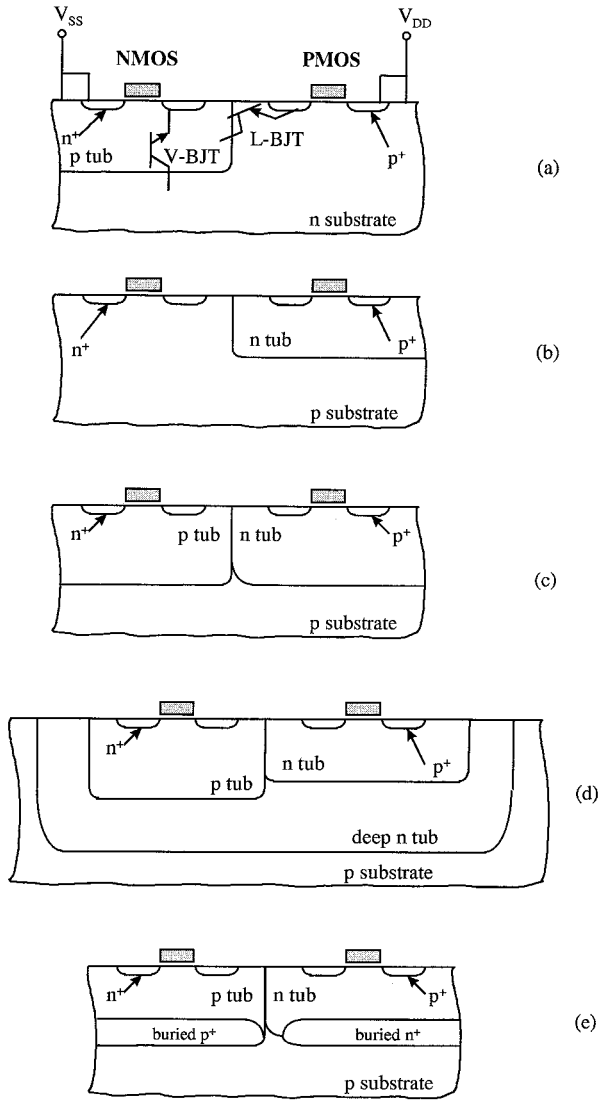

FIGURE 2.3 Tub structures of CMOS: (a) p tub; (b) n tup; (c) twin tub; (d) triple tub; (e) twin tub with buried p^+ and n^+ layers; and (f) twin tub on p-epi/p^+ substrate.

The other approach is to use an n tub.[5] As shown in Fig. 2.3(b), NMOS is formed in the p substrate.

Figure 2.3(c) shows the twin-tub structure,[4] that uses two separate tubs implanted into silicon substrate. In this case, doping profiles in each tub region can be controlled independently, and thus neither type of device suffers from excess doping effect.

In some cases, such as mixed signal LSIs, a deep n tub layer is sometimes formed optionally, as shown in Fig. 2.3(d), in order to prevent the crosstalk noise between digital and analog circuits. In this structure, both n and p tubs are electrically isolated from the substrate or other tubs on the substrate.

In order to realize high packing density, the tub design rule should be shrunk; however, an undesirable mechanism, the well-known latch-up, might occur.

Latch-up (i.e., the flow of high current between V_{DD} and V_{SS}) is caused by parasitic lateral pnp bipolar (L-BJT) and vertical npn bipolar (V-BJT) transistor actions[6] as shown in Fig. 2.3(a), and it sometimes destroys the functions of LSIs. The collectors of each of these bipolar transistors feed each others' bases and together make up a pnpn thyristor structure. In order to prevent latch-up, it is important to reduce the current gain, h_{FE}, of these parasitic bipolar transistors, and the doping concentration of the tub region should be higher. As a result, device performance might be suppressed because of large junction capacitances.

In order to solve this problem, several techniques have been proposed, such as p^+ or n^+ buried layer under p tub[7] as shown in Fig. 2.3(e), the use of high-dose, high-energy boron p tub implants,[8,9] and the shunt resistance for emitter-base junctions of parasitic bipolar transistors.[7,10,11] It is also effective to provide many well contacts to stabilize the well potential and hence to suppress the latch-up. Recently, substrate with p epitaxial silicon on p^+ substrate, can also be used to stabilize the potential for high-speed logic LSIs.[12]

Isolation

Local oxidation of silicon (LOCOS)[13] is a widely used isolation process, because this technique can allow channel-stop layers to be formed self-aligned to the active transistor area. It also has the advantage of recessing about half of the field oxide below the silicon surface, which makes the surface more planar.

Figure 2.4 shows the LOCOS isolation process. First, silicon nitride and pad oxide are etched for the definition of active transistor area. After channel implantation as shown in Fig. 2.4(a), the field oxide is selectively grown, typically to a thickness of several hundred nanometers.

A disadvantage of LOCOS is that involvement of nitrogen in the masking of silicon nitride layer sometimes causes the formation of a very thin nitride layer in the active region, and this often impedes the subsequent growth of gate oxide, thereby causing low gate breakdown voltage of the oxides. In order to prevent this problem, after stripping the masking silicon nitride, a sacrificial oxide is grown and then removed before the gate oxidation process.[14,15]

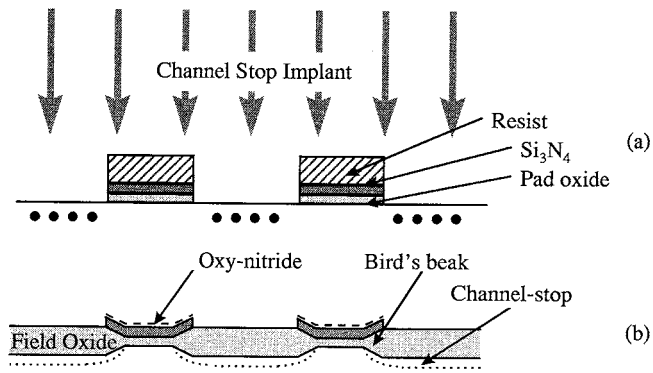

FIGURE 2.4 Process for local oxidation of silicon: (a) after silicon nitride/pad oxide etch and channel-stop implant; (b) after field oxidation, which produces an oxynitride film on nitride.

In addition, the lateral spread of field oxide (bird's beak)[14] poses a problem regarding reduction of the distance between active transistor areas in order to realize high packing density. This lateral spread is suppressed by increasing the thickness of silicon nitride and/or decreasing the thickness of pad oxide. However, there is a tradeoff with the generation of dislocation of silicon.

Recently, shallow trench isolation (STI)[16] has become a major isolation process for advanced CMOS devices. Figure 2.5 shows the process flow of STI. After digging the trench into the substrate by RIE as shown in Fig. 2.5(a), the trench is filled with insulator such as silicon dioxide as shown in Fig. 2.5(b). Finally, by planarization with chemical mechanical polishing (CMP),[17] filling material on the active transistor area is removed, as shown in Fig. 2.5(c).

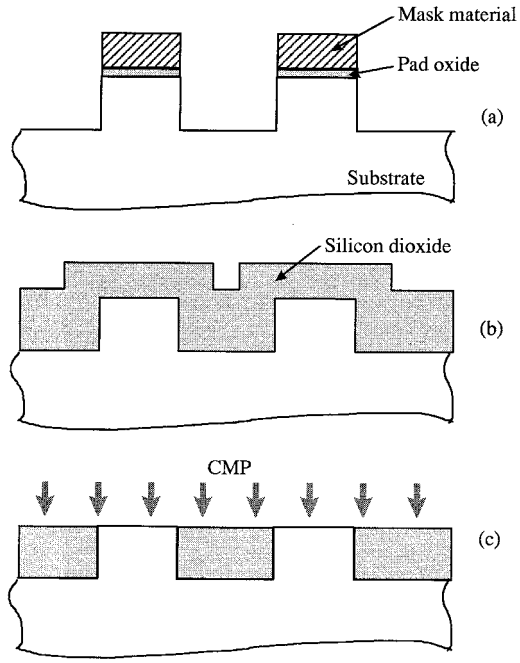

FIGURE 2.5 Process flow of STI: (a) trenches are formed by RIE; (b) filling by deposition of SiO_2; and (c) planarization by CMP.

STI is a useful technique for downsizing not only the distance between active areas, but also the active region itself. However, a mechanical stress problem[18] still remains, and several methods have been proposed[19] to deal with it.

Channel Doping

In order to adjust the threshold voltage of MOSFETs, V_{th}, to that required by a circuit design, the channel doping process is usually required. The doping is carried out by ion implantation, usually through a thin dummy oxide film (10 to 30 nm) thermally grown on the substrate in order to protect the surface from contamination, as shown in Fig. 2.6. This dummy oxide film is removed prior to the gate oxidation. Figure 2.7 shows a typical CMOS structure with channel doping. In this case, n^+ polysilicon gate electrodes are used for both n- and p-MOSFETs and, thus, this type of CMOS is called single-gate CMOS. The role of the channel doping is to enhance or raise the threshold voltage of n-MOSFETs. It is desirable to keep the concentration of p tub lower in order to reduce the junction capacitance of source and drain. Thus, channel doping of p-type impurity — boron — is required. Drain-to-source leakage current in short-channel MOSFETs flows in a deeper path, as shown in Fig. 2.8; this is called the short-channel effect. Thus, heavy doping of the deeper region is effective in suppressing the short-channel effect. This doping is called deep ion implantation.

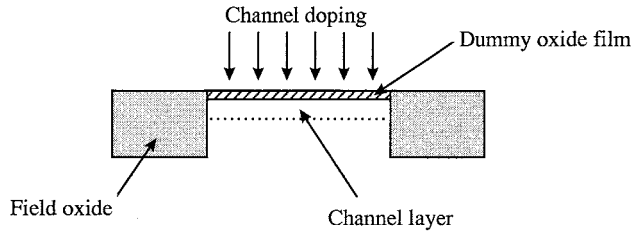

FIGURE 2.6 Channel doping process step.

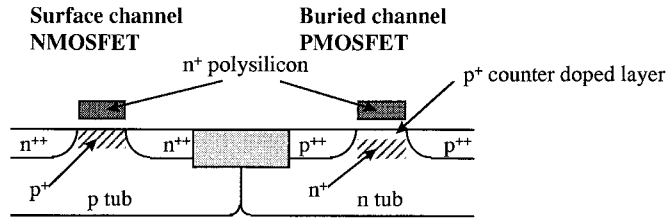

FIGURE 2.7 Schematic cross-section of single-gate CMOS structure.

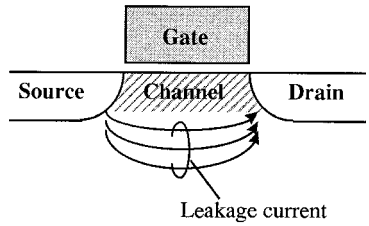

FIGURE 2.8 Leakage current flow in short-channel MOSFET.

In the case of p-MOSFET with an n^+ polysilicon gate electrode, the threshold voltage becomes too high in the negative direction if there is no channel doping. In order to adjust the threshold voltage, an ultra-shallow p-doped region is formed by the channel implantation of boron. This p-doped layer is often called a counter-doped layer or buried-channel layer, and p-MOSFETs with this structure are called buried-channel MOSFETs. (On the other hand, MOSFETs without a buried-channel layer are called surface-channel MOSFETs. n-MOSFETs in this case are the surface-channel MOSFETs.) In the buried-channel case, the short-channel effect is more severe, and, thus, deep implantation of an n-type impurity such as arsenic or phosphorus is necessary to suppress them.

In deep submicron gate length CMOS, it is difficult to suppress the short-channel effect,[20] and thus, a p^+-polysilicon electrode is used for p-MOSFETs, as shown in Fig. 2.9. For n-MOSFETs, an n^+-polysilicon electrode is used. Thus, this type of CMOS is called dual-gate CMOS. In the case of p^+-polysilicon p-MOSFET, the threshold voltage becomes close to 0 V because of the difference in work function between n- and p-polysilicon gate electrode,[21–23] and thus, buried layer is not required. Instead, n-type impurity channel doping such as arsenic is required to raise the threshold voltage slightly in the negative direction.

Impurity redistribution during high-temperature LSI manufacturing processes sometimes makes channel profile broader, which causes the short-channel effect. In order to suppress the redistribution, a dopant with a lower diffusion constant, such as indium, is used instead of boron.

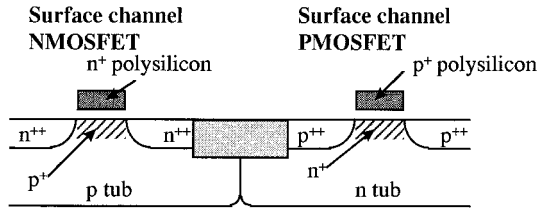

FIGURE 2.9 Schematic cross-section of dual-gate CMOS structure.

For the purpose of realizing a high-performance transistor, it is important to reduce junction capacitance. In order to realize lower junction capacitance, a localized diffused channel structure.[24,25] as shown in Fig. 2.10, is proposed. Since the channel layer exists only around the gate electrode, the junction capacitance of source and drain is reduced significantly.

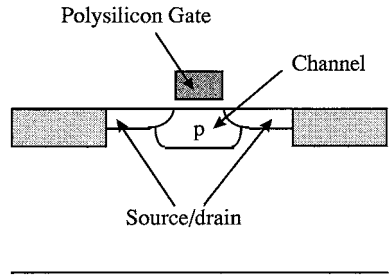

FIGURE 2.10 Localized channel structure.

Gate Insulator

The gate dielectric determines several important properties of MOSFETs and thus uniformity in its thickness, low defect density of the film, low fixed charge and interface state density at the dielectric and silicon interface, small roughness at the interface, high reliability of time-dependent dielectric breakdown (TDDB) and hot-carrier induced degradation, and high resistivity to boron penetration (explained in this section) are required. As a consequence of downsizing of MOSFET, the thickness of the gate dielectric has become thinner. Generally, the thickness of the gate oxide is 7 to 8 nm for 0.4-μm gate length MOSFETs, and 5 to 6 nm for 0.25-μm gate length MOSFETs.

Silicon dioxide (SiO_2) is commonly used for gate dielectrics, and can be formed by several methods, such as dry O_2 oxidation,[26] and wet or steam (H_2O) oxidation.[26] The steam is produced by the reaction of H_2 and O_2 ambient in the furnace. Recently, H_2O oxidation has been widely used for gate oxidation because of good controllability of oxide thickness and high reliability.

In the case of the dual-gate CMOS structure shown in Fig. 2.9, boron penetration from the p^+ gate electrode to the channel region through the gate silicon dioxide, which is described in the following section, is a problem. In order to prevent this problem, oxynitride has been used as the gate dielectric material.[27,28] In general, the oxynitride gate dielectric is formed by the annealing process in NH_3, NO (or N_2O) after silicon oxidation, or by direct oxynitridation of silicon in NO (or N_2O) ambient. Figure 2.11 shows the typical nitrogen profile of the oxynitride gate dielectric. Recently, remote plasma nitridation[29,30] has been much studied, and it is reported that the oxynitride gate dielectric grown by the remote plasma method showed better quality and reliability than that grown by the silicon nitridation method.

In the regime of a sub-quarter-micron CMOS device, gate oxide thickness is close to the limitation of tunneling current flow, around 3 nm thickness. In order to prevent tunneling current, high κ materials,

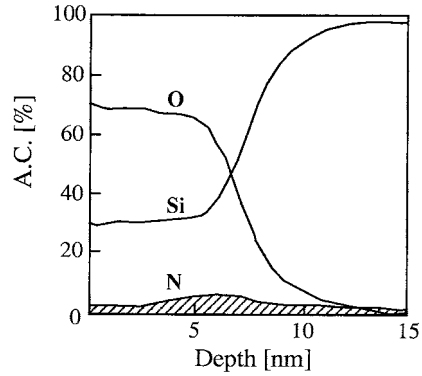

FIGURE 2.11 Oxygen, nitrogen, and silicon concentration profile of oxynitride gate dielectrics measued by AES.

such as Si_3N_4[31] and Ta_2O_5,[32] are proposed instead of silicon dioxide. In these cases, the thickness of the gate insulator can be kept relatively thick because high κ insulator realizes high gate capacitance, and thus better driving capability.

Gate Electrode

Heavily doped polysilicon has been widely used for gate electrodes because of its resistance to high-temperature LSI fabrication processing. In order to reduce the resistance of the gate electrode, which contributes significantly to RC delay time, silicides of refractory metals have been put on the polysilicon electrode.[33,34] Polycide,[34] the technique of combining a refractory metal silicide on top of doped polysilicon, has the advantage of preserving good electrical and physical properties at the interface between polysilicon and the gate oxide while, at the same time, the sheet resistance of gate electrode is reduced significantly.

For doping the gate polysilicon, ion implantation is usually employed. In the case of heavy doping, dopant penetration from boron-doped polysilicon to the Si substrate channel region through the gate oxide occurs in the high-temperature LSI fabrication process, as shown in Fig. 2.12. (On the other hand, usually, penetration of an n-type dopant [such as phosphorus or arsenic] does not occur.) When the doping of impurities in the polysilicon is not sufficient, the depletion of the gate electrode occurs as shown in Fig. 2.13, resulting in a significant decrease of the drive capability of the transistor, as shown in Fig. 2.14.[35] There is a tradeoff between the boron penetration and the gate electrode depletion, and so thermal process optimization is required.[36]

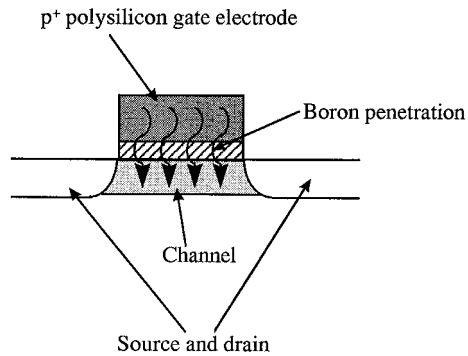

FIGURE 2.12 Dopant penetration from boron-doped polysilicon to silicon substrate channel region.

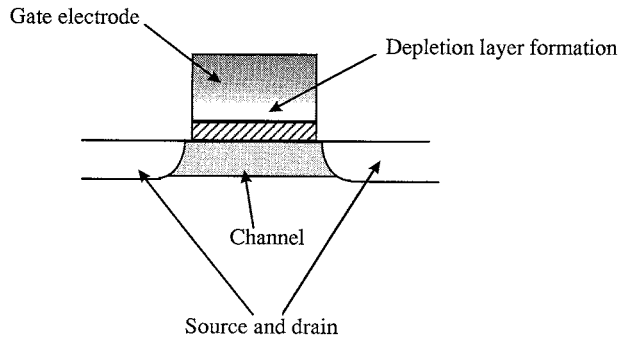

FIGURE 2.13 Depletion of gate electrode in the case that the doping of impurities in the gate electrode is not sufficient.

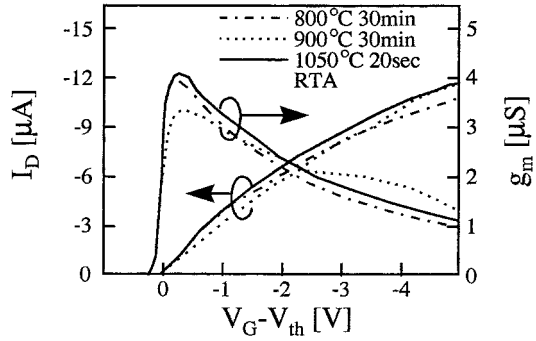

FIGURE 2.14 I_D, $g_m - V_G$ characteristics for various thermal conditions. In the case of 800°C/30 min, a significant decrease in drive capability of transistor occurs because of the depletion of the gate electrode.

Gate length is one of most important dimensions defining MOSFET performance; thus, the lithography process for gate electrode patterning requires high-resolution technology.

In the case of a light-wave source, the g-line (wavelength 436 nm) and the i-line (365 nm) of a mercury lamp were popular methods. Recently, a higher-resolution process, excimer laser lithography, has been used. In the excimer laser process, KrF (248 nm)[37] and ArF (193 nm)[38] have been proposed and developed. For a 0.25-μm gate length electrode, the KrF excimer laser process is widely used in the production of devices. In addition, electron-beam[39–41] and X-ray[42] lithography techniques are being studied for sub-0.1 μm gate electrodes.

For the etching of gate polysilicon, a high-selectivity RIE process is required for selecting polysilicon from SiO_2 because a gate dielectric beneath polysilicon is a very thin film in the case of recent devices.

Source/Drain Formation

Source and drain diffused layers are formed by the ion implantation process. As a consequence of transistor downsizing, at the drain edge (interface of channel region and drain) where reverse biased pn junctions exist, a higher electrical field has been observed. As a result, carriers across these junctions are suddenly accelerated and become hot carriers, which creates a serious reliability problem for MOSFET.[43]

In order to prevent the hot carrier problem, the lightly doped drain (LDD) structure is proposed.[44] The LDD process flow is shown in Fig. 2.15. After gate electrode formation, ion implantation is carried out to make extension layers, and the gate electrode plays the role of self-aligned mask that covers the channel layer, as shown in Fig. 2.15(b). In general, arsenic is doped for n-type extension of NMOS, and BF_2 for p-type extension of PMOS. To prevent the short-channel effect, the impurity profile of extension layers must

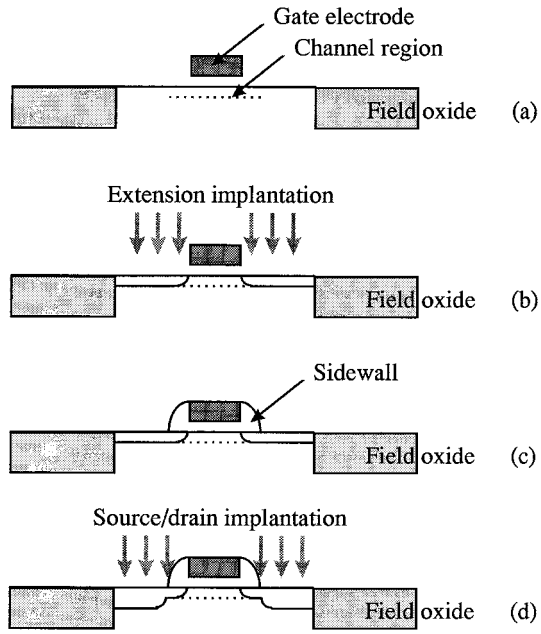

FIGURE 2.15 Process flow of LDD structure: (a) after gate electrode patterning; (b) extension implantation; (c) sidewall spacer formation; and (d) source/drain implantation.

be very shallow. Although shallow extension can be realized by ion implantation with low dose, the resistivity of extension layers becomes higher and, thus, MOSFET characteristics degrade. Hence, it is very difficult to meet these two requirements. Also, impurities diffusion in this extension affects the short-channel effect significantly. Thus, it is necessary to minimize the thermal process after forming the extension.

Insulating film, such as Si_3N_4 or SiO_2, is deposited by a chemical vapor deposition method. Then, etching back RIE treatment is performed on the whole wafer; as a result, the insulating film remains only at the gate electrode side, as shown in Fig. 2.15(c). This remaining film is called a sidewall spacer. This spacer works as a self-aligned mask for deep source/drain n^+ and p^+ doping, as shown in Fig. 2.15(d). In general, arsenic is doped for deep source/drain of n-MOSFET, and BF_2 for p-MOSFET. In the dual-gate CMOS process, gate polysilicon is also doped in this process step to prevent gate electrode depletion.

After that, in order to make doped impurities activate electrically and recover from implantation damage, an annealing process, such as rapid thermal annealing (RTA), is carried out.

According to the MOSFET scaling law, when gate length and other dimensions are shrunk by factor k, the diffusion depth also needs to be shrunk by $1/k$. Hence, the diffusion depth of the extension part is required to be especially shallow.

Several methods have been proposed for forming an ultra-shallow junction. For example, very low accelerating voltage implantation, the plasma doping method,[45] and implantation of heavy molecules, such as $B_{10}H_{14}$ for p-type extension,[46] are being studied.

Salicide Technique

As the vertical dimension of transistors is reduced with device downscaling, an increase is seen in sheet resistance — both of the diffused layers, such as source and drain, and the polysilicon films, such as the gate electrode. This is becoming a serious problem in the high-speed operation of integrated circuits.

Figure 2.16 shows the dependence of the propagation delay (t_{pd}) of CMOS inverters on the scaling factor, k, or gate length.[47] These results were obtained by simulations in which two cases were considered. First is the case in which source and drain contacts with the metal line were made at the edge of the diffused layers, as illustrated in the figure inset. In an actual LSI layout, it often happens that the metal

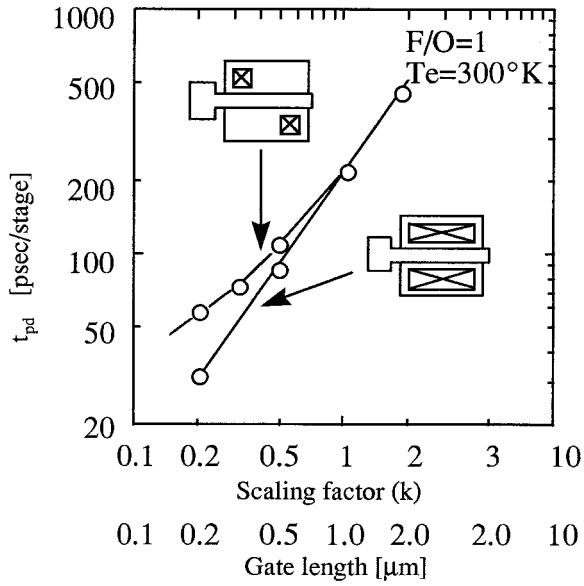

FIGURE 2.16 Dependence of the propogation delay (t_{pd}) of CMOS inverters on the scaling factor, k, or gate length.

contact to the source or drain can be made only to a portion of the diffused layers, since many other signal or power lines cross the diffused layers. The other case is that in which the source and drain contacts cover the entire area of the source and drain layers, thus reducing diffused line resistance. It is clear that without a technique to reduce the diffused line resistance, t_{pd} values cannot keep falling as transistor size is reduced; they will saturate at gate lengths of around a 0.25 microns.

In order to solve this problem — the high resistance of shallow diffused layers and thin polysilicon films — self-aligned silicide (salicide) structures for the source, drain, and gate have been proposed, as shown in Fig. 2.17.[48–50]

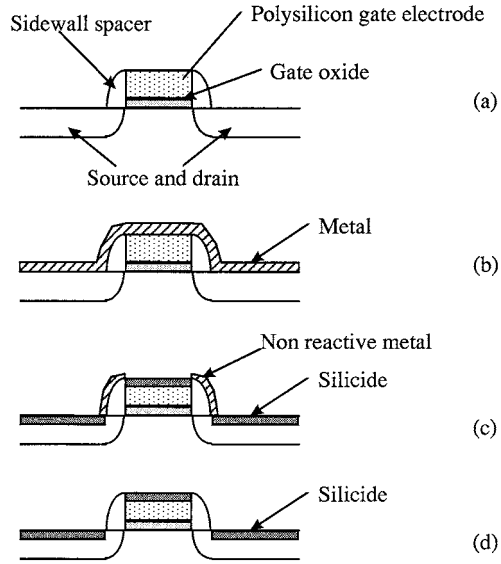

FIGURE 2.17 A typical process flow and schematic cross-section of salicide process: (a) MOSFET formation; (b) metal deposition; (c) silicidation by thermal annealing; and (d) removal of non-reactive metal.

First, a metal film such as Ti or Co is deposited on the surface of the MOSFET after formation of the polysilicon gate electrode, gate sidewall, and source and drain diffused layers, as shown in Fig. 2.17(b). The film is then annealed by rapid thermal annealing (RTA) in an inert ambient. During the annealing process, the areas of metal film in direct contact with the silicon layer — that is, the source, drain, and gate electrodes — are selectively converted to the silicide, and other areas remain metal, as shown in Fig. 2.17(c). The remaining metal can be etched off with an acid solution such as $H_2O_2 + H_2SO_4$, leaving the silicide self-aligned with the source, drain, and gate electrode, as shown in Fig. 2.17(d).

When the salicide process first came into use, furnace annealing was the most popular heat-treatment process[48–50]; however, RTA[51–53] replaced furnace annealing early on, because it is difficult to prevent small amounts of oxidant from entering through the furnace opening, and these degrade the silicide film significantly since silicide metals are easily oxidized. On the other hand, RTA reduces this oxidation problem significantly, resulting in reduced deterioration of the film and consequently of its resistance.

At present, $TiSi_2$[51–53] is widely used as a silicide in LSI applications. However, in the case of ultra-small geometry MOSFETs for VLSIs, use of $TiSi_2$ is subject to several problems. When the $TiSi_2$ is made thick, a large amount of silicon is consumed during silicidation, and this results in problems of junction leakage at the source or drain. On the contrary, if a thin layer of $TiSi_2$ is chosen, agglomeration of the film occurs[54] at higher silicidation temperatures.

On the other hand, $CoSi_2$[55] has a large silicidation temperature window for low sheet resistance; hence, it is expected to be widely used as silicidation material for advanced VLSI applications.[47]

Interconnect and Metallization

Aluminum is widely used as a wiring metal. However, in the case of downsized CMOS, electromigration (EM)[56] and stress migration (SM)[57] become serious problems. In order to prevent these problems, Al-Cu (typically ~0.5 wt % Cu)[58] is a useful wiring material. In addition, ultra-shallow junction for downsized CMOS sometimes needs barrier metal,[58] such as TiN, between the metal and silicon, in order to prevent junction leakage current.

Figure 2.18 shows a cross-sectional view of a multi-layer metallization structure. As a consequence of CMOS downscaling, contact or via aspect ratio becomes larger; and, as a result, filling of contact or via is not sufficient. Hence, new filling techniques, such as W-plug,[59,60] are widely used.

In addition, considering both reliability and low resistivity, Cu is a useful wiring material.[61] In the case of Cu is used, metal thickness can be reduced in order to realize the same interconnect resistance. The reduction of the metal thickness is useful for reducing the capacitance between the dense interconnect wires, resulting in the high-speed operation of the circuit. In order to reduce RC delay of wire

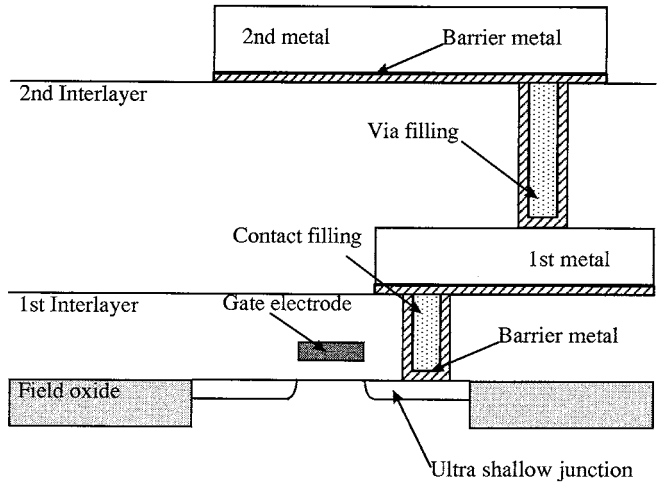

FIGURE 2.18 Cross-sectional view of multi-layer metallization.

in CMOS LSI, not only wiring material but also interlayer material is important. In particular, low-κ material[62] is widely studied.

In the case of Cu wiring, the dual damascene process[63] is being widely studied because it is difficult to realize fine Cu pattern by reactive ion etching. Figure 2.19 shows the process flow of Cu dual

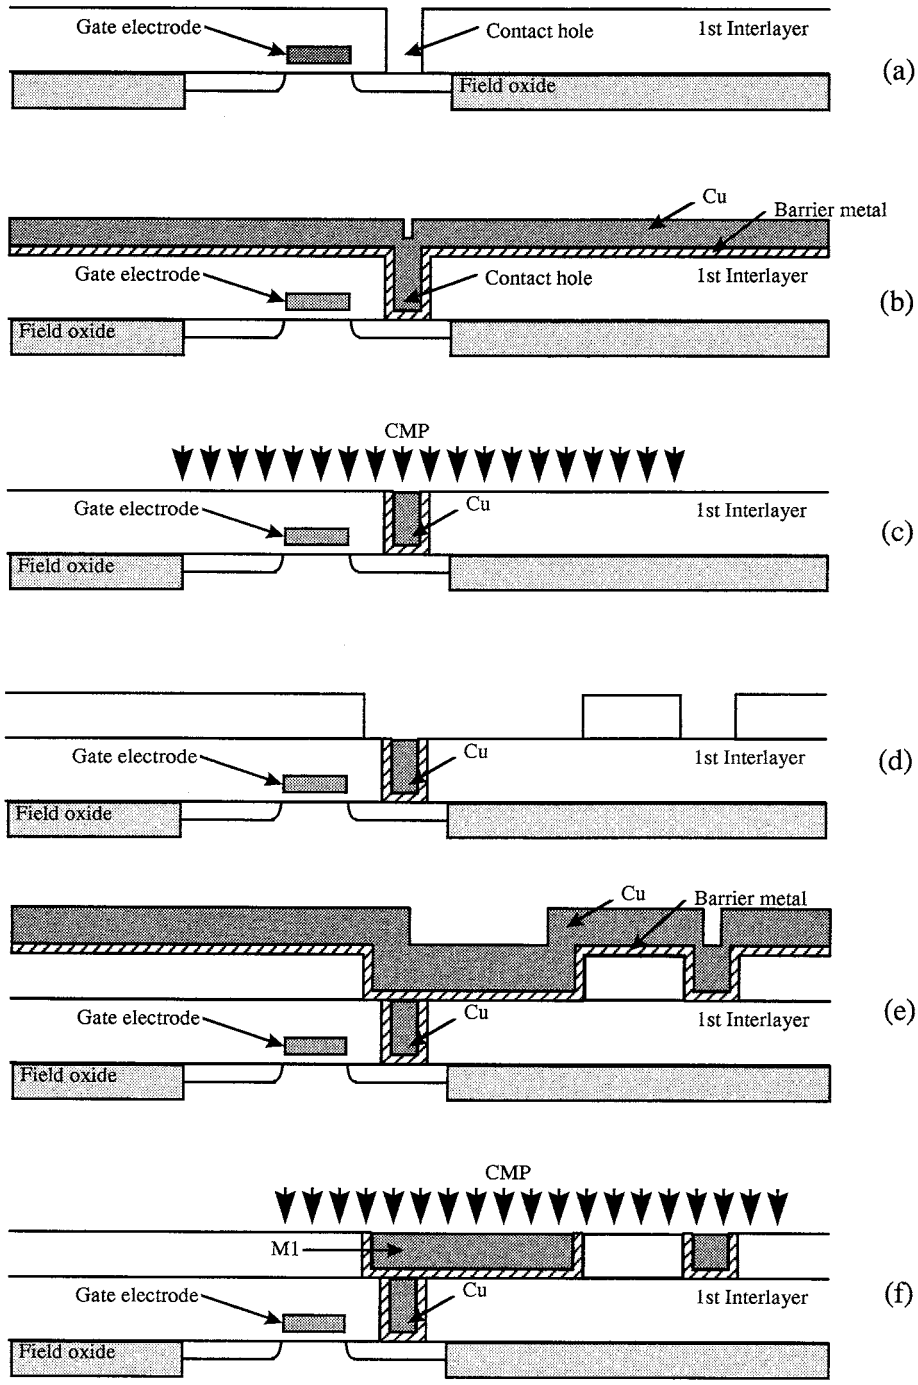

FIGURE 2.19 Typical process flow of Cu dual damascene.

damascene metallization. After formation of transistors and contact holes as shown in Fig. 2.19(a), barrier metal, such as TiN, and Cu are deposited as shown in Fig. 2.19(b). By using the CMP planarization process, Cu and barrier metal remains in the contact holes, as shown in Fig. 2.19(c). Insulator, such as silicon dioxide, is deposited and the grooves for first metal wires are formed by reactive ion etching, as shown in Fig. 2.19(d). After the deposition of barrier metal and Cu as shown in Fig. 2.19(e), Cu and barrier metal remain only in the wiring grooves due to use of a planarization process such as CMP, as shown in Fig. 2.19(f).

Passive Device for Analog Operation

System-on-chip technology has come into widespread use; and as a result, an LSI system sometimes requires analog functions. In this case, analog passive devices should be integrated,[64] as shown in Fig. 2.20.

Resistors and capacitors already have good performance, even for high-frequency applications. On the other hand, it is difficult to realize a high-quality inductor on a silicon chip because of inductance loss in Si substrate, in which the resistivity is lower than that in the compound semiconductor, such as GaAs, substrate. The relatively higher sheet resistance of aluminum wire used for high-density LSI is another problem. Recently, quality of inductor has been improved by using thicker Al or Cu wire[65] and by optimizing the substrate structure.[66]

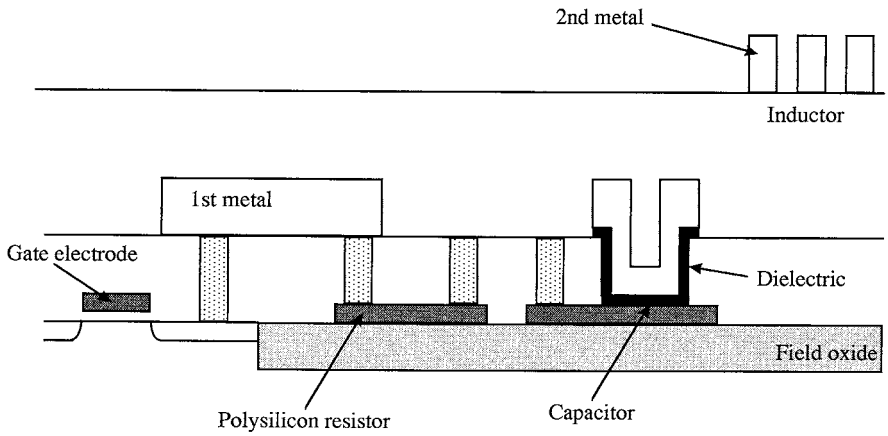

FIGURE 2.20 Various passive devices for analog application.

Embedded Memory Technology

Embedded DRAM

There has been strong motivation to merge DRAM cell arrays and logic circuits into a single silicon chip. This approach makes it possible to realize high bandwidth between memory and logic, low power consumption, and small footprint of the chip.[67] In order to merge logic and DRAM into a single chip, it is necessary to establish process integration for the embedded DRAM. Figure 2.21 shows a typical structure of embedded DRAM. However, the logic process and the DRAM process are not compatible with each other. There are many variations and options in constructing a consistent process integration for the embedded DRAM.

Trench Capacitor Cell versus Stacked Capacitor Cell

There are two types of DRAM cell structure: stacked capacitor cell[68–73] and trench capacitor cell.[74,75]

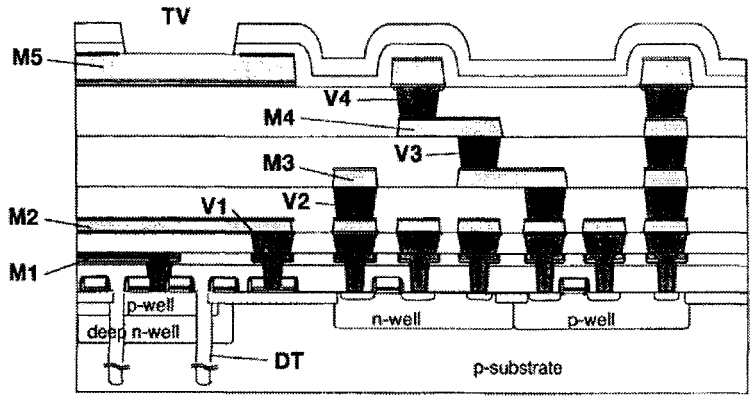

FIGURE 2.21 Schematic cross-section of the embedded DRAM, including DRAM cells and logic MOSFETs.

In trench cell technology, the cell capacitor process is completed before gate oxidation. Therefore, there is no thermal process due to cell capacitor formation after the MOSFET formation. Another advantage of the trench cell is that there is little height difference between the cell array region and the peripheral circuit region.[76–79]

In the stacked capacitor cell, the height difference high aspect ratio contact holes and difficulty in the planarization process after cell formation. The MOSFET formation steps are followed by the stacked capacitor formation steps, which include high-temperature process steps such as storage node insulator (SiO_2/Si_3N_4) formation, and Si_3N_4 deposition for the self-aligned contact formation. The salicide process for the source and drain of the MOSFETs should be carefully designed to endure the high-temperature process steps. Recently, high-permittivity film for capacitor insulators, such as Ta_2O_5 and BST, has been developed for commodity DRAM and embedded DRAM. The process temperature for Ta_2O_5 and BST is lower than that for SiO_2/Si_3N_4; this means the process compatibility is better with such high-permittivity film.[80–82]

MOSFET Structure

The MOSFET structure in DRAMs is different from that in logic ULSIs. In recent DRAMs, the gate is covered with Si_3N_4 for self-aligned contact process steps in the bit-line contact formation. It is very difficult to apply the salicide process to the gate, source, and drain at the same time. A solution to the problem is to apply the salicide process to the source and drain only. A comparison of the MOSFET structures is shown in Fig. 2.22. Tsukamoto et al.[68] proposed another approach, namely the use of W-bit line layer as the local interconnect in the logic portion.

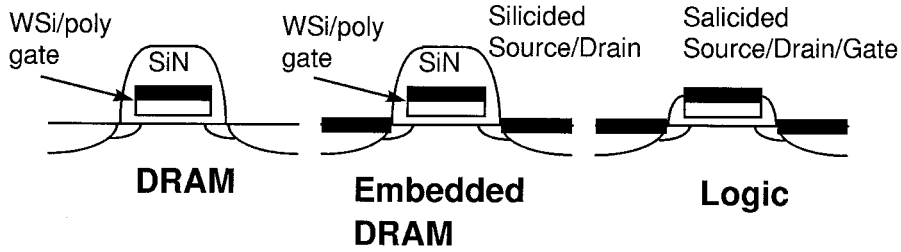

FIGURE 2.22 Typical MOSFET structures for DRAM, embedded DRAM, and logic.

Gate Oxide Thickness

Generally, DRAM gate oxide thickness is greater than that of logic ULSIs. This is because the maximum voltage of the transfer gate in the DRAM cells is higher than V_{CC}, the power supply voltage. In the logic ULSI, the maximum gate voltage is equal to V_{CC} in most cases. To keep up with the MOSFET performance in logic ULSIs, the oxide thickness of the embedded DRAMs needs to be scaled down further than in the DRAM case. To do so, a highly reliable gate oxide and/or new circuit scheme in the word line biasing, such as applying negative voltage to the cell transfer gate, is required.

Another approach is to use thick gate oxide in the DRAM cell and thin gate oxide in the logic.[83]

Fabrication Cost per Wafer

The conventional logic ULSIs do not need the process steps for DRAM cell formation. On the other hand, most of DRAMs use only two layers of aluminum. This raises wafer cost of the embedded DRAMs. Embedded DRAM chips are used only if the market can absorb the additional wafer cost for some reasons: high bandwidth, lower power consumption, small footprint, flexible memory configuration, lower chip assembly cost, etc.

Next-Generation Embedded DRAM

Process technology for the embedded DRAM with 0.18-μm or 0.15-μm design rules will include state-of-the-art DRAM cell array and high-performance MOSFETs in the logic circuit. The embedded DRAM could be a technology driver because the embedded DRAM contains most of the key process steps for DRAM and logic ULSIs.

Embedded Flash Memory Technology[84]

Recently, the importance of embedded flash technology has been increasing and logic chips with non-volatile functions have become indispensable for meeting various market requirements.

Key issues in the selection of an embedded flash cell[85] are (1) tunnel-oxide reliability (damage-less program/erase(P/E) mechanism), (2) process and transistor compatibility with CMOS logic, (3) fast read with low *Vcc*, (4) low power (especially in P/E), (5) simple control circuits, (6) fast program speed, and (7) cell size. This ordering greatly depends on target device specification and memory density, and, in general, is different from that of high-density stand-alone memories. NOR-type flash is essential and EEPROM functionality is also required on the same chip. Figure 2.23 shows the typical device structure of a NOR-type flash memory with logic device.[86]

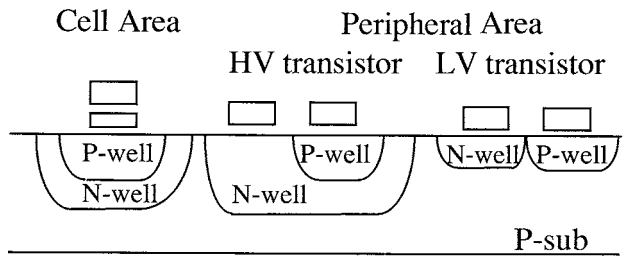

FIGURE 2.23 Device structure schematic view of the NOR flash memories with dual-gate Ti-salicide.

Process Technology[87]

To realize high-performance embedded flash chips, at least three kinds of gate insulators are required beyond the 0.25-μm regime in order to form flash tunnel oxide, CMOS gate oxide, high voltage transistor gate oxide, and I/O transistor gate oxide. Flash cells are usually made by a stacked gate process. Therefore, it is difficult to achieve less than 150% of the cost of pure logic devices.

The two different approaches to realize embedded flash chips are memory-based and logic-based, as shown in Fig. 2.24.

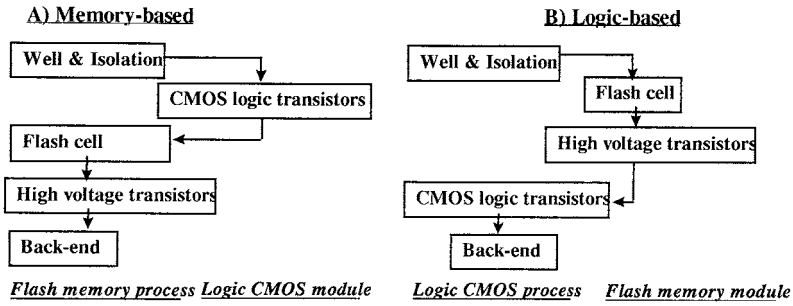

FIGURE 2.24 Process modules.

Memory-based approach is advantageous in that it exploits established flash reliability and yield guaranteed by memory mass production lines, but is disadvantageous for realizing high-performance CMOS transistors due to the additional flash process thermal budget. On the contrary, logic-based approach can use fully CMOS-compatible transistors as they are; but, due to the lack of dedicated mass production lines, great effort is required in order to establish flash cell reliability and performance. Historically, memory-based embedded flash chips have been adopted, but the logic-based chips have become more important recently. In general, the number of additional masks required to embed a flash cell into logic chips ranges from 4 to 9.

For high-density embedded flash chips, one transistor stack gate cell using channel hot electron programming and channel FN tunneling erasing will be mainstream. For medium- or low-density, high-speed embedded flash chips, two transistors will be important in the case of using the low power P/E method. From the reliability point of view, a p-channel cell using band-to-band tunneling-induced electron injection[88] and channel FN tunneling ejection are promising since page-programmable EEPROM can also be realized by this mechanism.[85]

2.3 BiCMOS Technology

The development of BiCMOS technology began in the early 1980s. In general, bipolar devices are attractive because of their high speed, better gain, better driving capability, and low wide-band noise properties that allow high-quality analog performance. CMOS is particularly attractive for digital applications because of its low power and high packing density. Thus, the combination would not only lead to the replacement and improvement of existing ICs, but would also provide access to completely new circuits.

Figure 2.25 shows a typical BiCMOS structure.[89] Generally, BiCMOS has a vertical npn bipolar transistor, a lateral pnp transistor, and CMOS on the same chip. Furthermore, if additional mask steps are

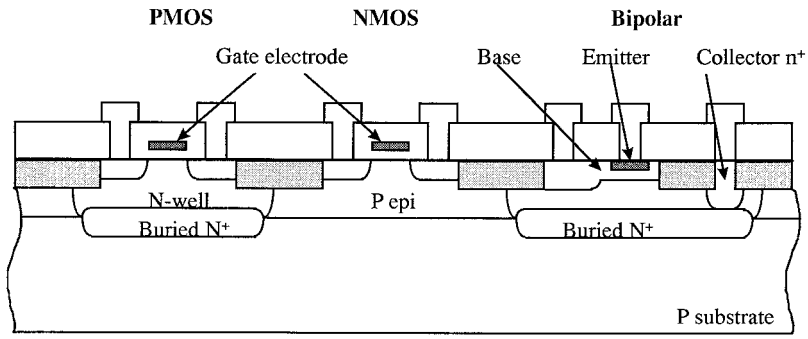

FIGURE 2.25 Cross-sectional view of BiCMOS structure.

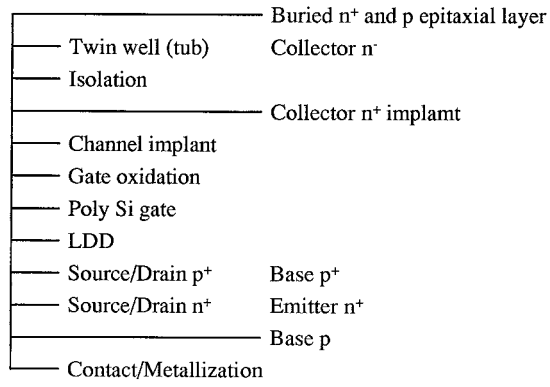

FIGURE 2.26 Typical process flow of BiCMOS device.

allowed, passive devices are integrated, as described in the previous section. The main feature of the BiCMOS structure is the existence of a buried layer because bipolar processes require an epitaxial layer grown on a heavily doped n^+ subcollector to reduce collector resistance.

Figure 2.26 shows typical process flow for BiCMOS. This is the simplest arrangement for incorporating bipolar devices and a kind of low-cost BiCMOS. Here, the BiCMOS process is completed with minimum additional process steps required to form the npn bipolar device, transforming the CMOS baseline process into a full BiCMOS technology. For this purpose, many processes are merged. The p tub of n-MOSFET shares an isolation of bipolar devices, the n tub of p-MOSFET device is used for the collector, the n^+ source and drain are used for the emitter regions and collector contacts, and also extrinsic base contacts have the p^+ source and drain of PMOS device for common use.

Recently, there have been two significant uses of BiCMOS technology. One is high-performance MPU[90] by using the high driving capability of bipolar transistor; the other is mixed signal products that utilize the excellent analog performance of the bipolar transistor, as shown in Table 2.1.

TABLE 2.1 Recent BiCMOS Structures

Type	Structure	Future
Digital BiCMOS		Simplified bipolar. Merged well or diffused layer. For digital application.
Mixed-signal BiCMOS		Double poly self-aligned bipolar, including Si or SiGe base. Non-merged process. For mixed-signal application.

For the high-performance MPU, merged processes were commonly used, and the mature version of the MPU product has been replaced by CMOS LSI. However, this application has become less popular now with reduction in the supply voltage. Mixed-signal BiCMOS requires high performance, especially with respect to f_T, f_{max}, and low noise figure. Hence, a double polysilicon structure with a silicon[91] or SiGe[92] base with trench isolation technology is used.

The fabrication cost of BiCMOS is a serious problem and, thus, a low-cost mixed-signal BiCMOS process[93] has also been proposed.

2.4 Future Technology

In this section, advanced technologies for realizing future downsized CMOS devices are introduced.

Ultra-Thin Gate Oxide MOSFET

From a performance point of view, ultra-thin gate oxide in a direct-tunneling regime is desirable for future LSIs.[94] In this section, the potential and possibility are discussed.

Figure 2.27 shows a TEM cross-section a 1.5-nm gate oxide. Figure 2.28 shows I_d-V_d characteristics for 1.5-nm gate oxide MOSFETs with various gate lengths. In the long-channel case, unusual electrical characteristics were observed because of the significant tunneling leakage current through the gate oxide. However, the characteristics become normal as the gate length is reduced because the gate leakage current decreases in proportion to the gate length and the drain current increases in inverse proportion to the gate length.[95,96] Recently, very high drive currents of 1.8 mA/mm and very high transconductances of more than 1.1 S/mm have been reported using a 1.3-nm gate oxide at a supply voltage of 1.5 V.[97] They also operate well at low power and high speed with a low supply voltage in the 0.5-V range.[98]

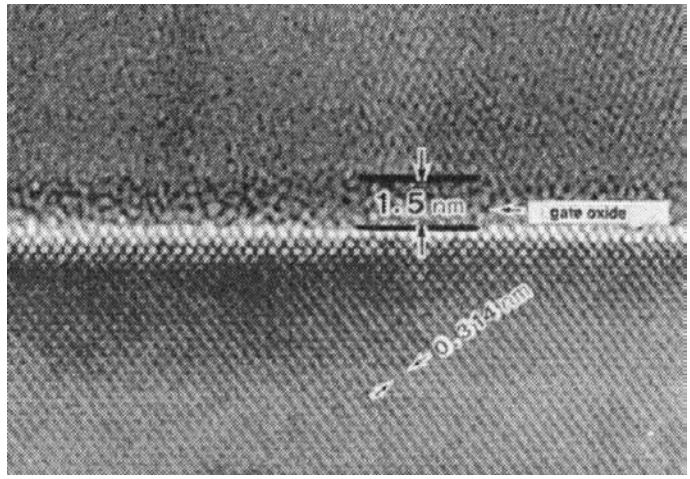

FIGURE 2.27 TEM cross-section of a 1.5-nm gate oxide film. Uniform oxide of 1.5-nm thickness is observed.

Figure 2.29 shows the dependence of cutoff frequency, f_T, of 1.5-nm gate oxide MOSFETs on gate length.[99] Very high cutoff frequencies of more than 150 GHz were obtained at gate lengths in the sub-0.1-μm regime due to the high transconductance. Further, it was confirmed that the high transconductance offers promise of a good noise figure.

Therefore, the MOSFETs with ultra-thin gate oxides beyond the direct-tunneling limit have the potential to enable extremely high-speed digital circuit operation as well as high RF performance in analog

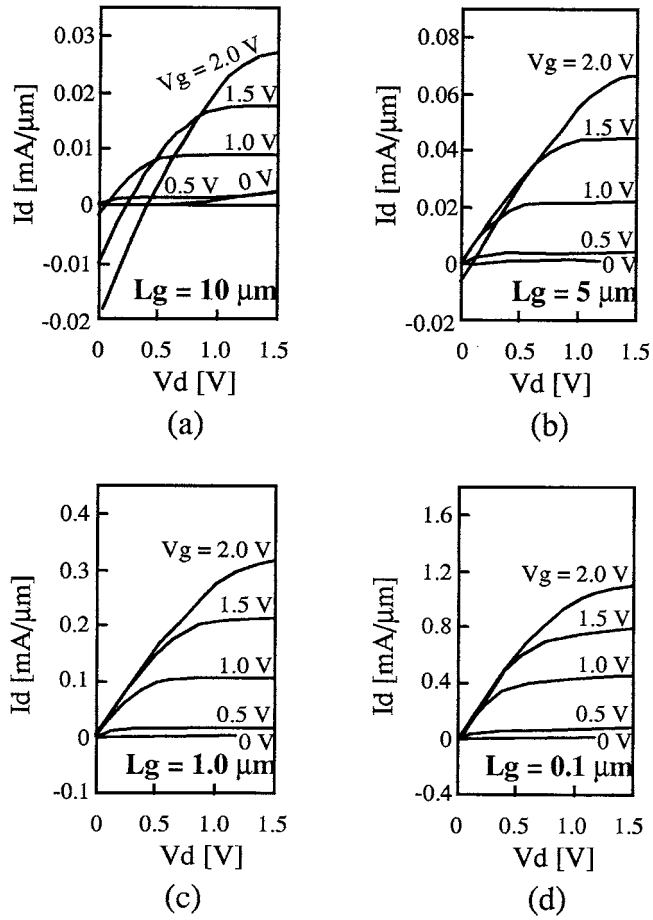

FIGURE 2.28 I_d-V_d characteristics of 1.5-nm gate oxide MOSFETs with several gate lengths: (a) Lg = 10 μm; (b) Lg = 5 μm; (c) Lg = 1.0 μm; and (d) Lg = 0.1 μm.

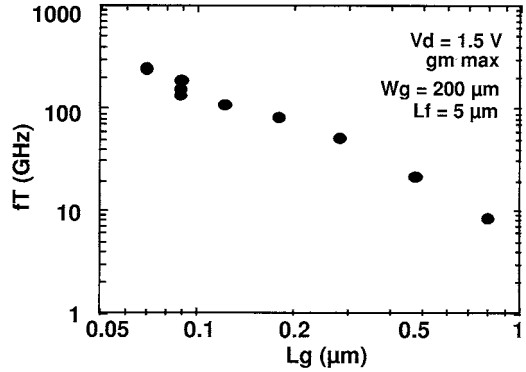

FIGURE 2.29 Dependence of cutoff frequency (f_T) on gate length (L_g) of 1.5-nm gate oxide MOSFETs.

applications. Fortunately, the hot-carrier and TDDB reliability of these ultra-thin gate oxides seems to be good.[95,96,100] Thus, ultra-thin gate oxides are likely to be used for such LSIs, for certain application.

In actual applications, even though the leakage current of a single transistor may be very small, the combined leakage of the huge number of transistors in a ULSI circuit poses problems, particularly for battery backup operation.[101,102] There is, however, the possibility of using these direct-tunneling gate oxide MOSFETs only for the smaller number of switches in the critical path determining operation speed. Also, use of a slightly thicker oxide of 2.0 or 2.5 nm would significantly reduce leakage current. The use of these direct-tunneling gate oxide MOSFETs in LSI devices with smaller integration is another possibility.

Epitaxial Channel MOSFET

As the design rule progresses, the supply voltage decreases. In order to obtain high drivability, lower V_{th} has been required under low supply voltage. However, substrate concentration must be higher in order to suppress the short-channel effects. The ideal channel profile for this requirement is that the channel surface concentration is lower to realize lower V_{th}, and the concentration around extension region is higher in order to suppress the short-channel effects. It is difficult to realize such a channel profile by using ion implantation because the profile is very broad. This requirement can be realized by non-doped epitaxial Si formation on doped Si substrate.[103] Figure 2.30 shows the process flow of MOSFETs with epitaxial Si channel, n channel, and p channel. Although the problem with this structure is the quality of epitaxial Si, degradation of the quality can be suppressed by wet treatment to clean the Si surface, and heating process before epitaxial growth. The zero V_{th} can be realized while suppressing the short-channel effect even when gate length is 0.1 μm. A 20% improvement of drivability can be realized.

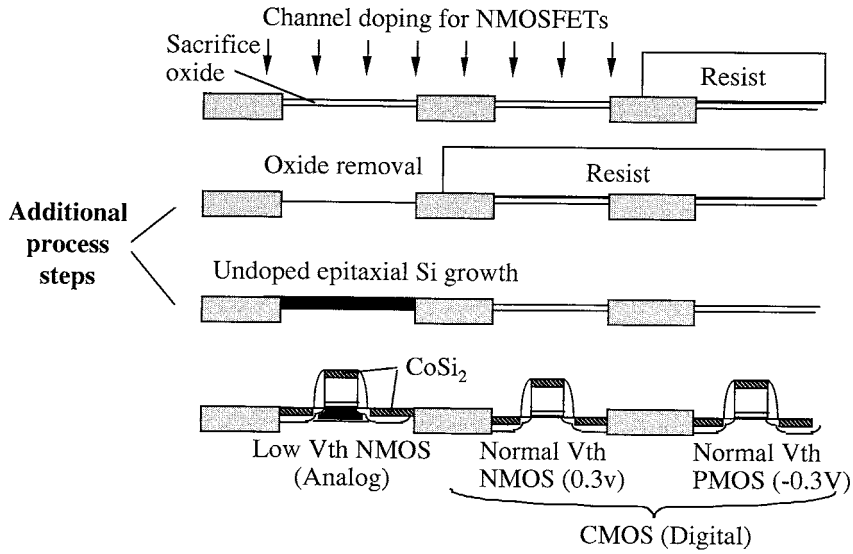

FIGURE 2.30 The process flow of MOSFETs with epitaxial Si channel, n channel, and p channel.

Raised Gate/Source/Drain Structure

In order to realize high drivability of MOSFETs, it is necessary to reduce the resistance under the gate sidewall. However, as the sidewall thickness becomes thinner, the stability of the short-channel effect degrades because the deeper source and drain become closer. If this junction depth becomes shallower, junction leakage degradation occurs because the distance between the bottom of the silicide and the junction becomes shorter. Raised gate/source/drain[104] has been proposed as one way to resolve these problems. The structure is shown in Fig. 2.31.

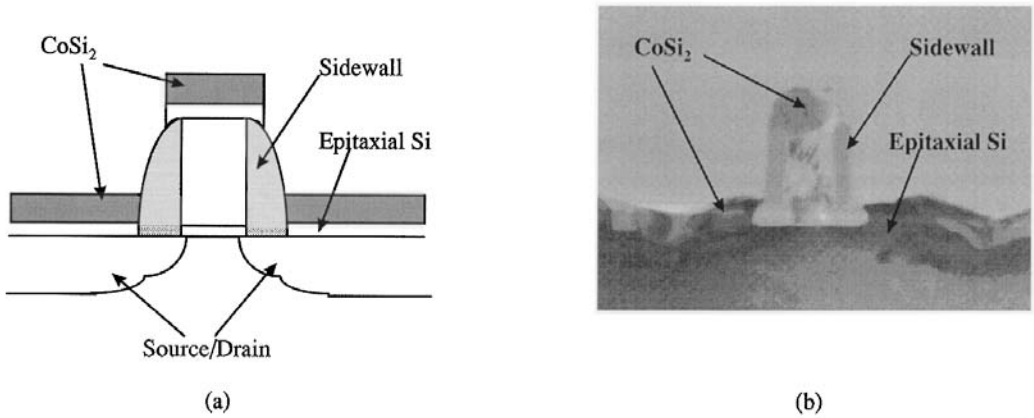

FIGURE 2.31 Structure of raised source/drain/gate FET: (a) schematic cross-section; (b) TEM photograph.

Even if the junction depth measured from the original Si substrate becomes shallower, the distance between the bottom of silicide and the junction becomes constant using this structure. Additionally, gate resistance becomes lower because top of the gate electrode is T-shaped. Thus, low gate, source, and drain resistance can be realized while the short-channel effects and junction leakage current degradation are suppressed.

2.5 Summary

This chapter has described CMOS and BiCMOS technology. CMOS is the most important device structure for realizing the future higher-performance devices required for multimedia and other demanding applications. However, certain problems are preventing the downsizing of device dimensions. The chapter described not only conventional technology but also advanced technology that has been proposed with a view to overcoming these problems.

BiCMOS technology is also important, especially for mixed-signal applications. However, CMOS device performance has already been demonstrated for RF applications and, thus, analog CMOS circuit technology will be very important for realizing the production of analog CMOS.

Royal Institute of Technology (KTH)

3.1 Introduction

The development of a bipolar technology for integrated circuits goes hand in hand with the steady improvement in semiconductor materials and discrete components during the 1950s and 1960s. Consequently, silicon bipolar technology formed the basis for the IC market during the 1970s. As circuit dimensions shrink, the MOSFET (or MOS) has gradually taken over as the major technological platform for silicon integrated circuits. The main reasons are the ease of miniaturization and high yield for MOS compared to bipolar technology. However, during the same period of MOS growth, much progress was simultaneously achieved in bipolar technology.[1,2] This is illustrated in Fig. 3.1 where the reported gate delay time for emitter-coupled logic (ECL) is plotted versus year. [2,3] In 1984, the 100 ps/gate limit was broken and, since then, the speed performance has been improved by a factor of ten. The high speed and large versatility of the silicon bipolar transistor still make it an attractive choice for a variety of digital and analog applications.[4]

Apart from high-speed performance, the bipolar transistor is recognized by its excellent analog properties. It features high linearity, superior low- and high-frequency noise behavior, and a very large transconductance.[5] Such properties are highly desirable for many RF applications, both for narrow-band as well as broad-band circuits.[6] The high current drive capability per unit silicon area makes the bipolar transistor suitable for input/output stages in many IC designs (e.g., in fast SRAMs). The disadvantage of bipolar technology is the low transistor density, combined with a large power dissipation. High-performance bipolar circuits are therefore normally fabricated at a modest integration level (MSI/LSI). By using BiCMOS design, the benefits of both MOS and bipolar technology are utilized.[7] One example is mixed analog/digital systems where a high-performance bipolar process is integrated with high-density CMOS. This technology forms a vital part in several system-on-a-chip designs (e.g., for telecommunication circuits).

In this chapter, a brief overview of bipolar technology is given with an emphasis on the integrated silicon bipolar transistor. The information presented here is based on the assumption that the reader is

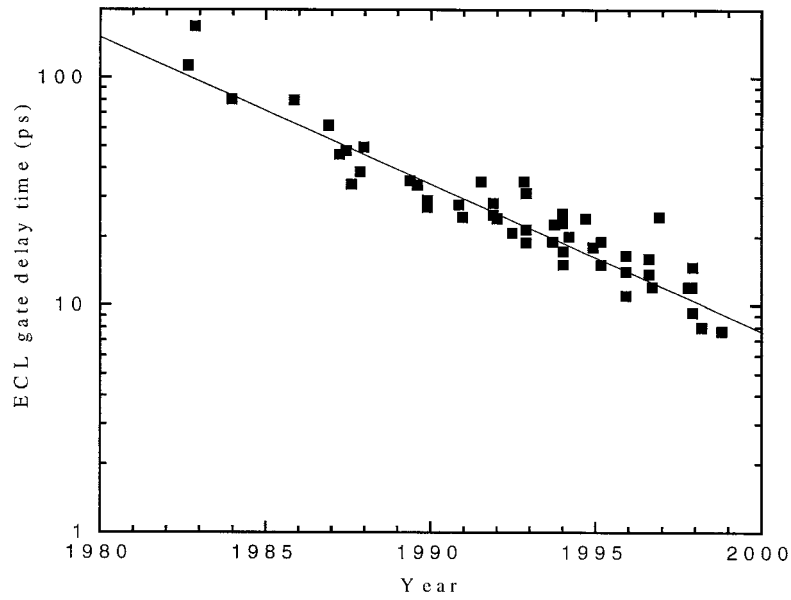

FIGURE 3.1 Reported gate delay time for bipolar ECL circuits vs. year.

familiar with bipolar device fundamentals and basic VLSI process technology. Bipolar transistors are treated in detail in the well-known textbooks by Ashburn[8] and Roulston.[9] The first part of this chapter will outline the general concepts in bipolar process design and optimization (Section 3.2). The second part will present the three generations of integrated devices representing state-of-the-art bipolar technologies for the 1970s, 1980s, and 1990s (Sections 3.3, 3.4, and 3.5, respectively). Finally, some future trends in bipolar technology are outlined.

3.2 Bipolar Process Design

The design of a bipolar process starts with the specification of the application target and its circuit technology (digital or analog). This leads to a number of requirements formulated in device parameters and associated figures-of-merit. These are mutually dependent and must therefore be traded off against each other, making the final bipolar process design a compromise between various conflicting device requirements.

Figures-of-Merit

In the digital bipolar process, the cutoff frequency (f_T) is a well-known figure-of-merit for speed. The f_T is defined for a common-emitter configuration with its output short-circuit when extrapolating the small signal current gain to unity. From a circuit perspective, a more adequate figure-of-merit is the gate delay time (τ_d) measured for a ring-oscillator circuit containing an odd number of inverters.[10] The τ_d can be expressed as a linear combination of the incoming time constants weighted by a factor determined by the circuit topology (e.g., ECL)[10,11] Alternative expressions for τ_d calculations have been proposed.[12] Besides speed, power dissipation can also be a critical issue in densely packed bipolar digital circuits, resulting in the power-delay product as a figure-of-merit.[4]

In the analog bipolar process, the dc properties of the transistor are of utmost importance. This involves minimum values on common-emitter current gain (β), Gummel plot linearity (β_{max}/β) breakdown voltage (BV_{CEO}), and Early voltage (V_A). The product $\beta \times V_A$ is often introduced as a figure-of-merit for the device

dc characteristics.[13] Rather than f_T, the maximum oscillation frequency, $f_{max} = \sqrt{f_T/(8\pi R_B C_{BC})}$ is preferred as a figure-of-merit in high-speed analog design, where R_B and C_{BC} denote the total base resistance and the base-collector capacitance, respectively.[14] Alternative figures-of-merit for speed have been proposed in the literature.[15,16] Analog bipolar circuits are often crucially dependent on a certain noise immunity, leading to the introduction of the corner frequency and noise figure as figures-of-merit for low-frequency and high-frequency noise properties, respectively.[17]

Process Optimization

The optimization of the bipolar process is divided between the intrinsic and extrinsic device design. This corresponds to the vertical impurity profile and the horizontal layout of the transistor, respectively.[10] See example in Fig. 3.2, where the device cross-section is also included. It is clear that the vertical profile and horizontal layout are primarily dictated by the given process and lithography constraints, respectively.

Figure 3.3 shows a simple flowchart of the bipolar design procedure. Starting from the specified dc parameters at a given operation point, the doping profiles can be derived. The horizontal layout must be adjusted for minimization of the parasitics. A (speed) figure-of-merit can then be calculated. An implicit relation is thus obtained between the figure-of-merit and the processing parameters.[11,18] In practice, several iterations must be performed in the optimization loop in order to find an acceptable compromise between the device parameters. This procedure is substantially alleviated by two-dimensional process simulations of the device fabrication[19] as well as device simulations of the bipolar transistor.[20,21] For optimization of a large number of device parameters, the strategy is based on screening out the unimportant factors, combined with a statistical approach (e.g., response surface methodology.)[22]

Vertical Structure

The engineering of the vertical structure involves the design of the collector, base, and emitter impurity profiles. In this respect, f_T is an adequate parameter to optimize. For a modern bipolar transistor with suppressed parasitics, the maximum f_T is usually determined by the forward transit time of minority carriers through the intrinsic component. The most important f_T tradeoff is against BV_{CEO}, as stated by the Johnson limit for silicon transistors:[23] the product $f_T \times BV_{CEO}$ cannot exceed 200 GHz-V (recently updated to 500 GHz-V).[24]

Collector Region

The vertical n-type collector of the bipolar device in Fig. 3.2 consists of two regions below the p-type base diffusion: a lowly or moderately doped n-type epitaxial (epi) layer, followed by a highly doped n^+-subcollector. The thickness and doping level of the subcollector are non-critical parameters; a high arsenic or antimony doping density between 10^{19} and 10^{20} cm^{-3} is representative, resulting in a sheet resistance of 20 to 40 Ω/sq. In contrast, the design of the epi-layer constitutes a fundamental topic in bipolar process optimization.

To first order, the collector doping in the epi-layer is determined by the operation point (more specifically, the collector current density) of the component (see Fig. 3.3). A normal condition is to have the operation point corresponding to maximum f_T, which typically means a collector current density on the order of $2–4 \times 10^4$ A/cm^2. As will be recognized later, bipolar scaling results in increased collector current densities. Above a certain current, there will be a rapid roll-off in current gain as well as cutoff frequency. This is due to high-current effects, primarily the base push-out or Kirk effect, leading to a steep increase in the forward transit time.[25] Since the critical current value is proportional to the collector doping,[26] a minimum impurity concentration for the epi-layer is required, thus avoiding f_T degradation (typically around 10^{17} cm^{-3} for a high-speed device). Usually, the epi-layer is doped only in the intrinsic structure by a selectively implanted collector (SIC) procedure.[27] An example of such a doping profile is seen in Fig. 3.4. Such a collector design permits an improved control over the base-collector junction; that is, shorter base width as well as suppressed Kirk effect. The high collector doping concentration,

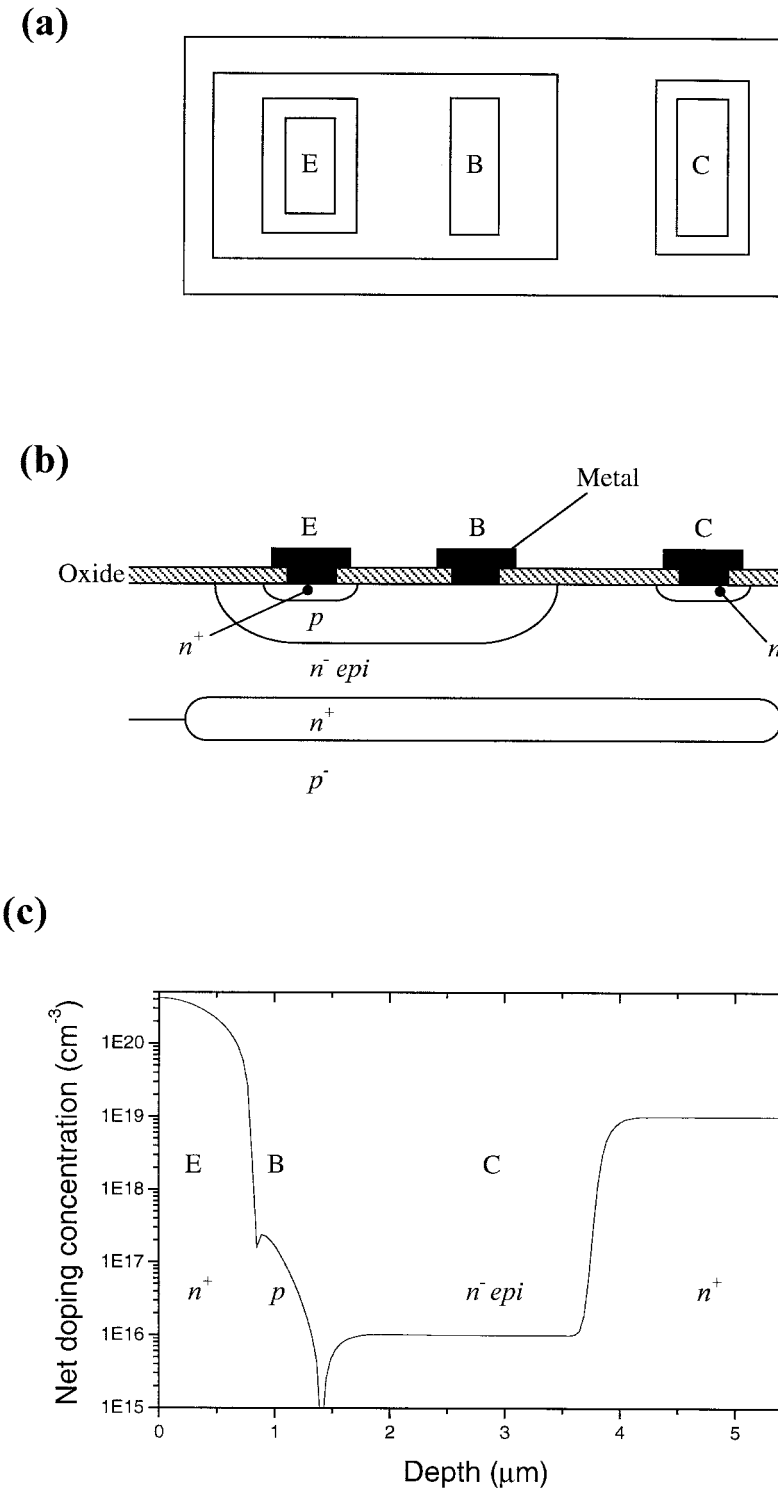

FIGURE 3.2 (a) Layout, (b) cross-section, and (c) simulated impurity profile through emitter window for an integrated bipolar transistor (E = emitter, B = base, C = collector).

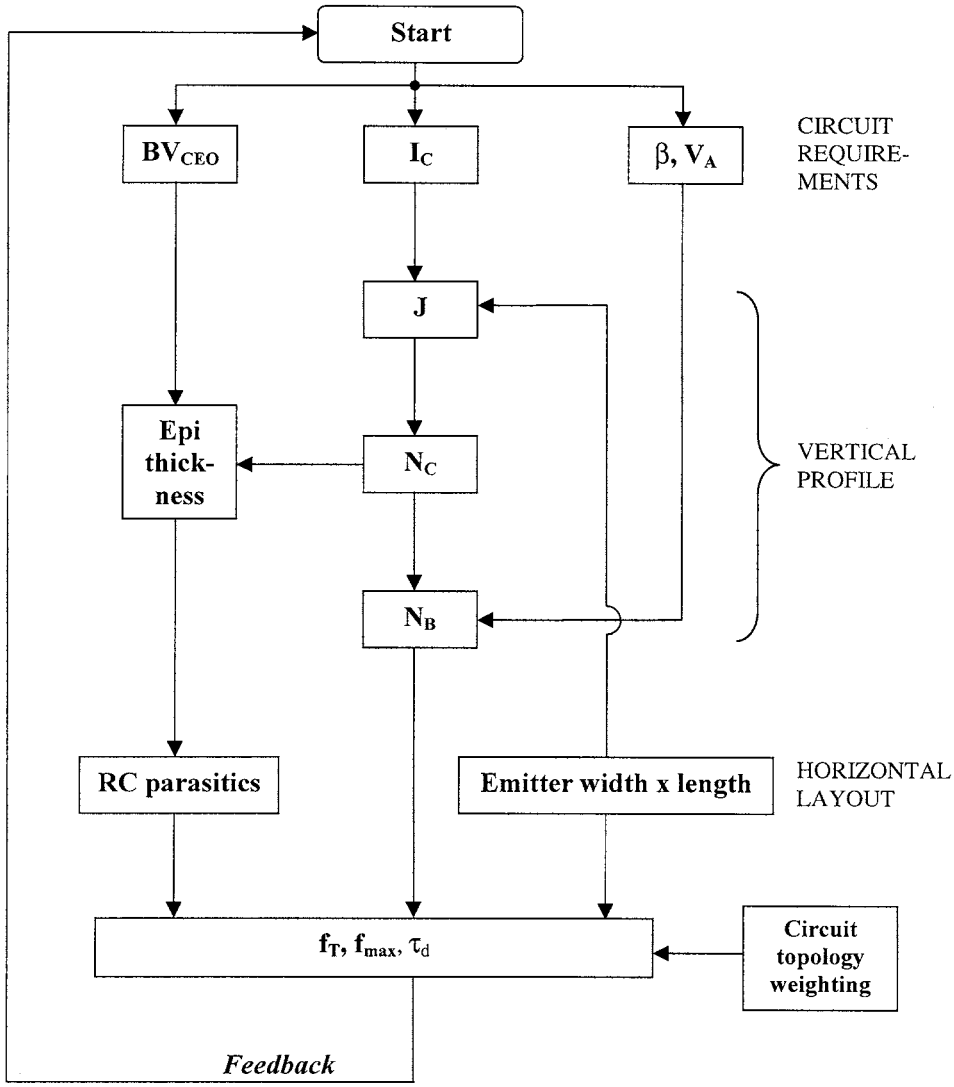

FIGURE 3.3 Generic bipolar device optimization flowchart.

however, may be a concern for both C_{BC} and BV_{CEO}. The latter value will therefore often set a higher limit on the collector doping value. One way to reduce the electrical field in the junction is to implement a lightly doped collector spacer layer between the heavily doped base and collector regions.[28,29] A retrograde collector profile with a low impurity concentration near the base-collector junction and then increasing toward the subcollector has also been reported to enhance f_T.[30,31]

The thickness of the epi-layer exhibits large variations between different device designs, extending several micrometers in depth for analog bipolar components, whereas a high-speed digital design typically has an epi-layer thickness around 1 μm or below, thus reducing total collector resistance. As a result, the transistor breakdown voltage is sometimes determined by reach-through breakdown (i.e., full depletion penetration of the epi-collector). The thickness of the collector layer can therefore be used as a parameter in determining BV_{CEO}, which in turn is traded off vs. f_T.[32]

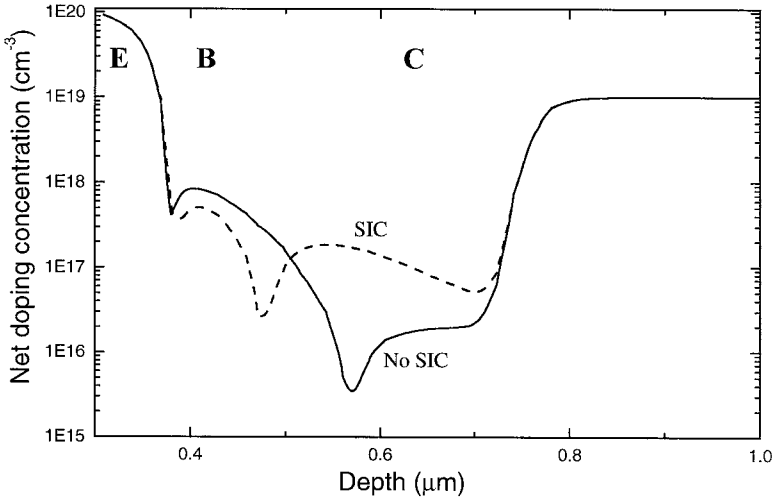

FIGURE 3.4 Simulated vertical impurity profile with and without SIC.

In cases where f_{max} is of interest, the collector design must be carefully taken into account. Compared to f_T, the optimum f_{max} is found for thicker and lower doped collector epi-layers.[33,34] The vertical collector design will therefore, to a large extent, determine the tradeoff between f_T and f_{max}.

Base Region

The width and peak concentration of the base profile are two of the most fundamental parameters in vertical profile design. The base width W_B is normally in the range 0.1 to 1 μm, whereas a typical base peak concentration lies between 10^{17} and 10^{18} cm^{-3}. The current gain of the transistor is determined by the ratio of the Gummel number in the emitter and base. Usually, a current gain of at least 100 is required for analog bipolar transistors, whereas in digital applications, β around 20 is often acceptable. A normal base sheet resistance (or pinch resistance) for conventional bipolar processes is of the order of 100 Ω/sq., whereas the number for high-speed devices typically is in the interval 1 to 10 kΩ/sq. This is due to the small $W_B < 0.1$ μm necessary for a short base transit time ($\propto W_B^2$). On the other hand, a too narrow base will have a negative impact on f_{max} because of its R_B dependence. As a result, f_{max} exhibits a maximum when plotted against W_B.[35]

The base impurity concentration must be kept high enough to avoid punch-through at low collector voltages; that is, the base-collector depletion layer penetrates across the neutral base. In other words, the base doping level is also dictated by the collector impurity concentration. Punch-through is the ultimate consequence of base width modulation or the Early effect manifested by a finite output resistance in the I_C-V_{CE} transistor characteristic.[36] The associated V_A or the product $\beta \times V_A$ serves as an indicator of the linear properties for the bipolar transistor. The V_A is typically at a relatively high level (>30 V) for analog applications, whereas digital designs often accept relatively low $V_A < 15$ V.

Figure 3.5 demonstrates simulations of current gain versus the base doping for various W_B.[37] It is clearly seen that the base doping interval permitting a high current gain while avoiding punch-through will be pushed to high impurity concentrations for narrow base widths. In addition, Fig. 3.5 points to another limiting factor for high base doping numbers above 5×10^{18} cm^{-3}, namely, the onset of forward-biased tunneling currents in the emitter-base junction[38] leading to non-ideal base current characteristics.[39] It is concluded that the allowable base doping interval will be very narrow for $W_B < 0.1$ μm.

The shape of the base profile has some influence over the device performance. The final base profile is the result of an implantation and diffusion process and, normally, only the peak base concentration is given along with the base width. Nonetheless, there will be an impurity grading along the base profile (see Figs. 3.2 and 3.4), creating a built-in electrical field and thereby adding a drift component for the

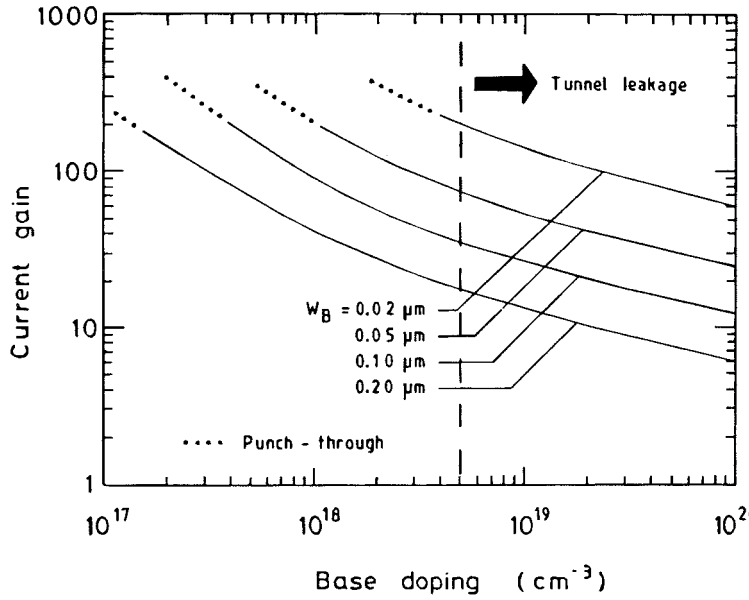

FIGURE 3.5 Simulated current gain vs. base doping density for different base widths ($N_C = 6 \times 10^{16}$ cm^{-3}, $N_E = 10^{20}$ cm^{-3}, and emitter depth 0.20 μm) (after Ref. 37, copyright© 1990, IEEE).

minority carrier transport.[40] Recent research has shown that for very narrow base transistors, the uniform doping profile is preferable when maximizing f_T.[41,42] This is also valid under high injection conditions in the base.[43] Uniformly doped base profiles are common in advanced bipolar processes using epitaxial techniques for growing the intrinsic base.

During recent years, base profile design has largely been devoted to implementation of narrow bandgap SiGe in the base. The resulting emitter-base heterojunction allows a considerable enhancement in current gain, which can be traded off against increased base doping, thus substantially alleviating the problem with elevated base sheet resistances typical of high-speed devices.[44] Excellent dc as well as high-frequency properties can be achieved. The position of the Ge profile with respect to the boron profile has been discussed extensively in the literature.[45–47] More details about SiGe heterojunction engineering are found in Chapter 5 by Cressler.

Emitter Region

The conventional metal-contacted emitter is characterized by an abrupt arsenic or phosphorus profile fabricated by direct diffusion or implantation into the base area (see Fig. 3.2).[48] In keeping emitter efficiency close to unity (and thus high current gain), the emitter junction cannot be made too shallow (~1 μm). The emitter doping level lies typically between 10^{20} and 10^{21} cm^{-3} close to the solid solubility limit at the silicon surface, hence providing a low emitter resistance as well as a large emitter Gummel number required for keeping current gain high. Bandgap narrowing, however, will be present in the emitter, causing a reduction in the efficient emitter doping.[49]

When scaling bipolar devices, the emitter junction must be made more shallow to ensure a low emitter-base capacitance. When the emitter depth becomes less than the minority carrier recombination length, the current gain will inevitably degrade. This precludes the use of conventional emitters in a high-performance bipolar technology. Instead, polycrystalline (poly) silicon emitter technology is utilized. By diffusing impurity species from the polysilicon contact into the monocrystalline (mono) silicon, a very shallow junction (< 0.2 μm) is formed; yet gain can be kept at a high level and even traded off against a higher base doping.[50] A gain enhancement factor between 3 and 30 for the polysilicon compared to the monosilicon emitter has been reported (see also Section 3.4).[51,52]

Scaling Rules

The principles for vertical design can be summarized in the bipolar scaling rules formulated by Solomon and Tang; [53,54] see Table 3.1. Since the bipolar transistor is scaled under constant voltage, the current density increases with reduced device dimensions. At medium or high current densities, the vertical structure determines the speed. At low current densities, performance is normally limited by device parasitics. Eventually, tunnel currents or contact resistances constitute a final limit to further speed improvement based on the scaling rules. A solution is to use SiGe bandgap engineering to further enhance device performance without scaling.

TABLE 3.1 Bipolar Scaling Rules (Scaling factor $\lambda < 1$)

Parameter	Scaling Factor
Voltage	1
Base width W_B	$\lambda^{0.8}$
Base doping N_B	W_B^{-2}
Current density J	λ^{-2}
Collecting doping	J
Depletion capacitances	λ
Delay	λ
Power	1
Power-delay product	λ

Horizontal Layout

The horizontal layout is carried out in order to minimize the device parasitics. Figure 3.6 shows the essential parasitic resistances and capacitances for a schematic bipolar structure containing two base contacts. The various RC constants in Fig. 3.6 introduce time delays. For conventional bipolar transistors, such parasitics often limit device speed. In contrast, the self-alignment technology applied in advanced bipolar transistor fabrication allows for efficient suppression of the parasitics.

In horizontal layout, f_{max} serves as a first-order indicator in the extrinsic optimization procedure because of its dependence on C_{BC} and (total) R_B. These two parasitics are strongly connected to the geometrical layout of the device. The more advanced τ_d calculation takes all major parasitics into account under given load conditions, thus providing good insight into the various time delay contributions of a bipolar logic gate.[55]

From Fig. 3.6, it is seen that the collector resistance is divided into three parts. Apart from the epi-layer and buried layer previously discussed, the collector contact also adds a series resistance. Provided the epi-layer is not too thick, the transistor is equipped with a deep phosphorus plug from the collector contact down to the buried layer, thus reducing the total R_C.

As illustrated in Fig. 3.6, the base resistance is divided into intrinsic (R_{Bi}) and extrinsic (R_{Bx}) components. The former is the pinched base resistance situated directly under the emitter diffusion, whereas the latter constitutes the base regions contacting the intrinsic base. The intrinsic part decreases with the current due to the lateral voltage drop in the base region.[56] At high current densities, this causes current crowding effects at the emitter diffusion edges. This results in a reduced onset for high-current effects in the transistor. The extrinsic base resistance is bias independent and must be kept as small as possible (e.g., by utilizing self-alignment architectures). By designing a device layout with two or more base contacts surrounding the emitter, the final R_B is further reduced at the expense of chip area. Apart from enhancing f_{max}, the R_B reduction is also beneficial for device noise performance.

The layout of the emitter is crucial since the effective emitter area defines the intrinsic device cross-section.[57] The minimum emitter area, within the lithography constraints, is determined by the operational collector current and the critical current density where high-current effects start to occur.[58] Eventually, a tradeoff must be made between the base resistance and device capacitances as a function of emitter geometry; this choice is largely dictated by the device application. Long, narrow emitter stripes, meaning

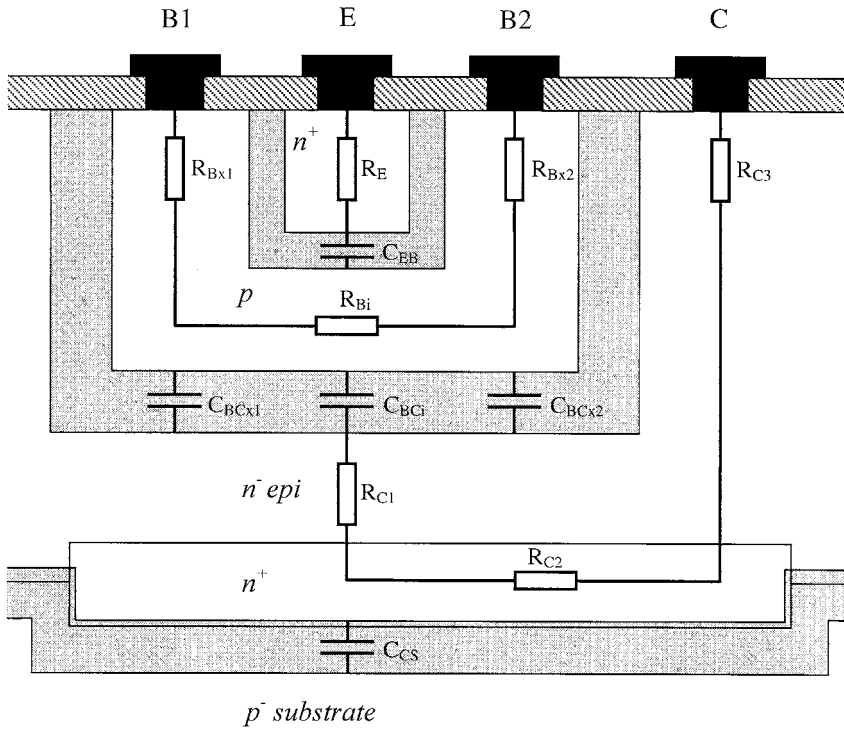

FIGURE 3.6 Schematic view of the parasitic elements in a bipolar transistor equipped with two base contacts. R_E = emitter resistance, R_{Bi} = intrinsic base resistance, R_{Bx} = extrinsic base resistance, R_C = collector resistance, C_{EB} = emitter-base capacitance, C_{BCi} = intrinsic base-collector capacitance, C_{BCx} = extrinisic base-collector capacitance, and C_{CS} = collector-substrate capacitance. Gray areas denote depletion regions. Contact resistances are not shown.

a reduction in the base resistance, are frequently used. The emitter resistance is usually non-critical for conventional devices; however, for polysilicon emitters, the emitter resistance may become a concern in very small-geometry layouts.[3]

Of the various junction capacitances in Fig. 3.6, the collector-base capacitance is the most significant. This parasitic is also divided into intrinsic (C_{BCi}) and extrinsic (C_{BCx}) contributions. Similar to R_{Bx}, the C_{BCx} is kept low by using self-aligned schemes. For example, the fabrication of a SIC causes an increase only in C_{BCi}, whereas C_{BCx} stays virtually unaffected. The collector-substrate capacitance C_{CS} is one of the minor contributors to f_T; the C_{CS} originates from the depletion regions created in the epi-layer and under the buried layer. C_{CS} will become significant at very high frequencies due to substrate coupling effects.[59]

3.3 Conventional Bipolar Technology

Conventional bipolar technology is based on the device designs developed during the 1960s and 1970s. Despite its age, the basic concept still constitutes a workhorse in many commercial analog processes where ultimate speed and high packing density are not of primary importance. In addition, a conventional bipolar component is often implemented in low-cost BiCMOS processes.

Junction-Isolated Transistors

The early planar transistor technology took advantage of a reverse-biased pn junction in providing the necessary isolation between components. One of the earliest junction-isolated transistors, the so-called triple-diffused process, is simply based on three ion implantations and subsequent diffusion.[60] This device

has been integrated into a standard CMOS process using one extra masking step.[61] The triple-diffused bipolar process, however, suffers from a large collector resistance due to the absence of a subcollector, and the npn performance will be low.

By far, the most common junction-isolated transistor is represented by the device cross-section of Fig. 3.7, the so-called buried-collector process.[60] This device is based on the concept previously shown in Fig. 3.2 but with the addition of an n^+-collector plug and isolation. This is provided by the diffused p^+-regions surrounding the transistor. The diffusion of the base and emitter impurities into the epi-layer allows relatively good control of the base width (more details of the fabrication is given in the next section on oxide-isolated transistors).

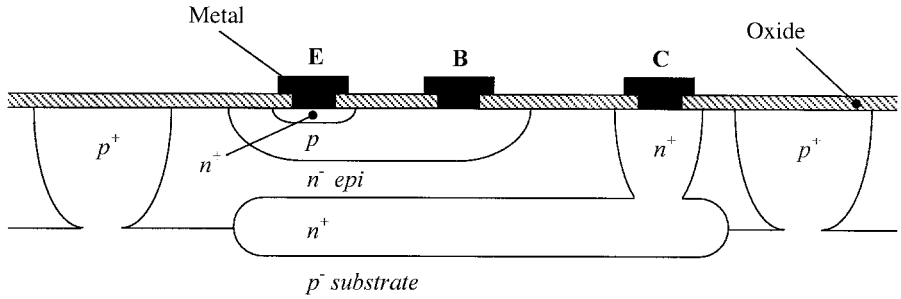

FIGURE 3.7 Cross-section of the buried-collector transistor with junction isolation and collector plug.

A somewhat different approach of the buried-collector process is the so-called collector-isolation diffusion.[62] This process requires a p-type epi-layer after formation of the subcollector. An n^+-diffusion serves both as isolation and the collector plug to the buried layer. After an emitter diffusion, the p-type epi-layer will constitute the base of the final device. Compared to the buried-layer collector process, the collector-isolated device concept does not result in very accurate control over the final base width.

The main disadvantage of the junction-isolated transistor is the relatively large chip area occupied by the isolation region, thus precluding the use of such a device in any VLSI application. Furthermore, high-speed operation is ruled out because of the large parasitic capacitances associated with the junction isolation and the relatively deep diffusions involved. Indeed, many of the conventional junction-isolated processes were designed for doping from the gas phase at high temperatures.

Oxide-Isolated Transistors

Oxide isolation permits a considerable reduction in the lateral and vertical dimensions of the buried-layer collector process. The reason is that the base and collector contacts can be extended to the edge of the isolation region. More chip area can be saved by having the emitter walled against the oxide edge. The principal difference between scaling of junction-and oxide-isolated transistors is visualized in Fig. 3.8.[63] The device layouts are Schottky clamped; that is, the base contact extends over the collector region. This hinders the transistor to enter saturation mode under device operation. In Fig. 3.8(b), the effective surface area of the emitter contact has been reduced by a so-called washed emitter approach: since the oxide formed on the emitter window during emitter diffusion has a much higher doping concentration than its surroundings, this particular oxide can be removed by a mask-less wet etching. Hence, the emitter contact becomes self-aligned to the emitter diffusion area.

The process flow including mask layouts for an oxide-isolated bipolar transistor of the buried-layer collector type is shown in Fig. 3.9.[64] After formation of the subcollector by arsenic implantation through an oxide mask in the p^--substrate, the upper collector layer is grown epitaxially on top (Fig. 3.9(a)). The device isolation is fabricated by local oxidation of silicon (LOCOS) or recessed oxide (ROX) process

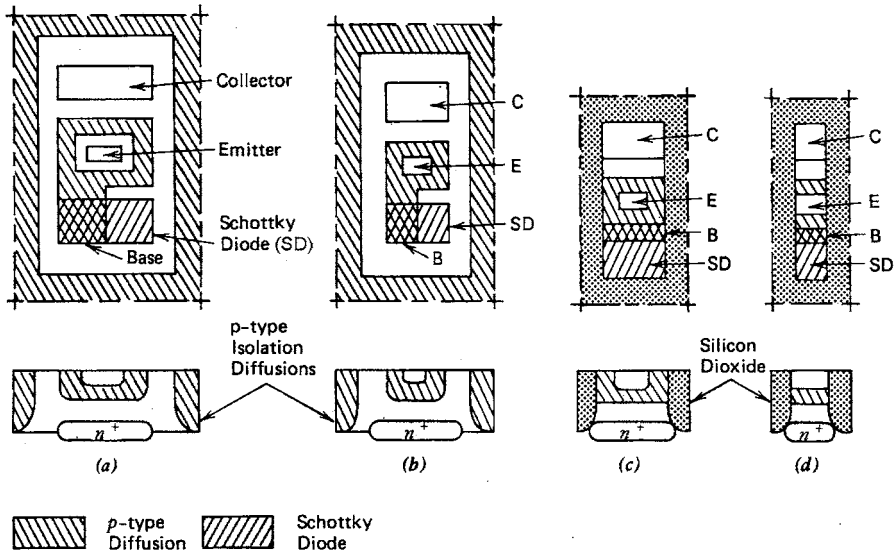

FIGURE 3.8 Device layout and cross-section demonstrating scaling of (a)-(b) junction-isolated and (c)-(d) oxide-isolated bipolar transistors (after Ref. 63, copyright© 1986, Wiley).

(Figs. 3.9(b) to (d)). The isolation mask in Fig. 3.9(b) is aligned to the buried layer using the step in the silicon (Fig. 3.9(a)) originating from the enhanced oxidation rate for highly doped n^+-silicon compared to the p^--substrate during activation of the buried layer. The ROX is thermally grown (Fig. 3.9(d)) after the boron field implantation (or chan-stop) (Fig. 3.9(c)). This p^+-implant is necessary for suppressing a conducting channel otherwise present under the ROX. The base is then formed by ion implantation of boron or BF_2 through a screen oxide (Fig. 3.9(d)); in the simple device of Fig. 3.9, a single base implantation is used; in a more advanced bipolar process, the fabrication of the intrinsic and extrinsic base must be divided into one low dose and one high dose implantation, respectively, adding one more mask to the total flow. After base formation, an emitter/base contact mask is patterned in a thermally grown oxide (Fig. 3.9(e)). The emitter is then implanted using a heavy dose arsenic implant (Fig. 3.9(f)). An n^+ contact is simultaneously formed in the collector window. After annealing, the device is ready for metallization and passivation.

Apart from the strong reduction in isolation capacitances, the replacement of a junction-isolated process with an oxide-isolated process also adds other high-speed features such as thinner epitaxial layer and shallower emitter/base diffusions. A typical base width is a few 1000 Å and the resulting f_T typically lies in the range of 1 to 10 GHz. The doping of the epitaxial layer is determined by the required breakdown voltage. Further speed enhancement of the oxide-isolated transistor is difficult due to the parasitic capacitances and resistances originating from contact areas and design-rule tolerances related to alignment accuracy.

Lateral pnp Transistors

The conventional npn flow permits the bipolar designer to simultaneously create a lateral pnp transistor. This is made by placing two base diffusions in close proximity to each other in the epi-layer, one of them (pnp-collector) surrounding the other (pnp-emitter) (see Fig. 3.10). In general, the lateral pnp device exhibits poor performance since the base width is determined by lithography constraints rather than vertical base control as in the npn device. In addition, there will be electron injection from the subcollector into the p-type emitter, thus reducing emitter efficiency.

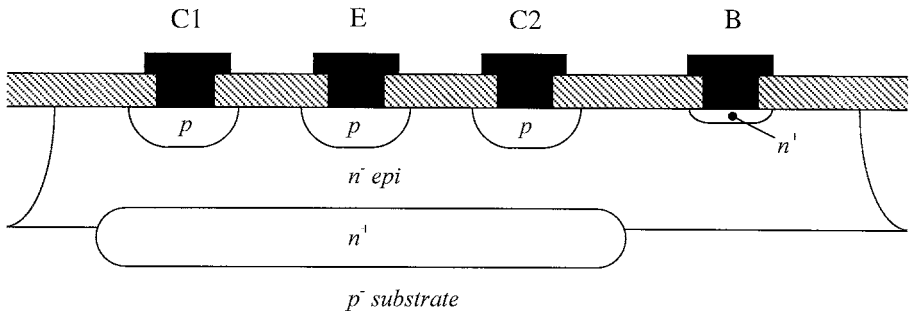

FIGURE 3.10 Schematic cross-section of the lateral pnp transistor.

3.4 High-Performance Bipolar Technology

The development of a high-performance bipolar technology for integrated circuits signified a large step forward, both with respect to speed and packing density of bipolar transistors. A representative device cross-section of a so-called double-poly transistor is depicted in Fig. 3.11. The important characteristics for this bipolar technology are the polysilicon emitter contact, the advanced device isolation, and the self-aligned structure. These three features are discussed here with an emphasis on self-alignment where the two basic process flows are outlined — the single-poly and double-poly transistor.

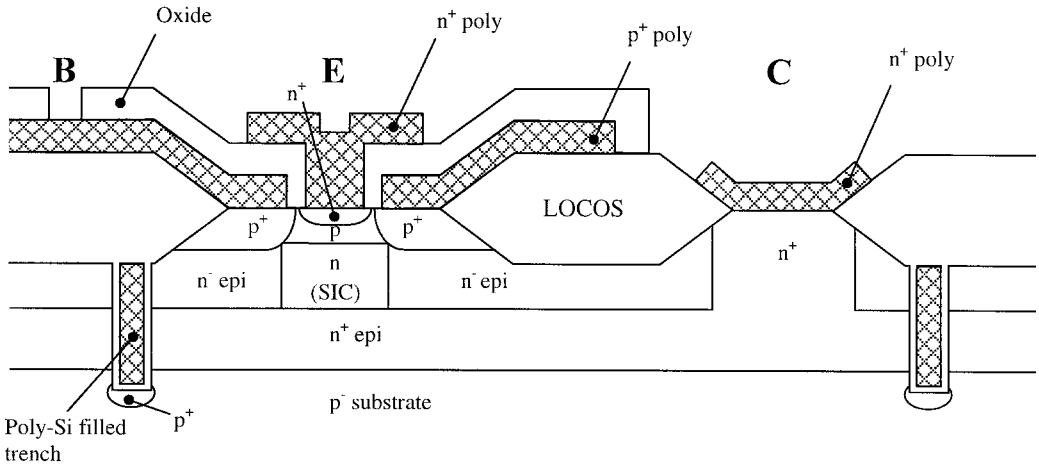

FIGURE 3.11 A double-poly self-aligned bipolar transistor with deep-trench isolation, polysilicon emitter and SIC. Metallization is not shown.

Polysilicon Emitter Contact

The polysilicon emitter contact is fabricated by a shallow diffusion of n-type species (usually arsenic) from an implanted n^+- polysilicon layer into the silicon substrate[65] (see emitter region in Fig. 3.11). The thin oxide sandwiched between the poly- and monosilicon is partially or fully broken up during contact formation. The mechanism behind the improved current gain is strongly related to the details of the interface between the polysilicon layer and the monosilicon substrate.[52] Hence, the cleaning procedure of the emitter window surface before polysilicon deposition must be carefully engineered for process robustness. Otherwise, the average current gain from wafer-to-wafer will exhibit unacceptable variations.

The emitter window preparation and subsequent drive-in anneal conditions can also be used in tailoring the process with respect to gain and emitter resistance.

From a fabrication point of view, there are further advantages when introducing polysilicon emitter technology. By implanting into the polysilicon rather than into single-crystalline material, the total defect generation as well as related anomalous diffusion effects are strongly suppressed in the internal transistor after the drive-in anneal. Moreover, the risk for spiking of aluminum during the metallization process, causing short-circuiting of the pn junction, is strongly reduced compared to the conventional contact formation. As a result, some of the yield problems associated with monosilicon emitter fabrication are, to a large extent, avoided when utilizing polysilicon emitter technology.

Advanced Device Isolation

With advanced device isolation, one usually refers to the deep trenches combined with LOCOS or ROX as seen in Fig. 3.11.[66] The starting material before etching is then a double-epitaxial layer (n^+-n) grown on a lowly doped p^--substrate. The deep trench must reach all the way through the double epi-layer, meaning a high-aspect ratio reactive-ion etch. Hence, the trenches will define the extension of the buried layer collector for the transistor.

The main reason for introducing advanced isolation in bipolar technology is the need for a compact chip layout.[67] Quite naturally, the bipolar isolation technology has benefited from the trench capacitor development in the MOS memory area. The deep trench isolation allows bipolar transistors to be designed at the packing density of VLSI.

The fabrication of a deep-trench isolation includes deep-silicon etching, chan-stop p^+-implantation, an oxide/nitride stack serving as isolation, intrinsic polysilicon fill-up, planarization, and cap oxidation.[66] The deep-trench isolation is combined with an ordinary LOCOS or ROX isolation, which is added before or after trench formation. The most advanced isolation schemes take advantage of shallow-trench isolation rather than ordinary LOCOS after the deep-trench process; in this way, a very planar surface with no oxide lateral encroachment ("birds beak") is achieved after the planarization step. The concern regarding stress-induced crystal defects originating from trench etching requires careful attention so as not to seriously affect yield.

Self-Aligned Structures

Advanced bipolar transistors are based on self-aligned structures made possible by polysilicon emitter technology. As a result, the emitter-base alignment is not dependent on the overlay accuracy of the lithography tool. The device contacts can be separated without affecting the active device area. It is also possible to create structures where the base is self-aligned both to the collector and emitter, the so-called sidewall-based contact structure (SICOS).[68] This process, however, has not been able to compete successfully with the self-aligned schemes discussed below.

The self-aligned structures are divided into single-polysilicon (single-poly) and double-polysilicon (double-poly) architectures, as visualized in Fig. 3.12.[69] The double-poly structure refers to the emitter polysilicon and base polysilicon electrode, whereas the single-poly only refers to the emitter polysilicon. From Fig. 3.12, it is seen that the double-poly approach benefits from a smaller active area than the single-poly, manifested in a reduced base-collector capacitance. Moreover, the double-poly transistor in general exhibits a lower base resistance. The double-poly transistor, however, is more complex to fabricate than the single-poly device. On the other hand, by applying inside spacer technology for the double-poly emitter structure, the lithography requirements are not as strict as in the single-poly case where more conventional MOS design rules are used for definition of the emitter electrode.

Single-Poly Structure

The fabrication of a single-poly transistor has been presented in several versions, more or less similar to the traditional MOS flow. An example of a standard single-poly process is shown in Fig. 3.13.[70] After

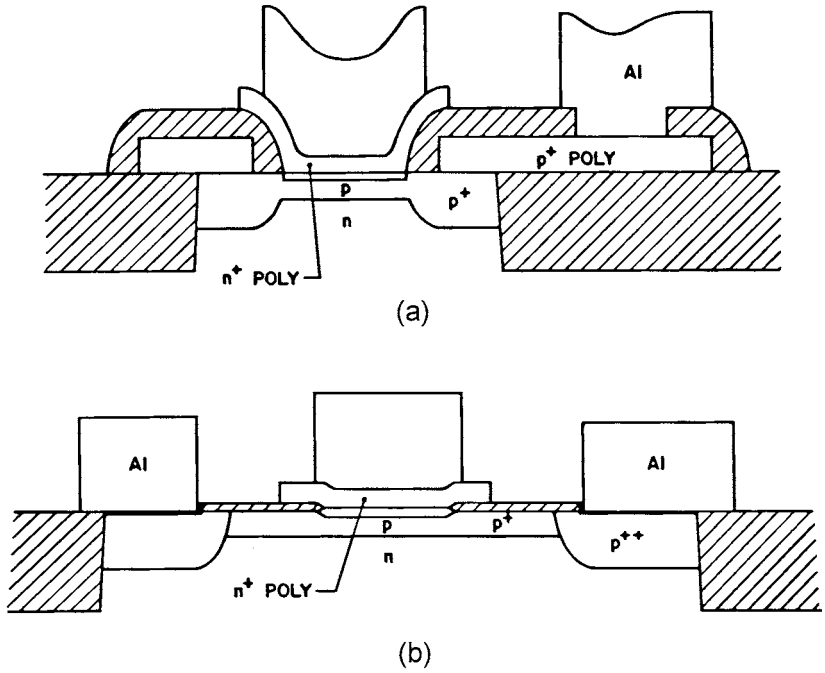

FIGURE 3.12 (a) Double-poly structure and (b) single-poly structure. Buried layer and collector contact are not shown (after Ref. 69, copyright© 1989, IEEE).

arsenic emitter implantation (Fig. 3.13(a)) and polysilicon patterning, a so-called base-link is implanted using boron ions (Fig. 3.13(b)). Oxide is then deposited and anisotropically etched to form outside spacers, followed by the heavy extrinsic base implantation (Fig. 3.13(c)). Shallow junctions (including emitter diffusion) are formed by rapid thermal annealing (RTA). A salicide or polycide metallization completes the structure (Fig. 3.13(d)).

The intrinsic base does not necessarily need to be formed prior to the extrinsic part. Li et al.[71] have presented a reverse extrinsic-intrinsic base scheme based on a disposable emitter pedestal with spacers. This leads to improved control over the intrinsic base width and a lower surface topography compared to the process represented in Fig. 3.13.

Another variation of the single-poly architecture is the so-called quasi-self-aligned process (see Fig. 3.14).[72] A base oxide is formed by thermal oxidation in the active area and an emitter window is opened (Fig. 13.14(a)). Following intrinsic base implantation, the emitter polysilicon is deposited, implanted, and annealed. The polysilicon emitter pedestal is then etched out (Fig. 3.14(b)). The extrinsic base process, junction formation, and metallization are essentially the same as in the single-poly process shown in Fig. 3.13. Note that in Fig. 13.4, the emitter-base formation is self-aligned to the emitter window in the oxide, not to the emitter itself, hence explaining the term quasi-self-aligned. As a result, a higher total base resistance is obtained compared to the standard single-poly process.

The boron implantation illustrated in Fig. 3.13(b) is an example of so-called base-link engineering aimed at securing the electrical contact between the heavily doped p^+-extrinsic base and the much lower doped intrinsic base. Too weak a base link will result in high total base resistance, whereas too strong a base link may create a lateral emitter-base tunnel junction leading to non-ideal base current characteristics.[73] Furthermore, a poorly designed base link jeopardizes matching between individual transistors since the final current gain may vary substantially with the emitter width.

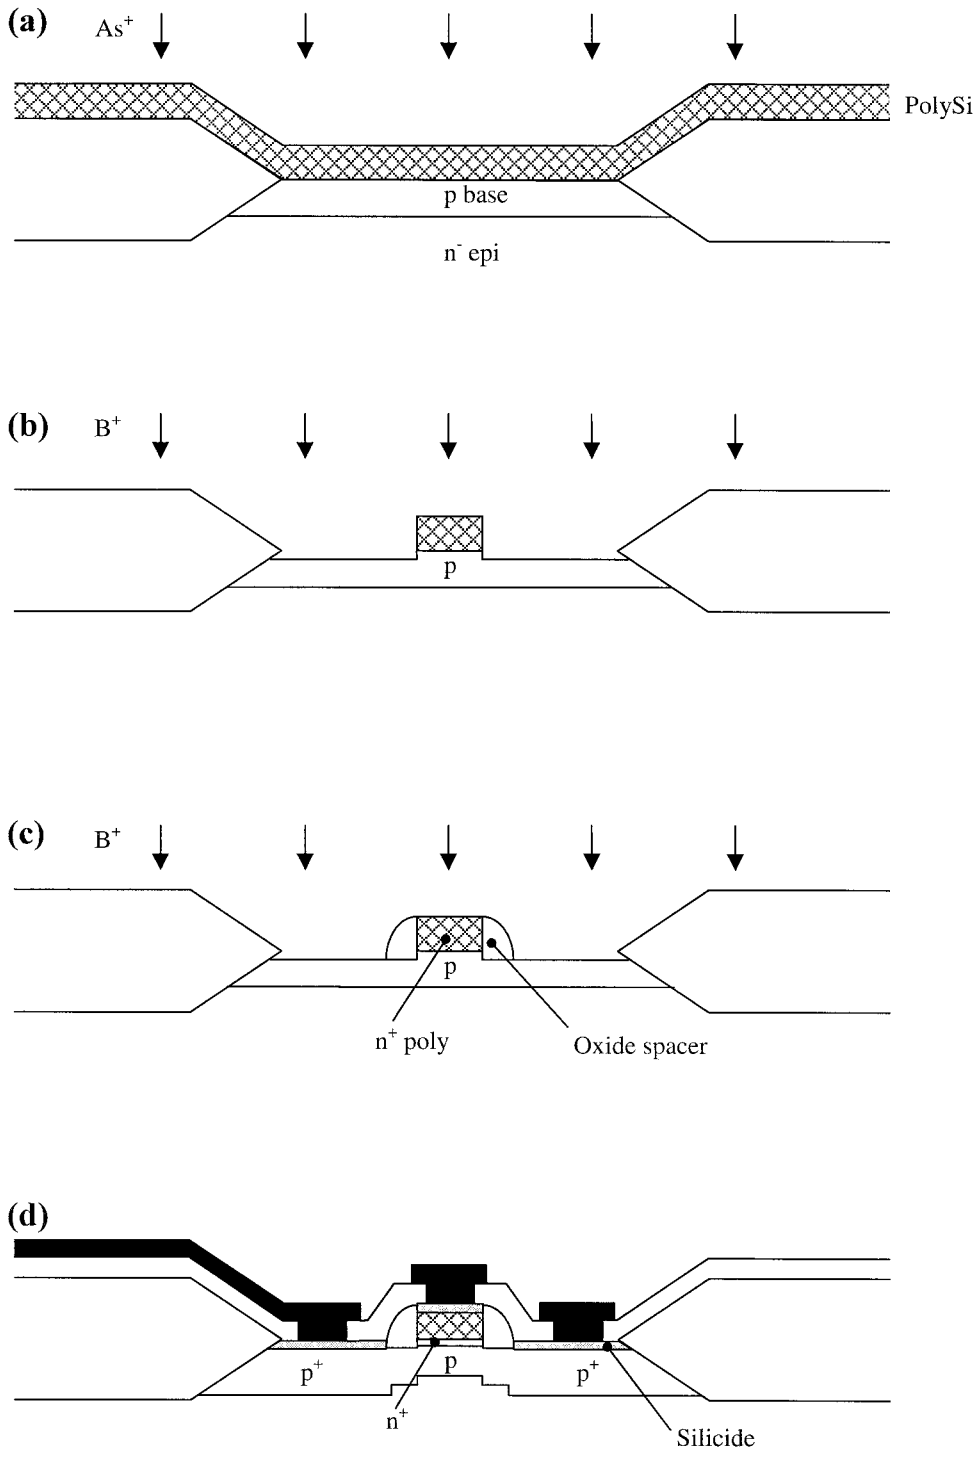

FIGURE 3.13 The single-poly, self-aligned process: (a) polyemitter implantation, (b) emitter etch and base link implantation, (c) oxide spacer formation and extrinsic base implantation, and (d) final device after junction formation and metallization.

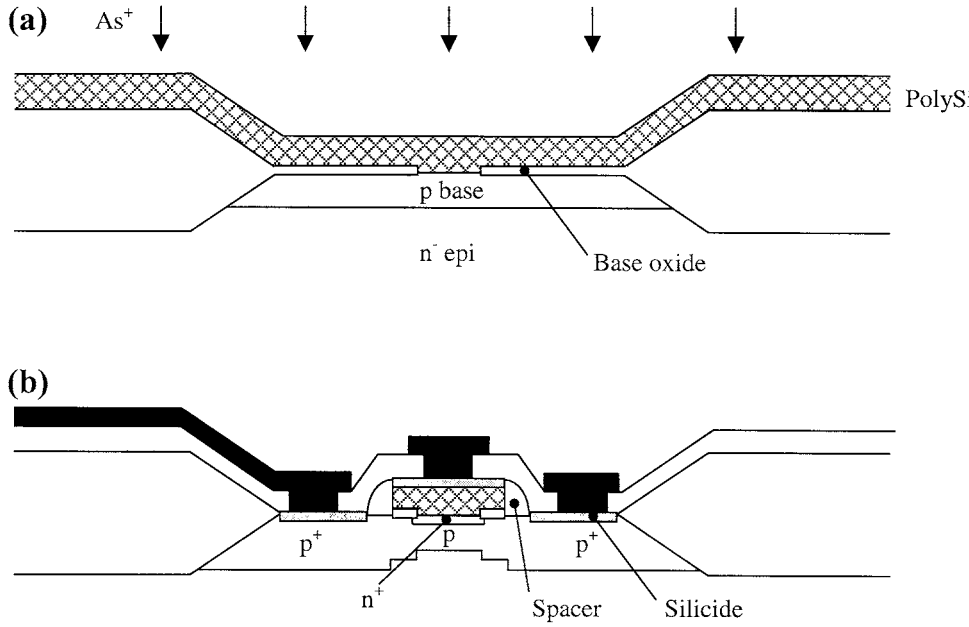

FIGURE 3.14 The single-poly, quasi-self-aligned process: (a) polyemitter implantation, (b) final device.

Double-Poly Structure

The double-poly structure originates from the classical IBM structure presented in 1981.[74] Most high-performance commercial processes today are based on double-poly technology. The number of variations are less than for the single-poly, mainly with different aspects on base-link engineering, spacer technology, and SIC formation. One example of a double-poly fabrication is presented in Fig. 3.15. After deposition of the base polysilicon and oxide stack, the emitter window is opened (Fig. 3.15(a)) and thermally oxidized. During this step, p^+-impurities from the base polysilicon diffuse into the monosilicon, thus forming the extrinsic base. In addition, the oxidation repairs the crystal damage caused by the dry etch when opening the emitter window. A thin silicon nitride layer is then deposited, the intrinsic base is implanted using boron, followed by the fabrication of amorphous silicon spacers inside the emitter window (Fig. 3.15(b)). The nitride is exposed to a short dry etch, the spacers are removed, and the thin oxide is opened up by an HF dip. Deposition and implantation of the polysilicon emitter film is carried out (Fig. 3.15(c)). The structure is patterned and completed by RTA emitter drive-in and metallization (Fig. 3.15(d)). The emitter will thus be fully self-aligned with respect to the base. Note that the inside spacer technology implies that the actual emitter width will be significantly less than the drawn emitter width.

The definition of the polyemitter in the single- and double-poly process inevitably leads to some overetching into the epi-layer, see Figs. 3.13(b) and 3.15(a), respectively. The final recessed region will make control over base-link formation more awkward.[75,76] In fact, the base link will depend both on the degree of overetch as well as the implantation parameters.[77] This situation is of no concern for the quasi-self-aligned process where the etch of the polysilicon emitter stops on the base oxide.

In a modification of the double-poly process, a more advanced base-link technology is proposed.[78] After extrinsic base drive-in and emitter window opening, BF_2-implanted poly-spacers are formed inside the emitter window. The boron is out-diffused through the emitter oxide, thus forming the base link. The intrinsic base is subsequently formed by conventional implantation through the emitter window. New dielectric inside spacers are formed prior to polysilicon emitter deposition, followed by arsenic implantation and emitter drive-in.

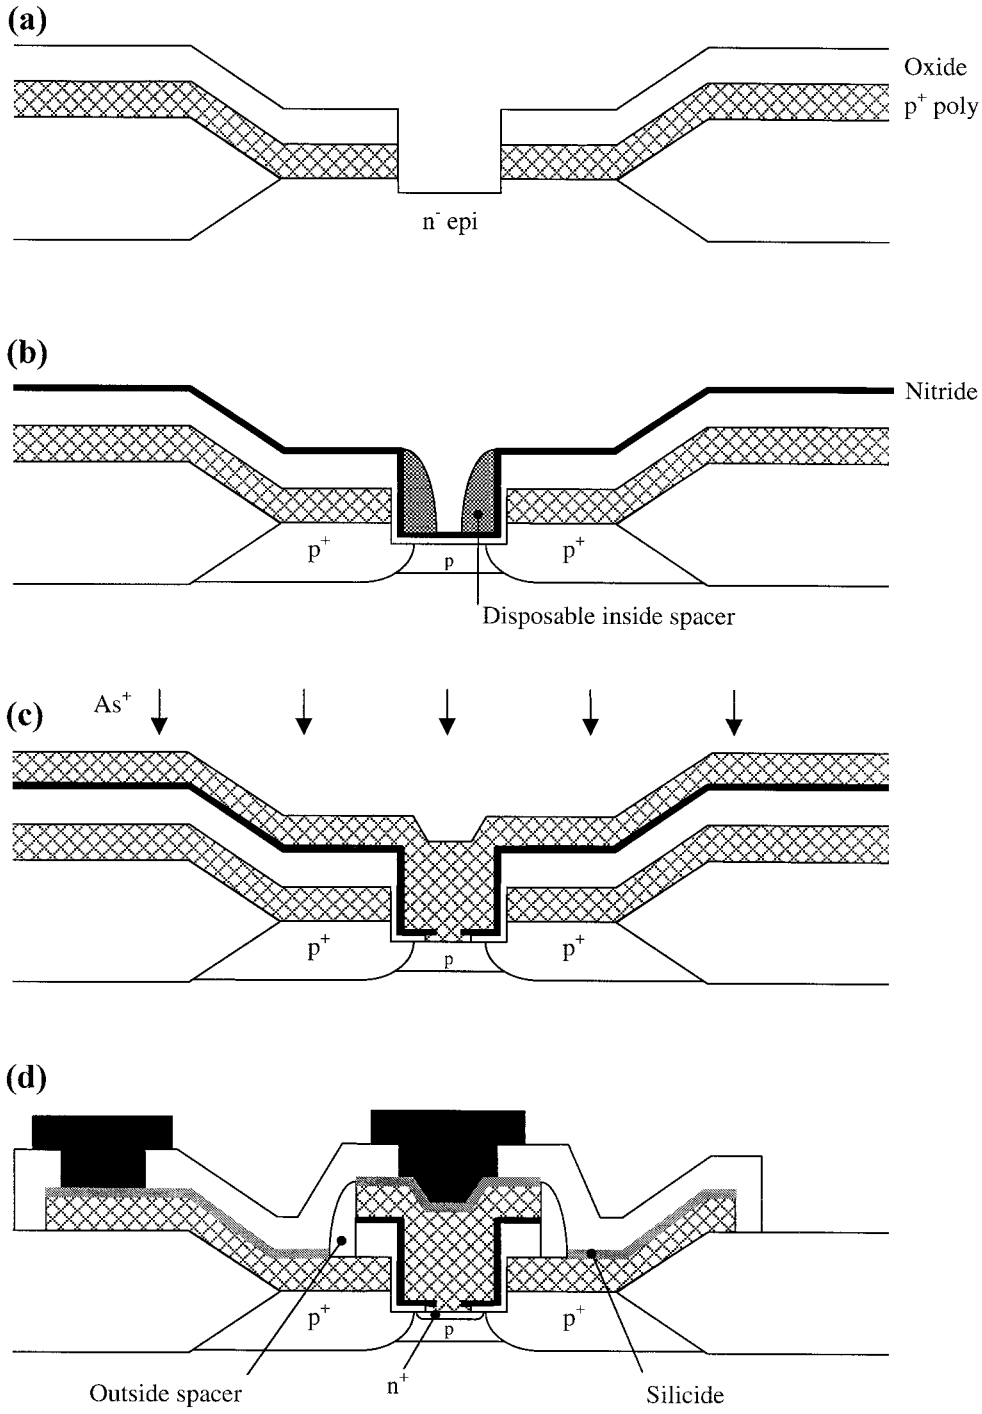

FIGURE 3.15 The double-poly, self-aligned process: (a) emitter window etch, (b) intrinsic base implantation through thin oxide/nitride stack followed by inside spacer formation, (c) polyemitter implantation, (d) final device after emitter drive-in and metallization.

Also, vertical pnp bipolar transistors based on the double-poly concept have been demonstrated.[79] Either boron or BF_2 is used for the polyemitter implantation. A pnp device with f_T of 35 GHz has been presented in a classical double-poly structure.[80]

3.5 Advanced Bipolar Technology

This chapter section treats state-of-the-art bipolar technologies reported during the 1990s (but not necessarily put into production). Alongside the traditional down-scaling in design rules, efforts have focused on new innovations in emitter and base electrode fabrication. A key issue has been the integration of epitaxial Si or SiGe intrinsic base into the standard npn process flow. This section concludes with an outlook on the future trends in bipolar technology after the year 2000.

Implanted Base

Today's most advanced commercial processes are specified with an f_T around 30 GHz. The major developments are being carried out using double-poly technology, although new improvements have also been reported for single-poly architectures.[72,81] For double-poly transistors, it was demonstrated relatively early that by optimizing a very low intrinsic base implant energy below 10 keV, devices with an f_T around 50 GHz are possible to fabricate.[82] The emitter out-diffusion is performed by a combined furnace anneal and RTA. In this way, the intrinsic base width is controlled below 1000 Å, whereas the emitter depth is only around 250 Å.

Since ion implantation is associated with a number of drawbacks such as channeling, shadowing effects, and crystal defects, it may be difficult to reach an f_T above 50 to 60 GHz based on such a technology. The intrinsic base implantation has been replaced by rapid vapor deposition using B_2H_6 gas around 900°C.[83] The in-diffused boron profile will form a thin and low-resistive base. Also, the emitter implantation can be removed by utilizing *in situ* doped emitter technology (e.g., AsH_3 gas during polysilicon deposition).[84] Two detrimental effects are then avoided; namely, emitter perimeter depletion and the emitter plug effect.[85] The former effect causes a reduced doping concentration close to the emitter perimeter, whereas the latter implies the plugging of doping atoms in narrow emitter windows causing shallower junctions compared to larger openings on the same chip.

Arsenic came to replace phosphorus as the emitter impurity during the 1970s, mainly because of the emitter push-effect plaguing phosphorus monosilicon emitters. The phosphorus emitter has, however, experienced a renaissance in advanced bipolar transistors by introducing the so-called *in situ* phosphorus doped polysilicon (IDP) emitter.[86] One motivation for using IDP technology is the reduction in final emitter resistance compared to the traditional As polyemitter, in particular for aggressively down-scaled devices with very narrow emitter windows. In addition, the emitter drive-in for an IDP emitter is carried out at a lower thermal budget than the corresponding arsenic emitter due to the difference in diffusivity between the impurity atoms. Using IDP and RVD, very high f_T values (above 60 GHz) have been realized.[83] It has been suggested that the residual stress of the IDP emitter and the interfacial oxide between the poly- and the monosilicon creates a heteroemitter action for the device, thus explaining the high current gains of IDP bipolar transistors.[87]

Base electrode engineering in advanced devices has become an important field in reducing the total base resistance, thus improving f_{max} of the transistor. One straightforward method in lowering the base sheet resistance is by shunting the base polysilicon with an extended silicide across the total base electrode. This has recently been demonstrated in an $f_{max} = 60$ GHz double-poly process.[88] A still more effective concept is to integrate metal base electrodes.[89] This approach is combined with *in situ* doped boron polysilicon base electrodes as well as an IDP emitter in a double-poly process (see Fig. 3.16). The tungsten electrodes are fully self-aligned using WF_6-selective deposition. The technology, denoted SMI (self-aligned metal IDP), has been applied together with RVD base formation. The bipolar process was shown to produce f_T and f_{max} figures of 100 GHz at a breakdown voltage of 2.5 V.[90]

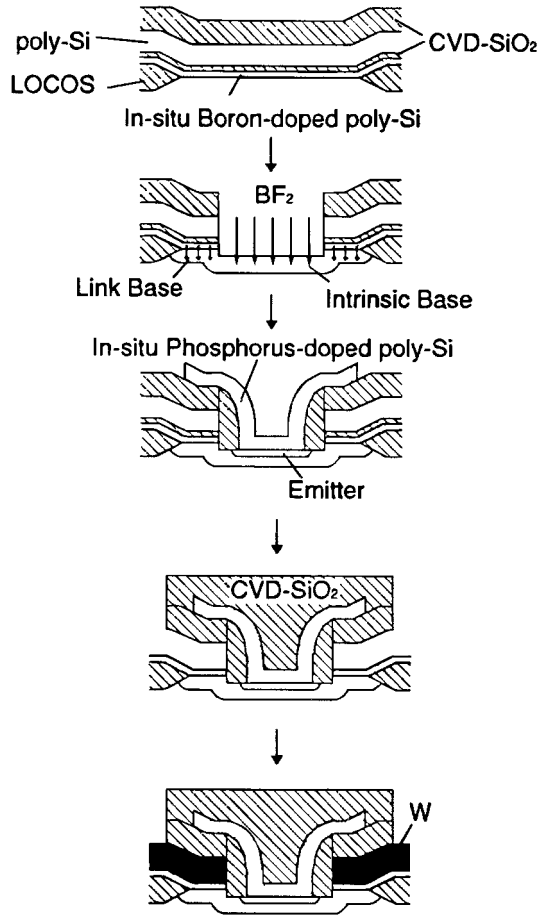

FIGURE 3.16 The self-aligned metal IDP process using selective deposition of tungsten base electrodes (after Ref. 89, copyright© 1997, IEEE).

Epitaxial Base

By introducing epitaxial film growth techniques for intrinsic base formation, the base width is readily controlled on the order of some hundred angstroms. Both selective and non-selective epitaxial growth (SEG and NSEG, respectively) have been reported. One example of a SEG transistor flow is illustrated in Fig. 3.17.[91] Not only the epitaxial base, but also the n^--collector is grown using SEG. The p^+-poly overhangs warrant a strong base link between the SEG intrinsic base and the base electrode. This $f_T = 44$ GHz process was capable of delivering divider circuits working at 25 GHz.

A natural extension of the Si epitaxy is to apply the previously mentioned SiGe epitaxy, thus creating a heterojunction bipolar transistor (HBT). For example, the transistor process in Fig. 3.17 was later extended to a SiGe process with $f_T = 61$ GHz and $f_{max} = 74$ GHz.[92] Apart from high speed, low base resistance is a trademark for many SiGe bipolar processes. For details of the SiGe HBT, the reader is referred to Chapter 5. Here, only some process integration points of view are given of this very important technology for advanced silicon-based bipolar devices during the 1990s.

While the first world records in terms of f_T and f_{max} were broken for non-self-aligned structures or mesa HBTs, planar self-aligned process schemes taking advantage of the benefits using SiGe have

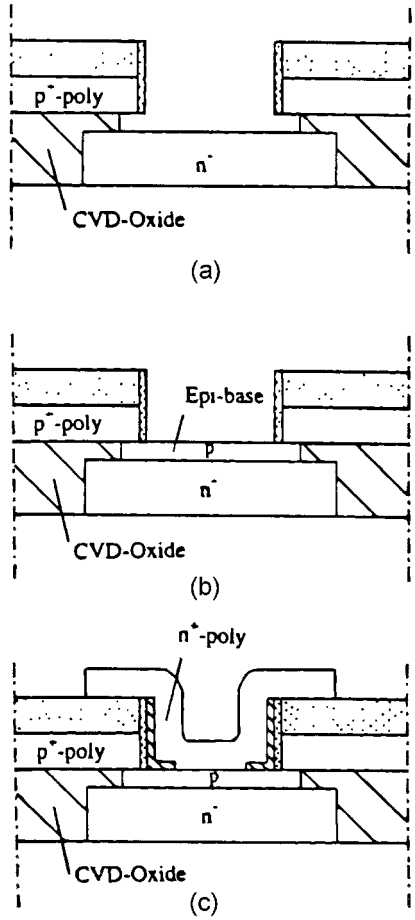

FIGURE 3.17 Process demonstrating selective epitaxial growth: (a) self-aligned formation of p^+-poly overhangs, (b) selective epitaxial growth of the intrinsic base, (c) emitter fabrication (after Ref. 91, copyright© 1992, IEEE).

subsequently been demonstrated. In recent years, both single-poly and double-poly SiGe transistors exhibiting excellent dc and ac properties have been presented. This also includes the quasi-self-aligned approach where a fully CMOS compatible process featuring an f_{max} of 71 GHz has been shown.[93] A similar concept featuring NSEG, so-called differential epitaxy, has been applied in the design of an HBT with a single-crystalline emitter rather than a polysilicon emitter.[94] This process, however, requires a very low thermal budget because of the high boron and germanium content in the intrinsic base of the transistor. Excellent properties for RF applications are made possible by this approach, such as high f_T and f_{max} around 50 GHz, combined with good dc properties and low noise figures.[95]

In double-poly structures, the extrinsic base is usually deposited prior to SiGe base epitaxy, which is then carried out by SEG (as shown in Fig. 3.17). Several groups report τ_d below 20 ps using this approach. One example of the most advanced bipolar technologies is the SiGe double-poly structure shown in Fig. 3.18.[96] This technology features the SMI base electrode technology, together with SEG of SiGe. The device is isolated by oxide-filled trenches. The reported τ_d was 7.7 ps and the f_{max} was 108 GHz, thus approaching the SiGe HBT mesa record of 160 GHz.[97] A device similar to the one in Fig. 3.18 was also reported to yield an f_T of 130 GHz.[98]

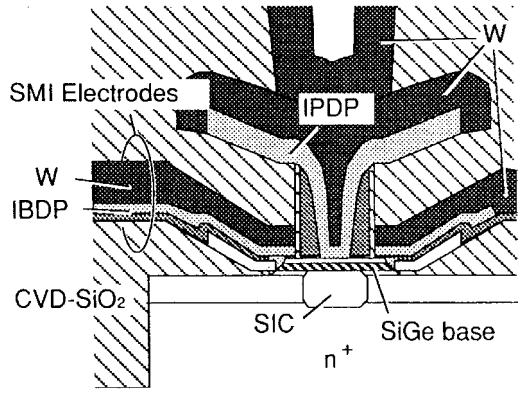

FIGURE 3.18 A state-of-the-art bipolar device featuring SMI electrodes, selectively grown epitaxial SiGe base, *in situ* doped polysilicon emitter/base and oxide-filled trenches (after Ref. 96, copyright© 1998, IEEE).

Future Trends

The shrinking of dimensions in bipolar devices, in particular for digital applications, will proceed one or two generations behind the MOS frontier, leading to a further reduction in τ_d. Several of the concepts reviewed above for advanced bipolar components are expected to be introduced in the next commercial high-performance processes; for example, *in situ* doped emitter and low-resistivity base electrodes. Similar to CMOS, the overall temperature budget must be reduced in processing. Evidently, bipolar technology in the future also continues to benefit from the progress made in CMOS technology; for example, in isolation and back-end processing. CMOS compatibility will be a general requirement for the majority of bipolar process development because of the strong interest in mixed-signal BiCMOS processes.

Advanced isolation technology combining deep and shallow trenches, perhaps on silicon-on-insulator (SOI) or high-resistivity substrates, marks one key trend in future bipolar transistors. Bipolar technology based on SOI substrates may well be accelerated by the current introduction of SOI into CMOS production. However, thermal effects for high current drive bipolar devices must be solved when using SOI. An interesting low-cost alternative insulating substrate for RF-bipolar technology is the silicon-on-anything concept recently presented.[99] In addition, copper metallization will be introduced for advanced bipolars provided that intermetal dielectrics as well as passive components are developed to meet this additional advantage.[100]

The epitaxial base constitutes another important trend where both Si and SiGe are expected to enhance performance in the high-frequency domain, although the introduction may be delayed due to progress in ion-implanted technology. In this respect, SEG technology has yet to prove its manufacturability.

Future Si-based bipolar technology with f_T and f_{max} greater than 100 GHz will continue to play an important role in small-density, high-performance designs. The most important applications are found in communication systems in the range 1 to 10 GHz (wireless telephony and local area networks) and 10 to 70 GHz (microwave and optical-fiber communication systems) where Si and/or SiGe bipolar technologies are expected to seriously challenge existing III-V technologies.[101]

Acknowledgments

We are grateful to G. Malm and M. Linder for carrying out the process simulations. The support from the Swedish High-Frequency Bipolar Technology Consortium is greatly acknowledged.

Silicon on Insulator Technology

Sorin Cristoloveanu
Institut National Polytechnique de Grenoble

4.1 Introduction

Silicon on Insulator (SOI) technology (more specifically, silicon on sapphire) was originally invented for the niche of radiation-hard circuits. In the last 20 years, a variety of SOI structures have been conceived with the aim of dielectrically separating, using a buried oxide (Fig. 4.1(b)), the active device volume from the silicon substrate.[1] Indeed, in an MOS transistor, only the very top region (0.1–0.2 μm thick, i.e., less than 0.1% of the total thickness) of the silicon wafer is useful for electron transport and device operation, whereas the substrate is responsible for detrimental, parasitic effects (Fig. 4.1(a)).

More recently, the advent of new SOI materials (Unibond, ITOX) and the explosive growth of portable microelectronic devices have attracted considerable attention on SOI for the fabrication of low-power (LP), low-voltage (LV), and high-frequency (HF) CMOS circuits.

The aim of this chapter is to overview the state-of-the-art of SOI technologies, including the material synthesis (Section 4.2), the key advantages of SOI circuits (Section 4.3), the structure and performance of typical devices (Section 4.4), and the operation modes of fully depleted (Section 4.5), and partially depleted SOI MOSFETs (Section 4.6). Section 4.7 is dedicated to short-channel effects. The main challenges that SOI is facing, in order to successfully compete with bulk–Si in the commercial arena, are critically discussed in Section 4.8.

4.2 Fabrication of SOI Wafers

Many techniques, more or less mature and effective, are available for the synthesis of SOI wafers.[1]

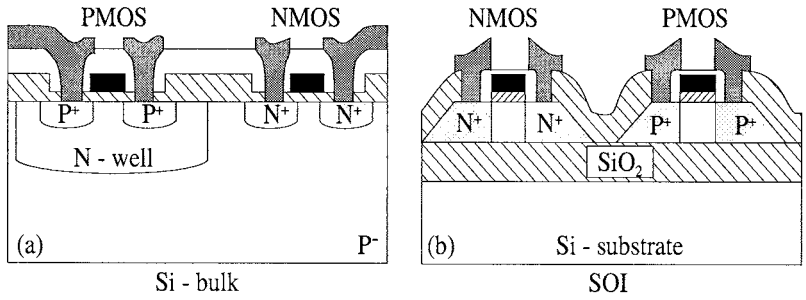

FIGURE 4.1 Basic architecture of MOS transistors in (a) bulk silicon and (b) SOI.

Silicon on Sapphire

Silicon on sapphire (SOS, Fig. 4.2(a_1)) is the initial member of SOI family. The epitaxial growth of Si films on Al_2O_3 gives rise to small silicon islands that eventually coalesce. The interface transition region contains crystallographic defects due to the lattice mismatch and Al contamination from the substrate. The electrical properties suffer from lateral stress, in-depth inhomogeneity of SOS films, and defective transition layer.[2]

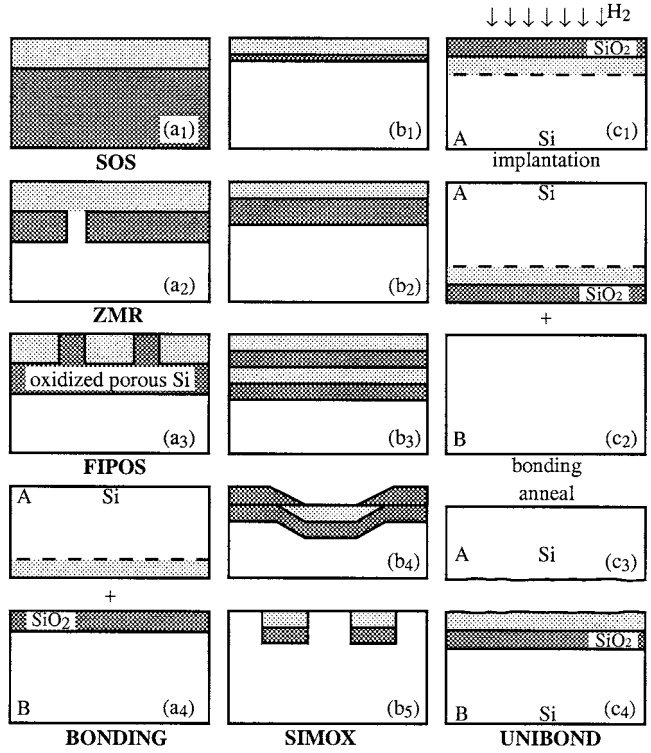

FIGURE 4.2 SOI family: (a) SOS, ZMR, FIPOS, and wafer bonding, (b) SIMOX variants, (c) UNIBOND processing sequence.

SOS has recently undergone a significant lifting: larger wafers and thinner films with higher crystal quality. This improvement is achieved by *solid-phase epitaxial regrowth*. Silicon ions are implanted to amorphise the film and erase the memory of damaged lattice and interface. Annealing allows the epitaxial regrowth of the film, starting from the 'seeding' surface towards the $Si–Al_2O_3$ interface. The result is visible in terms of higher carrier mobility and lifetime; 100-nm thick SOS films with good quality have recently been grown on 6 in. wafers.[3]

Thanks to the 'infinite' thickness of the insulator, SOS looks promising for the integration of RF and radiation-hard circuits.

ELO and ZMR

The *epitaxial lateral overgrowth* (ELO) method consists of growing a single-crystal Si film on a seeded and, often, patterned oxide (Fig. 4.2(a_2)). Since the epitaxial growth proceeds in both lateral and vertical directions, the ELO process requires a post-epitaxy thinning of the Si film. Alternatively, poly-silicon can be deposited directly on SiO_2; subsequently, *zone melting recrystallization* (ZMR) is achieved by scanning high-energy sources (lamps, lasers, beams, or strip heaters) across the wafer. The ZMR process can be seeded or unseeded; it is basically limited by the lateral extension of single-crystal regions, free from grain subboundaries and associated defects. ELO and ZMR are basic techniques for the integration of 3-D stacked circuits.

FIPOS

The FIPOS method (*full isolation by porous oxidized silicon*) makes use of the very large surface-to-volume ratio (10^3 cm^2 per cm^3) of porous silicon which is, thereafter, subject to selective oxidation (Fig. 4.2(a_3)). The critical step is the conversion of selected p-type regions of the Si wafer into porous silicon, via anodic reaction. FIPOS may enlighten Si technology because there are prospects, at least from a conceptual viewpoint, for combining electroluminescent porous Si devices with fast SOI–CMOS circuits.

SIMOX

In the last decade, the dominant SOI technology was SIMOX (*separation by implantation of oxygen*). The buried oxide (BOX) is synthesized by internal oxidation during the deep implantation of oxygen ions into a Si wafer. Annealing at high temperature (1320°C, for 6 h) is necessary to recover a suitable crystalline quality of the film. High current implanters (100 mA) have been conceived to produce 8 in. wafers with good thickness uniformity, low defect density (except threading dislocations: 10^4–10^6 cm^{-2}), sharp $Si–SiO_2$ interface, robust BOX, and high carrier mobility.[4]

The family of SOI structures is presented in Figure 4.2(b):

- Thin and thick Si films fabricated by adjusting the implant energy.
- Low-dose SIMOX: a dose of 4×10^{17} O^+/cm^2 and an additional oxygen-rich anneal for enhanced BOX integrity (ITOX process) yield a 0.1-μm thick BOX (Fig. 4.2(b_1)).
- Standard SIMOX obtained with 1.8×10^{18} O^+/cm^2 implant dose, at 190keV and 650°C; the thicknesses of the Si film and BOX are roughly 0.2 μm and 0.4 μm, respectively (Fig. 4.2(b_2)).
- Double SIMOX (Fig. 4.2(b_3)), where the Si layer sandwiched between the two oxides can serve for interconnects, wave guiding, additional gates, or electric shielding.
- Laterally-isolated single-transistor islands (Fig. 4.2(b_4)), formed by implantation through a patterned oxide.
- Interrupted oxides (Fig. 4.2(b_5)) which can be viewed as SOI regions integrated into a bulk Si wafer.

Wafer Bonding

Wafer bonding (WB) and etch-back stands as a rather mature SOI technology. An oxidized wafer is mated to another SOI wafer (Fig. 4.2(a_4)). The challenge is to drastically thin down one side of the bonded structure in order to reach the targeted thickness of the silicon film. Etch-stop layers can be achieved by doping steps (P^+/P^-, P/N) or porous silicon (Eltran process).[5] The advantage of wafer bonding is to provide unlimited combinations of BOX and film thicknesses, whereas its weakness comes from the difficulty to produce ultra-thin films with good uniformity.

UNIBOND

A recent, revolutionary bonding-related process (UNIBOND) uses the deep implantation of hydrogen into an oxidized Si wafer (Fig. 4.2(c_1)) to generate microcavities and thus circumvent the thinning problem.[6] After bonding wafer *A* to a second wafer *B* and subsequent annealing to enhance the bonding strength (Fig. 4.2(c_2)), the hydrogen-induced microcavities coalesce. The two wafers separate, not at the bonded interface but at a depth defined by the location of hydrogen microcavities. This mechanism, named *Smart-cut*, results in a rough SOI structure (Fig. 4.2(c_4)). The process is completed by touch-polishing to erase the surface roughness.

The extraordinary potential of the Smart-cut approach comes from several distinct advantages: (1) the etch-back step is avoided, (2) the second wafer (Fig. 4.2(c_3)) being recyclable, UNIBOND is a single-wafer process, (3) only conventional equipment is needed for mass production, (4) relatively inexpensive 12 in. wafers are manufacturable, and (5) the thickness of the silicon film and/or buried oxide can be adjusted to match most device configurations (ultra-thin CMOS or thick-film power transistors and sensors). The defect density in the film is very low, the electrical properties are excellent, and the BOX quality is comparable to that of the original thermal oxide. The Smart-cut process is adaptable to a variety of materials: SiC or III–V compounds on insulator, silicon on diamond, etc. Smart-cut can be used to transfer already fabricated bulk-Si CMOS circuits on glass or on other substrates.

4.3 Generic Advantages of SOI

SOI circuits consist of single-device islands dielectrically isolated from each other and from the underlying substrate (Fig. 4.1(b)). The lateral isolation offers more compact design and simplified technology than in bulk silicon; there is no need of wells or interdevice trenches. In addition, the vertical isolation renders the *latch-up* mechanisms impossible.

The source and drain regions extend down to the buried oxide; thus, the junction surface is minimized. This implies reduced leakage currents and junction capacitances, which further translates into improved speed, lower power, and wider temperature range of operation.

The limited extension of drain and source regions allows SOI devices to be less affected by short-channel effects, originated from 'charge sharing' between gate and junctions. Besides the outstanding tolerance of transient radiation effects, SOI MOSFETs experience a lower electric-field peak than in bulk Si and are potentially more immune to hot carrier damage.

It is in the highly competitive domain of LV/LP circuits, operated with one-battery supply (0.9–1.5V), that SOI can express its entire potential. A small gate voltage gap is suited to switch a transistor from off- to on-state. SOI offers the possibility to achieve a quasi-ideal subthreshold slope (60mV/decade at room temperature); hence, a threshold voltage shrunk below 0.3V. Low leakage currents limit the *static* power dissipation, as compared to bulk Si, whereas, the *dynamic* power dissipation is minimized by the combined effects of low parasitic capacitances and reduced voltage supply.

Two arguments can be given to outline unequivocally the advantage of SOI over bulk Si:

- Operation at similar *voltage* consistently shows about 30% increase in performance, whereas operation at similar *low-power* dissipation yields as much as 300% performance gain in SOI. It is

believed, at least in the SOI community, that SOI circuits of generation (n) and bulk-Si circuits from the *next* generation ($n + 1$) perform comparably.

- Bulk Si technology does attempt to mimic a number of features that are natural in SOI: the double-gate configuration is reproduced by processing surrounded-gate vertical MOSFETs on bulk Si, full depletion is approached by tailoring a low-high step doping, and the dynamic-threshold operation is borrowed from SOI.

The problem for SOI is that such an enthusiastic list of merits did not perturb the fantastic progress and authority of bulk Si technology. There has been no room or need so far for an alternative technology such as SOI. However, the SOI community remains confident that the SOI advantages together with the predictable approach of bulk-Si limits will be enough for SOI to succeed soon.

4.4 SOI Devices

CMOS Circuits

High-performance SOI CMOS circuits, compatible with LV/LP and high-speed ULSI applications have been repeatedly demonstrated on submicron devices. Quarter-micron ring oscillators showed delay times of 14 ps/stage at 1.5 V[7] and of 45 ps/stage at 1V.[8] PLL operated at 2.5 V and 4 GHz dissipate 19 mW only.[8] Microwave SOS MOSFETs, with T-gate configuration, had 66-MHz maximum frequency and low noise figure.[3]

More complex SOI circuits, with direct impact on mainstream microelectronics, have also been fabricated: 0.5 V–200 MHz microprocessor,[9] 4 Mb SRAM,[10] 16 Mb and 1 Gb DRAM,[11] etc.[1,12] Several companies (IBM, Motorola, Sharp) have announced the imminent commercial deployment of 'SOI-enhanced' PC processors and mobile communication devices.

CMOS SOI circuits show capability of successful operation at temperatures higher than 300°C: the leakage currents are much smaller and the threshold voltage is less temperature sensitive (≈0.5mV/°C for fully depleted MOSFETs) than in bulk Si.[13] In addition, many SOI circuits are radiation-hard, able to sustain doses above 10 Mrad.

Bipolar Transistors

As a consequence of the small film thickness, most bipolar transistors have a lateral configuration. The implementation of BiCMOS technology on SOI has resulted in devices with a cutoff frequency above 27 GHz.[14] Hybrid MOS–bipolar transistors with increased current drive and transconductance are formed by connecting the gate to the floating body (or base); the MOSFET action governs in strong inversion whereas, in weak inversion, the bipolar current prevails.[12]

Vertical bipolar transistors have been processed in thick-film SOI (wafer bonding or epitaxial growth over SIMOX). An elegant solution for thin-film SOI is to replace the buried collector by an inversion layer activated by the back gate.[12]

High-Voltage Devices

Lateral double-diffused MOSFETs (DMOS), with long drift region, were fabricated on SIMOX and showed 90 V/1.3A capability.[15] Vertical DMOS can be accommodated in thicker wafer-bonding SOI.

The SIMOX process offers the possibility to synthesize locally a buried oxide ('interrupted' SIMOX, Fig. 4.2(b_5)). Therefore, a vertical power device (DMOS, IGBT, UMOS, etc.), located in the bulk region of the wafer, can be controlled by a low-power CMOS/SOI circuit (Fig. 4.3(a)). A variant of this concept is the 'mezzanine' structure, which served for the fabrication of a 600V/25A smart-power device.[16] Double SIMOX (Fig. 4.2(b_3)) has also been used to combine a power MOSFET with a double-shielded high-voltage lateral CMOS and an intelligent low-voltage CMOS circuit.[17]

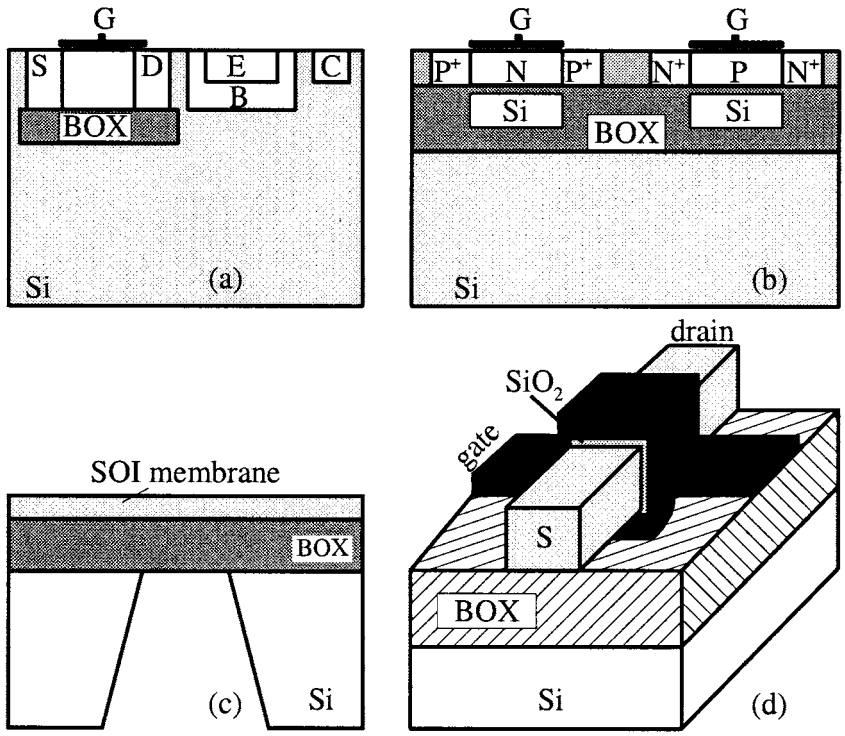

FIGURE 4.3 Examples of innovative SOI devices: (a) combined bipolar (or high power) bulk-Si transistor with low-voltage SOI CMOS circuits, (b) dual-gate transistors, (c) pressure sensor, and (d) gate-all-around (GAA) MOSFET.

Innovative Devices

Most innovative devices make use of special SOI features, including the possibility to (1) combine bulk Si and SOI on a single chip (Fig. 4.3(a)), (2) adjust the thickness of the Si overlay and buried oxide, and (3) implement additional gates in the buried oxide (Fig. 4.3(b)), by ELO process or by local oxidation of the sandwiched Si layer in double SIMOX (Fig. 4.2(b_3)).

SOI is an ideal material for microsensors because the Si/BOX interface gives a perfect etch-stop mark, making it possible to fabricate very thin membranes (Fig. 4.3(c)). Transducers for detection of pressure, acceleration, gas flow, temperature, radiation, magnetic field, etc. have successfully been integrated on SOI.[1,16]

The feasibility of three-dimensional circuits has been demonstrated on ZMR structures. For example, an image-signal processor is organized in three levels: photodiode arrays in the upper SOI layer, fast A/D converters in the intermediate SOI layer, and arithmetic units and shift registers in the bottom bulk Si level.[18]

The *gate all–around* (GAA) transistor of Fig. 4.3(d), based on the concept of volume inversion, is fabricated by etching a cavity into the BOX and wrapping the oxidized transistor body into a poly-Si gate.[12] Similar devices include the Delta transistor[19] and various double-gate MOSFETs.

The family of SOI devices also includes optical waveguides and modulators, microwave transistors integrated on high-resistivity SIMOX, twin-gate MOSFETs, and other exotic devices.[1,12] They do not belong to science fiction: the devices have already been demonstrated in terms of technology and functionality… even if most people still do not believe that they can operate.

4.5 Fully–Depleted SOI Transistors

In SOI MOSFETs (Fig. 4.1(b)), inversion channels can be activated at both the front Si–SiO_2 interface (via gate modulation V_{G_1}) and back Si–BOX interface (via substrate, back-gate bias V_{G_2}).

Full depletion means that the depletion region covers the entire transistor body. The depletion charge is constant and cannot extend according to the gate bias. A better coupling develops between the gate bias and the inversion charge, leading to enhanced drain current. In addition, the front- and back-surface potentials become coupled too. The coupling factor is roughly equal to the thickness ratio between gate oxide and buried oxide. The electrical characteristics of one channel vary remarkably with the bias applied to the opposite gate. Due to *interface coupling*, the front-gate measurements are all reminiscent of the back-gate bias and quality of the buried oxide and interface.

Totally new $I_D(V_G)$ relations apply to fully depleted SOI–MOSFETs whose complex behavior is controlled by both gate biases. The typical characteristics of the front-channel transistor are schematically illustrated in Fig. 4.4, for three distinct bias conditions of the back interface (inversion, depletion, and accumulation), and will be explained next.

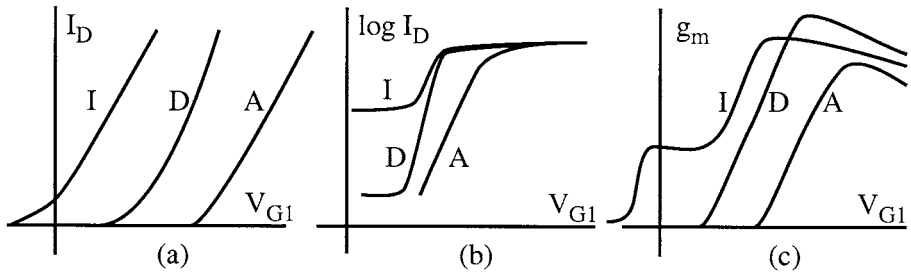

FIGURE 4.4 Generic front-channel characteristics of a fully depleted n-channel SOI MOSFET for accumulation (A), depletion (D), and inversion (I) at the back interface: (a) $I_D(V_{G_1})$ curves in strong inversion, (b) log $I_D(V_{G_1})$ curves in weak inversion, and (c) transconductance $g_m(V_{G_1})$ curves.

Threshold Voltage

The lateral shift of $I_D(V_{G_1})$ curves (Fig. 4.4(a)) is explained by the linear variation of the front-channel threshold voltage, $V_{T_1}^{dep}$, with back-gate bias. This *potential coupling* causes $V_{T_1}^{dep}$ to decrease linearly, with increasing V_{G_2}, between two plateaus corresponding, respectively, to accumulation and inversion at the back interface[20]:

$$V_{T_1}^{dep} = V_{T_1}^{acc} - \frac{C_{si}C_{ox_2}(V_{G_2} - V_{G_2}^{acc})}{C_{ox_1}(C_{ox_2} + C_{si} + C_{it_2})} \tag{4.1}$$

where $V_{T_1}^{acc}$ is the threshold voltage when the back interface is accumulated

$$V_{T_1}^{acc} = \Phi_{fb_1} + \frac{C_{ox_1} + C_{si} + C_{it_1}}{C_{ox_1}} 2\Phi_F - \frac{Q_{si}}{2C_{ox_1}} \tag{4.2}$$

and $V_{G_2}^{acc}$ is given by

$$V_{G_2}^{acc} = \Phi_{fb_2} - \frac{C_{si}}{C_{ox_2}} 2\Phi_F - \frac{Q_{si}}{2C_{ox_2}} \tag{4.3}$$

In the above equations, C_{si}, C_{ox}, and C_{it} are the capacitances of the fully depleted film, oxide, and interface traps, respectively; Q_{si} is the depletion charge, Φ_F is the Fermi potential, and Φ_{fb} is the flat-band potential. The subscripts 1 and 2 hold for the front- or the back-channel parameters and can be interchanged to account for the variation of the back-channel threshold voltage V_{T_2} with V_{G_1}.

The difference between the two plateaus, $\Delta V_{T_1} = (C_{si}/C_{ox_1})\,2\Phi_F$, slightly depends on doping, whereas the slope does not. We must insist on the polyvalence of Eqs.(4.1) to (4.3) as compared to the simple case of bulk Si MOSFETs (or partially depleted MOSFETs), where

$$V_{T_1} = \Phi_{fb_1} + \left(1 + \frac{C_{it_1}}{C_{ox_1}}\right)2\Phi_F + \frac{\sqrt{4q\varepsilon_{si}N_A\Phi_F}}{C_{ox_1}} \tag{4.4}$$

The extension to p-channels or accumulation-mode SOI–MOSFETs is also straightforward.[1]

In fully depleted MOSFETs, the threshold voltage decreases in thinner films (i.e., reduced depletion charge) until quantum effects arise and lead to the formation of a 2-D subband system. In ultra-thin films ($t_{si} \leq 10$ nm), the separation between the ground state and the bottom of the conduction band increases with reducing thickness: a V_T rebound is then observed.[21]

Subthreshold Slope

For depletion at the back interface, the subthreshold slope (Fig. 4.4(b)) is very steep and the subthreshold *swing S* is given by[22]:

$$S_1^{dep} = 2.3\frac{kT}{q}\left(1 + \frac{C_{it_1}}{C_{ox_1}} + \alpha_1\frac{C_{si}}{C_{ox_1}}\right) \tag{4.5}$$

The interface coupling coefficient α_1

$$\alpha_1 = \frac{C_{ox_2} + C_{it_2}}{C_{si} + C_{ox_2} + C_{it_2}} < 1 \tag{4.6}$$

accounts for the influence of back interface traps C_{it_2} and buried oxide thickness C_{ox_2} on the front channel current.[22]

In the ideal case, where $C_{it_{1,2}} \cong 0$ and the buried oxide is much thicker than both the film and the gate oxide (i.e., $\alpha_1 \cong 0$), the swing approaches the theoretical limit $S_1^{dep} \cong 60$ mV/decade at 300K. Accumulation at the back interface does decouple the front inversion channel from back interface defects but, in turn, makes α_1 tend to unity (as in bulk–Si or partially depleted MOSFETs), causing an overall degradation of the swing.

It is worth noting that the above simplified analysis and equations are valid only when the buried oxide is thick enough, such that substrate effects occurring underneath the BOX can be overlooked. The capacitances of the BOX and Si substrate are actually connected in series. Therefore, the swing may depend, essentially for thin buried oxides, on the density of the traps and surface charge (accumulation, depletion, or inversion) at the *third* interface: BOX–Si substrate. The general trend is that the subthreshold slope improves for thinner silicon films and thicker buried oxides.

Transconductance

For strong inversion and ohmic region of operation, the front-channel drain current and transconductance are given by

$$I_D = \frac{C_{ox_1}WV_D}{L} \cdot \frac{\mu_1}{1 + \theta_1(V_{G_1} - V_{T_1}(V_{G_2}))} \cdot (V_{G_1} - V_{T_1}(V_{G_2})) \tag{4.7}$$

$$g_{m_1} = \frac{C_{ox_1} W V_D}{L} \cdot \frac{\mu_1}{[1 + \theta_1(V_{G_1} - V_{T_1}(V_{G_2}))]^2} \tag{4.8}$$

where μ_1 is the mobility of front-channel carriers, and θ_1 is the mobility attenuation coefficient.

The complexity of the transconductance curves in fully depleted MOSFETs (Fig. 4.4(c)) is explained by the influence of the back gate bias via $V_{T_1}(V_{G_2})$. The effective mobility and transconductance peak are maximum for depletion at the back interface, due to combined effects of reduced vertical field and series resistances.

An unusual feature is the distortion of the transconductance (curve I, Fig. 4.4(c)), which reflects the possible activation of the back channel, far before the inversion charge build-up is completed at the front channel.[23] While the front interface is still depleted, increasing V_{G_1} reduces the back threshold voltage and eventually opens the *back* channel. The plateau of the front-channel transconductance (Fig. 4.4(c)) can be used to derive directly the back-channel mobility.

Volume Inversion

In thin and low-doped films, the simultaneous activation of front and back channels induces by continuity (i.e., *charge coupling*) the onset of *volume inversion*.[24] Unknown in bulk Si, this effect enables the inversion charge to cover the whole film. Self-consistent solutions of Poisson and Schrödinger equations indicate that the maximum density of the inversion charge is reached in the middle of the film. This results in increased current drive and transconductance, attenuated influence of interface defects (traps, fixed charges, roughness), and reduced $1/f$ noise.

Double-gate MOSFETs (*DELTA* and *GAA* transistors), designed to take full advantage from volume inversion, also benefit from reduced short-channel effects (V_T drop, punch-through, DIBL, hot-carrier injection, etc.), and are therefore very attractive, if not unique, devices for down-scaling below 30-nm gate length.

Defect Coupling

In fully depleted MOSFETs, carriers flowing at one interface may sense the presence of defects located at the opposite interface. *Defect coupling* is observed as an apparent degradation of the front-channel properties, which is actually induced by the buried oxide damage. This unusual mechanism is notorious after back interface degradation via radiation or hot-carrier injection (see also Fig. 4.7 in Section 4.7).

4.6 Partially Depleted SOI Transistors

In partially depleted SOI MOSFETs, the depletion charge controlled by one or both gates does not extend from an interface to the other. A neutral region subsists and, therefore, the interface coupling effects are disabled. When the body is grounded (via independent body contacts or body-source ties), partially depleted SOI transistors behave very much like bulk–Si MOSFETs and most of the standard $I_D(V_G, V_D)$ equations and design concepts apply. If body contacts are not supplied, so-called *floating-body* effects arise, leading to detrimental consequences, which will be explained next.

The *kink* effect is due to majority carriers, generated by impact ionization, that collect in the transistor body. The body potential is raised, which reduces the threshold voltage. This feedback gives rise to extra drain current (kink) in $I_D(V_D)$ characteristics (Fig. 4.5(a)), which is annoying in analog circuits.

In weak inversion and for high drain bias, a similar positive feedback (increased inversion charge → more impact ionization → body charging → threshold voltage lowering) is responsible for negative resistance regions, hysteresis in log $I_D(V_G)$ curves, and eventually latch (loss of gate control, Fig. 4.5(b)).

The floating body may also induce transient effects. A drain current *overshoot* is observed when the gate is turned on (Fig. 4.5(c)). Majority carriers are expelled from the depletion region and collect in

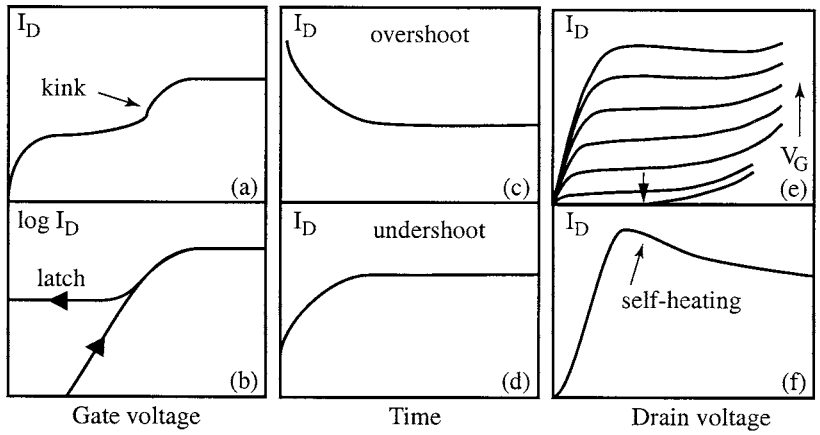

FIGURE 4.5 Parasitic effects in partially depleted SOI MOSFETs: (a) kink in $I_D(V_D)$ curves, (b) latch in $I_D(V_G)$ curves, (c) drain current overshoot, (d) current undershoot, (e) premature breakdown, and (f) self-heating.

the neutral body, increasing the potential. Equilibrium is reached through electron-hole recombination, which eliminates the excess majority carriers, making the drain current decrease gradually with time. A reciprocal *undershoot* occurs when the gate is switched from strong to weak inversion: the current now increases with time (Fig. 4.5(d)) as the majority carrier generation allows the depletion depth to shrink gradually. In short-channel MOSFETs, the transient times are dramatically reduced because of the additional contribution of source and drain junctions to establish equilibrium.

An obvious solution to alleviate floating-body effects is to sacrifice chip space for designing body contacts. The problem is that, in ultra-thin films with large sheet resistance, the body contacts are far from ideal. Their intrinsic resistance does not allow the body to be perfectly grounded and may generate additional noise. A floating body is then preferable to a poor body contact.

An exciting partially depleted device is the *dynamic-threshold* DT-MOS transistor. It is simply configured by interconnecting the gate and the body. As the gate voltage increases in weak inversion, the simultaneous raise in body potential makes the threshold voltage decrease. DT-MOSFETs achieve perfect gate-charge coupling, maximum subthreshold slope, and enhanced current, which are attractive features for LV/LP circuits.

4.7 Short–Channel Effects

In both fully and partially depleted MOSFETs with submicron length, the source–body junction can easily be turned on. The inherent activation of the lateral bipolar transistor has favorable (extra current flow in the body) or detrimental (premature breakdown, Fig. 4.5(e)) consequences. The breakdown voltage is evaluated near threshold, where the bipolar action prevails. The breakdown voltage is especially lowered for n-channels, shorter devices, thinner films, and higher temperatures. As expected, the impact ionization rate and related floating-body effects are attenuated at high temperature. However, the bipolar gain increases dramatically with temperature and accentuates the bipolar action: lower breakdown and latch voltages.[13]

Another concern is *self-heating*, induced by the power dissipation of short-channel MOSFETs and exacerbated by the poor thermal conductivity of the surrounding SiO_2 layers. Self-heating is responsible for mobility degradation, threshold voltage shift, and negative differential conductance shown in Fig. 4.5(f). The temperature rise can exceed 100 to 150°C in SOI, which is far more than in bulk Si.[25] Electromigration may even be initiated by the resulting increase in interconnect temperature. Thin buried oxides (≤100 nm) and thicker Si films (≥100 nm) are suitable when self-heating becomes a major issue.

A familiar short-channel effect is the threshold voltage roll-off due to charge sharing between the gate and source and drain terminals. The key parameters in SOI are the doping level, film thickness, and BOX thickness.[26] Ultra-thin, fully depleted MOSFETs show improved performance in terms of both V_T roll-off and drain-induced barrier lowering (DIBL) as compared to partially depleted SOI or bulk Si transistors (Fig. 4.6(a)).[27] The worst case happens when the film thickness corresponds to the transition between full and partial depletion. An additional origin of V_T roll-off in fully depleted MOSFETs is the field penetration into the buried oxide. An obvious solution is again the use of relatively thin buried oxides.

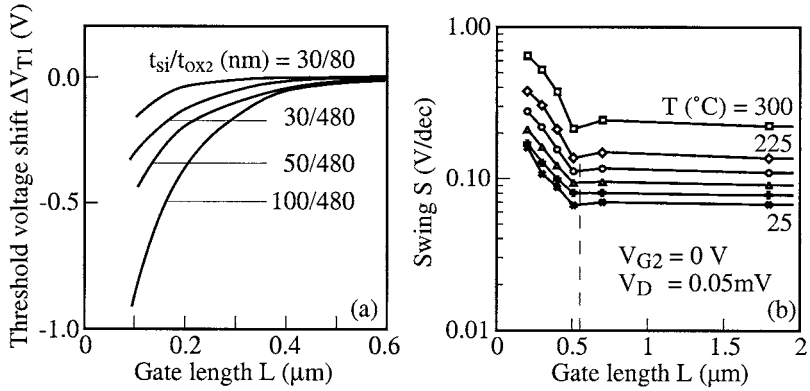

FIGURE 4.6 Typical short-channel effects in fully depleted SOI MOSFETs: (a) threshold voltage roll-off for different thicknesses of film and buried oxide[26] and (b) subthreshold swing degradation below 0.2-μm channel length for various temperatures.[13]

A degradation of the subthreshold swing is observed in very short ($L \leq 0.1$–0.5 μm), fully depleted MOSFETs (Fig. 4.6(b)). Two effects are involved: (1) conventional charge sharing, and (2) a surprising non-uniform coupling effect. We have seen that the subthreshold swing is minimum for depletion and increases for inversion at the back interface. In very short transistors, the lateral profile of the back interface potential can be highly inhomogeneous: from depletion in the middle of the channel to weak inversion near the channel ends, due to the proximity of source and drain regions. This localized weak inversion region explains the degradation of the swing.[13]

The transconductance is obviously improved in deep submicron transistors. Velocity saturation occurs as in bulk silicon. The main short-channel limitation of the transconductance comes from series resistance effects.

The lifetime of submicron MOSFETs is affected by hot-carrier injection into the gate oxide(s). The degradation mechanisms are more complex in SOI than in bulk-Si, due to the presence of two oxides, two channels, and related coupling mechanisms. For example, in Fig. 4.7, the front-channel threshold voltage is monitored during back channel stress. The shift ΔV_{T_1}, measured for $V_{G_2} = 0$ (depleted back interface), would imply that many defects are being generated at the front interface. Such a conclusion is totally negated by measurements performed with $V_{G_2} = -40V$: the influence of buried-oxide defects is now masked by the accumulation layer and indeed the apparent front-interface damage disappears ($\Delta V_{T_1} \cong 0$).[28]

In n-channels, the defects are created at the interface where the electrons flow; exceptionally, injection into the opposite interface may arise when the transistor is biased in the breakdown region. Although the device lifetime is relatively similar in bulk Si and SOI, the influence of stressing bias is different: SOI MOSFETs degrade less than bulk Si MOSFETs for $V_G \cong V_D/2$ (i.e., for maximum substrate current) and more for $V_G \cong V_T$ (i.e., enhanced hole injection). Device aging is accelerated by accumulating the back interface.[28]

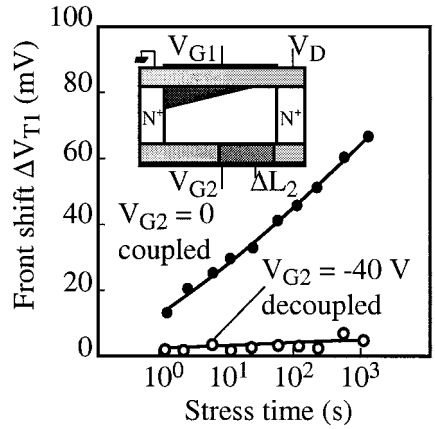

FIGURE 4.7 Front-channel threshold voltage shift during back-channel stress in a SIMOX MOSFET.[28] The apparent degradation of the gate oxide disappears when the stress-induced defects in the buried oxide are masked by interface accumulation ($V_{G_2} = -40$ V).

In p-channels, the key mechanism involves the electrons generated by front-channel impact ionization, which become trapped into the buried oxide. An apparent degradation of the front interface again occurs via coupling.[28]

4.8 SOI Challenges

SOI stands already as a pretty mature technology. However, there are still serious challenges in various domains — fundamental and device physics, technology, device modeling, and circuit design — before SOI will become fully competitive in the commercial market.

The minimum dimensions thus far achieved for SOI MOSFETs are: 70 nm length, 10 nm width (quantum wires), and 1 to 2 nm thickness.[21] When these features will be cumulative in a single transistor, the body volume ($\leq 10^{-18}$ cm^3!) will contain 10^4–10^5 silicon atoms and 0 to 1 defects. The body doping (10^{17}–10^{18} cm^{-3}) will be provided by a unique impurity, whose location may become important. Moreover, quantum transport phenomena are already being observed in ultra-thin SOI transistors. It is clear that new physical concepts, ideas, and modeling tools will be needed to account for minimum-size mechanisms in order to take advantage of them.

As far as the technology is concerned, a primary challenge is the mass-production of SOI wafers with large diameter (≥12 in.), low defect content, and reasonable cost (2 to 3 times higher than for bulk-Si wafers). The thickness uniformity of the silicon layer is especially important for fully depleted MOSFETs because it governs the fluctuations of the threshold voltage. It is predictable that several SOI technologies will not survive, except for special niches.

There is a demand for appropriate characterization techniques, either imported from other semiconductors or entirely conceived for SOI.[1] Such a pure SOI technique is the pseudo-MOS transistor (Ψ–MOSFET).[29] Ironically, it behaves very much like the MOS device that Shockley attempted to demonstrate 50 years ago but, at that time, he didn't have the chance to know about SOI. The inset of Figure 4.8 shows that the Si substrate is biased as a gate and induces a conduction channel (inversion or accumulation) at the film–oxide interface. Source and drain probes are used to measure $I_D(V_G)$ characteristics. The Ψ–MOSFET does not require any processing, hence valuable information is directly available: quality of the film, interface and oxide, electron/hole mobilities, and lifetime.

Full CMOS processing must address typical SOI requirements such as the series resistance reduction in ultra-thin MOSFETs (via local film oxidation, elevated source and drain structures, etc.), the lowering

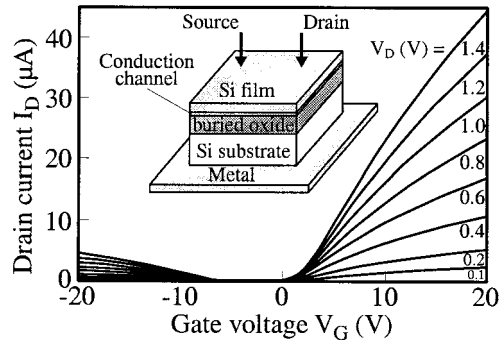

FIGURE 4.8 Pseudo-MOSFET transistor and $I_D(V_G)$ characteristics in SOI.

of the source–body barrier by source engineering (silicidation, Si–Ge, etc.), the control of the parasitic bipolar transistor, and the limitation of self-heating effects. It is now clear that the best of SOI is certainly not achievable by simply using a very good bulk-Si technology. For example, double-gate SOI MOSFETs deserve special processing and design.

According to process engineers and circuit designers, partially depleted SOI MOSFETs are more user friendly as they maintain the flavor of bulk-Si technology. On the other hand, fully depleted transistors have superior capability; they need to be domesticated in order to become more tolerant to short-channel effects. A possible solution, which requires further investigation, is the incorporation of a ground plane underneath the buried oxide.

Advanced modeling is required for correct transcription of the transistor behavior, including the transient effects due to body charging and discharging, floating-body mechanisms, bipolar transistor, dual-gate operation, quantum effects, self-heating, and short-channel limitations. Based on such physical models, compact models should then be conceived for customized simulation and design.

It is obvious that SOI does need SOI-dedicated CAD libraries. This implies a substantial amount of work which, in turn, will guarantee that the advantages and peculiar constraints of SOI devices are properly accounted for. The optimum configuration of memories, microprocessors, DSP, etc., will most likely be different in SOI as compared to bulk. Not only can SOI afford to combine fully/partially depleted, low/high power, and DT-MOSFETs in a single chip, but also the basic mechanisms of operation may differ.

4.9 Conclusion

For the next millennium, SOI offers the opportunity to integrate high-performance and/or innovative devices that can push away the present frontiers of the CMOS down-scaling. SOI will play a significant role in the future of microelectronics if subsisting problems can be rapidly solved. The short-term prospects of SOI-based microelectronics will also closely depend on the penetration rate of LV/LP SOI circuits into the market. Not only does SOI offer enhanced performance, but also most of SOI disadvantages (self-heating, hot carriers, early breakdown, etc.) tend to disappear for operation at low voltage.

A key challenge is associated with industrial strategy, which must be oriented to overcome the bulk-Si monocultural barrier. Designers, process engineers, and managers are extremely busy loading the bulk-Si machine. When, eventually, they can afford to take a careful look at the assets of SOI technology, they will realize the immediate and long-term benefits offered in terms of performance and scaling extensions.

This is so because SOI is not a totally different technology — it is just a metamorphosis of silicon.

5.1 Introduction

The concept of bandgap engineering has been used for many years in compound semiconductors such as gallium arsenide (GaAs) and indium phosphide (InP) to realize a host of novel electronic devices. A bandgap-engineered transistor is compositionally altered in a manner that improves a specific device metric (e.g., speed). A transistor designer might choose, for instance, to make a bipolar transistor that has a GaAs base and collector region, but which also has a AlGaAs emitter. Such a device has electrical properties that are inherently superior to what could be achieved using a single semiconductor. In addition to simply combining two different materials (e.g., AlGaAs and GaAs), bandgap engineering often involves compositional grading of materials within a device. For instance, one might choose to vary the Al content in an AlGaAs/GaAs transistor from a mole fraction of 0.4 to 0.6 across a given distance within the emitter.

Device designers have long sought to combine the bandgap engineering techniques enjoyed in compound semiconductors technologies with the fabrication maturity, high yield, and hence low cost associated with conventional silicon (Si) integrated circuit manufacturing. Epitaxial silicon-germanium (SiGe) alloys offer considerable potential for realizing viable bandgap-engineered transistors in the Si material system. This is exciting because it potentially allows Si electronic devices to achieve performance levels that were once thought impossible, and thus dramatically extends the number of high-performance circuit applications that can be addressed using Si technology. This chapter reviews the recent progress in both SiGe heterojunction bipolar transistor (HBT) technology and SiGe field effect transistor (FET) technology.

5.2 SiGe Strained Layer Epitaxy

Si and Ge, being chemically compatible elements, can be intermixed to form a stable alloy. Unfortunately, however, the lattice constant of Si is about 4.2% smaller than that of Ge. The difficulties associated with realizing viable SiGe bandgap-engineered transistors can be traced to the problems encountered in growing high-quality, defect-free epitaxial SiGe alloys in the presence of this lattice mismatch. For electronic applications, it is essential to obtain a SiGe film that adopts the same lattice constant as the underlying Si substrate with perfect alignment across the growth interface. In this case, the resultant SiGe alloy is under compressive strain. This strained SiGe film is thermodynamically stable only under a narrow range of conditions that depend on the film thickness and the effective strain (determined by

the Ge concentration).[1] The critical thickness below which the grown film is unconditionally stable depends reciprocally on the effective strain (Fig. 5.1). Thus, for practical electronic device applications, SiGe alloys must be thin (typically <100–200 nm) and contain only modest amounts of Ge (typically <20–30%). It is essential for electronic devices that the SiGe films remain thermodynamically stable so that conventional Si fabrication techniques such as high-temperature annealing, oxidation, and ion implantation can be employed without generating defects.

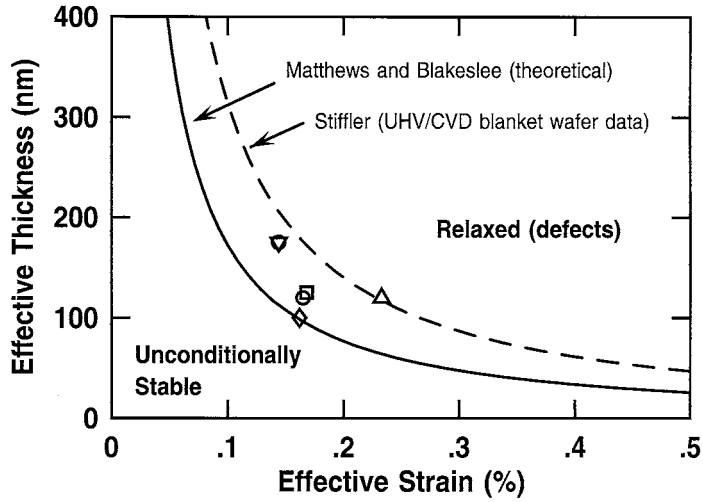

FIGURE 5.1 Effective thickness versus effective strain for SiGe strained layer epitaxy. Shown are a theoretical stability curve (Matthews-Blakeslee), and an empirical curve for UHV/CVD SiGe epitaxy. The symbols represent actual films used in UHV/CVD SiGe HBTs.

From an electronic device viewpoint, the property of the strained SiGe alloy that is most often exploited is the reduction in bandgap with strain and Ge content (roughly 75 meV per 10% Ge).[2] This band offset appears mostly in the valence band, which is particularly useful for realizing n-p-n bipolar transistors and p-channel FETs.[3] While these band offsets are modest compared to those that can be achieved in III–V semiconductors, the Ge content can be compositionally graded to produce local electric fields that aid carrier transport. For instance, in a SiGe HBT, the Ge content might be graded from 0 to 15% across distances as short as 50 to 60 nm, producing built-in drift fields as large as 15 to 20 kV · cm^{-1}. Such fields can rapidly accelerate the carriers to scattering-limited velocity (1×10^7 cm · s^{-1}), thereby improving the transistor frequency response. Another benefit of using SiGe strained layers is the enhancement in carrier mobility. This advantage will be exploited in SiGe channel FETs, as discussed below.

Epitaxial SiGe strained layers on Si substrates can be successfully grown today by a number of different techniques, including molecular beam epitaxy (MBE), ultra-high vacuum/chemical vapor deposition (UHV/CVD), rapid-thermal CVD (RTCVD), atmospheric pressure CVD (APCVD), and reduced pressure CVD (RPCVD). Each growth technique has advantages and disadvantages, but it is generally agreed that UHV/CVD,[4] has a number of appealing features for the commercialization of SiGe integrated circuits. The features of UHV/CVD that make it particularly suitable for manufacturing include: (1) batch processing on up to 16 wafers simultaneously, (2) excellent doping and thickness control on large (e.g., 200 mm) wafers, (3) very low background oxygen and carbon concentrations, (4) compatibility with patterned wafers and hence conventional Si bipolar and CMOS fabrication techniques, and (5) the ability to compositionally grade the Ge content in a controllable manner across short distances. The experimental results presented in this chapter are based on the UHV/CVD growth technique as practiced at IBM Corporation, and are representative of the state-of-the-art in SiGe technology.

5.3 The SiGe Heterojunction Bipolar Transistor (HBT)

The SiGe HBT is by far the most mature Si-based bandgap-engineered electronic device.[5] The first SiGe HBT was reported in 1987,[6,7] and began commercial production in 1998. Significant steps along the path to manufacturing included the first demonstration of high-frequency (75 GHz) operation of a SiGe HBT in a non-self-aligned structure in early 1990.[8] This result garnered much attention worldwide because the performance of the SiGe HBT was roughly twice what a state-of-the-art Si BJT could achieve (Fig. 5.2). The first fully integrated, self-aligned SiGe HBT technology was demonstrated later in 1990,[9] the first fully integrated 0.5-μm SiGe BiCMOS technology (SiGe HBT + Si CMOS) in 1992,[10] and SiGe HBTs with frequency response above 100 GHz in 1993 and 1994.[11,12] A number of research laboratories around the world have demonstrated robust SiGe HBT technologies, including IBM,[13–17] Daimler-Benz/TEMIC,[18–21] NEC,[22–24] and Siemens.[25] More recent work has begun to focus on practical SiGe HBT circuits for radio-frequency (RF) and microwave applications.[26–28]

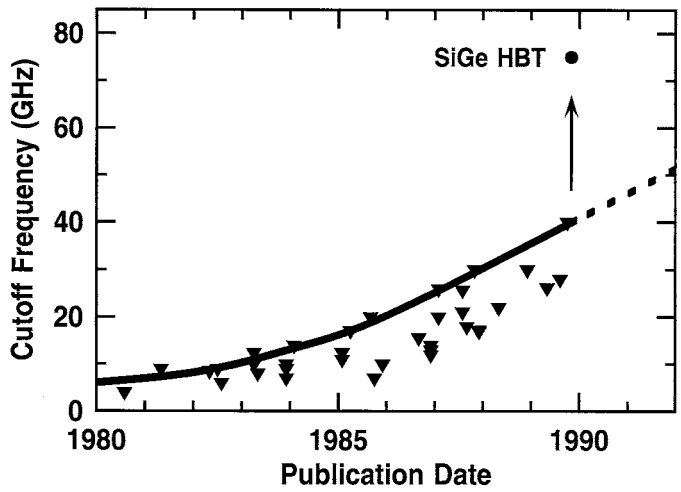

FIGURE 5.2 Transistor cutoff frequency as a function of publication date comparing Si BJT performance and the first SiGe HBT result.

Because the intent in SiGe technology is to combine bandgap engineering with conventional Si fabrication techniques, most SiGe HBT technologies appear very similar to conventional Si bipolar technologies. A typical device cross-section is shown in Fig. 5.3. This SiGe HBT has a planar, self-aligned structure with a conventional polysilicon emitter contact, silicided extrinsic base, and deep- and shallow-trench isolation. A 3-5 level, chemical-mechanical-polishing (CMP) planarized, W-stud, AlCu CMOS metalization scheme is used. The extrinsic resistive and capacitive parasitics are intentionally minimized to improve the maximum oscillation frequency (f_{max}) of the transistor. Observe that the Ge is introduced only into the thin base region of the transistor, and is deposited with a thickness and Ge content that ensures the film is thermodynamically stable (examples of real SiGe HBT profiles are shown as symbols in stability space in Fig. 5.1). The *in situ* boron-doped, graded SiGe base is deposited across the entire wafer using the ultra-high vacuum/chemical vapor deposition (UHV/CVD) technique. In areas that are not covered by oxide, the UHV/CVD film consisting of an intrinsic-Si/strained boron-doped SiGe/intrinsic-Si stack is deposited as a perfect single-crystal layer on the Si substrate. Over the oxide, the deposited layer is polycrystalline (poly) and will serve either as the extrinsic base contact of the SiGe HBT, the poly-on-oxide resistor, or the gate electrode of the Si CMOS devices. The metallurgical base and single-crystal emitter widths range from 75 to 90 nm and 25 to 35 nm, respectively. A masked phosphorous implant is used to tailor the intrinsic collector profile for optimum frequency response at high current densities.

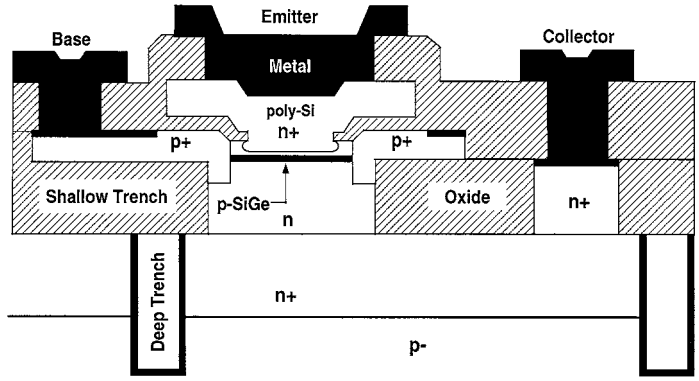

FIGURE 5.3 Schematic cross-section of a self-aligned UHV/CVD SiGe HBT.

A conventional deep-trench/shallow-trench bipolar isolation scheme is used, as well as a conventional arsenic-doped polysilicon emitter layer. This approach ensures that the SiGe HBT is compatible with commonly used (low-cost) bipolar/CMOS fabrication processes. A typical doping profile measured by secondary ion mass spectroscopy (SIMS) of the resultant SiGe HBT is shown in Fig. 5.4.

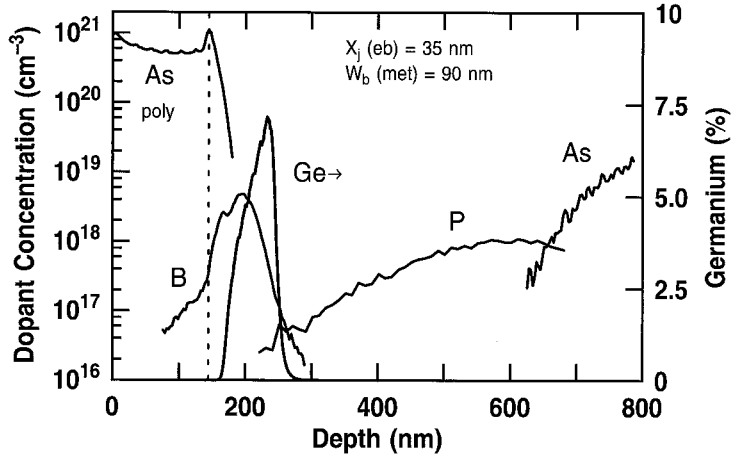

FIGURE 5.4 Secondary ion mass spectroscopy (SIMS) doping profile of a graded-base SiGe HBT.

The smaller base bandgap of the SiGe HBT can be exploited in three major ways, and is best illustrated by examining an energy band diagram comparing a SiGe HBT with a Si BJT (Fig. 5.5). First, note the reduction in base bandgap at the emitter–base junction. The reduction in the potential barrier at the emitter–base junction in a SiGe HBT will exponentially increase the collector current density and, hence, current gain ($\beta = J_C/J_B$) for a given bias voltage compared to a comparably designed Si BJT. Compared to a Si BJT of identical doping profile, this enhancement in current gain is given by:

$$\frac{J_{C,SiGe}}{J_{C,Si}} = \frac{\beta_{SiGe}}{\beta_{Si}} = \gamma\eta \frac{\Delta E_{g,Ge}(grade)/kT \; e^{\Delta E_{g,Ge}(0)/kT}}{1 - e^{-\Delta E_{g,Ge}(grade)/kT}} \tag{5.1}$$

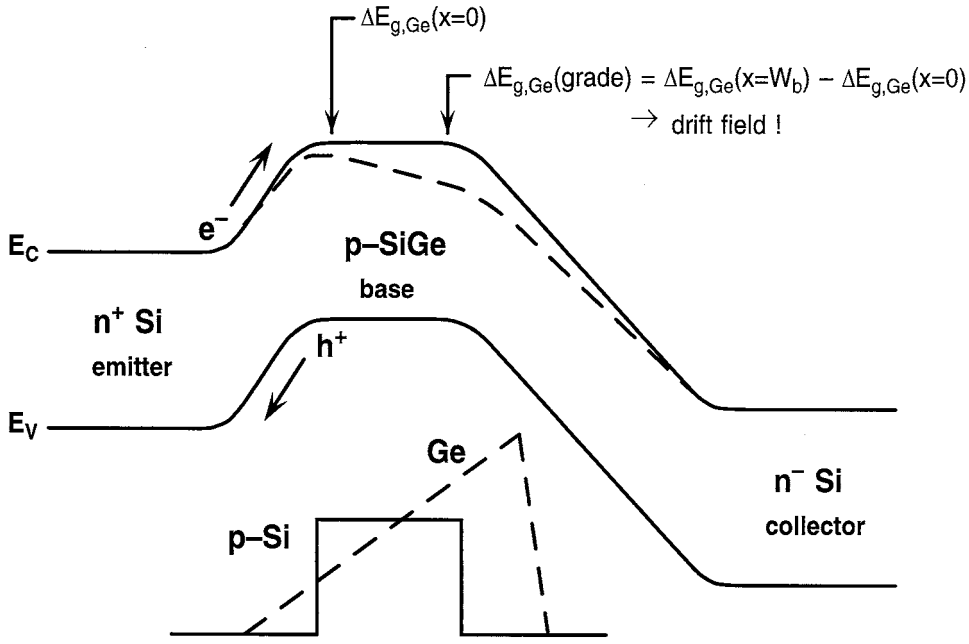

FIGURE 5.5 Energy band diagram for both a Si BJT and a graded-base SiGe HBT.

where $\gamma = N_C N_V$ (SiGe)/$N_C N_V$(Si) is the ratio of the density-of-states product between SiGe and Si, and $\eta = D_{nb}$(SiGe)/D_{nb}(Si) accounts for the differences between the electron and hole mobilities in the base. The position dependence of the band offset with respect to Si is conveniently expressed as a bandgap grading term ($\Delta E_{g,Ge}$(grade) = $\Delta E_{g,Ge}$(Wb) – $\Delta E_{g,Ge}$(0)). As can be seen in Fig. 5.6, which compares the measued Gummel characteristics for two identically constructed SiGe HBTs and Si BJTs, these theoretical expectations are clearly borne out in practice.

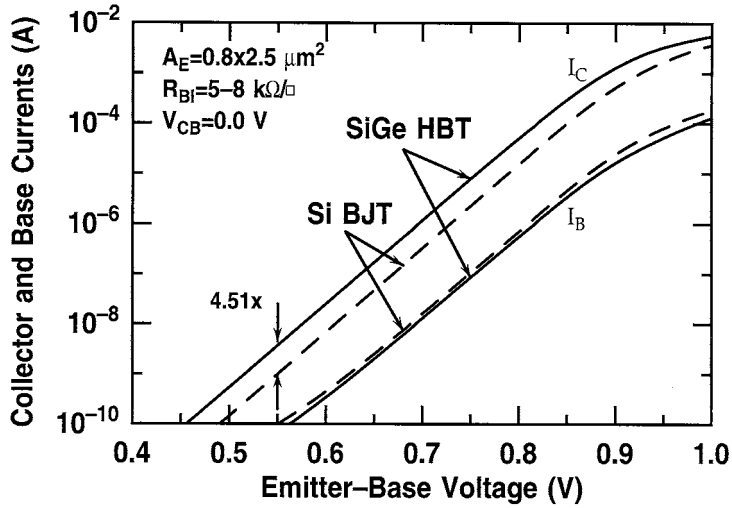

FIGURE 5.6 Measured current/voltage characteristics of both SiGe HBT and Si BJT with a comparable doping profile.

Secondly, if the Ge content is graded across the base region of the transistor, the conduction band edge becomes position dependent (refer to Fig. 5.5), inducing an electric field in the base that accelerates the injected electrons. The base transit time is thereby shortened and the frequency response of the transistor is improved according to:

$$\frac{\tau_{b,\,SiGe}}{\tau_{b,\,Si}} = \frac{f_{T,\,Si}}{f_{T,\,SiGe}} = \frac{2}{\eta}\left(\frac{kT}{\Delta E_{g,\,Ge}(grade)}\right)\left[1 - \frac{1 - e^{-\Delta E_{g,\,Ge}(grade)/kT}}{\Delta E_{g,\,Ge}(grade)/kT}\right] \tag{5.2}$$

Figure 5.7 compares the measured unity gain cutoff frequency (f_T) of a SiGe HBT and a comparably constructed Si BJT, and shows that an improvement in peak f_T of 1.7X can be obtained with relatively modest Ge profile grading (0–7.5% in this case). More recent studies demonstrate that peak cutoff frequencies in excess of 100 GHz can be obtained using more aggressively designed (although still stable) Ge profiles[12] (see Fig. 5.8).

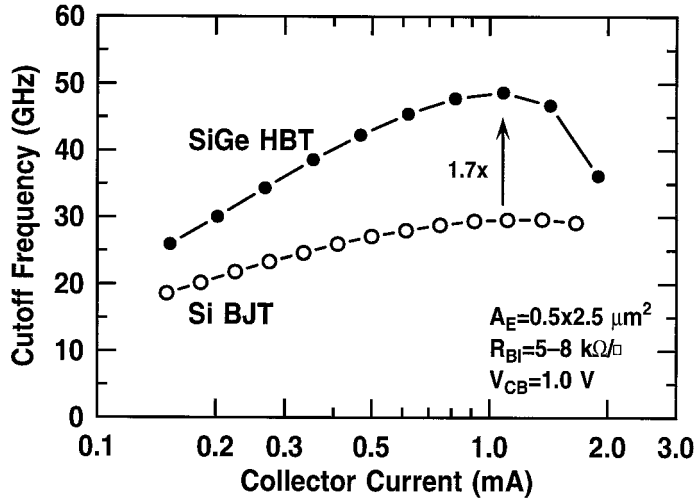

FIGURE 5.7 Measured cutoff frequency as a function of bias current for both SiGe HBT and Si BJT with a comparable doping profile.

The final advantage of using a graded Ge profile in a SiGe HBT is the improvement in the output conductance of the transistor, an important analog design metric. For a graded-base SiGe HBT, the Early voltage (a measure of output conductance) increases exponentially compared to a Si BJT of comparable doping, according to:

$$\frac{V_{A,\,SiGe}}{V_{A,\,Si}} = e^{\Delta E_{g,\,Ge}(grade)/kT}\left[\frac{1 - e^{-\Delta E_{g,\,Ge}(grade)/kT}}{(\Delta E_{g,\,Ge}(grade)/kT)}\right] \tag{5.3}$$

In essence, the position dependence of the bandgap in the graded-base SiGe HBT weights the base profile toward the collector region, making it harder to deplete the base with collector-base bias, hence yielding a larger Early voltage. A transistor with a high Early voltage has a very flat common-emitter output characteristic, and hence low output conductance. For the device shown in Fig. 5.6, the Early voltage increases from 18 V in the Si BJT to 53 V in the SiGe HBT, a 3X improvement.

SiGe HBTs have been successfully integrated with conventional high-performance Si CMOS to realize a SiGe BiCMOS technology.[15] The SiGe HBT and ac performance in this SiGe BiCMOS technology is

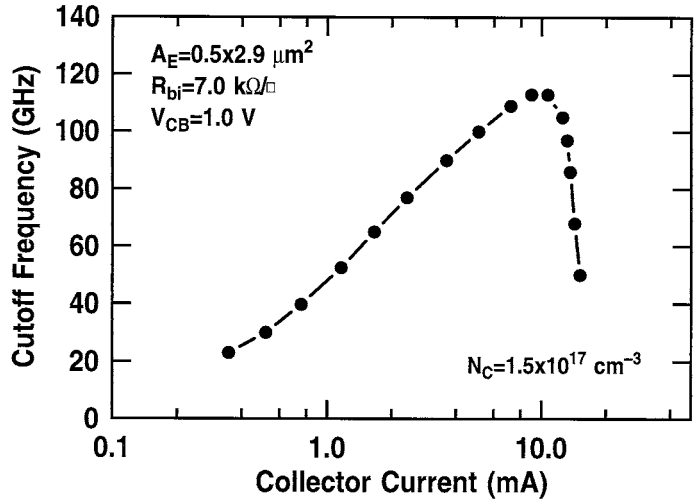

FIGURE 5.8 Cutoff frequency as a function of bias current for an aggressively designed UHV/CVD SiGe HBT.

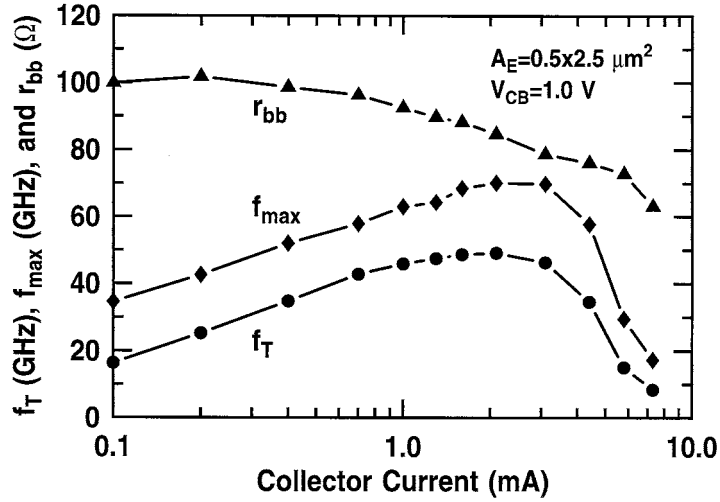

FIGURE 5.9 Cutoff frequency, maximum oscillation frequency, and small-signal base resistance for a small-geometry, state-of-the-art SiGe HBT.

shown in Fig. 5.9, and is not compromised by the addition of the CMOS devices. Table 5.1 shows the suite of resultant elements in this SiGe BiCMOS technology. Two SiGe HBTs are available, one with a reduced collector implant and hence higher BV_{CEO} (5.3 V vs. 3.3 V) that is suitable for RF power applications. Table 5.2 gives the typical SiGe HBT device parameters at 300K.

Bandgap-engineered SiGe HBTs have other attractive features that make them ideal candidates for certain circuit applications. For instance, Si BJT technology is well known to have superior low-frequency noise properties compared to compound semiconductor technologies. Low-frequency noise is often a major limitation for RF and microwave systems because it directly limits the spectral purity of the transmitted signal. Recent work suggests that SiGe HBTs have low-frequency properties as good as or better than Si BJTs, superior to that obtained in AlGaAs/GaAs HBTs and Si CMOS (Fig. 5.10).[29,30] The

TABLE 5.1 Elements in IBM's SiGe BiCMOS Technology

Element	Characteristics
Standard SiGe HBT	47 GHz f_T at BV_{CEO} = 3.3V
High-breakdown SiGe HBT	28 GHz f_T at BV_{CEO} = 5.3V
Si CMOS	0.36 mm L_{eff} for 2.5 V V_{DD}
Gated lateral pnp	1.0 GHz f_T
Polysilicon resistor	342 Ω/□
Ion-implanted resistor	1,600 Ω/□
Thin-oxide decoupling capacitor	1.52 fF/μm²
MIM precision capacitor	0.70 fF/μm²
Inductor (6-turn)	10 nH with Q = 10 at 1.0 GHz
Schottky barrier diode	213 mV at 100 μA
p-i-n diode	790 mV at 100 μA
Varactor diode	810 mV at 100 μA
ESD diode	1.2 kV

TABLE 5.2 Typical Parameters for a SiGe HBT with $A_E = 0.5 \times 2.5$ μm². All ac Parameters Were Measured at V_{CB} = 1.0V and f_{max} was Extracted Using MAG.

Parameter	Standard SiGe HBT	High-BVCEO SiGe HBT
Peak β	113	97
V_A (V)	61	132
βV_A (V)	6,893	12,804
Peak f_T (GHz)	48	28
rbb at peak f_T (Ω)	80	N/A
Peak f_{max} (GHz)	69	57
BV_{CEO} (V)	3.3	5.3
BV_{EBO} (V)	4.2	4.1
Peak $f_T \times BV_{CEO}$ (GHz V)	158	143

broadband (RF) noise in SiGe HBTs is competitive with GaAs MESFET technology and superior to Si BJTs. In addition, SiGe HBTs have recently been shown to be very robust with respect to ionizing radiation, an important feature for space-based electronic systems.[31,32] Finally, cooling enhances all of the advantages of a SiGe HBT. In striking contrast to a Si BJT, which strongly degrades with cooling, the current gain, Early voltage, cutoff frequency, and maximum oscillation frequency (f_{max}) all improve significantly as the temperature drops.[33–35] This means that the SiGe HBT is well-suited for operation in the cryogenic environment (e.g., 77K), historically the exclusive domain of Si CMOS and III–V compound semiconductor technologies. Cryogenic electronics is in growing use in both military and commercial applications such as space-based satellites, high-sensitivity instrumentation, high-T_C superconductors, and future cryogenic computers.

5.4 The SiGe Heterojunction Field Effect Transistor (HFET)

The effective carrier mobility (μ_{eff}) is the fundamental parameter that limits the speed of field effect transistors (FETs), and SiGe bandgap engineering can be used in two principal ways to significantly improve the mobility and, hence, the speed of the device. First, the valence band offset associated with SiGe can be used to spatially confine carriers such that they are effectively removed from the Si/SiO_2 interface. The surface roughness scattering associated with the Si/SiO_2 interface degrades the mobility in a conventional MOSFET, particularly at high gate bias. If, in addition, the holes are confined to a region of the semiconductor that is intentionally left undoped, the result is a reduction in ionized impurity scattering and, hence, further increase in mobility.[2] This is exactly the approach taken in bandgap-engineered compound semiconductor FETs known as HEMTs (high electron mobility transistor). Second, the strain associated with SiGe epitaxy is known to lift the degeneracy of the light and heavy hole valence bands, resulting in a reduced hole effective mass and hence higher hole mobility.[3]

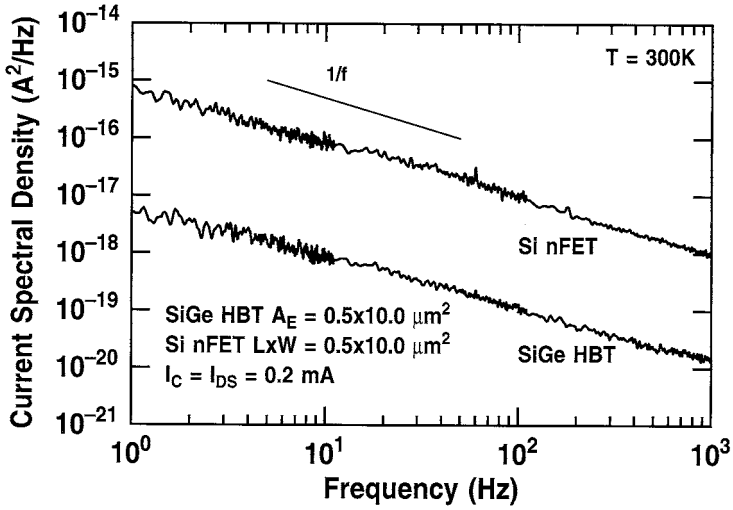

FIGURE 5.10 Low-frequency noise spectra of SiGe HBT and a conventional Si nFET of identical geometry.

Because it is the hole mobility that is improved in strained SiGe, and the valence band offset can be used to confine these holes, the p-channel FET (pFET) is the logical device to pursue with SiGe bandgap engineering. A SiGe pFET with an improved hole mobility is particularly desirable in CMOS technology because the conventional Si pFET has a mobility that is about a factor of two lower than the Si nFET mobility. This mobility asymmetry between pFET and nFET in conventional Si CMOS technology requires a doubling of the pFET gate width, and thus a serious real estate penalty, to obtain proper switching characteristics in the CMOS logic gate. If SiGe can be used to equalize the pFET and nFET mobilities, then substantial area advantages can be realized in CMOS logic gates, and tighter packing densities achieved.

It is interesting to note that despite the fact that the SiGe HBT is the most commercially mature SiGe device, the first SiGe FET (actually a HEMT structure) predates the first SiGe HBT by one year, having been first reported in 1986.[36,37] A number of different SiGe pFET designs have been successfully demonstrated[38–43] with improvements in mobility as high at 50% at 0.25-μm gate lengths.[40] Figure 5.11 shows perhaps the simplest configuration of a SiGe pFET, which consists of a SiGe hole channel buried underneath a thin Si cap layer and the conventional thermal oxide.[44,45] In this case, the entire device is fabricated on a silicon-on-sapphire substrate to improve microwave performance. Significant mobility advantage can be realized over a comparable Si pFET (Fig. 5.12).

Because a complementary circuit configuration offers many advantages from a power dissipation standpoint, the realization of n-channel SiGe devices is highly desirable. Strictly speaking, this is not possible in strained SiGe on Si substrates because only a valence band offset is available and the electrons cannot be confined as in the SiGe pFET. Fortunately, however, recent work[46–51] using strained Si on relaxed SiGe layers has proven particularly promising because it provides a conduction band offset and enhanced electron mobility compared to Si.

The fabrication of strained Si nFETs on relaxed SiGe layers is, in general, more complicated than fabricating strained SiGe pFETs in Si substrates. For the strained Si nFET, a graded SiGe buffer layer is used to reduce and confine the dislocations associated with the growth of relaxed SiGe layers.[46] Using this technique, both strained Si nFETs and strained SiGe pFETs can be jointly fabricated to form a Si-based heterojunction CMOS (HCMOS) technology. Figure 5.13 shows a schematic cross-section of such a Si/SiGe HCMOS technology,[51] and represents the state-of-the-art in the field of Si/SiGe HCMOS. Observe that the conducting channels of both transistors are grown in a single step (using UHV/CVD in this case), and electron and hole confinement occurs in the strained SiGe and strained Si for the pFET and nFET, respectively. In this technology, both the pFET and nFET are realized in a planar structure,

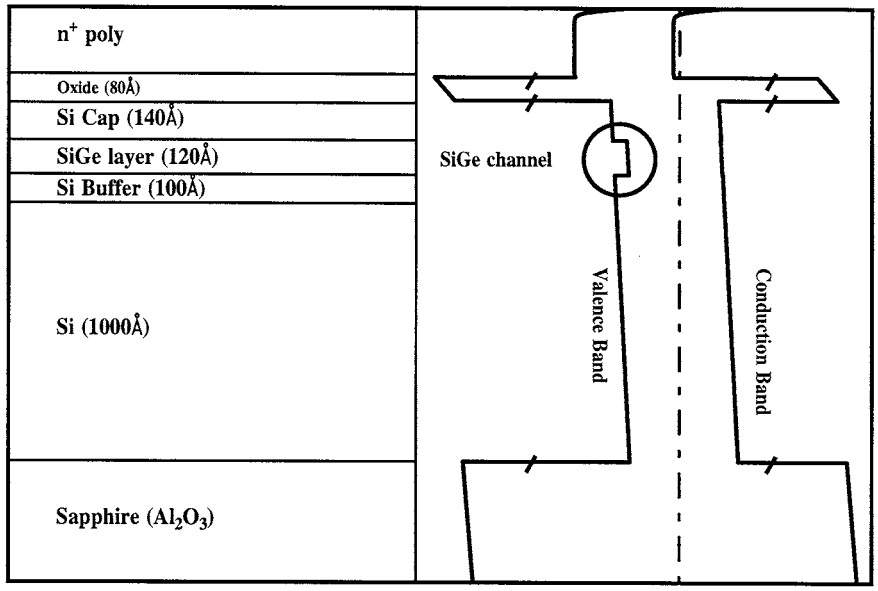

FIGURE 5.11 Schematic cross-section of SiGe pFET on silicon-on-sapphire (SOS).

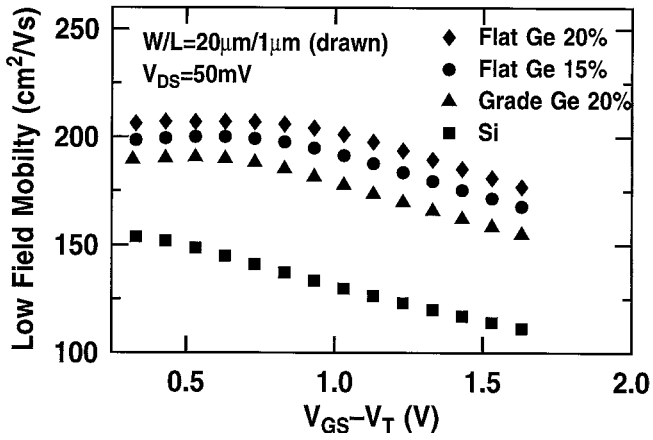

FIGURE 5.12 Effective mobility as a function of gate drive comparing SiGe pFETs on SOS and conventional Si pFETs on SOS.

and are expected to show substantial improvements in performance over conventional Si CMOS. With layer and doping profile optimization, the parasitic surface channel (which degrades mobility) can be minimized. Simulation results of anticipated circuit performance indicate that substantial improvements (4 to 6X) in power-delay product over conventional Si CMOS can be obtained using Si/SiGe HCMOS technology at 0.2-μm effective gate length.

5.5 Future Directions

The future developments in SiGe electronic devices will likely follow two paths. The first path will be toward increased integration and scaling of existing SiGe technologies. There is already a clear trend toward integrating SiGe HBTs with conventional Si CMOS to form a SiGe BiCMOS technology.[14,15]

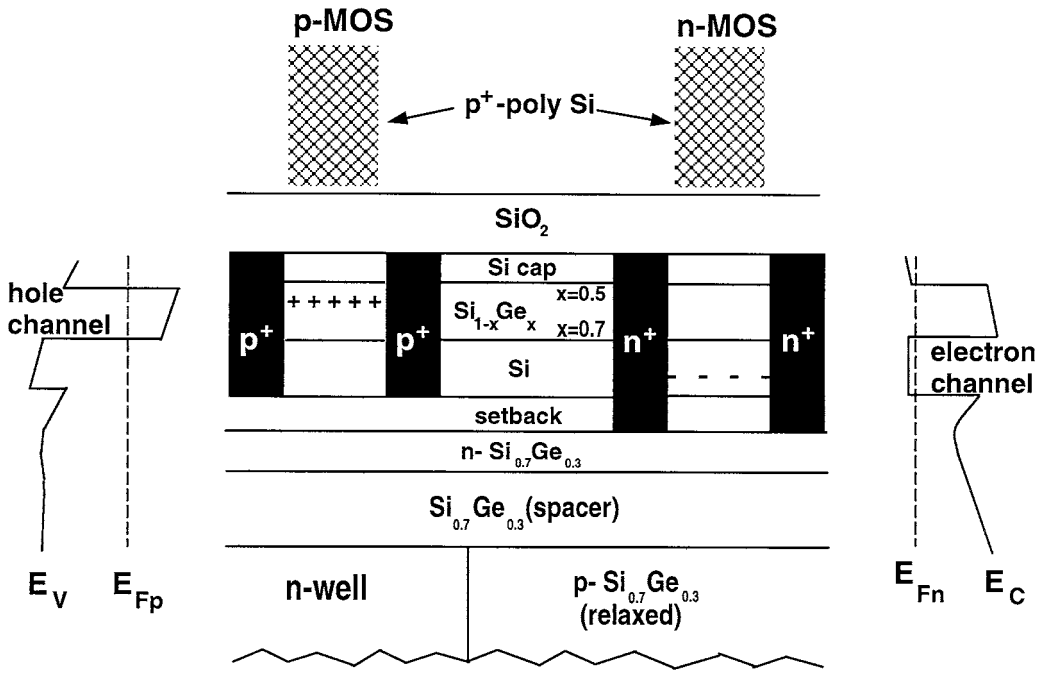

FIGURE 5.13 Schematic device cross-section of SiGe CMOS technology, consisting of a strained SiGe pFET and a strained Si nFET (after Ref. 51).

Eventually, one would like to merge SiGe HBTs, Si CMOS, Si/SiGe HCMOS, and SiGe photonic devices on the same chip to provide a complete solution for future RF and microwave electronic and optoelectronic transceivers containing precision analog functions (mixers, LNAs, VCOs, DACs, ADCs, power amps, etc.), digital signal processing and computing functions (traditionally done in CMOS), as well as integrated photonic detectors and possibly transmitters.

The second path in SiGe electronic devices will be to pursue new Si-based material systems that offer the promise of lattice-matching to Si substrates. The intent here is to remove the stability constraints that SiGe device designers currently face, and that limit the useful range of Ge content in practical SiGe devices. The most promising of these new materials is silicon-germanium-carbon (SiGeC). The lattice constant of C is larger than Si and thus can be used reduce the strain in a SiGe film. Theoretically, it would only take 1% C to lattice match a 9% Ge film to a Si substrate, 2% C for 18% Ge, etc. While research is just beginning on the growth of device-quality SiGeC films, and the properties of the resultant films has not been firmly established, the SiGeC material system clearly offers exciting possibilities for the future evolution of SiGe technology. In addition, it has recently been shown that low concentrations of C can serve to dramatically reduce boron diffusion in conventional SiGe HBTs.[52] This has the potential to allow much more aggressive SiGe HBT profiles to be realized with stable SiGe strained layers. More research is required to quantify the impact of C on the device electrical characteristics, although initial studies appear promising.

Acknowledgments

The author would like to thank D.L. Harame, B.S. Meyerson, S. Subbanna, D. Ahlgren, M. Gilbert, K. Ismail, and the members of the SiGe team at IBM Corporation, as well as the past and present members of the Auburn University SiGe research group (A. Joseph, D. Richey, L. Vempati, S. Mathew, J. Roldán, G. Bradford, G. Niu, B. Ansley, K. Shivaram, G. Banerjee, S. Zhang, S. Salmon, and

U. Gogineni) for their contributions to this work. The support of the Alabama Microelectronics Science and Technology Center, ONR, DARPA, NRL, U.S. Army SSDC, Navy NCCOSC, Navy Crane, and MRC are gratefully acknowledged.

6.1 Introduction

Silicon carbide (SiC)-based semiconductor electronic devices and circuits are presently being developed for use in high-temperature, high-power, and/or high-radiation conditions under which conventional semiconductors cannot adequately perform. Silicon carbide's ability to function under such extreme conditions is expected to enable significant improvements to a far-ranging variety of applications and systems. These range from greatly improved high-voltage switching[1–4] for energy savings in public electric power distribution and electric motor drives, to more powerful microwave electronics for radar and communications,[5–7] to sensors and controls for cleaner-burning more fuel-efficient jet aircraft and automobile engines. In the particular area of power devices, theoretical appraisals have indicated that SiC power MOSFETs and diode rectifiers would operate over higher voltage and temperature ranges, have superior switching characteristics, and yet have die sizes nearly 20 times smaller than correspondingly rated silicon-based devices.[8] However, these tremendous theoretical advantages have yet to be realized in experimental SiC devices, primarily due to the fact that SiC's relatively immature crystal growth and device fabrication technologies are not yet sufficiently developed to the degree required for reliable incorporation into most electronic systems.[9]

This chapter briefly surveys the SiC semiconductor electronics technology. In particular, the differences (both good and bad) between SiC electronics technology and well-known silicon VLSI technology are highlighted. Projected performance benefits of SiC electronics are highlighted for several large-scale applications. Key crystal growth and device-fabrication issues that presently limit the performance and capability of high-temperature and/or high-power SiC electronics are identified.

6.2 Fundamental SiC Material Properties

SiC Crystallography: Important Polytypes and Definitions

Silicon carbide occurs in many different crystal structures, called polytypes. A comprehensive introduction to SiC crystallography and polytypism can be found in Ref. 10. Despite the fact that all SiC polytypes chemically consist of 50% carbon atoms covalently bonded with 50% silicon atoms, each SiC polytype has its own distinct set of electrical semiconductor properties. While there are over 100 known polytypes of SiC, only a few are commonly grown in a reproducible form acceptable for use as an electronic semiconductor. The most common polytypes of SiC presently being developed for electronics are 3C-SiC, 4H-SiC, and 6H-SiC. 3C-SiC, also referred to as β-SiC, is the only form of SiC with a cubic crystal lattice structure. The non-cubic polytypes of SiC are sometimes ambiguously referred to as α-SiC. 4H-SiC and 6H-SiC are only two of many possible SiC polytypes with hexagonal crystal structure. Similarly, 15R-SiC is the most common of many possible SiC polytypes with a rhombohedral crystal structure.

Because some important electrical device properties are non-isotropic with respect to crystal orientation, lattice site, and surface polarity, some further understanding of SiC crystal structure and terminology is necessary. As discussed much more thoroughly in Ref. 10, different polytypes of SiC are actually composed of different stacking sequences of Si-C bilayers (also called Si-C double layers), where each single Si-C bilayer can simplistically be viewed as a planar sheet of silicon atoms coupled with a planar sheet of carbon atoms. The plane formed by a bilayer sheet of Si and C atoms is known as the basal plane, while the crystallographic *c*-axis direction, also known as the stacking direction or the [0001] direction, is defined normal to Si-C bilayer plane. Figure 6.1 schematically depicts the stacking sequence of the 6H-SiC polytype, which requires six Si-C bilayers to define the unit cell repeat distance along the *c*-axis [0001] direction. The [1100] direction depicted in Fig. 6.1 is often referred to as the a-axis direction. The silicon atoms labeled "h" or "k" in Figure 1 denote Si-C double layers that reside in "quasi-hexagonal" or "quasi-cubic" environments with respect to their immediately neighboring above and below bilayers. SiC is a polar semiconductor across the *c*-axis, in that one surface normal to the *c*-axis is terminated with silicon atoms, while the opposite normal *c*-axis surface is terminated with carbon atoms. As shown in Fig. 6.1, these surfaces are typically referred to as "silicon face" and "carbon face" surfaces, respectively.

SiC Semiconductor Electrical Properties

Owing to the differing arrangements of Si and C atoms within the SiC crystal lattice, each SiC polytype exhibits unique fundamental electrical and optical properties. Some of the more important semiconductor electrical properties of the 3C, 4H, and 6H silicon carbide polytypes are given in Table 6.1. Much more detailed electrical properties can be found in Refs. 11 to 13 and references therein. Even within a given polytype, some important electrical properties are non-isotropic, in that they are a strong functions of crystallographic direction of current flow and applied electric field (e.g., electron mobility for 6H-SiC). Dopants in SiC can incorporate into energetically inequivalent quasi-hexagonal (*h*) C-sites or Si-sites, or quasi-cubic (*k*) C-sites or Si-sites (only Si-sites are *h* or *k* labeled in Fig. 6.1). While all dopant ionization energies associated with various dopant incorporation sites should normally be considered for utmost accuracy, Table 6.1 lists only the shallowest ionization energies of each impurity.

For comparison, Table 6.1 also includes comparable properties of silicon and GaAs. Because silicon is the semiconductor employed in most commercial solid-state electronics, it is the yardstick against which

other semiconductor materials must be evaluated. To varying degrees, the major SiC polytypes exhibit advantages and disadvantages in basic material properties compared to silicon. The most beneficial inherent material superiorities of SiC over silicon listed in Table 6.1 are its exceptionally high breakdown electric field, wide bandgap energy, high thermal conductivity, and high carrier saturation velocity. The electrical device performance benefits that each of these properties enable are discussed in the next section, as are system-level benefits enabled by improved SiC devices.

6.3 Applications and Benefits of SiC Electronics

Two of the most beneficial advantages that SiC-based electronics offer are in the areas of high-temperature device operation and high-power device operation. The specific SiC device physics that enables high-temperature and high-power capabilities will be examined first, followed by several examples of revolutionary system-level performance improvements these enhanced capabilities enable.

High-Temperature Device Operation

The wide bandgap energy and low intrinsic carrier concentration of SiC allow SiC to maintain semiconductor behavior at much higher temperatures than silicon, which in turn permits SiC semiconductor device functionality at much higher temperatures than silicon. As discussed in basic semiconductor physics textbooks,[14,15] semiconductor electronic devices function in the temperature range where intrinsic carriers are negligible so that conductivity is controlled by intentionally introduced dopant impurities. Furthermore, the intrinsic carrier concentration n_i is a fundamental prefactor to well-known equations governing undesired junction reverse-bias leakage currents.[15–18] As temperature increases, intrinsic carriers increase exponentially so that undesired leakage currents grow unacceptably large, and eventually at still higher temperatures, the semiconductor device operation is overcome by uncontrolled conductivity as intrinsic carriers exceed intentional device dopings. Depending on specific device design, the intrinsic carrier concentration of silicon generally confines silicon device operation to junction temperatures less than 300°C. The much smaller intrinsic carrier concentration of SiC theoretically permits device operation at junction temperatures exceeding 800°C; 600°C SiC device operation has been experimentally demonstrated on a variety of SiC devices (Section 6.6).

High-Power Device Operation

The high breakdown field and high thermal conductivity of SiC, coupled with high operational junction temperatures, theoretically permit extremely high-power densities and efficiencies to be realized in SiC devices. Figures 6.2 and 6.3 demonstrate the theoretical advantage of SiC's high breakdown field compared to silicon in shrinking the drift-region and associated parasitic on-state resistance of a 3000 V rated unipolar power MOSFET device.[8] The high breakdown field of SiC relative to silicon enables the blocking voltage region to be roughly 10X thinner and 10X heavier-doped, permitting a roughly 100-fold decrease in the dominant blocking region (N-Drift Region) resistance R_D of Fig. 6.2 for the SiC device relative to an identically rated 3000-V silicon power MOSFET.

Significant energy losses in many silicon high-power system circuits, particularly hard-switching motor drive and power conversion circuits, arise from semiconductor switching energy loss.[1,19] While the physics of semiconductor device switching loss are discussed in detail elsewhere,[15–17] switching energy loss is often a function of the turn-off time of the semiconductor switching device, generally defined as the time lapse between when a turn-off bias is applied and the time that the device actually cuts off most current flow. The faster a device turns off, the smaller its energy loss in a switched power conversion circuit. For device-topology reasons discussed in Refs. 8, 20–22, SiC's high breakdown field and wide energy bandgap enable much faster power switching than is possible in comparably volt-amp rated silicon power-switching devices. Therefore, SiC-based power converters could operate at higher switching frequencies with much greater efficiency (i.e., less switching energy loss). Higher switching frequency in

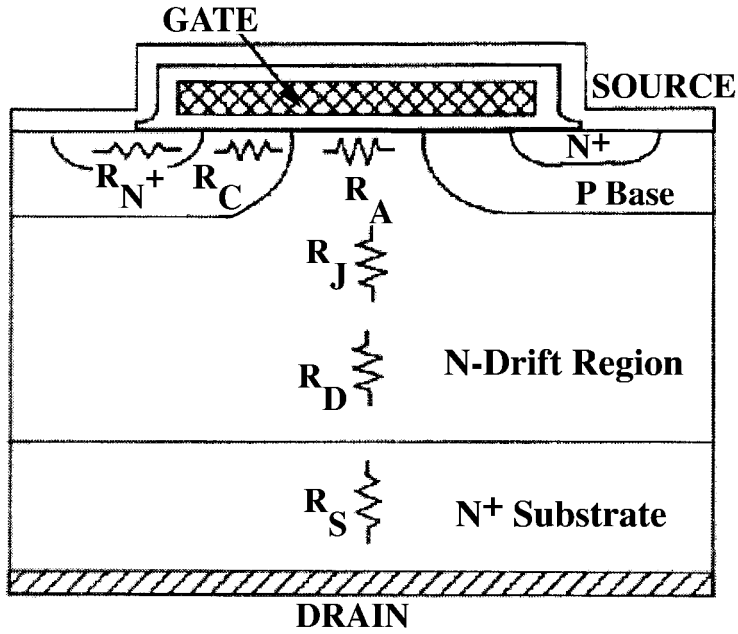

FIGURE 6.2 Cross-section of power MOSFET structure showing various internal resistances. The resistance R_D of the N-Drift Region is the dominant resistance in high-voltage power devices. (From Ref. 8. With permission.)

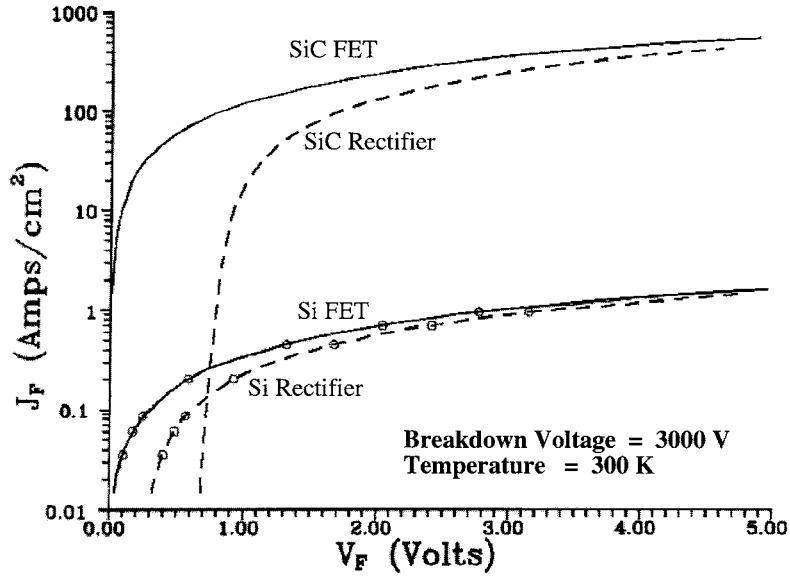

FIGURE 6.3 Simulated forward conduction characteristics of ideal Si and SiC 3000 V power MOSFETs and Schottky rectifiers. The high breakdown field of SiC relative to silicon (Table 6.1) enables the blocking voltage region (N-Drift Region in Fig. 6.2) to be roughly 10X thinner and 10X heavier-doped, permitting a roughly 100-fold increase in on-state current density for the 3000-V SiC devices relative to 3000-V silicon devices. (From Ref. 8. With permission.)

power converters is highly desirable because it permits use of proportionally smaller capacitors, inductors, and transformers, which in turn can greatly reduce overall system size and weight.

While SiC's smaller on-resistance and faster switching help minimize energy loss and heat generation, SiC's higher thermal conductivity enables more efficient removal of waste heat energy from the active device. Because heat energy radiation efficiency increases greatly with increasing temperature difference between the device and the cooling ambient, SiC's ability to operate at high junction temperatures permits much more efficient cooling to take place, so that heatsinks and other device-cooling hardware (i.e., fan cooling, liquid cooling, air conditioning, etc.) typically needed to keep high-power devices from overheating can be made much smaller or even eliminated.

While the preceding discussion focused on high-power switching for power conversion, many of the same arguments can be applied to devices used to generate and amplify RF signals used in radar and communications applications. In particular, the high breakdown voltage and high thermal conductivity, coupled with high carrier saturation velocity, allow SiC microwave devices to handle much higher power densities than their silicon or GaAs RF counterparts, despite SiC's disadvantage in low-field carrier mobility (Section 6.6).[6,7,23]

System Benefits of High-Power, High-Temperature SiC Devices

Uncooled operation of high-temperature and/or high-power SiC electronics would enable revolutionary improvements to aerospace systems. Replacement of hydraulic controls and auxiliary power units with distributed "smart" electromechanical controls capable of harsh-ambient operation will enable substantial jet-aircraft weight savings, reduced maintenance, reduced pollution, higher fuel efficiency, and increased operational reliability.[24–26] SiC high-power solid-state switches will also enable large efficiency gains in electric power management and control. Performance gains from SiC electronics could enable the public power grid to provide increased consumer electricity demand without building additional generation plants, and improve power quality and operational reliability through "smart" power management. More efficient electric motor drives will benefit industrial production systems as well as transportation systems such as diesel-electric railroad locomotives, electric mass-transit systems, nuclear-powered ships, and electric automobiles and buses.

From the above discussions, it should be apparent that SiC high-power and/or high-temperature solid-state electronics promise tremendous advantages that could significantly impact transportation systems and power usage on a global scale. By improving the way in which electricity is distributed and used, improving electric vehicles so that they become more viable replacements for internal combustion-engine vehicles, and improving the fuel efficiency and reducing pollution of remaining fuel-burning engines and generation plants, SiC electronics promises the potential to better the daily lives of all citizens of planet Earth.

6.4 SiC Semicondcutor Crystal Growth

As of this writing, much of the outstanding theoretical promise of SiC electronics highlighted in the previous section has largely gone unrealized. A brief historical examination quickly shows that serious shortcomings in SiC semiconductor material manufacturability and quality have greatly hindered the development of SiC semiconductor electronics. From a simple-minded point of view, SiC electronics development has very much followed the general rule of thumb that a solid-state electronic device can only be as good as the semiconductor material from which it is made.

Historical Lack of SiC Wafers

Most of silicon carbide's superior intrinsic electrical properties have been known for decades. At the genesis of the semiconductor electronics era, SiC was considered an early transistor material candidate, along with germanium and silicon. However, reproducible wafers of reasonable consistency, size, quality,

and availability are a prerequisite for commercial mass-production of semiconductor electronics. Many semiconductor materials can be melted and reproducibly recrystallized into large, single crystals with the aid of a seed crystal, such as in the Czochralski method employed in the manufacture of almost all silicon wafers, enabling reasonably large wafers to be mass-produced. However, because SiC sublimes instead of melting at reasonably attainable pressures, SiC cannot be grown by conventional melt-growth techniques. This prevented the realization of SiC crystals suitable for mass-production until the late 1980s. Prior to 1980, experimental SiC electronic devices were confined to small (typically ~1 cm^2), irregularly shaped SiC crystal platelets (Fig. 6.4, right side) grown as a by-product of the Acheson process for manufacturing industrial abrasives (e.g., sandpaper)[27] or by the Lely process.[28] In the Lely process, SiC sublimed from polycrystalline SiC powder at temperatures near 2500°C are randomly condensed on the walls of a cavity forming small hexagonally shaped platelets. While these small, nonreproducible crystals permitted some basic SiC electronics research, they were clearly not suitable for semiconductor mass-production. As such, silicon became the dominant semiconductor fueling the solid-state technology revolution, while interest in SiC-based microelectronics was limited.

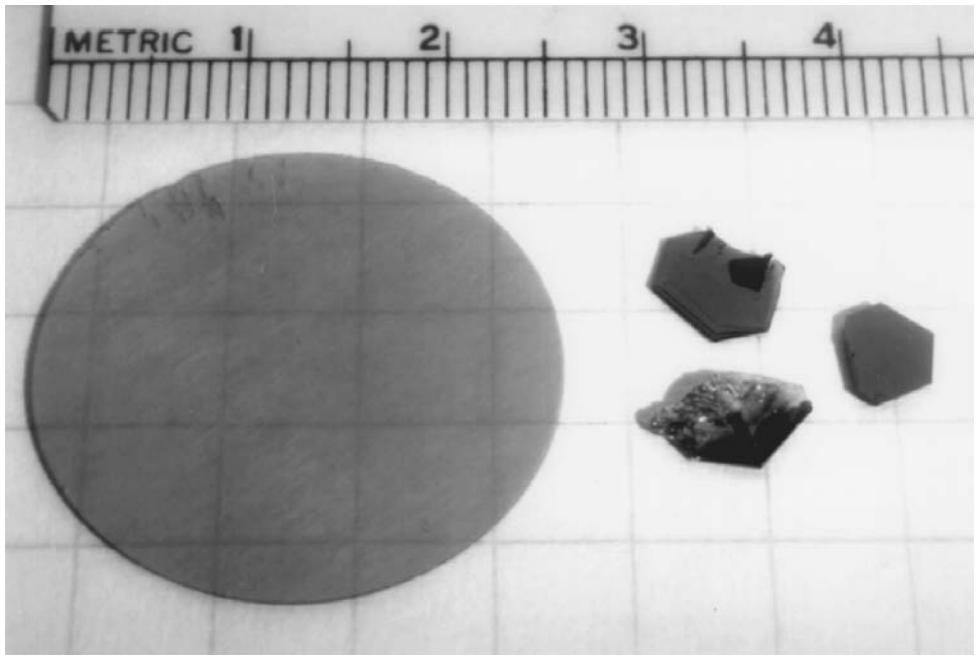

FIGURE 6.4 Mass-produced 2.5-cm diameter 6H-SiC wafer manufactured circa 1990 via seeded sublimation by Cree Research (left), and 6H-SiC Lely and Acheson platelet crystals (right) representative of single-crystal SiC substrates available prior to 1989. 5.1-cm diameter seeded sublimation SiC wafers entered the commercial market in 1997.

Growth of 3C-SiC on Large-Area (Silicon) Substrates

Despite the absence of SiC substrates, the potential benefits of SiC hostile-environment electronics nevertheless drove modest research efforts aimed at obtaining SiC in a manufacturable wafer form. Toward this end, the heteroepitaxial growth of single-crystal SiC layers on top of large-area silicon substrates was first carried out in 1983,[29] and subsequently followed by a great many others over the years using a variety of growth techniques. Primarily due to large differences in lattice constant (20% difference between SiC and Si) and thermal expansion coefficient (8% difference), heteroepitaxy of SiC using silicon as a substrate always results in growth of 3C-SiC with a very high density of crystallographic

structural defects such as stacking faults, microtwins, and inversion domain boundaries.[30,31] Furthermore, the as-grown surface morphology of 3C-SiC grown on silicon is microscopically textured, making submicron lithography somewhat problematic. Other large-area wafer materials, such as sapphire, silicon-on-insulator, TiC, etc.), have been employed as substrates for heteroepitaxial growth of SiC epilayers, but the resulting films have been of comparably poor quality with high crystallographic defect densities.

While some limited semiconductor electronic devices and circuits have been implemented in 3C-SiC grown on silicon,[32,33] the performance of these electronics can be summarized as severely limited by the high density of crystallographic defects to the degree that almost none of the operational benefits discussed in Section 6.3 have been viably realized. Among other problems, the crystal defects "leak" parasitic current across reverse-biased device junctions where current flow is not desired. Because excessive crystal defects lead to electrical device shortcomings, there are as yet no commercial electronics manufactured in 3C-SiC grown on large-area substrates.

Despite the lack of major technical progress, there is strong economic motivation to continue to pursue heteroepitaxial growth of SiC on large-area substrates, as this would provide cheap wafers for SiC electronics that would be immediately compatible with silicon integrated circuit manufacturing equipment. If ongoing work ever solves the extremely challenging crystallographic defect problems associated with the heteroepitaxial growth of SiC, it would likely become the material of choice for mass-production of SiC-based electronics. Given the present electrical deficiencies of heteroepitaxial SiC, 3C-SiC grown on silicon is more likely to be commercialized as a mechanical material in microelectromechanical systems (MEMS) applications (Section 6.6) instead of being used purely as a semiconductor in traditional solid-state electronics.

Sublimation Growth of SiC Wafers

In the late 1970s, Tairov and Tzvetkov established the basic principles of a modified seeded sublimation growth process for growth of 6H-SiC.[34,35] This process, also referred to as the modified Lely process, was a breakthrough for SiC in that it offered the first possibility of reproducibly growing acceptably large single crystals of SiC that could be cut and polished into mass-produced SiC wafers. The basic growth process is based on heating polycrystalline SiC source material to ~2400°C under conditions where it sublimes into the vapor phase and subsequently condenses onto a cooler SiC seed crystal. This produces a somewhat cylindrical boule of single-crystal SiC that grows taller at a rate of a few millimeters per hour. To date, the preferred orientation of the growth in the sublimation process is such that vertical growth of a taller cylindrical boule proceeds along the [0001] crystallographic *c*-axis direction (i.e., vertical direction in Fig. 6.1). Circular "*c*-axis" wafers with surfaces that lie normal (perpendicular) to the *c*-axis can be sawed from the roughly cylindrical boule. While other growth orientations (such as growth along the a-axis) continue to be investigated, the electronic quality of this material has thus far proven inferior to *c*-axis-grown wafers.[36,37]

Commercially Available SiC Wafers

After years of further development of the sublimation growth process, Cree Research became the first company to sell 2.5-cm diameter semiconductor wafers of 6H-SiC (Fig. 6.4, left side) in 1989.[38] Only with the development of the modified Lely seeded sublimation growth technique have acceptably large and reproducible single-crystal SiC wafers of usable electrical quality become available. Correspondingly, the vast majority of silicon carbide semiconductor electronics development has taken place since 1990. Other companies have subsequently entered the SiC wafer market, and sublimation grown wafers of the 4H-SiC polytype have also been commercialized, as summarized in Table 6.2.

Commercially available 4H- and 6H-SiC wafer specifications are given in Table 6.2. N-type, p-type, and semi-insulating SiC wafers are commercially available at different prices. Wafer size, cost, and quality are all very critical to the manufacturability and process yield of mass-produced semiconductor microelectronics. Compared to commonplace silicon and GaAs wafer standards, present-day 4H- and 6H-SiC wafers are small, expensive, and generally of inferior quality. In addition to high densities of crystalline

defects such as micropipes and closed-core screw dislocations discussed in the next subsection, commercial SiC wafers also exhibit significantly rougher surfaces, and larger warpage and bow than is typical for silicon and GaAs wafers.[39] This disparity is not surprising considering that silicon and GaAs wafers have undergone several decades of commercial process refinement, and that SiC is an extraordinarily hard material, making it very difficult to properly saw and polish. Nevertheless, ongoing wafer sawing and polishing process improvements should eventually alleviate wafer surface quality deficiencies.

SiC Wafer Crystal Defects

While the specific electrical effects of SiC crystal defects are discussed later in Section 6.6, the micropipe defect (Table 6.2) is regarded as the most damaging defect that is limiting upscaling of SiC electronics capabilities.[9,40] A micropipe is a screw dislocation with a hollow core and a larger Burgers vector, which becomes a tubular void (with a hollow diameter on the order of micrometers) in the SiC wafer that extends roughly parallel to the crystallographic *c*-axis normal to the polished *c*-axis wafer surface.[41–44] Sublimation-grown 4H- and 6H-SiC wafers also contain high densities of closed-core screw dislocation defects that, like micropipes, cause a considerable amount of localized strain and SiC lattice deformation.[42,43,45,46] Similar to horizontal branches on a tree with its trunk running up the *c*-axis, dislocation loops emanate out along the basal plane from screw dislocations.[41,47] As shown in Table 6.2, micropipe densities in commercial SiC wafers have shown steady improvement over a 5-year period, leading to wafers with less than 30 micropipes per square centimeter of wafer area. However, as discussed in Section 6.6, SiC wafer improvement trends will have to accelerate if some of SiC's most beneficial high-power applications are going to reach timely commercial fruition.

SiC Epilayers

Most SiC electronic devices are not fabricated directly in sublimation-grown wafers, but are instead fabricated in much higher quality epitaxial SiC layers that are grown on top of the initial sublimation-grown wafer. Well-grown SiC epilayers have superior electrical properties and are more controllable and

reproducible than bulk sublimation-grown SiC wafer material. Therefore, the controlled growth of high-quality epilayers is highly important in the realization of useful SiC electronics.

SiC Epitaxial Growth Processes

An interesting variety of SiC epitaxial growth methodologies — ranging from liquid-phase epitaxy, molecular beam epitaxy, and chemical vapor deposition — has been investigated.[11,12,32] The chemical vapor deposition (CVD) growth technique is generally accepted as the most promising method for attaining epilayer reproducibility, quality, and throughputs required for mass-production. In simplest terms, variations of SiC CVD are carried out by heating SiC substrates in a chamber with flowing silicon and carbon containing gases that decompose and deposit Si and C onto the wafer, allowing an epilayer to grow in a well-ordered single-crystal fashion under well-controlled conditions. Conventional SiC CVD epitaxial growth processes are carried out at substrate growth temperatures between 1400 and 1600°C at pressures from 0.1 to 1 atm, resulting in growth rates on the order of micrometers per hour.[39,48–50] Higher-temperature (up to 2000°C) SiC CVD growth processes are also being pioneered to obtain higher SiC epilayer growth rates — on the order of hundreds of micrometers per hour.[51]

SiC Homoepitaxial Growth

Homoepitaxial growth, whereby the polytype of the SiC epilayer matches the polytype of the SiC substrate, is accomplished by step-controlled epitaxy.[39,49,52] Step-controlled epitaxy is based on growing epilayers on an SiC wafer polished at an angle (called the "tilt-angle" or "off-axis angle") of typically 3° to 8° off the (0001) basal plane, resulting in a surface with atomic steps and flat terraces between steps, as schematically depicted in Fig. 6.5. When growth conditions are properly controlled and there is a sufficiently short distance between steps, Si and C atoms impinging onto the growth surface find their way to steps where they bond and incorporate into the crystal. Thus, ordered lateral "step flow" growth takes place, which enables the polytypic stacking sequence of the substrate to be exactly mirrored in the growing epilayer. When growth conditions are not properly controlled or when steps are too far apart (as can occur with SiC substrate surfaces that are polished to within less than 1° of the basal plane), growth adatoms can nucleate and bond in the middle of terraces instead of at the steps; this leads to heteroepitaxial growth of poor-quality 3C-SiC.[39,49] To help prevent spurious nucleation of 3C-SiC "triangular inclusions" during epitaxial growth, most commercial 4H- and 6H-SiC substrates are polished to tilt angles of 8° and 3.5° off the (0001) basal plane, respectively.

It is important to note that most present-day, as-grown SiC epilayers contain varying densities of undesirable surface morphological features that could affect SiC device processing and performance.[39,48] In addition to "triangular inclusions," these include "growth pits" as well as large macrosteps formed by

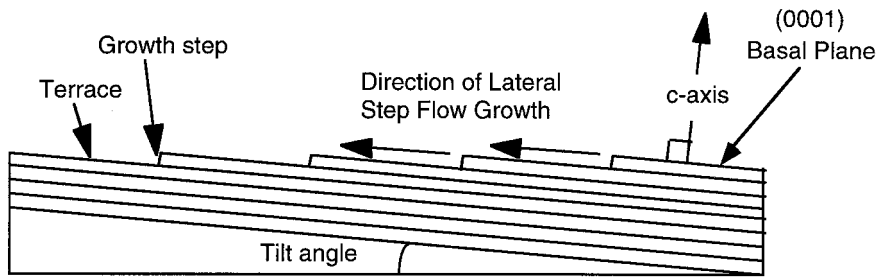

FIGURE 6.5 Cross-sectional schematic representation of "off-axis" polished SiC surface used for homoepitaxial growth. When growth conditions are properly controlled and there is a sufficiently short distance between steps, Si and C atoms impinging onto the growth surface find their way to steps where they bond and incorporate into the crystal. Thus, ordered lateral "step-flow" growth takes place, which enables the polytypic stacking sequence of the substrate to be exactly mirrored in the growing epilayer. (Modified from Ref. 10. With permission.)

coalescence of multiple SiC growth steps (i.e., "step bunching") during epitaxy. Pre-growth wafer polishing as well as growth initiation procedures have been shown to strongly impact the formation of undesirable epitaxial growth features.[39,48] Further optimization of pre-growth treatments and epitaxial growth initiation processes are expected to reduce undesired morphological growth features.

SiC Epilayer Doping

In situ doping during CVD epitaxial growth is primarily accomplished through the introduction of nitrogen (usually N_2) for n-type and aluminum (usually trimethyl- or triethylaluminum) for p-type epilayers.[12] Some alternative dopants such as phosphorous, boron, and vanadium have also been investigated for n-type, p-type, and semi-insulating epilayers, respectively. While some variation in epilayer doping can be carried out strictly by varying the flow of dopant gasses, the site-competition doping methodology[53,54] has enabled a much broader range of SiC doping to be accomplished. In addition, site-competition epitaxy has also made moderate epilayer dopings more reliable and repeatable. The site-competition dopant-control technique is based on the fact that many dopants of SiC preferentially incorporate into either Si lattice sites or C lattice sites. As an example, nitrogen preferentially incorporates into lattice sites normally occupied by carbon atoms. By epitaxially growing SiC under carbon-rich conditions, most of the nitrogen present in the CVD system (whether it is a residual contaminant or intentionally introduced) can be excluded from incorporating into the growing SiC crystal. Conversely, by growing in a carbon-deficient environment, the incorporation of nitrogen can be enhanced to form very heavily doped epilayers for ohmic contacts. Aluminum, which is opposite to nitrogen, prefers the Si-site of SiC, and other dopants have also been controlled through site competition by properly varying the Si/C ratio during crystal growth. SiC epilayer dopings ranging from 9×10^{14} to 1×10^{19} cm^{-3} are commercially available, and researchers have reported obtaining dopings nearly a factor of 10 larger and smaller than this range for n-type and p-type dopings. Commercial epilayer thickness and doping tolerances are presently specified at 25% and 100%, respectively,[38] while doping uniformities of 7% and thickness uniformities of 4% over a 30-mm wafer have been reported in developmental research.[48]

SiC Epilayer Crystal Defects

Improvements in epilayer quality are needed as SiC electronics upscale toward production integrated circuits, as there are presently many observable defects present in state-of-the-art SiC homoepilayers. Non-ideal surface morphological features, such as "growth pits," 3C-SiC triangular inclusions ("triangle defects") introduced in Section 6.4, are generally more prevalent in 4H-SiC epilayers than 6H-SiC epilayers. Most of these features appear to be manifestations of non-optimal "step flow" during epilayer growth arising from substrate defects, non-ideal substrate surface finish, contamination, and/or unoptimized epitaxial growth conditions. While by no means trivial, it is anticipated that SiC epilayer surface morphology will greatly improve as refined substrate preparation and epilayer growth processes are developed.

Many impurities and crystallographic defects found in sublimation-grown SiC wafers do not propagate into SiC homoepitaxial layers. For example, basal-plane dislocation loops emanating from micropipes and screw dislocations in sublimation-grown SiC wafers (Section 6.4) are not generally observed in SiC epilayers.[47] Unfortunately, however, screw dislocations (both micropipes and closed-core screw dislocations) present in commercial *c*-axis wafers do replicate themselves up the crystallographic *c*-axis into SiC homoepilayers grown on commercial wafers. Therefore, as discussed later in Section 6.6, devices fabricated in commercial epilayers are still subject to electrical performance and yield limitations imposed by commercial substrate screw-dislocation defect densities.

Alternative Growth Methods to Reduce SiC Epilayer Dislocations

As of this writing, there is no known practical method of realizing screw-dislocation-free 4H- or 6H-SiC homoepilayers on conventional sublimation-grown substrates. Some non-conventional epitaxial growth techniques have been attempted in an effort to prevent the propagation of micropipes into an epilayer.[55,56] While these approaches have scored modest success in closing and covering up micropipes, to date there

has been little, if any, improvement demonstrated in electrical devices fabricated in the resulting material. This is perhaps due to the fact that screw dislocations and associated harmful stresses may still be present in the epilayer, despite the fact that some open cores may have been converted to closed cores.

Because screw dislocations propagate up the *c*-axis, one could conceivably alleviate screw dislocations by growing epilayers on SiC wafers with their surface parallel to the *c*-axis using "a-axis" wafers. Unfortunately, efforts directed at realizing a-axis wafers and epilayers have to date been much less successful than *c*-axis wafers and epilayers, primarily because defects that form and propagate up the basal plane (the vertical wafer and epilayer growth direction in a-axis-oriented wafers) have proven more harmful and difficult to eliminate than screw dislocations in conventional *c*-axis wafers and epilayers.[36,37]

Selected-area epitaxial growth techniques have recently led to startling reductions in GaN epilayer defect densities.[57] While selective-area epitaxial growth of 3C-SiC has been demonstrated, the applicability of similar techniques to realizing superior electrical-quality SiC will be much more difficult due to the step-flow homoepitaxial growth mechanism of α-SiC as well as high growth temperatures (>1400°C), which are incompatible with conventional growth-masking materials like SiO_2.

6.5 SiC Device Fundamentals

In order to minimize the development and production costs of SiC electronics, it is essential that SiC device fabrication take advantage of the existing silicon and GaAs wafer processing infrastructure as much as possible. As will be discussed in this section, most of the steps necessary to fabricate SiC electronics starting from SiC wafers can be accomplished using somewhat modified commercial silicon electronics processes and fabrication tools.

Choice of Polytype for Devices

As discussed in Section 6.4, 4H-SiC and 6H-SiC are the far superior forms of semiconductor device quality SiC commercially available in mass-produced wafer form. Therefore, only 4H-SiC and 6H-SiC device processing methods will be explicitly considered in the rest of this section. It should be noted, however, that most of the processing methods discussed in this section are applicable to other polytypes of SiC, except for the case of 3C-SiC grown on silicon where all processing temperatures need to be kept well below the melting temperature of silicon (~1400°C).

It is generally accepted that 4H-SiC's substantially higher carrier mobility and shallower dopant ionization energies compared to 6H-SiC (Table 6.1) should make it the polytype of choice for most SiC electronic devices, provided that all other device processing, performance, and cost-related issues play out as being roughly equal between the two polytypes. Furthermore, the inherent mobility anisotropy that degrades conduction parallel to the crystallographic *c*-axis in 6H-SiC[58] will particularly favor 4H-SiC for vertical power device configurations (Section 6.6).

SiC Selective Doping: Ion Implantation

The fact that diffusion coefficients of most SiC dopants are negligibly small below ~1800°C is excellent for maintaining device junction stability, because dopants do not undesirably diffuse as the device is operated long-term at high-temperatures. Unfortunately, however, this characteristic also precludes the use of conventional dopant diffusion, a highly useful technique widely employed in silicon microelectronics manufacturing for patterned doping of SiC.

Laterally patterned doping of SiC is carried out by ion implantation. This somewhat restricts the depth to which most dopants can be conventionally implanted to less than 1 μm using conventional dopants and implantation equipment. Compared to silicon processes, SiC ion-implantation requires a much higher thermal budget to achieve acceptable dopant implant electrical activation. Summaries of ion-implantation processes for various dopants can be found in Refs. 11, 59, and 60. Most of these processes are based on carrying out implantation at elevated temperatures (~500 to 800°C) using a

patterned high-temperature masking material. The elevated temperature during implantation promotes some lattice self-healing during the implant, so that damage and segregation of displaced silicon and carbon atoms does not become excessive, especially in high-dose implants often employed for ohmic contact formation.[59,60] Co-implantation of carbon with p-type dopants has recently been investigated as a means to improve the electrical conductivity of implanted p-type contact layers.[61]

Following implantation, the patterning mask is stripped and a much higher temperature (~1200 to 1800°C) anneal is carried out to achieve maximum electrical activation of dopant donor or acceptor ions. The final annealing conditions are crucial for obtaining desired electrical properties from ion-implanted layers. At higher implant anneal temperatures, the SiC surface morphology can seriously degrade as damage-assisted sublimation etching of the SiC surface begins to take place.[62] Because sublimation etching is driven primarily by loss of silicon from the crystal surface, annealing in silicon overpressures can be used to prevent surface degradation during high-temperature anneals. Such overpressure can be achieved by close-proximity solid sources, such as using an enclosed SiC crucible with SiC lid and/or SiC powder near the wafer, or by annealing in a silane-containing atmosphere.

SiC Contacts and Interconnects

All useful semiconductor electronics require conductive signal paths in and out of each device, as well as conductive interconnects to carry signals between devices on the same chip and to external circuit elements that reside off-chip. While SiC itself is theoretically capable of fantastic operation under extreme conditions (Section 6.3), such functionality is useless without contacts and interconnects that are also capable of operation under the same conditions to enable complete extreme-condition circuit functionality. Previously developed conventional contact and interconnect technologies will likely not be sufficient for reliable operation in extreme conditions that SiC enables. The durability and reliability of metal–semiconductor contacts and interconnects are two of the main factors limiting the operational high-temperature limits of SiC electronics. Similarly, SiC high-power device contacts and metallizations will have to withstand both high-temperature and high current density stress never before encountered in silicon power electronics experience.

The subject of metal–semiconductor contact formation is a very important technical field, too broad to be discussed in detail here. For general background discussions on metal–semiconductor contact physics and formation, the reader should consult narratives presented in Refs. 15 and 63. These references primarily discuss ohmic contacts to conventional narrow-bandgap semiconductors such as silicon and GaAs. Specific overviews of SiC metal–semiconductor contact technology can be found in Refs. 64 to 67.

As discussed in Refs. 64 to 67, there are both similarities and a few differences between SiC ohmic contacts and ohmic contacts to conventional narrow-bandgap semiconductors (e.g., silicon, GaAs). The same basic physics and current transport mechanisms that are present in narrow-bandgap contacts — such as surface states, Fermi-pinning, thermionic emission, and tunneling — also apply to SiC contacts. A natural consequence of the wider bandgap of SiC is higher effective Schottky barrier heights. Analogous with narrow-bandgap ohmic contact physics, the microstructural and chemical state of the SiC–metal interface is crucial to contact electrical properties. Therefore, pre-metal-deposition surface preparation, metal deposition process, choice of metal, and post-deposition annealing can all greatly impact the resulting performance of metal–SiC contacts. Because the chemical nature of the starting SiC surface is strongly dependent on surface polarity, it is not uncommon to obtain significantly different results when the same contact process is applied to the silicon face surface vs. the carbon face surface.

SiC Ohmic Contacts

Ohmic contacts serve the purpose of carrying electrical current into and out of the semiconductor, ideally with no parasitic resistance. The properties of various ohmic contacts to SiC reported to date are summarized in Refs. 66 and 67. While SiC specific ohmic contact resistances at room temperature are generally higher than in contacts to narrow-bandgap semiconductors, they are nevertheless sufficiently low for most envisioned SiC applications. Lower specific contact resistances are usually obtained to n-type 4H- and

6H-SiC (~10^{-4} to 10^{-6} ohm-cm^2) than to p-type 4H- and 6H-SiC (~10^{-3} to 10^{-5} ohm-cm^2). Consistent with narrow-bandgap ohmic contact technology, it is easier to make low-resistance ohmic contacts to heavily doped SiC. While it is possible to achieve ohmic contacts to lighter-doped SiC using high-temperature annealing, the lowest-resistance ohmic contacts are most easily implemented on SiC degenerately doped by site competition (Section 6.4) or high-dose ion implantation (Section 6.5). If the SiC doping is sufficiently degenerate, many metals deposited on a relatively clean SiC surface are ohmic in the "as deposited" state.[68] Regardless of doping, it is common practice in SiC to thermally anneal contacts to obtain the minimum possible ohmic contact resistance. Most SiC ohmic contact anneals are performed at temperatures around 1000°C in non-oxidizing environments. Depending on the contact metallization employed, this anneal generally causes limited interfacial reactions (usually metal-carbide or metal-silicide formation) that broaden and/or roughen the metal–semiconductor interface, resulting in enhanced conductivity through the contact.

Truly enabling harsh-environment SiC electronics will require ohmic contacts that can reliably withstand prolonged harsh-environment operation. Most reported SiC ohmic metallizations appear sufficient for long-term device operation up to 300°C. SiC ohmic contacts that withstand heat soaking under no electrical bias at 500 to 600°C for hundreds or thousands of hours in non-oxidizing gas or vacuum environments have also been demonstrated. In air, however, there has only been demonstration to date of a contact that can withstand heat soaking (no electrical bias) for 60 hours at 650°C.[69] Some very beneficial aerospace systems will require simultaneous high-temperature ($T > 300$°C) and high current density operation in oxidizing air environments. Electromigration, oxidation, and other electrochemical reactions driven by high-temperature electrical bias in a reactive oxidizing environment are likely to limit SiC ohmic contact reliability for the most demanding applications. The durability and reliability of SiC ohmic contacts is one of the critical factors limiting the practical high-temperature limits of SiC electronics.

SiC Schottky Contacts

Rectifying metal–semiconductor Schottky barrier contacts to SiC are useful for a number of devices, including metal–semiconductor field-effect transistors (MESFETs) and fast-switching rectifiers. References 64, 65, 67, and 70 summarize electrical results obtained in a variety of SiC Schottky studies to date. Due to the wide bandgap of SiC, almost all unannealed metal contacts to lightly doped 4H- and 6H-SiC are rectifying. Rectifying contacts permit extraction of Schottky barrier heights and diode ideality factors by well-known current-voltage (I-V) and capacitance-voltage (C-V) electrical measurement techniques.[63] While these measurements show a general trend that Schottky junction barrier height does somewhat depend on metal–semiconductor workfunction difference, the dependence is weak enough to suggest that surface state charge also plays a significant role in determining the effective barrier height of SiC Schottky junctions. At least some experimental scatter exhibited for identical metals can be attributed to cleaning and metal deposition process differences, as well as different barrier height measurement procedures. The work by Teraji et al.,[71] in which two different surface cleaning procedures prior to titanium deposition lead to ohmic behavior in one case and rectifying behavior in the other, clearly shows the important role that process recipe can play in determining SiC Schottky contact electrical properties.

It is worth noting that barrier heights calculated from C-V data are often somewhat higher than barrier heights extracted from I-V data taken from the same diode. Furthermore, the reverse current drawn in experimental SiC diodes, while small, is nevertheless larger than expected based on theoretical substitution of SiC parameters into well-known Schottky diode reverse leakage current equations developed for narrow-bandgap semiconductors. Bhatnagar et al.[72] proposed a model to explain these behaviors, in which localized surface defects, perhaps elementary screw dislocations where they intersect the SiC-metal interface, cause locally reduced junction barriers in the immediate vicinity of defects. Because current is exponentially dependent on Schottky barrier height, this results in the majority of measured current flowing at local defect sites instead of evenly distributed over the entire Schottky diode area. In addition to local defects, electric field crowding along the edge of the SiC Schottky barrier can also lead to increased reverse-bias leakage current and reduced reverse breakdown voltage.[15,16,63]

Schottky diode edge termination techniques to relieve electric field edge crowding and improve Schottky rectifier reverse properties are discussed later in Section 6.6. Quantum mechanical tunneling of carriers through the barrier may also account for some excess reverse leakage current in SiC Schottky diodes.[73]

The high-temperature operation of rectifying SiC Schottky diodes is primarily limited by reverse-bias thermionic leakage of carriers over the junction barrier. Depending on the specific application and the barrier height of the particular device, SiC Schottky diode reverse leakage currents generally grow to excessive levels at around 300 to 400°C. As with ohmic contacts, electrochemical interfacial reactions must also be considered for long-term Schottky diode operation at the highest temperatures.

Patterned Etching of SiC for Device Fabrication

At room temperature, no known wet chemical etches single-crystal SiC. Therefore, most patterned etching of SiC for electronic devices and circuits is accomplished using dry etching techniques. The reader should consult Ref. 74; it contains an excellent summary of dry SiC etching results obtained to date. The most commonly employed process involves reactive ion etching (RIE) of SiC in fluorinated plasmas. Sacrificial etch masks (often aluminum metal) are deposited and photolithographically patterned to protect desired areas from being etched. The SiC RIE process can be implemented using standard silicon RIE hardware, and typical 4H- and 6H-SiC RIE etch rates are on the order of hundreds of angstroms per minute. Well-optimized SiC RIE processes are typically highly anisotropic with little undercutting of the etch mask, leaving smooth surfaces. One of the keys to achieving smooth surfaces is preventing "micromasking," wherein masking material is slightly etched and randomly redeposited onto the sample, effectively masking very small areas on the sample that were intended for uniform etching. This can result in "grass"-like etch-residue features being formed in the unmasked regions, which is undesirable in most cases. In special cases, RIE etching under conditions promoting micromasking is useful in greatly roughening the SiC surface to reduce the contact resistance of subsequently deposited ohmic metallizations.

While RIE etch rates are sufficient for many electronic applications, much higher SiC etch rates are necessary to carve features on the order of tens to hundreds of micrometers deep that are needed to realize advanced sensors, microelectromechanical systems (MEMS), and some very high-voltage power device structures. High-density plasma dry etching techniques, such as electron cyclotron resonance (ECR) and inductively coupled plasma (ICP), have been developed to meet the need for deep-etching of SiC. Residue-free patterned etch rates exceeding a thousand angstroms a minute have been demonstrated.[74–76]

Patterned etching of SiC at very high etch rates has also been demonstrated using photo-assisted and dark electrochemical wet etching.[77,78] By choosing proper etching conditions, this technique has demonstrated a very useful dopant-selective etch-stop capability. However, there are major incompatibilities of the electrochemical process that make it undesirable for VLSI mass-production, including extensive pre-etching and post-etching sample preparation, etch isotropy and mask undercutting, and somewhat non-uniform etching across the sample.

SiC Insulators: Thermal Oxides and MOS Technology

The vast majority of semiconductor integrated circuit chips in use today rely on silicon metal-oxide-semiconductor field effect transistors (MOSFETs), whose electronic advantages and operational device physics are summarized in Choma's chapter on devices and their models and elsewhere.[15,16,79] Given the extreme usefulness and success of MOSFET-based electronics in VLSI silicon, it is naturally desirable to implement high-performance inversion channel MOSFETs in SiC. Like silicon, SiC forms a thermal SiO_2 oxide when it is sufficiently heated in an oxygen environment. While this enables SiC MOS technology to somewhat follow the highly successful path of silicon MOS technology, there are nevertheless important differences in insulator quality and device processing that are presently preventing SiC MOSFETs from realizing their full beneficial potential. While the following discourse attempts to quickly highlight key issues facing SiC MOSFET development, more detailed insights can be found in Refs. 80 to 83. In

highlighting the difficulties facing SiC MOSFET development, it is important to keep in mind that early silicon MOSFETs faced similar developmental challenges that took many years of dedicated research effort to successfully overcome.

From a purely electrical point of view, there are two prime operational deficiencies of SiC oxides and MOSFETs compared to silicon MOSFETs. First, effective inversion channel mobilities in most SiC MOSFETs are much lower (typically well under 100 cm^2/V-s for inversion electrons) than one would expect based on silicon inversion channel MOSFET carrier mobilities. This seriously reduces the transistor gain and current-carrying capability of SiC MOSFETs, so that SiC MOSFETs are not nearly as advantageous as theoretically predicted. Second, SiC oxides have not proven as reliable and immutable as well-developed silicon oxides, in that SiC MOSFETs are more prone to threshold voltage shifts, gate leakage, and oxide failures than comparably biased silicon MOSFETs. The excellent works by Cooper[80] and Brown et al.[83] discuss noteworthy differences between the basic electrical properties of n-type versus p-type SiC MOS devices. SiC MOSFET oxide electrical performance deficiencies appear mostly attributable to differences between silicon and SiC thermal oxide quality and interface structure that cause the SiC oxide to exhibit undesirably higher levels of interface state densities (~10^{11} to 10^{13} $eV^{-1}cm^{-2}$), fixed oxide charges (~10^{11} to 10^{12} cm^{-2}), charge trapping, carrier oxide tunneling, and roughness-related scattering of inversion channel carriers.

One of the most obvious differences between thermal oxidation of silicon and SiC to form SiO_2 is the presence of C in SiC. While most of the C in SiC converts to gaseous CO and CO_2 and escapes the oxide layer during thermal oxidation, leftover C species residing near the SiC–SiO_2 interface nevertheless appear to have a detrimental impact on SiO_2 electrical quality.[80,81] Cleaning treatments and oxidation/anneal recipes aimed at reducing interfacial C appear to improve SiC oxide quality. Another procedure employed to minimize detrimental carbon effects has been to form gate oxides by thermally oxidizing layers of silicon deposited on top of SiC.[84] Likewise, deposited insulators also show promise toward improving SiC MOSFET characteristics, as Sridevan et al.[85] have recently reported greatly improved SiC inversion channel carrier mobilities (>100 cm^2/V-s) using thick deposited gate insulators.

SiC surfaces are well known to be much rougher than silicon surfaces, due to off-angle polishing needed to support SiC homoepitaxy (Fig. 6.5) as well as step-bunching (particularly pronounced in 4H-SiC) that occurs during SiC homoepilayer growth (Section 6.4).[39,86] The impact of surface morphology on inversion channel mobility is highlighted by the recent work of Scharnholz et al.,[87] in which improved mobility (>100 cm^2/V-s) was obtained by specifically orienting SiC MOSFETs in a direction such that current flowed parallel to surface step texture. The interface roughness of SiC may also be a factor in poor oxide reliability by assisting unwanted injection of carriers that damage and degrade the oxide.

As Agarwal et al.[88] have pointed out, the wide bandgap of SiC reduces the potential barrier impeding tunneling of damaging carriers through SiC thermal oxides, so that perfectly grown oxides on atomically smooth SiC would not be as reliable as silicon thermal oxides. Therefore, it is highly probable that alternative gate insulators will have to be developed for optimized implementation of inversion-channel SiC FETs for the most demanding high-power and/or high-temperature electronic applications.

SiC Device Packaging and System Considerations

Hostile-environment SiC semiconductor devices and ICs are of little advantage if they cannot be reliably packaged and connected to form a complete system capable of hostile-environment operation. With proper materials selection, modifications of existing IC packaging technologies appear feasible for non-power SiC circuit packaging up to 300°C.[89,90] Prototype electronic packages that can withstand over a thousand hours of heat soaking without electrical bias at 500°C have been demonstrated.[91] Much work remains before electronics system packaging can meet the needs of the most demanding aerospace electronic applications, whose requirements include high-power operation in high-vibration, 500 to 600°C, oxidizing-ambient environments. Similarly, harsh-environment passive components, such as inductors, capacitors, and transformers, must also be developed for operation in demanding conditions before the full system-level benefits of SiC electronics discussed in Section 6.3 can be successfully realized.

6.6 SiC Electronic Devices and Circuits

This section briefly summarizes a variety of SiC electronic device designs broken down by major application areas. The operational performance of experimental SiC devices is compared to theoretically predicted SiC performance as well as the capabilities of existing silicon and GaAs devices. SiC process and materials technology issues limiting the capabilities of various SiC device topologies are highlighted as key issues to be addressed in further SiC technology maturation.

SiC Optoelectronic Devices

The wide bandgap of SiC is useful for realizing short wavelength blue and ultraviolet (UV) optoelectronics. 6H-SiC-based blue pn junction light-emitting diodes (LEDs) were the first silicon carbide-based devices to reach high-volume commercial sales. These epitaxially grown, dry-etch, mesa-isolated pn junction diodes were the first mass-produced LEDs to cover the blue (~250 to 280 nm peak wavelength) portion of the visible color spectrum, which in turn enabled the realization of the first viable full-color LED-based displays.[92] Because the SiC bandgap is indirect (i.e., the conduction minimum and valence band maximum do not coincide in crystal momentum space), luminescent recombination in the LEDs is governed by inherently inefficient indirect transitions mediated by impurities and phonons.[93] Therefore, the external quantum efficiency of SiC blue LEDs (i.e., percentage of light energy output obtained vs. electrical energy input) was limited to well below 1%. While commercially successful during the 1989 to 1995 timeframe, SiC-based blue LEDs have now been totally obsoleted by the emergence of much brighter, much more efficient, direct-bandgap GaN blue LEDs.

SiC has proven much more efficient at absorbing short-wavelength light, which has enabled the realization of SiC UV-sensitive photodiodes that serve as excellent flame sensors in turbine-engine combustion monitoring and control.[92,94] The wide bandgap of 6H-SiC is useful for realizing low photodiode dark currents, as well as sensors that are blind to undesired near-infrared wavelengths produced by heat and solar radiation. Commercial SiC-based UV flame sensors, again based on epitaxially grown, dry-etch, mesa-isolated 6H-SiC pn junction diodes, have successfully reduced harmful pollution emissions from gas-fired, ground-based turbines used in electrical power generation systems. Prototype SiC photodiodes are also being developed to improve combustion control in jet-aircraft engines.[95]

SiC RF Devices

The main use of SiC RF devices appears to lie in high-frequency solid-state high-power amplification at frequencies from around 600 MHz (UHF-band) to perhaps around 10 GHz (X-band). As discussed in better detail in Refs. 6, 7, 23, 96, and 97, the high breakdown voltage and high thermal conductivity, coupled with high carrier saturation velocity, allow SiC RF transistors to handle much higher power densities than their silicon or GaAs RF counterparts, despite SiC's disadvantage in low-field carrier mobility (Section 6.2). This power output advantage of SiC is briefly illustrated in Fig. 6.6 for the specific case of a Class A MESFET-based RF amplifier. The maximum theoretical RF power of a Class A MESFET operating along the DC load line shown in Fig. 6.6 is approximated by[7]:

$$P_{max} = \frac{I_{dson}(V_b - V_{knee})}{8} \tag{6.1}$$

The higher breakdown field of SiC permits higher drain breakdown voltage (V_b), permitting RF operation at higher drain biases. Given that there is little degradation in I_{dson} and V_{knee} for SiC vs. GaAs and silicon, the increased drain voltage directly leads to higher SiC MESFET output power densities. The higher thermal conductivity of SiC is also crucial in minimizing channel self-heating so that phonon scattering does not seriously degrade channel carrier velocity and I_{dson}. As discussed in Refs. 7 and 97, similar RF output power arguments can be made for SiC-based static induction transistors (SITs).

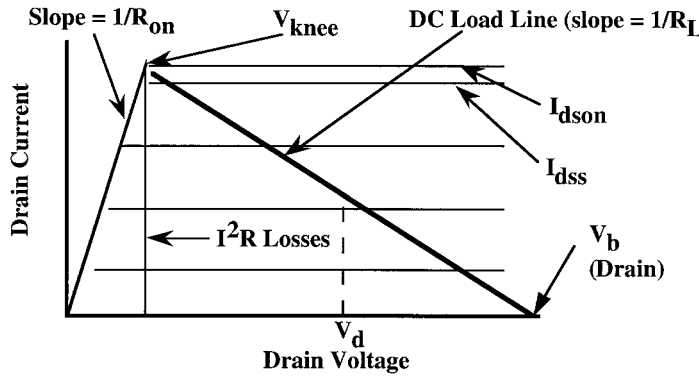

FIGURE 6.6 Piecewise linear MESFET drain characteristic showing DC load line used in Class A RF amplifier operation. The higher breakdown voltage V_b enabled by SiC's higher breakdown field enables operation at higher drain biases, leading to higher RF power densities. (From Ref. 7. With permission.)

The high power density of high-frequency SiC transistors could prove very useful in realizing solid-state transmitters for cell phone base stations, high-definition television (HDTV) transmitters, and radar transmitters, because it reduces the number of devices needed to generate sufficient RF power for these applications. Fewer transistors capable of operating at higher temperatures reduces matching and cooling requirements, leading to reduced overall size and cost of these systems. While excellent for fixed-base high-power RF transmission systems, SiC RF transistors are not well suited for portable handheld RF transceivers where drain voltage and power are restricted to function within the operational limitations of small-sized battery packs.

Because rapid progress is being made toward improving the capabilities of SiC RF power transistors, the reader should consult the latest electron device literature for up-to-date SiC RF transistor capabilities. A late-1997 summary of solid-state high-power RF amplification transistor results, including 4H-SiC, 6H-SiC, silicon, GaAs, and GaN device results, is given in Fig. 6.7.[7] Despite the fact that SiC RF transistors are not nearly as optimized, they have still demonstrated higher power densities than silicon and GaAs RF power transistors. The commercial availability of semi-insulating SiC substrates to minimize parasitic capacitances is crucial to the high-frequency performance of SiC RF MESFETs. MESFET devices fabricated on semi-insulating substrates are conceivably less susceptible to adverse yield consequences arising from micropipes than vertical high-power switching devices, primarily because a *c*-axis micropipe can no longer short together two conducting sides of a high field junction in most areas of the lateral channel MESFET structure. In addition to micropipes, other nonidealities, such as variations in epilayer doping and thickness, surface morphological defects, and slow charge trapping/detrapping phenomena causing unwanted device I-V drift,[98] also limit the yield, size, and manufacturability of SiC RF transistors. However, increasingly beneficial SiC RF transistors should continue to evolve as SiC crystal quality and device processing technology continues to improve.

In addition to high-power RF transistors, SiC mixer diodes show excellent promise for reducing undesired intermodulation interference in RF receivers.[99] More than 20-dB dynamic range improvement was demonstrated using non-optimized SiC Schottky diode mixers. Following further development and optimization, SiC-based mixers should improve the interference immunity of a number of RF systems where receivers and high-power transmitters are closely located, as well as improve the reliability and safety of flight RF-based avionics instruments used to guide aircraft in low-visibility weather conditions.

High-Temperature Signal-Level Devices

Most analog signal conditioning and digital logic circuits are considered "signal level" in that individual transistors in these circuits do not require any more than a few milliamperes of current and less than

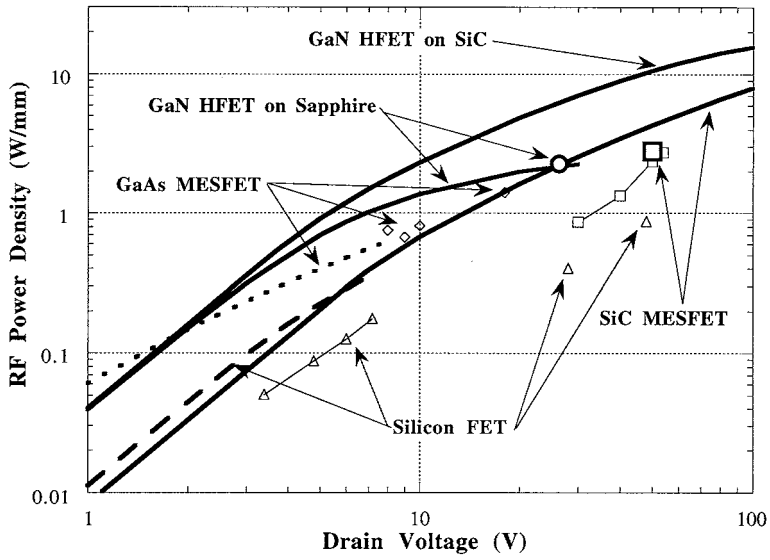

FIGURE 6.7 Theoretical (lines) and experimental (symbols) RF power densities of RF transistors fabricated in silicon, GaAs, SiC, and GaN as of late 1997. (From Ref. 96. With permission.)

20 V to function properly. Commercially available silicon-on-insulator circuits can perform complex digital and analog signal-level functions up to 300°C when high-power output is not required.[100,101] Aside from ICs where it is advantageous to combine signal-level functions with high-power or unique SiC sensors/MEMS onto a single chip, more expensive SiC circuits solely performing low-power signal-level functions appear largely unjustifiable for low-radiation applications at temperatures below 250 to 300°C.

Achieving long-term operational reliability is one of the primary challenges of realizing 300 to 600°C devices and circuits. Circuit technologies that have been used to successfully implement VLSI circuits in silicon and GaAs, such as CMOS, ECL, BiCMOS, DCFL, etc., are to varying degrees candidates for T > 300°C SiC integrated circuits. High temperature gate-insulator reliability (Section 6.5) is critical to the successful realization of MOSFET-based integrated circuits. Gate-to-channel Schottky diode leakage limits the peak operating temperature of SiC MESFET circuits to around 400°C (Section 6.5). Prototype bipolar SiC transistors have exhibited poor gains,[102] but improvements in SiC crystal growth and surface passivation should improve SiC BJT gains.[103] As discussed in Section 6.5, a common obstacle to all technologies is reliable long-term operation of contacts, interconnect, passivation, and packaging at T > 300°C. Because signal-level circuits are operated at relatively low electric fields well below the electrical failure voltage of most micropipes, micropipes affect signal-level circuit process yields to a much lesser degree than they affect high-field power device yields. Nonidealities in SiC epilayers, such as variations in epilayer doping and thickness, surface morphological defects, and slow charge trapping/detrapping phenomena causing unwanted device I–V drift, presently limit the yield, size, and manufacturability of SiC high-temperature integrated circuits.[83] However, continued progress in maturing SiC crystal growth and device fabrication technology should eventually enable the realization of SiC VLSI circuits.

Robust circuit designs that accommodate large changes in device operating parameters with temperature will be necessary for circuits to function successfully over the very wide temperature ranges (as large as 650°C spread) enabled by SiC. While there are similarities to silicon device behavior as a function of temperature, there are also significant differences that will present challenges to SiC integrated circuit designers. For example, in silicon devices, dopant atoms are fully ionized at standard operating temperatures of interest, so that free carrier concentrations correspond with dopant impurity concentrations.[14,15] Therefore, the resistivity of silicon increases with increasing temperature as phonon scattering reduces carrier mobility. SiC device layers, on the other hand, are significantly "frozen-out" due to deeper donor

and acceptor dopant ionization energies, so that non-trivial percentages of dopants are not ionized to produce free carriers that carry current at or near room temperature. Thus, the resistivity of SiC layers can sometimes initially decrease with increasing temperature as dopant atoms ionize to contribute more current-conducting free carriers, then decrease similar to silicon after most dopant atoms have ionized and increased phonon scattering degrades free carrier mobility. Thus, SiC transistor parameters can exhibit temperature variations not found in silicon devices, so that new device-behavior models are sometimes necessary to carry out proper design of wider-temperature range SiC integrated circuits. Because of carrier freeze-out effects, it will be difficult to realize SiC-based ICs operational at temperatures much lower than –55°C (the lower end of the U.S. Mil-Spec. temperature range).

Small-scale prototype logic and analog amplifier SiC-based ICs (one of which is shown in Fig. 6.8) have been demonstrated using SiC variations of NMOS, CMOS, JFET, and MESFET device topologies.[33,83,104–108] These prototypes are not commercially viable as of this writing, largely due to their high cost, unproven reliability, and limited temperature range that is mostly covered by silicon-on-insulator-based circuitry. However, increasingly capable and economical SiC integrated circuits will continue to evolve as SiC crystal growth and device fabrication technology continues to improve.

SiC High-Power Switching Devices

Operational Limitations Imposed by SiC Material Quality

As discussed in Section 6.3, the most lucrative system benefits of SiC electronics arguably lie in high-power devices. Unfortunately, these devices are also the most susceptible to present-day deficiencies in SiC material quality and process variations, mostly because they operate at high electric fields and high current densities that place the greatest electrical stresses on the semiconductor and surrounding device materials. Prototype SiC devices have demonstrated excellent area-normalized performance, often well beyond (>10X) the theoretical power density of silicon power electronics (Fig. 6.9). However, the presence of micropipe crystal defects has thus far prevented scale-up of small-area prototypes to large areas that can reliably deliver high total operating currents in large-scale power systems, as discussed in Section 6.4 and Refs. 9 and 40. Rectifying power device junctions responsible for OFF-state blocking fail at micropipe defects, leading to undesired (often damaging) localized current flow through micropipes at unacceptably low electric fields well below the critical reverse-breakdown field of defect-free SiC. Over the last decade, SiC micropipe densities have dropped from several hundred per square centimeter of wafer area to tens per square centimeter of wafer area (Section 6.4, Table 6.2), resulting in corresponding improvements in peak SiC device operating currents from less than 1 A to 10s of A. However, further defect reductions

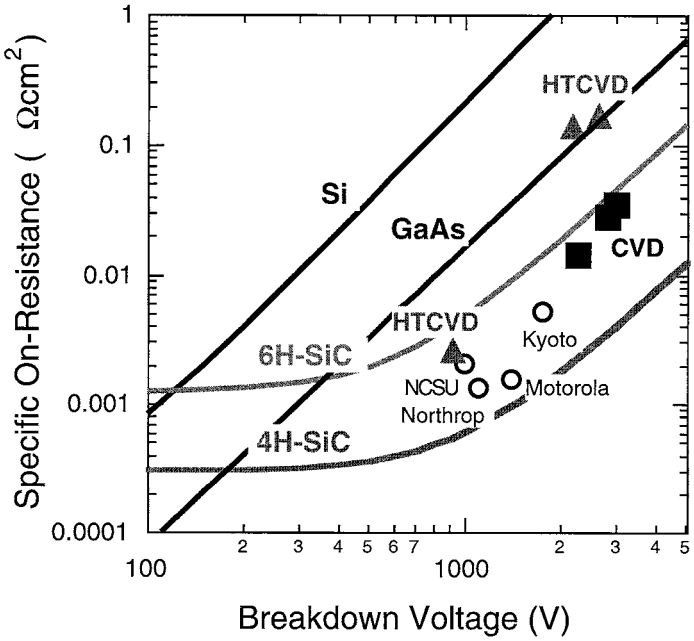

FIGURE 6.9 Experimental SiC (symbols) and theoretical SiC and silicon (lines) Schottky diode specific on resistance plotted as a function of off-state blocking voltage. While the graph clearly shows that the area-normalized performance of small-area SiC devices is orders of magnitude better than silicon, these results have not been successfully upscaled to realize large-area high-current SiC devices due to high densities of device-degrading defects present in commercial SiC wafers and epilayers. (From Ref. 117. With permission.)

of at least an additional order of magnitude will be necessary before reasonably good power device yields and currents will be obtained.

In addition to micropipe defects, the density of non-hollow core (elementary) screw dislocation defects in SiC wafers and epilayers has been measured on the order of several thousands per square centimeter of wafer area (Section 6.4). While these defects are not nearly as detrimental to device performance as micropipes, recent experiments have shown that they degrade the leakage and breakdown characteristics of pn junctions.[109,110] Less direct experimental evidence exists to suggest that elementary screw dislocations may also cause localized reductions in minority carrier diffusion lengths[111,112] and non-uniformities and catastrophic localized failure to high-voltage Schottky rectifiers under reverse bias.[72,113] While localized breakdown is well-known to adversely degrade silicon device reliability in high-power switching applications, the exact impact of localized breakdown in SiC devices has yet to be quantified. If it turns out that SiC power devices roughly adhere to the same reliability physics well-known for silicon power devices, it is possible that SiC devices containing non-hollow core screw dislocations could prove unacceptably unreliable for use in the most demanding high-power conversion applications, such as large-motor control and public power distribution. Thus, these applications might require much larger (i.e., much longer-term) improvements in SiC material quality so as to eliminate all screw dislocations (both hollow core and non-hollow core) from any given device.

SiC High-Voltage Edge Termination

For SiC power devices to successfully function at high voltages, peripheral breakdown due to edge-related electric field crowding[15,16,63] must be avoided through careful device design and proper choice of insulating/passivating dielectric materials. The peak voltage of most prototype high-voltage SiC devices has been limited by often destructive edge-related breakdown, especially in SiC devices capable of blocking multiple kilovolts.[114,115] In addition, most testing of multi-kilovolt SiC devices has required the device to

be immersed in specialized high-dielectric strength fluids or gas atmospheres to minimize damaging electrical arcing and surface flashover at device peripheries.[114,116,117]

A variety of edge termination methodologies, many of which were originally pioneered in silicon high-voltage devices, have been applied to prototype SiC power devices with varying degrees of success. Some of these approaches include tailored dopant guard rings,[122–124] tailored etches,[118–121] neutral ion implant damage rings,[125,126] metal guard rings,[127] and anode contact-insulator overlap.[128,129] The higher voltages and higher local electric fields of SiC power devices will place larger stresses on packaging and on wafer insulating materials, so it is unclear that traditional materials used to insulate/passivate silicon high-voltage devices will prove sufficient for reliable use in SiC high-voltage devices, especially if those devices are to be operated at high-temperatures.

SiC High-Power Rectifiers

The high-power diode rectifier is a critical building block of power conversion circuits. A good review of experimental SiC rectifier results is given in Ref. 67. As discussed in Refs. 8 and 20 to 22, the most important SiC diode rectifier device design tradeoffs roughly parallel well-known silicon rectifier tradeoffs, except for the fact that numbers for current densities, voltages, power densities, and switching speeds are much higher in SiC. SiC's high breakdown field and wide energy bandgap permit operation of SiC metal–semiconductor Schottky diodes at much higher voltages (i.e., kilovolts) and current densities (kA/cm^2) than is practical with silicon-based Schottky diodes. A drawback of the wide bandgap of SiC is that it requires larger forward bias voltages (~1 V) to reach the turn-on "knee" where significant ON-state current begins flowing, and this can lead to an undesirable increase in ON-state power dissipation. However, the benefits of 100X decreased drift region resistance and much faster dynamic switching should greatly overcome SiC ON-state knee voltage disadvantages in most high-power systems. Figure 6.9 summarizes experimental Schottky diode specific on-resistance versus breakdown voltage results published up through 1997.[117] For blocking voltages up to 3 kV, unipolar SiC Schottky rectifiers offer lower turn-on voltages (~1 to 2 V vs. ~3 V) and faster switching speeds (due to no appreciable minority carrier injection/charge storage) than SiC pn junctions.[21,22]

In rectifiers that block over ~3 kV, bipolar minority carrier charge injection (i.e., conductivity modulation) should enable SiC pn diodes to carry higher current densities than unipolar Schottky diodes whose drift regions conduct solely using dopant-atom majority carriers.[20–22] SiC pn junction blocking voltages as high as 5.5 kV have been realized as of this writing,[130] and further blocking voltage improvements are expected as SiC materials growth and processing further improve. Consistent with silicon rectifier experience, SiC pn junction generation-related reverse leakage is usually smaller than thermionic-assisted Schottky diode reverse leakage. While it has not yet been experimentally verified for SiC, silicon power device experience[131] strongly suggests that SiC pn junction rectifiers should offer significantly better reverse breakdown immunity to overvoltage/overcurrent faults that can occur in high-power switching circuits with large inductors than SiC Schottky rectifiers. As with silicon bipolar devices, reproducible localized control of minority carrier lifetime will be essential in optimizing the switching-speed versus ON-state current density performance tradeoffs of SiC bipolar devices for specific applications. SiC minority carrier lifetimes on the order of several microseconds have been obtained in high-quality epilayers,[132] and lifetime reduction via intentional impurity incorporation and introduction of radiation-induced structural defects appears feasible.

Hybrid Schottky/pn rectifier structures first developed in silicon that combine pn junction reverse blocking with low Schottky forward turn-on should prove extremely useful to realizing application-optimized SiC rectifiers.[133,134] Similarly, combinations of dual Schottky metal structures and trench pinch rectifier structures can also be used to optimize SiC rectifier forward turn-on and reverse leakage properties.[135]

SiC High-Power Switching Transistors

Three terminal power switches that use small drive signals to control large voltages and currents are also a critical building blocks of high-power conversion circuits. As well summarized in Ref. 21, a variety of

prototype three-terminal SiC power switches have been demonstrated in recent years. For the most part, SiC solid-state switches are based on well-known silicon device topologies, like the thyristor, vertical MOSFETs, IGBT, GTO, etc., that try to maximize power density via vertical current flow using the substrate as one of the device terminals. Because these switches all contain high-field junctions responsible for blocking current flow in the OFF-state, their maximum operating currents are primarily restricted by the material quality deficiencies discussed in Section 6.6. Therefore, while blocking voltages over 2 kV have been demonstrated in low-current devices,[116] experimental SiC power switches have only realized modest current ratings (under 1 A in most devices).

Silicon power MOSFETs and IGBTs are extremely popular in power circuits, largely because their MOS gate drives are well insulated and require little drive signal power, and the devices are "normally off" in that there is no current flow when the gate is unbiased at 0 V. However, as discussed in Section 6.5, the performance and reliability of SiC power device structures with inversion channel MOS field-effect gates (i.e., MOSFETs, IGBTs, etc.) are limited by poor inversion channel mobilities and questionable oxide reliability at high-temperatures. Thus, SiC device structures that do not rely on high-quality gate oxides, such as the thyristor, appear more favorable for more immediate realization, despite some non-trivial drawbacks in operational circuit design and switching speed.

Recently, some non-traditional power switch topologies have been proposed to somewhat alleviate SiC oxide and material quality deficiencies while maintaining normally off insulated gate operation. Shenoy et al.[136] and Hara[137] respectively, have implemented lateral and vertical doped-channel depletion/accumulation mode power SiC MOSFETs that can be completely depleted by built-in potentials at zero gate bias so that they are "normally off." Spitz et al.[116] recently demonstrated high-voltage SiC lateral MOSFETs implemented on semi-insulating substrates. These devices could conceivably reduce the adverse yield consequences of micropipes, because a *c*-axis micropipe can no longer short together two conducting sides of a high-field junction in most regions of the device. With the assistance of lateral surface electric field tailoring techniques, Baliga[138] has suggested that lateral-conduction SiC power devices could deliver better power densities than traditional vertical SiC power device structures. Baliga has also proposed the advantageous high-voltage switching by pairing a high-voltage SiC MESFET or JFET with a lower-voltage silicon power MOSFET.[138]

SiC for Sensors and Microelectromechanical Systems (MEMS)

Silicon carbide's high-temperature capabilities have enabled the realization of catalytic metal–SiC and metal–insulator–SiC (MIS) prototype gas sensor structures with great promise for emissions monitoring applications.[139,140] High-temperature operation of these structures, not possible with silicon, enables rapid detection of changes in hydrogen and hydrocarbon content to sensitivities of parts-per-million in very small-sized sensors that could easily be placed unobtrusively anywhere on an engine. Once they have been more fully developed, these sensors could assist in active combustion control to reduce harmful pollution emissions from automobile and aircraft engines.

Hesketh's chapter on micromachining describes conventional silicon-based microelectromechanical systems (MEMS). While the previous sections in this chapter have centered on the use of SiC for traditional semiconductor electronic devices, SiC is also likely to play a significant role in emerging MEMS applications.[141] In addition to high-temperature electrical operation, SiC has excellent mechanical properties vital to durable operation of microsystems that address some shortcomings of silicon-based MEMS, such as extreme hardness and low friction, reducing mechanical wear-out as well as excellent chemical inertness to corrosive ambients. Unfortunately, the same properties that make SiC more durable than silicon also make SiC more difficult to process into MEMS structures than silicon. Nevertheless, SiC-based pressure sensors, accelerometers, resonators (Fig. 6.10), and other MEMS systems are being developed for use in harsh-environment applications beyond the reach of silicon-based microsystems. The general approaches to fabricating harsh-environment MEMS structures in SiC and prototype SiC-MEMS results obtained to date are discussed in Ref. 141.

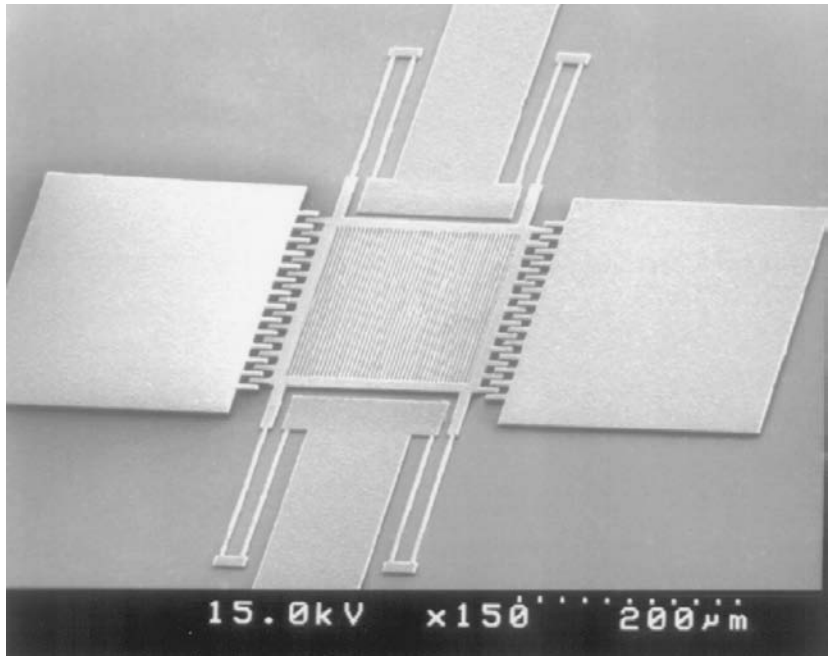

FIGURE 6.10 Micromachined SiC-based lateral resonator device. The excellent mechanical and electrical properties of SiC are enabling the development of harsh-environment microelectromechanical systems (MEMS) for operation beyond the limits of conventional silicon-based MEMS. 6.7 Further Recommended Reading

This chapter has presented a brief summary overview of evolving SiC semiconductor device technology. The following publications, which were heavily referenced in this chapter, are highly recommended as advanced, supplemental reading that more completely covers the work being done to develop SiC electronics in much greater technical detail than possible within this short chapter. Reference 12 is a two-volume collection of invited in-depth papers from recognized leaders in SiC technology development that first appeared in special issues of the journal *Physica Status Solidi* (a, 162, No. 1) and (b, 202, No. 1) in 1997. Reference 11 is a two-volume collection of papers from the *7th International Conference on Silicon Carbide, III-Nitrides, and Related Materials* held in Stockholm, Sweden, in September 1997. As SiC electronics is evolving rapidly to fulfill the needs of a steadily increasing array of applications, the reader should consult the current literature for updates on SiC device capabilities. One of the best ongoing sources of SiC electronics information is the *International Conference on Silicon Carbide and Related Materials*, which is held every two years. A meeting was scheduled for October 1999 in Research Triangle Park, North Carolina (internet Web site: www.ISCRM99.ncsu.edu). In addition, a variety of Internet Web sites contain useful SiC information and links, including www.grc.nasa.gov/WWW/SiC/SiC.html, www.hiten.com, www.cree.com, www.ecn.purdue.edu/WBG/, www.sterling-semiconductor.com/, www.imc.kth.se/sic/, and www.ifm.liu.se/Matephys/new_page/research/sic/index.html, among others that can be easily located using widely available World Wide Web Internet search engine services.

7.1 Magnetic Components

Integration Issues

It is well known and recognized that magnetic components should be avoided when designing integrated circuits due to their lack of integrability. New developments in the field of magnetic component fabrication are promising devices that can be integrated and miniaturized using monolithic fabrication techniques as opposed to today's bulk methods. The driving forces for such developments rest in certain applications that benefit or rely on inductive or magnetically coupled devices using ferromagnetic media. Examples of such applications include tuned RF tanks, matching networks, dc-dc power conversion and regulation, network filters, and line isolators/couplers.

Emerging applications requiring more mobility, lower power dissipation, and smaller component and system sizes have been drivers for the development of highly integrated systems and/or subsystems. In order to match these trends, it has become necessary to be able to integrate high-quality magnetic devices (i.e., inductors and transformers) with the systems they operate in as opposed to being stand-alone discrete devices. Not only does their discrete nature prevent further miniaturization, but their very nature also hampers improved performance (e.g., speed).

The main features of a monolithic magnetic device include:

1. High values of inductance compared to air core spirals
2. Enhanced high-frequency performance
3. Energy storage, dc bias, and power handling capabilities
4. Use of ferromagnetic materials as a magnetic core
5. Photolithographic fabrication of windings and magnetic core
6. Multi-layer mask fabrication for complete magnetic device design
7. Standard or semi-standard IC processing techniques

Due to the use of standard photolithography, etching, and patterning methods for their fabrication, monolithic magnetic devices may appear compatible with IC processes. However, two main characteristics make these devices more suitably fabricated off-line from a mainstream IC process:

- Coarser design rules. Usually, magnetic device designs do not require sub-micron geometries as demanded by semiconductor designs. This discrepancy means that an expensive sub-micron process for these components would unnecessarily raise the device cost.
- Use of ferromagnetic core materials. The use of iron, cobalt, nickel, and their alloys is at the heart of a high-quality magnetic device. Some of these materials are alien and contaminating to semiconductor cleanrooms. As a result, processing sequences and logistics for full integration with semiconductors is still in the development phase.

With these two major differences, integration of magnetics and semiconductors may require the use of multi-chip modules or single package multi-die cases. Full integration into a single monolithic die requires separate processing procedures using the same substrate.

The construction of a monolithic micromagnetic device fabricated on a substrate such as silicon or glass is shown in Fig. 7.1. In this diagram, the magnetic layer is sandwiched between upper and lower conductor layers that are connected together by means of an electrically conducting via. This structure is referred to as a *toroidal device* from its discrete counterpart.

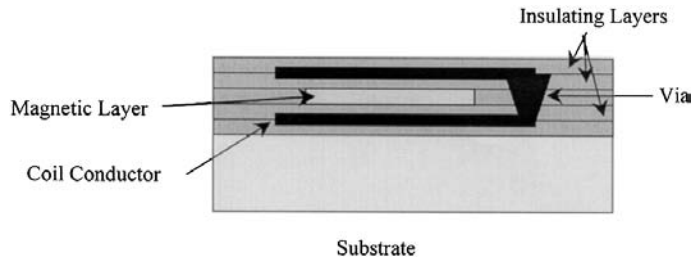

FIGURE 7.1 Cross-section of a monolithic micromagnetic device fabricated using IC methods.

Conversely, a dual structure can be made where two magnetic layers sandwich the conductor layer (or layers). This dual structure can be referred to as an *EE device* since it is derived from the standard discrete "EE" core type. In either case, as required by the operation of any magnetically coupled device, the magnetic flux path in the magnetic film and the current flow in the coil conductor are orthogonal, in accordance with Ampere's circuital law. Interlayer insulation between conductors and the magnetic layer(s) is necessary, both to reduce capacitive effects and to provide a degree of electrical voltage breakdown. These parameters are affected by the choice of insulator systems used in microfabricated circuits, due to the differing values of dielectric constants and breakdown voltages used. Some commonly used insulator systems include silicon dioxide and polyimide, each of which has distinctly different processing methods and physical characteristics. Conductor layers for the coil windings can be fabricated using standard aluminum metallization. In some cases, copper conductors are a better choice due to their higher conductivity and hence lower resistive losses. This is especially important if the device is to handle any significant power. The magnetic film layer is a thin film of chosen magnetic material typically between 1 and 10 μm in thickness. Such materials can be routinely deposited by standard techniques such as sputtering or electrodeposition. The specific method chosen must yield magnetic films with the desired properties, namely permeability, parallel loss resistance, and maximum flux density. These parameters vary with the deposition conditions and techniques, such that significant development and optimization has occurred to produce the desired results.

Since the design may call for energy storage and hence gaps in the core, the fabrication method can be modified to incorporate these features. Figure 7.2 shows the geometry of a planar magnetic core with a gap produced by photolithography. In this case, the gap is formed as a result of the artwork generated for the core design. Figure 7.3 shows the design of a gap using multi-layer magnetic films. The energy storage region exists in the edge insulation region between the two magnetic layers.

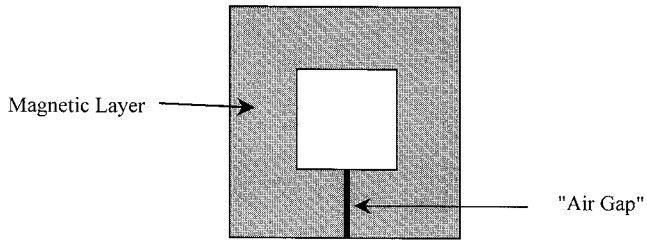

FIGURE 7.2 Planar, single-layer magnetic core configuration for energy storage (top view).

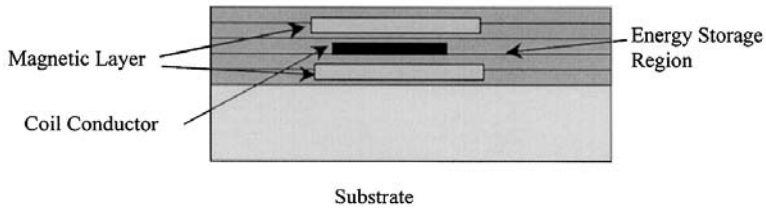

FIGURE 7.3 Multiple magnetic layers for energy storage micromagnetics (cross-sectional view).

The fabrication and construction of conductors for the coil usually involve depositing standard interconnect metals (e.g., aluminum) by sputter deposition. The thicknesses are chosen based on the current-carrying capability and the frequency of operation, as well as the desired configuration (inductor or transformer). The dc resistance of the conductors must be minimized to reduce dc losses, but the conductor thickness and arrangement must also result in minimal ac losses. This can be accomplished by reduced resistivity (i.e., copper vs. aluminum) and by multiple conductor layers to reduce skin and proximity effects at high frequencies.

Designs for Integrated Circuits

Unlike discrete magnetic components, monolithic micromagnetic devices are designed to operate at substantially higher frequencies. Due to their integrated nature and smaller physical size, interconnection and coupling parasitics are lower, thus enabling high-frequency response. However, the smaller physical size also places upper limits on such characteristics as inductance, current levels, power levels, and dissipation. With these limits, the maximum energy storage, *E*, is lower. In any inductor, the energy stored due to the current flowing (*I*) is related to the magnetic fields in the volume of the device by:

$$E = \frac{1}{2}LI^2 = \frac{1}{2}\iiint \bar{B} \cdot \bar{H} dv \tag{7.1}$$

where *L* is the transformer or inductor's inductance in Henries, and *I* (A) is the maximum current carried by the corresponding winding. This is related to the magnetic flux density, *B*, and magnetic field, *H*, present in the volume of the device. So, for a small physical volume, one can see from Eq. (7.1) that the energy stored is also small. This limited energy storage capability limits these devices to operation in low-power circuits. In order to obtain a high *B-H* product for more energy storage, a combination of high-permeability and low-permeability regions should be fabricated (i.e., a gap in the high permeability path is introduced). This gap region helps to maintain a high flux density as well as an appreciable field. The highly permeable region, on the other hand, while being able to maintain high flux density does not support large magnetic fields due to the fundamental relationship between magnetic field and flux:

$$\bar{B} = \mu_0 \mu_r \bar{H} \tag{7.2}$$

In Eq. (7.2), μ_0 is the permeability of vacuum ($4\pi \times 10^{-7}$ H/m) and μ_r is the relative permeability of the medium in which the magnetic field produces the corresponding magnetic flux density. The size of this gap determines both the energy storage levels and the inductance attainable (which is lower than the inductance attainable without a gap). In micromagnetic fabrication, two approaches may be taken to create this "air gap" region. One is to introduce a planar lithographical feature into the core structure (Fig. 7.2), and the other is to rely on multiple magnetic core layers separated by insulating layers (Fig. 7.3). The drawback of the lithographical gap is the limits imposed by the design rules. In this case, the gap may not be any smaller than the minimum design rule, which can be quite coarse. Excessive gap sizes result in very low inductance, requiring an increase in number of turns to compensate for this drop. Consequently, electrical losses in these windings increase and also the fabrication becomes more complicated. The drawback of multiple magnetic core layers is the need to add another level of processing to obtain at least a second (or more) magnetic layer(s). The stack-up of these layers and the edge terminations determine the amount of energy storage possible in the device. Unlike the lithographically produced gap, the energy storage in this case is much more difficult to estimate due to the two-dimensional nature of the edge termination fields in the gap region surrounding the multi-layer magnetic cores. In uniform field cases, the energy stored in volume of the gap can be obtained from Eqs. (7.1) and (7.2) due to the continuity and uniformity of the flux density vector in both the core and gap regions, giving:

$$E = \frac{1}{2} L I^2 \approx \frac{1}{2} \frac{B^2 V_{gap}}{\mu_0} \tag{7.3}$$

where V_{gap} is the volume of the gap region in cubic meters (m^3). The approximation is valid as long as the gap region carries a uniform flux density and is "magnetically long" compared to the length of the highly permeable core region (i.e., gap length/$\mu_{r\,gap}$ >> core length/$\mu_{r\,mag}$). Usually, this condition can be satisfied with most ferromagnetic materials of choice, but some ferromagnetic materials may have low enough permeabilities to render this approximation invalid. In this event, some energy is stored within the ferromagnetic material and Eq. (7.3) should be modified. Eq. (7.3) is very useful in determining the size of gap needed to support the desired inductance and current levels for the device. For example, if a 250-nH inductor operating at 250 mA of current bias were needed, the gap volume necessary to support these specifications would be about 2×10^{-5} mm^3, assuming a material with a maximum flux density of 1.0 T. In the planar device of Fig. 7.2 with nominal magnetic film dimensions of 2 μm in the normal direction and 200 μm in the planar direction, the required gap width would be about 5 μm. Since the gap in this case is obtained by photolithography, the minimum feature size for this process would need to be 5 μm. If a different material of lower maximum flux density capability of 0.5 T were used instead, the rated current level of 250 mA would have to be downgraded to 62 mA to prevent saturation of the magnetic material. Conversely, the gap length of 5 μm could be increased to 20 μm while maintaining the same current level, assuming adjustments are made to the turns to maintain the desired inductance. Such tradeoffs are common, but are more involved due to the interaction of gap size with inductance level and number of turns.

Another aspect of the design is the conductor for coil windings for an inductor or for primary and secondary windings in the case of a transformer. The number of turns is usually selected based on the desired inductance and turns ratio (for a transformer), which are typically circuit design parameters. As is well known, the number of turns around a magnetic core gives rise to an inductance, *L*, given by:

$$L = \frac{\mu_0 \mu_r N^2 A}{l} H \tag{7.4}$$

In this relation, N is the number of turns around a magnetic core of cross-sectional area A (m^2) and magnetic path length l (m). The inductance is reduced by the presence of a gap since this will serve to increase the path length. The choice of conductor thickness is always made in light of the ac losses occurring when conductors carry high-frequency currents. The conductors will experience various current redistribution effects due to the presence of eddy currents induced by the high-frequency magnetic fields surrounding the conductors. The well-known *skin effect* is one of such effects. Current will crowd toward the surface of the conductor and flow mainly in a thickness related to the skin depth, δ,

$$\delta = \frac{1}{\sqrt{\pi f \mu_0 \sigma}} \text{ m} \tag{7.5}$$

For a copper conductor, $\delta = 66/\sqrt{f(\text{MHz})}$ μm. At 10 MHz, the skin depth in copper is 20 μm, placing an upper limit on conductor thickness. When the interconnect metallization is aluminum, $\delta = 81/\sqrt{f(\text{MHz})}$ μm, so the upper limit at 10 MHz becomes 25 μm of metal thickness. Usually, the proximity of conductors to one another forces further optimization due to the introduction of losses due to eddy currents induced by neighboring conductors. In this case, the conductor thickness should be further adjusted with respect to the skin depth to reduce the induced eddy currents. The increase in conductor resistance due to the combined skin and proximity effects in a simple primary-secondary winding metallization scheme (shown in Fig. 7.4) can be calculated as an increase over the dc resistance of the conductor from:

$$Rac = Rdc \cdot \frac{1}{2}\frac{h}{\delta}\left\{\frac{\sinh h/\delta + \sin h/\delta}{\cosh h/\delta - \cos h/\delta} + \frac{\sinh h/\delta - \sin h/\delta}{\cosh h/\delta + \cos h/\delta}\right\} \tag{7.6}$$

In this relationship, h is the thickness of the metallization being used and Rac is obtained once the dc resistance (Rdc, also a function of h) is known. A distinct minimum for Rac can be obtained and yields the lowest possible ac resistance when:

$$\frac{h}{\delta} = \frac{\pi}{2} \tag{7.7}$$

with a corresponding minimum value of ac resistance of:

$$Rac = \frac{\pi}{2} Rdc \tanh\frac{\pi}{2} = 1.44 Rdc \tag{7.8}$$

When the geometry differs from the simple primary-to-secondary interface of Fig. 7.4 to more turns, layers, shapes, etc., a more complicated analysis is necessary.[4] The simple relation of Eq. (7.7) is no longer

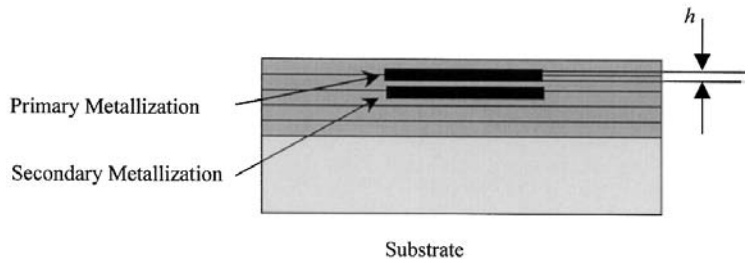

FIGURE 7.4 Configuration of primary and secondary transformer metallization for ac resistance calculation.

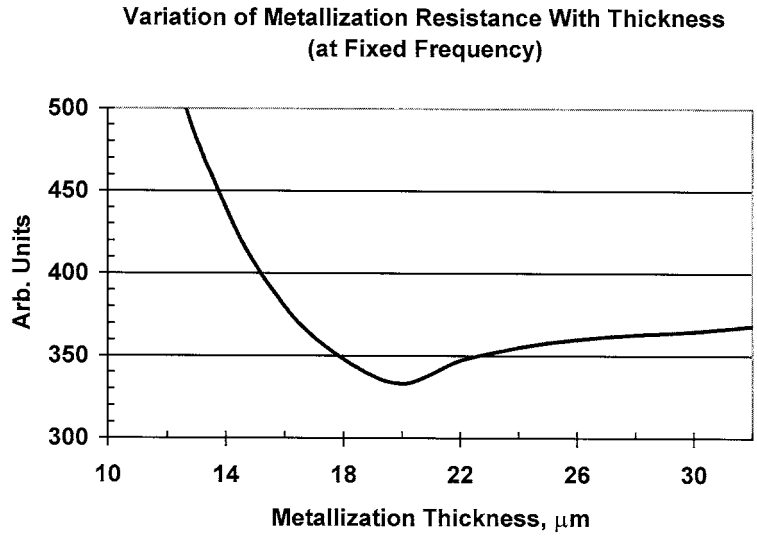

FIGURE 7.5 The variation of high-frequency metallization resistance with metal thickness for the configuration in Fig. 7.4. A distinct minimum is observed due to skin and proximity effects.

valid. Nevertheless, this relation provides a very good starting point for many designs. A qualitative explanation of this behavior stems from the fact that a thicker metallization will produce less dc resistance, but provides poor ac utilization due to current crowding near the surface. On the other hand, a thinner metallization increases the dc resistance, while providing better ac conductor utilization. The optimum situation is somewhere in between these two extreme cases, as can be seen from Fig. 7.5.

The principles presented in this section regarding design issues are at the core of every magnetic component design for integrated circuits. However, many design details — especially at elevated frequencies — are beyond the scope of this text. It is important to note that many of the limitations on high-frequency designs (100 MHz and higher) are imposed by the properties of the magnetic materials used in the cores of these devices.

Magnetic Core Materials

The most common magnetic materials used for discrete magnetic components operating at higher frequencies are ferrites. This is mainly due to their high resistivity (1 to 10 Ωm). Despite a low saturation flux density of about 0.3T, such a high resistivity makes ferrites suitable for applications up to 1 MHz, where hysteresis core losses are still limited. When the frequency is raised over 1MHz, the core losses become excessive, thus degrading the quality factor and efficiency of the circuit. Moreover, the permeability of all magnetic materials experiences a roll-off beyond a maximum upper frequency. Commonly used ferrites (e.g., MnZn ferrites) operate up to 1 to 2 MHz before permeability roll-off occurs. Higher roll-off frequencies are available, but with higher loss factors (e.g., NiZn ferrites). Ferrites, however, are not amenable to integrated circuit fabrication since they are produced by a high-temperature sintering process. In addition, their low flux saturation levels would not result in the smallest possible device per unit area. A set of more suitable materials for integrated circuit fabrication are the magnetic metal alloys usually derived from iron, cobalt, or nickel. These alloys can be deposited as thin films using IC fabrication techniques such as sputtering or electrodeposition and possess saturation flux levels of 0.8T to as high as 2.0T. Their main drawback due to their metallic nature is a much lower resistivity. Permalloy, a common magnetic alloy (80% nickel and 20% iron) has a resistivity of 20×10^{-8} Ωm, with a saturation flux density of 0.8T. Other materials such as sendust (iron-aluminum-silicon) have improved resistivity of 120×10^{-8} Ωm and saturation flux density of 0.95T.

To overcome the problem of low resistivity, the magnetic layers must be deposited in thin films with limited thickness. Since eddy currents flow in the metallic films at high frequencies, their effect can be greatly reduced by making the film thickness less than a skin depth. The skin depth in the magnetic film, δ_m, is given by:

$$\delta_m = \frac{1}{\sqrt{\pi f \mu_o \mu_r \sigma}} \text{ m} \tag{7.9}$$

In a thin film of permalloy ($\mu_r = 2000$), the skin depth at 10 MHz is 3 μm. In order to limit eddy current losses in the film, its thickness must be chosen to be less than 3 μm. This limitation will conflict with the inductance requirement, since a larger inductance requires a thicker magnetic film (see Eq. 7.4). Such difficulties can be overcome by depositing the magnetic film in multiple layers insulated from one another to restrict eddy current circulation. Such a structure would still provide the overall thickness needed to achieve the specified inductance while limiting the eddy current loss factor. The use of multi-layers also allows the reduction of die size due to the build-up of magnetic core cross-section (A in Eq. 7.4) in vertical layers, rather than by increasing the planar dimensions. As a result, it can be seen that a tradeoff exists between number of layers and die size to yield the most economical die cost.

In addition to eddy current losses due to the low magnetic metal resistivity, hysteresis losses occur in any magnetic material due to the traversing of the non-linear *B-H* loop at the frequency of operation. This is due to the loss of energy needed to rotate magnetic domains within the material. This loss is given by

$$P_{hys} = f \cdot \oint \bar{H} \cdot d\bar{B} \tag{7.10}$$

which is the area enclosed by the particular *B-H* loop demanded by the circuit operation and f is the frequency of operation. Total loss is expressed in many forms, depending on the application. In many cases, it is given in the form of a "parallel" or "shunt resistance" (Fig. 7.6) and it therefore presents a reduction in impedance to the source as well as a reduction in the overall quality factor of the inductor or transformer. It also represents a finite power loss since this loss is simply V^2/R_p watts, where V is the applied voltage.

Notice that R_p is a non-linear resistance with both frequency and flux level dependencies. It can be specified at a given frequency and flux level and is usually experimentally measured. It can also be extracted from core loss data usually available in the form

$$P = kf^{\alpha}B^{\beta} = \frac{V^2}{R_p} \tag{7.11}$$

In this relation, k, α, and β are constants for the material at hand. This model is useful for circuit simulation purposes, thereby avoiding the non-linear properties of the magnetic material. Care, however, should be exercised in using such models since with a large enough excitation, the value of the shunt resistor changes.

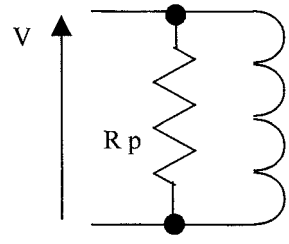

FIGURE 7.6 Magnetic material losses are represented by a parallel shunt resistance.

7.2 Air Core Inductors

Air core inductors do not use a magnetic core to concentrate the lines of magnetic flux. Instead, the flux lines exist in the immediate neighborhood of the coils without tight confinement. As a result, the inductance of an air core coil is considerably lower than one with a magnetic core. In fact, at low frequencies, the quality factor is reduced by a factor of μ_r when the loss factor is small. At high frequencies, however, the loss factor may be so high that the addition of a magnetic core and increased inductance actually ends up degrading the quality factor below the air core value. Discrete air core inductors have been used in RF applications and have been wound using discrete magnet or Litz wire onto forming cylinders.

For integrated circuits, especially RF and microwave circuits, spiral metallization deposited on a substrate is a common means to obtain small amounts of inductance with relatively high quality factors. Inductance values that can be obtained by these techniques are usually in the low nH range (1 to 20 nH). Estimating inductance values using air cores is much more complicated than in the case of highly permeable cores due to the lack of flux concentration. Formulas have been derived for different spiral air coil shapes (*assuming perfectly insulating substrates*) and are tabulated in several handbooks for inductance calculations.[6–9] An example of a useful inductance formula[9] is:

$$L = 4\pi \times 10^{-7} N^2 r_{avg} \left\{ \ln \frac{8 r_{avg}}{(r_{out} - r_{in})} + \frac{1}{24} \left(\frac{(r_{out} - r_{in})}{r_{avg}} \right)^2 \left(\ln \frac{8 r_{avg}}{(r_{out} - r_{in})} + 3.583 \right) - 0.5 \right\} \quad (7.12)$$

In this formula, r_{out} and r_{in} are the outer and inner radii of the spiral, respectively, and the average radius r_{avg} is

$$r_{avg} = \frac{(r_{out} + r_{in})}{2} \quad (7.13)$$

The formula is an approximation that loses accuracy as the device size becomes large (i.e., large r_{out} with respect to r_{in}).

The loss factors of such devices are strongly influenced by the non-idealities of the substrates and insulators on which they are deposited. For example, aluminum spiral inductors fabricated on silicon with highly doped substrates and epitaxial layers can have significant reductions in quality factor due to the conductivity of the underlying layers. These layers act as ground planes, producing the effect of an image of the spiral underneath. This in turn causes a loss in inductance. This can be as much as 30 to 60% when compared to a spiral over a perfect insulator. In addition, an increase in the loss factor occurs due to circulating eddy currents in the conductive under-layers. Increases in the effective resistance of 5 to 10 times the perfect insulator case are possible, increasing with increased frequency. All these effects can be seen to degrade the performance of these inductors, thus requiring design optimization.[10–12]

These substrate effects appear in the form of coupling capacitances from the spiral metal to the substrates, as well as spreading resistances in the substrate itself. The spreading resistance is frequency dependent, increasing with higher frequency. The amount of coupling to the substrate depends on the coupling capacitances and hence the separation of the spiral from the substrate. This distance is the dielectric thickness used in the IC process. Only with very large dielectric thicknesses are the substrate effects negligible. In practical cases where it is relatively thin and limited to a few microns, the effects are very large, giving an overall quality factor, Q, which is significantly lower than the Q of the spiral without the substrate. Fig. 7.7 shows a typical degradation curve of Q on a resistive substrate for "thick" and "thin" separations or dielectric thicknesses. The trends of this curve are also similar if the dielectric thickness variable is replaced by the substrate resistivity as a variable. The exact amount of degradation depends on the separation involved, the dielectric constant, and the resistivity of the substrate. With

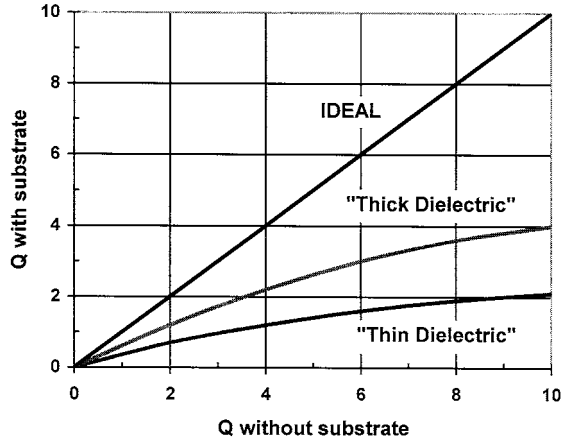

FIGURE 7.7 Degradation of inductor quality factor by placement on a resistive substrate.

these quantities known, it is possible to construct a circuit model to include these effects and hence solve for the overall quality factor, including the substrate effects.

In order to improve the inductor quality factor on a resistive substrate, some design solutions are possible. One solution to this problem is to increase the substrate resistivity. Another is to design a spiral with small footprint to reduce coupling to the substrate. In order to offset the increased resistance (which also reduces Q), thicker metallization would be necessary and clearly a tradeoff situation arises requiring some design optimization by circuit modeling or, more accurately, by electromagnetic finite-element analysis.

7.3 Resistors

Resistors have been available for use in integrated circuits for many years.[13–16] Some of these are made in silicon and thus are directly integrated with the rest of the IC process. Others, similar to the magnetic device case, are thin-film resistors fabricated in an off-line process that is not necessarily compatible with silicon IC processing. Integrated silicon resistors offer simplicity in fabrication but have less than ideal characteristics with loose tolerances. For this reason, many circuits rely on the ratio of resistor values rather than on their absolute values. Thin-film resistors, on the other hand, are far superior, offering tight tolerances and the ability to trim their absolute value down to very precise values. They also display more stability in terms of temperature and frequency dependence.[17]

Usually, resistors in integrated circuits are characterized in terms of their sheet resistance rather than their absolute resistance value. Sheet resistance, R_{sheet}, is defined as the resistance of a resistive strip with equal length and width so that

$$R_{sheet} = \frac{\rho}{t}(\Omega/\square) \tag{7.14}$$

where ρ is the material resistivity ($\Omega\cdot$m) and t is its thickness (m). Once R_{sheet} is given, the resulting resistor value is obtained by multiplying by its length-to-width aspect ratio. In order to avoid very high aspect ratios, an appropriate sheet resistivity should be used. For example, with $R_{sheet} = 10\ \Omega/\square$ a 10:1 length-to-width ratio would give a 100-Ω resistor. However, to obtain a 1-kΩ resistor, it would be better to use a different material with, for example, $R_{sheet} = 100\ \Omega/\square$ with the same 10:1 ratio instead of using a 100:1 ratio with the low-resistivity material.

Integrated Semiconductor Resistors

In this category, the existing semiconductor is used as the resistive material. The resistor may be fabricated at a number of stages during the IC process, giving rise to different resistors with different characteristics. Some of the most common include:

Diffused Resistors

This can be formed during either the base or emitter diffusion of a bipolar process. For an npn process, the base diffusion resistor is a p-type of moderate sheet resistivity, typically in the range of 100 to 200 Ω /□. This can provide resistors in the 50 to 10 kΩ range. The heavily doped n^+ emitter diffusion will produce an n^+-type resistor with low sheet resistivity of 2 to 10 Ω/□. This can provide resistors with low values in the 1 to 100 Ω range. Due to tolerances in the photolithographic and etching processes, the tolerance in the absolute resistance can be as high as range. Due to tolerances on the photolithographic and etching processes, the tolerance on the absolute resistance can be as high as ±30%. However, resistor pairs can be matched closely in temperature coefficients and doping profiles, especially when placed side-by-side on the chip, so that the resultant tolerance of the resistor ratio can be made to be less than ±1%. Since a diffusion resistor is based on a p-type base over an n-type epitaxy, or an n^+-type emitter over a p-type base, it is essential that the formed p-n junctions are always reverse-biased to ensure that current flows in the intended portion of the resistor. The presence of such a reverse-biased p-n junction also introduces a distributed capacitance from the resistor body to the substrate. This will cause high-frequency degradation, whereby the resistor value drops from its nominal design value to a lower impedance value due to the shunting capacitance.

Pinched Resistors

A variation to the diffused resistor that is used to increase the sheet resistivity of base region is to use the n^+-type emitter as a means to reduce the cross-sectional area of the base region, thereby increasing the sheet resistivity. This can increase the sheet resistance to about 1 kΩ/□. In this case, one end of the n^+-type emitter must be tied to one end of the resistor to contain all current flow to the pinched base region.

Epitaxial Resistors

High resistor values can be formed using the epitaxial layer since it has higher resistivity than other regions. Epitaxial resistors can have sheet resistances around 5 kΩ /□. However, epitaxial resistors have even looser tolerances due to the wide tolerances on both epitaxial resistivity and epitaxial layer thickness.

MOS Resistors

A MOSFET can be biased to provide a non-linear resistor. Such a resistor provides much greater values than diffused ones while occupying a much smaller area. When the gate is shorted to the drain in a MOSFET, a quadratic relation between current and voltage exists and the device conducts current only when the voltage exceeds the threshold voltage. Under these circumstances, the current flowing in this resistor (i.e., the MOSFET drain current) depends on the ratio of channel width-to-length. Hence, to increase the resistor value, the aspect ratio of the MOSFET should be reduced to give longer channel length and narrower channel width.

Thin-Film Resistors

As mentioned before in the magnetic core case, a resistive thin-film layer can be deposited (e.g., by sputtering) on the substrate to provide a resistor with very tight absolute-value tolerance. In addition, given a large variety of resistor materials, a wide range of resistor values can be obtained in small footprints, thereby providing very small parasitic capacitances and small temperature coefficients. Some common thin-film resistor materials include tantalum, tantalum nitride, and nickel-chromium. Unlike semiconductor resistors, thin-film resistors can be laser trimmed to adjust their values to very high accuracies of up to 0.01%. Laser trimming can only increase the resistor value since the fine beam

evaporates a portion of the thin-film material. By its nature, laser trimming is a slow and costly operation that is only justified when very high accuracy on absolute values is necessary.

7.4 Capacitors

As in the inductor case, the limitation on integrated capacitors is die size, due to the limited capacitance/unit area available on a die. These limitations are imposed by the dielectrics used with their dielectric constants and breakdown voltages. Most integrated capacitors are either junction capacitors or MOS capacitors.

Junction Capacitors

A *junction capacitor* is formed when a p-n junction is reversed-biased. This can be formed using the base–emitter, base–collector, or collector–substrate junctions of an npn structure in bipolar ICs. Of course, the particular junction must be maintained in reverse-bias to provide the desired capacitance. Since the capacitance arises from the parallel plate effect across the depletion region, whose thickness in turn is voltage dependent, the capacitance is also voltage dependent, decreasing with increased reverse-bias. The capacitance depends on the reverse-voltage in the following form:

$$C(V) = \frac{C_0}{(1 + V/\psi_0)^n} \tag{7.15}$$

The built-in potential, Ψ_0, depends on the impurity concentrations of the junction being used. For example, $\Psi_0 = 0.7$ V for a typical bipolar base–emitter junction. The exponent n depends on the doping profile of the junction. The approximations $n = 1/2$ for a step junction and $n = 1/3$ for a linearly graded junction are commonly used. The resultant capacitance depends on C_0, the capacitance per unit area with zero bias applied. This depends on the doping level and profile. The base–emitter junction provides the highest capacitance per unit area, around 1000 pF/mm^2 with a low breakdown voltage (~5 V). The base–collector junction provides about 100 pF/mm^2 with a higher breakdown voltage (~40 V).

MOS Capacitors

MOS capacitors are usually formed as parallel plate devices with a top metallization and a high conductivity n^+ emitter diffusion as the two plates, with a thin oxide dielectric sandwiched in between. The oxide is usually a thin layer of SiO_2 with a relative dielectric constant ε_r of 3 to 4, or Si_3N_4 with ε_r of 5 to 8. Since the capacitance obtained is $\varepsilon_0\varepsilon_r A/t_{oxide}$, the oxide thickness, t_{oxide} is critical. The lower limit on the oxide thickness depends on the process yields and tolerances, as well as the desired breakdown voltage and reliability. MOS capacitors can provide around 1000 pF/mm^2, with breakdown voltages up to 100 V. Unlike junction capacitors, MOS capacitors are voltage independent and can be biased either positively or negatively. Their breakdown, however, is destructive since the oxide fails permanently. Care should be taken to prevent overvoltage conditions.

Power IC Technologies

Akio Nakagawa
Toshiba Corporation

8.1 Introduction

VLSI technology has advanced so greatly that Gigabit DRAMs have become a reality, and the technology faces an optical lithography limit. Microelectronics mostly advances signal processing LSIs such as memories and microprocessors. Power systems and the related circuits cannot be outside the influence of VLSI technology.[1] It would be quite strange for power systems alone to still continue to consume a large space while brains become smaller and smaller. On the other hand, almost all of the systems require actuators or power devices to control motors, displays, and multimedia equipment. The advances in microelectronics have made it possible to integrate large-scale circuits in a small silicon chip, ending up in high system performance and resultant system miniaturization. The system miniaturization inevitably necessitated power IC development. Typical early power ICs were audio power amplifiers, which used bipolar transistors as output devices. The pn junction isolation method was well suited to integrate bipolar transistors with control circuits.

Real advancements in intelligent power ICs were triggered by the invention of power DMOSFETs[2] in the 1970s. DMOS transistors have ideal features for output devices of power ICs. No driving dc current is necessary, and large currents can be controlled simply by changing the gate voltage. In addition, DMOS switching speed is sufficiently fast.

The on-resistance of vertical DMOSFETs has been greatly reduced year by year with advances in fine lithography in LSI technology. In the mid-1980s, the new concept "Smart Power"[3] was introduced. Smart Power integrates bipolar and CMOS devices with vertical DMOS, using a process primarily optimized for poly-silicon gate self-aligned DMOS. The main objective is to integrate control and protection circuits with vertical power devices, not only to increase device reliability and performance, but also to realize easy use of power devices. The concept of Smart Power was applied to high-voltage vertical DMOS with

drain contact on the back side of the chip because discrete DMOS technology was already well advanced in the early 1980s. The main application field was automotive, replacing mechanical relays and eliminating wire harnesses.

As the technology of microlithography has further advanced, the on-resistance of DMOS, especially low-voltage DMOS, has continuously decreased. In the early 1990s, the on-resistance of low-voltage lateral DMOS became lower than that of bipolar transistors.[4] It was even realized that low-voltage lateral DMOS is superior to vertical planar discrete DMOS since fine lithography does not contribute to a decrease in on-resistance of vertical DMOS because of JFET resistance. Recently, with the introduction of a 0.6-μm design rule, lateral DMOS has become predominant over the wide voltage range — from 20 V up to 150 V. Mixed technology, called BCD,[4] integrating BiCMOS and DMOS, is now widely accepted for low-voltage power ICs.

For high-voltage power ICs, DMOS is not suitable for output devices because of a high on-resistance. Thyristor-like devices, such as GTOs, have conventionally been used for high-voltage applications. Integration of thyristor-like devices needs a method of dielectric device isolation (DI). The conventional DI method, called EPIC,[5] has been used for high-voltage telecommunication ICs, called SLIC. However, it has problems of high cost and large wafer warpage. In 1985 and 1986, wafer direct-bonding technology was invented,[6,7] and low-cost DI wafers became available. Wafer warpage of directly bonded SOI wafers is very small. This made it possible not only to fabricate large-diameter (8-in.) SOI wafers, but also to apply advanced lithography to DI power ICs. The chip size of DI power ICs can be reduced by narrow-trench isolation and by the use of high-performance lateral IGBTs. The low-cost DI wafers and the chip size reduction have widened the application fields of DI power ICs, covering automotive, motor control, and PDP drivers.

8.2 Intelligent Power ICs

Figure 8.1 shows typical functions integrated into intelligent power ICs. The most important feature of the intelligent power IC is that a large power can be controlled by logic-level input signals and all the cumbersome circuits such as driving circuits, sense circuits, and protection circuits required for power device control are inside the power ICs.

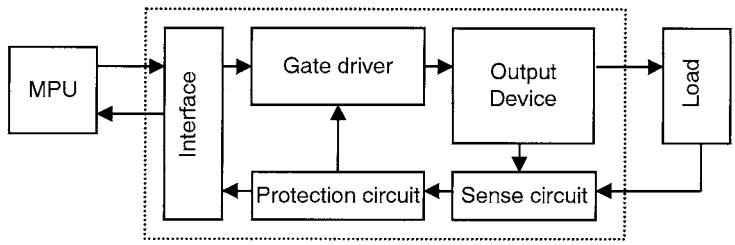

FIGURE 8.1 Typical integrated functions in intelligent power ICs.

Technologies for realizing such power ICs are classified into three categories, as shown in Figs. 8.2 to 8.4. These are self-isolation, junction isolation, and dielectric isolation. Self-isolation is a method that does not use any special means to isolate each device, and each device structure automatically isolates itself from the other.

Junction isolation (JI) is a method that uses reverse-biased junction depletion layers to isolate each device. JI is the most frequently used method for low-voltage power ICs, using bipolar transistor or DMOS outputs.

Junction isolation is not sufficient to isolate IGBTs or thyristors. Dielectric isolation is a method that uses silicon dioxide film to isolate devices and thus offers complete device isolation. Although the EPIC method has conventionally been used, the high cost of wafer fabrication has been a problem. Recently, wafer direct-bonding technology was invented and bonded SOI wafers are available at a lower price.

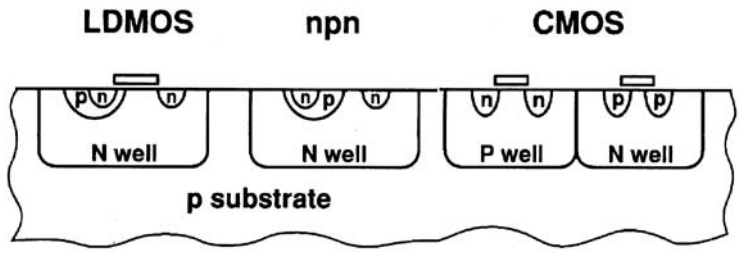

FIGURE 8.2 Self-isolation technology.

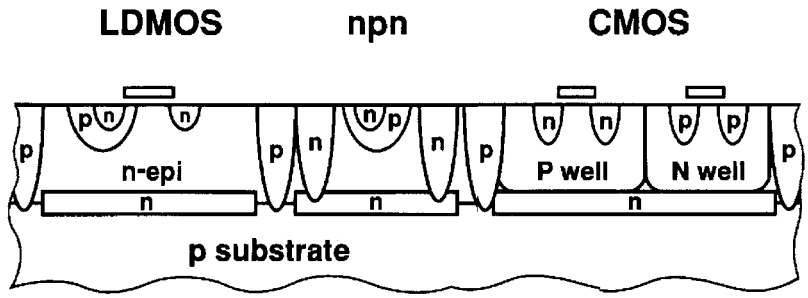

FIGURE 8.3 Junction isolation (JI) technology.

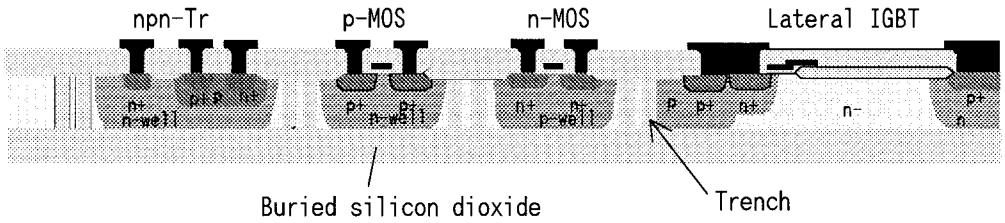

FIGURE 8.4 Dielectric isolation (DI) technology.

pn Junction Isolation

One of the fundamental issues in integrated circuits is how to electrically isolate each device from the others. pn junction isolation is the most familiar method and has been used since the beginning of bipolar IC history. Figure 8.5 shows the cross-section of a typical junction isolation structure. First, an n-type

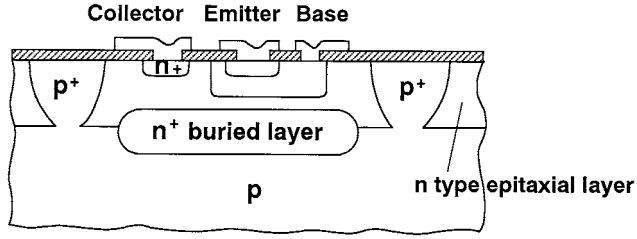

FIGURE 8.5 Junction isolation structure.

epitaxial layer is formed on p-type silicon substrate. p-type diffusion layers are then formed to reach the p-type substrate, resulting in isolated n-type islands surrounded by p-type regions. By keeping the substrate potential in the lowest level, the pn junctions, surrounding the islands, are reverse-biased and the depletion layers are formed to electrically isolate each island from the others.

If this method is applied to high-voltage power ICs, a thick n-type epitaxial layer is required and deep isolation diffusions are necessary. Deep diffusion accompanies large lateral diffusion, ending up in a large isolation area. One solution for this is to use buried p^+ diffusion layers for upward isolation diffusions, as shown in Fig. 8.6. However, 200 V is a practical limit for conventional pn junction isolation.

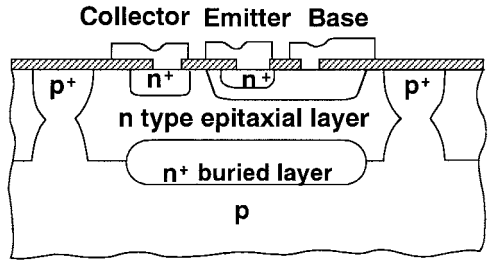

FIGURE 8.6 Junction isolation with upward isolation diffusions.

A variety of methods have been proposed to overcome this voltage limit. Figure 8.7 shows a typical example for this.[8] A shallow hole is formed where a high-voltage device is formed before the n-type epitaxial growth. This allows a locally thicker n-type epitaxial layer for high-voltage transistors.

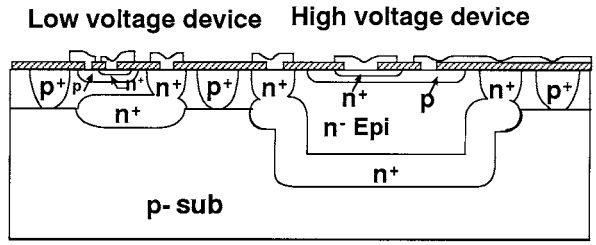

FIGURE 8.7 An example to overcome the junction isolation voltage limit.

Another distinguished example is shown in Fig. 8.8, where an n^+-substrate is used in place of a p-type substrate. p-type and n-type epitaxial layers are subsequently formed. This example makes it possible to integrate a vertical DMOSFET with a backside drain contact with junction-isolated BiCMOS control circuits. This structure was proposed as "Smart Power" in the mid-1980s.

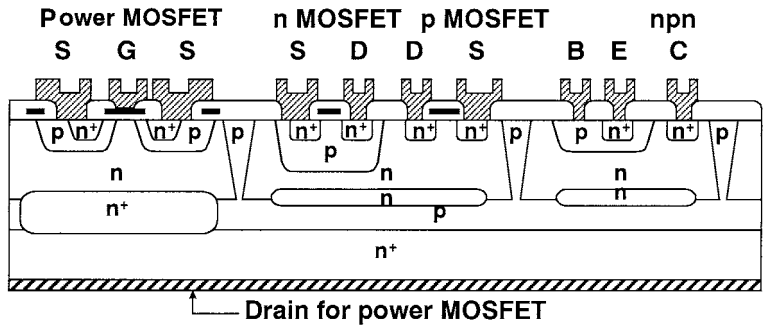

FIGURE 8.8 Junction isolation with VDMOSFET.

Impact of Dielectric Isolation

Dielectric isolation (DI) is a superior method for integrating many kinds of devices in a single chip. DI has many advantages[9–11] over junction-isolation techniques, including,

1. Virtually all integrated components can be treated as if they were discrete devices, so that circuit design becomes easy.
2. Bipolar devices, including thyristors, can be integrated without any difficulties.
3. Coupling between two devices can be minimized, thus attaining better IC performances: no latch-up, high speed, large noise immunity, and ruggedness.
4. High-temperature operation is feasible because there are virtually no parasitics and leakage current is low.
5. Radiation hardness for space use.

Figure 8.9 shows a cross-section of the conventional DI, called EPIC. The crystalline silicon islands completely surrounded by silicon dioxide film are floating in the supporting substrate made of a thick polysilicon layer. The fabrication process of EPIC wafers is complicated and illustrated in Fig. 8.10. The problem with EPIC is the high cost of wafers and large wafer warpage. The development of the EPIC method was initiated by the early works of J.W. Lathlop et al.,[12] and J. Bouchard et al.,[13] in 1964. The EPIC method was first applied to high-speed bipolar ICs owing to its low parasitic capacitance.

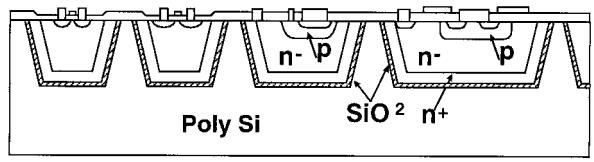

FIGURE 8.9 Dielectric isolation with EPIC technology.

Early work on high-voltage integrated circuits was triggered by the need for display drivers and high-voltage telecommunication circuits. Efforts to achieve high-voltage lateral MOSFETs started in the early 1970s, and the 800-V lateral MOSFET, using RESURF concept and DMOS (DSA[2]) technology, was developed for display drivers in 1976, before the RESURF concept was fully established.[14]

The need for high-voltage SLICs advanced the EPIC technology because it required electrically floating high-voltage bi-directional switches, which were realized only by the DI technique.

A variety of dielectric isolation methods, classified as silicon on insulator (SOI) technology, were invented in the 1970s. These are SOS (silicon on sapphire[15]), SIMOX,[16] and recrystallized poly-silicon such as ZMR.[17] And, silicon wafer direct-bonding (SDB)[6,7] was proposed in 1985.

The SOI wafer structure is simple. A single crystalline silicon layer is formed on the buried oxide layer or insulator substrate. Major methods are SIMOX and wafer bonding. SIMOX is a method that forms a buried oxide layer by a high dose of oxygen ion implantation and subsequent high-temperature annealing. Wafer bonding is a method that bonds an oxidized wafer and a substrate wafer at room temperature and strengthens the bond by annealing at high temperature. The thickness of the bonded SOI layer is adjusted by mechanical grinding and polishing.

In the late 1980s, MOS gate power device technology was greatly improved. In particular, the success of the MOS bipolar composite devices such as IGBTs[18,19] and MCTs[20] made it possible to control a large current by the MOS gate. The large current-handling capability of IGBTs has accelerated adopting DI with IGBT outputs.

In the early SLICs, double-injection devices with current control gates such as gated diodes and GTOs were used for such switches.[21] Recently developed SLICs (telecommunication ICs) have adopted lateral IGBTs or MOS gated thyristors because of the ease of gate drive. All the commercialized SLICs, so far,

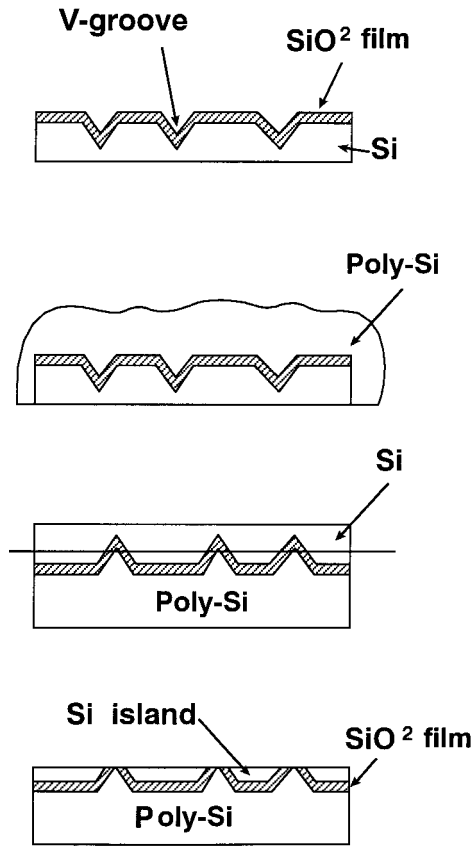

FIGURE 8.10 Fabrication process of EPIC wafers. A very thick poly-crystalline silicon layer is deposited on oxidized single-crystal silicon with a grooved surface. The crystalline silicon is grounded and polished so that the silicon layers isolate each other by the grooves.

have adopted the conventional DI method. The success of SLIC was supported by the fact that monolithic integration and added function deserved expensive DIs for telecommunications application.

In the 1990s, wafer bonding technology was well established and low-cost SOI wafers were made available. A low-cost DI method realized by SOI technology, using several micron thick or less silicon layers, changed the situation of DI research and widened the application fields.

If the silicon layer is thin, devices in the SOI layer are isolated with narrow trenches. This makes SOI technology very attractive for high-voltage applications because chip size can be reduced and resultant chip cost is reduced. The SOI technology widened the application field of DI toward consumer use.

High-voltage SOI research work started in the early 1990s. Research efforts have been directed toward:

1. Monolithic device integration of multiple number of high-voltage, high-current devices with control circuits
2. ICs allowing high temperature operation and ruggedness
3. Low-cost DI power IC process development
4. High-current, high-speed, MOS-controlled lateral output devices with self-protection functions

8.3 High-Voltage Technology

It is quite important to realize a high breakdown voltage in an integrated device structure. There are two major techniques for high-voltage power ICs. These are the field plate and resurf techniques.

Field Plate

It is very important to realize a high breakdown voltage in a planar device structure. In other words, it is ideal if a one-dimensional pn junction breakdown voltage is realized in an actual pn junction, formed by thermal impurity diffusion. Actual pn junctions consist of cylindrical junctions and spherical junctions near the surface. Generally, the breakdown voltage of cylindrical or spherical junctions is significantly lower than that of an ideal 1-D planar junction, if junction curvature is small.

A *field plate* is a simple and frequently used technique to increase the breakdown voltage of an actual planar junction. Figure 8.11 shows an example. Field plates, placed on the thick-field oxide, induce depletion layers underneath themselves. The curvature of the formed depletion layers can be increased with the induced depletion layers, thereby relaxing the curvature effects of the field plate.

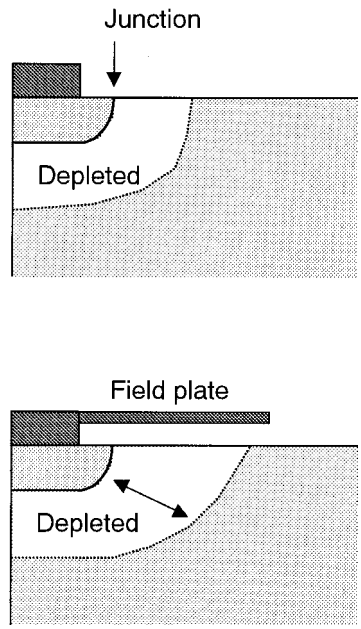

FIGURE 8.11 Field plate structure.

Resurf Technique

The *resurf* technique was originally proposed in 1979[14] as a method to obtain a high breakdown voltage in a conventional JI structure, where the breakdown voltage is limited by the thickness of the epitaxial layer. Figure 8.12 shows a high-voltage structure, where the depletion layer develops in the p-substrate and n-epitaxial-layer. If the epi-layer is thick or impurity doping is high (a), breakdown occurs before n-epi layer is completely depleted. If an appropriate epi-layer thickness is chosen (b), the epi-layer is completely depleted when breakdown occurs. The achieved breakdown voltage is very high because the depletion layer is sufficiently thick, both in lateral direction and vertical direction. The important point is that the total charge Q_c in the epi-layer is chosen so that the value satisfies the equation:

$$Q_c = \varepsilon E_c \tag{8.1}$$

where E_c denotes critical electric field in silicon (3×10^5 V/cm). This charge can be depleted just when the electric field becomes E_c or breakdown occurs. In other words, the epi-layer is completely depleted just when breakdown occurs, if the total epi-layer dose is Q_c/q, which is approximately $2 \times 10^{12}/cm^2$.

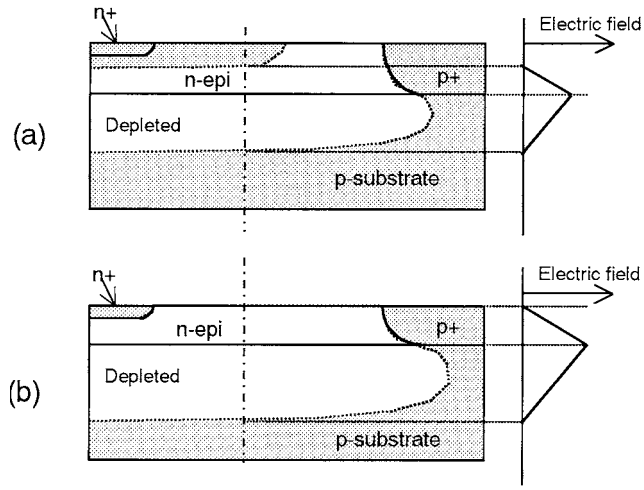

FIGURE 8.12 Resurf technique.

8.4 High-Voltage Metal Interconnection

In high-voltage power ICs, there must be interconnection layers crossing high-voltage junctions. These high-voltage interconnection layers may cause degradation of the breakdown voltage of high-voltage devices. These problems are often solved with a thicker insulator layer under the interconnection layers. However, special means are required if the breakdown voltage is over 400 V.

Figure 8.13 shows one of the methods to shield the influence of metal interconnection layers on the underlying devices. A spiral-shaped high-resistance poly-silicon layer, connecting source and drain electrodes, effectively shields the influence of the interconnection layer on the depletion layer.[22] This is because the potential of the high-resistance poly-silicon layer is determined by small leakage current.

Another typical example is multiple floating field plates. The cross-section of the structure is similar to Fig. 8.13. The difference is that the poly-silicon forms multiple closed field rings, which are electrically floating each other. Multiple floating field plates also prevent breakdown voltage reduction due to metal interconnection.

8.5 High-Voltage SOI Technology

SOI power ICs are classified into two categories from the viewpoint of SOI wafer structure. The difference is whether there is a buried n^+ layer on the buried oxide. Figure 8.14 shows a typical device structure, employing an n^+ buried layer on the buried oxide. The breakdown voltage is determined with the thickness of the high-resistivity n-layer or the thickness of the depletion layer. The maximum breakdown voltage is limited to below 100 V because of SOI layer thickness or practically available trench depth. For this case, SOI wafers are used as a simple replacement for conventional DI wafers.

Figure 8.15 shows another typical SOI power IC structure, employing a high-voltage lateral IGBT. The n^- drift layer is fully depleted by application of a high voltage. As the buried oxide and the depletion layer both share the applied voltage, high breakdown voltage is realized in a relatively thin SOI. This type of power IC fully enjoys the features of SOI technology:

1. Complete device isolation by trench technique and small isolation region
2. Virtually no parasitic active component
3. A high breakdown voltage exceeding 500 V is realized by applying a large portion of the voltage across the thick buried oxide

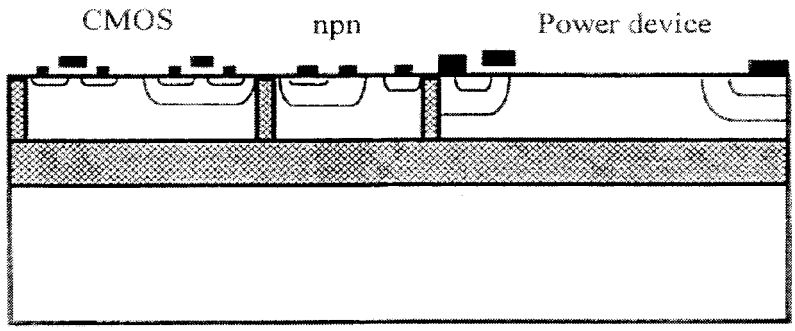

FIGURE 8.15 A high-voltage SOI device structure without n^+ buried layer on the buried oxide.

4. Small wafer warpage and fine lithography is applicable
5. High-temperature operation is possible

There are two big issues associated with high-voltage devices on SOI.[11] One is how to realize a high breakdown voltage under the influence of substrate ground potential. The other is how to attain a low on-resistance with a thin silicon layer. In the conventional DI, the wrap-around n^+ region (see Fig. 8.14) is used in the DI island to prevent the influence of substrate potential on the device breakdown voltage. However, for thin silicon layers, this method cannot be used. The bottom silicon dioxide layer simply works as an undoped layer as far as the Poisson equation is concerned. Thus, a SOI layer on a grounded silicon substrate structure behaves in a way similar to the structure of a doped n-type thin silicon layer on undoped silicon layer (corresponding to silicon dioxide) on a grounded p silicon substrate. Thus, the SOI layer works in the same way as a resurf layer.

A high breakdown voltage of a thin silicon layer device can be realized by sharing a large applied voltage with the buried dioxide film, whose breakdown field is far greater than that of silicon. The buried oxide film is able to sustain a large share of applied voltage, because the dielectric breakdown field is larger than that of silicon.

Figure 8.16 shows a typical SOI diode structure and its potential distribution. It is seen that almost a half of the voltage is applied across the buried oxide. Figure 8.17 shows the electric field distribution along the symmetry axis of the diode of Fig. 8.16. The electric field in the oxide is larger than that in silicon because the following relation holds.

The two electric field components $E_t(Si)$, $E_t(I)$, normal to the interface of the silicon and the bottom insulator layer, have the relation:

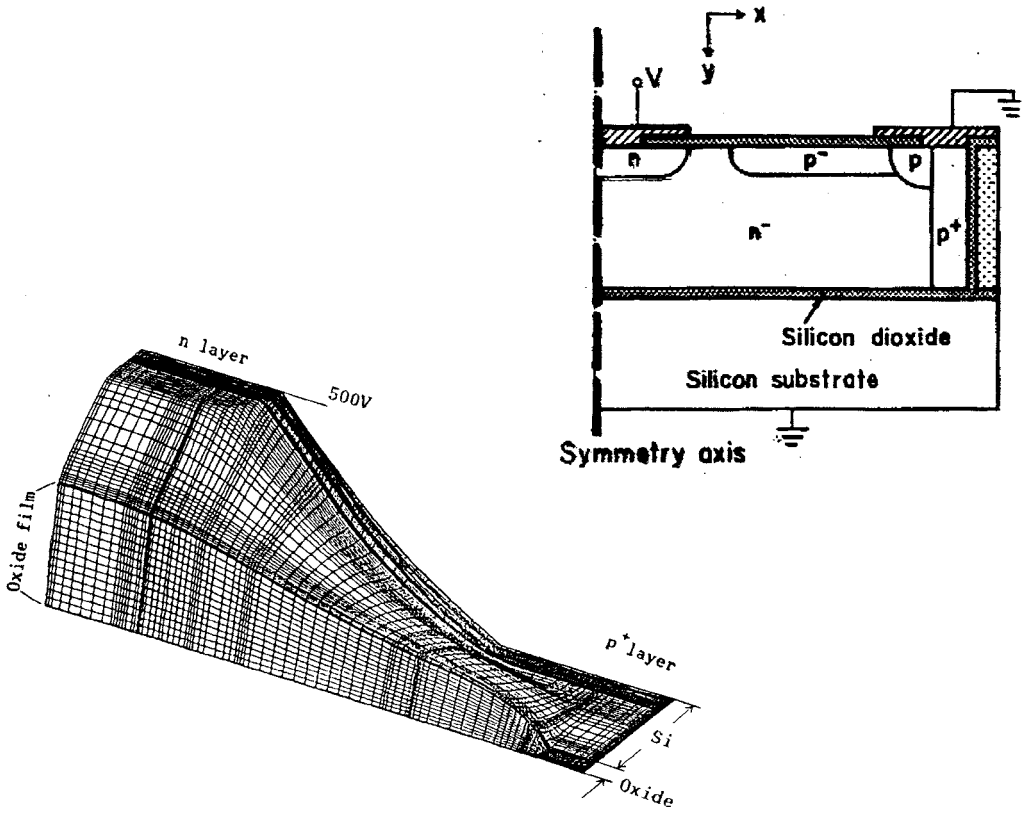

FIGURE 8.16 SOI diode and potential distribution in the diode.

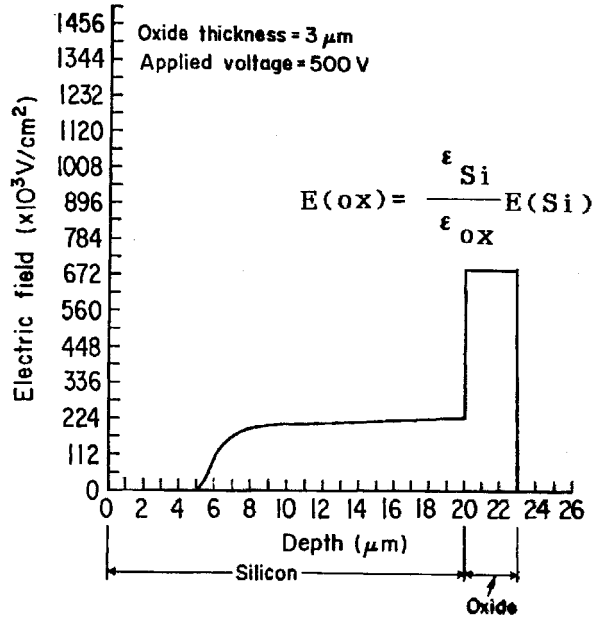

FIGURE 8.17 Electric field distribution along the symmetry axis of diode shown in Fig. 8.16.

$$\varepsilon(\mathrm{Si})E_t(\mathrm{Si}) = \varepsilon(\mathrm{I})E_t(\mathrm{I}) \tag{8.2}$$

where $\varepsilon(\mathrm{Si})$, $\varepsilon(\mathrm{I})$ denote dielectric constants for silicon and silicon dioxide, respectively. Using an insulator film with a lower dielectric constant will increase the device breakdown voltage because the insulator layer sustains a larger share of the applied voltage.

For optimized SOI diodes, the breakdown voltage is substantially limited to the breakdown voltage of the 1-D MOS diode portion, as illustrated in Fig. 8.18, consisting of n^+/n^-/oxide/substrate. Figure 8.19 shows the measured SOI device breakdown voltage as a function of SOI layer thickness with buried oxide thickness as a parameter. The calculated breakdown voltage of 1-D MOS diodes are shown together. A 500-V breakdown voltage can be obtained with a 13-μm thick SOI with 3-μm thick buried oxide.

It is very difficult to achieve a high breakdown voltage exceeding 600 V in simple SOI structures, because a thicker buried oxide layer of 4 μm or more is required. Maximum breakdown voltage is substantially limited with the breakdown voltage of the 1-D MOS diode and actually the realized

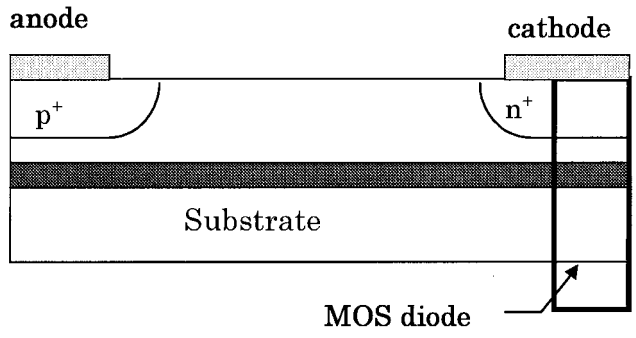

FIGURE 8.18 1-D MOS-diode structure in SOI diode.

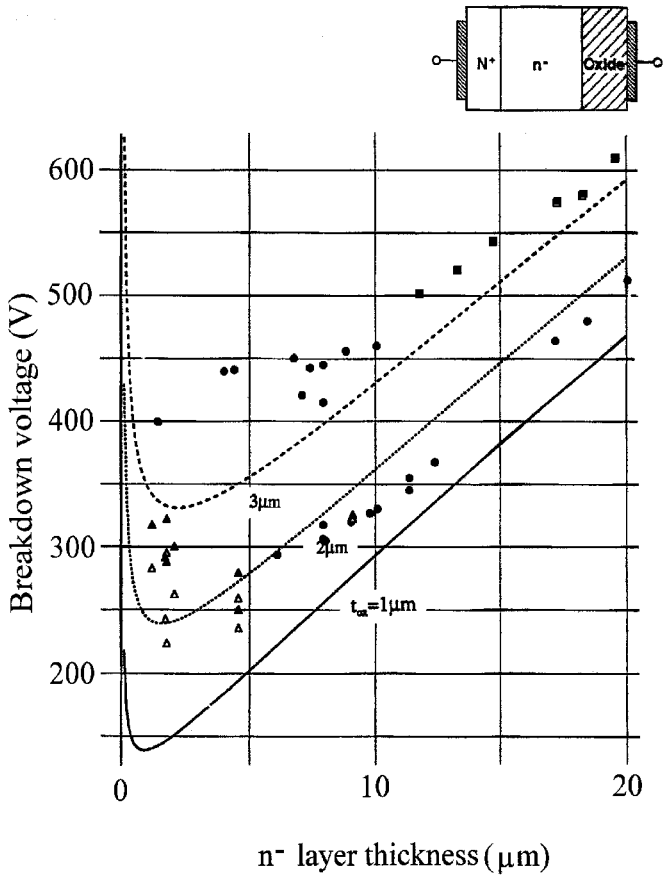

FIGURE 8.19 Measured and calculated SOI device breakdown voltage.

breakdown voltage is lower than this limit. If the influence of the substrate potential can be shielded, it is possible to achieve a higher breakdown voltage in the SOI device.

A new high-voltage SOI device structure, free from the above constraints, was proposed in 1991,[1] that realizes a 1200-V breakdown voltage.[23]

To improve the breakdown voltage, an SOI structure with a shallow n^+ layer diffused from the bottom of SOI layer was proposed.[24] Figure 8.20 shows the structure of an SOI diode with a shallow n^+ layer and the electric field strength in the MOS diode portion compared to that without a shallow n^+ layer. In general, if a larger portion of the applied voltage is carried with the bottom oxide layer, a higher breakdown voltage can be achieved. The problem is how to apply a higher electric field across the buried oxide without increasing the electric field strength in the SOI layer. This problem can be solved by placing a certain amount of positive charge on the SOI layer– buried oxide interface. The positive charge at the interface shields the high electric field in the buried oxide, so that a voltage across the oxide layer can be increased without applying a higher electric field in the SOI layer. The shallow n^+ layer diffused from the bottom is a practical technique to place the positive charge on the SOI layer–buried oxide interface, as shown in Fig 8.20. The required dose of the shallow n^+ layer is around $1 \times 10^{12}\text{cm}^{-2}$.

Very Thin SOI Case

Merchant et al.[25] showed that the SOI diode breakdown voltage is significantly enhanced if the SOI layer thickness is very thin, such as 0.1 μm. As shown in Fig. 8.19, reduction in the SOI layer thickness enhances

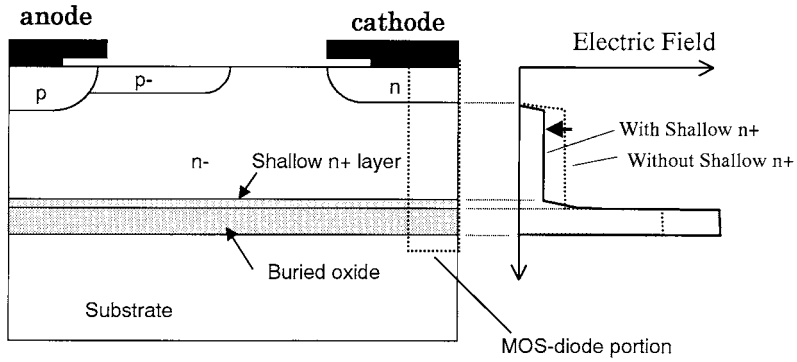

FIGURE 8.20 SOI diode with shallow n^+ layer diffused from the bottom of the SOI layer.

the breakdown voltage if the thickness is less than 1 μm. This is because the carrier path along the vertical high electric field is as short as the SOI layer thickness, so that the carriers reach the top or bottom surface of the SOI layer before ionizing a sufficient amount of carriers for avalanche multiplication along the path. They proposed a combination of the very thin SOI layer and a linearly graded impurity profile of the n-type silicon layer for a high-voltage $n^+n^-p^+$ lateral diode. A 700-V breakdown voltage was realized by this structure.

The exact 2-D simulations revealed that the ideal profile for a lateral diode is approximated by a function that is similar to a tangent function, as shown in Fig. 8.21. The important point is that the p-layer impurity profile should also be graded and that the linearly graded portion is terminated with the exponentially increasing ending portions. By using the proposed profile, a 5000-V lateral diode was predicted to be realized on 0.1-μm SOI on a 600-μm thick quartz substrate. A completely uniform lateral electric field is realized at 5000 V (see Fig. 8.21).

8.6 High-Voltage Output Devices

High-voltage output devices are the most important part of power ICs. An entire power system can be integrated on a single silicon chip if high-voltage power devices can be integrated with analog and digital circuits as well as MPUs. Recently, MOS gate power devices were adopted, primarily because of the low on-resistance and the ease of gate control. These are DMOSFETs and IGBTs.

Lateral Power MOSFET

pn junction-isolated power ICs are frequently used for low-voltage applications, where DMOS is the primary choice for output devices. Since the reliability of junction isolation is not sufficient, SOI DMOS power ICs will be used where high reliability is required. In this section, DMOS electrical characteristics are described, using mostly the junction-isolated DMOS data.

For above a 60-V breakdown voltage range, the vertical DMOS structure with upside surface drain contact (up-drain DMOS, see Fig. 8.22) has conventionally been used. However, recently, the lateral DMOS (LDMOS) structure (Fig. 8.23) tends to be used for the entire voltage range. This is because the LDMOS on-resistance can be directly improved by adopting finer lithography. On the other hand, up-drain vertical DMOS on-resistance includes the resistances of the buried n^+ layer and sinker plug diffusions, which are not improved by finer lithography.

Figure 8.24 shows state-of-the-art DMOS on-resistance as a function of breakdown voltage. The figure also shows state-of-the-art on-resistance for vertical discrete trench MOSFETs as a comparison. Black circles show lateral DMOS, and open squares show trench MOSFETs. Recently, battery-operated mobile equipment and computer peripherals have opened a large applications area, and lateral MOSFETs of the less than 60 V are the major output devices. It is astonishing that the state-of-the-art on-resistances of

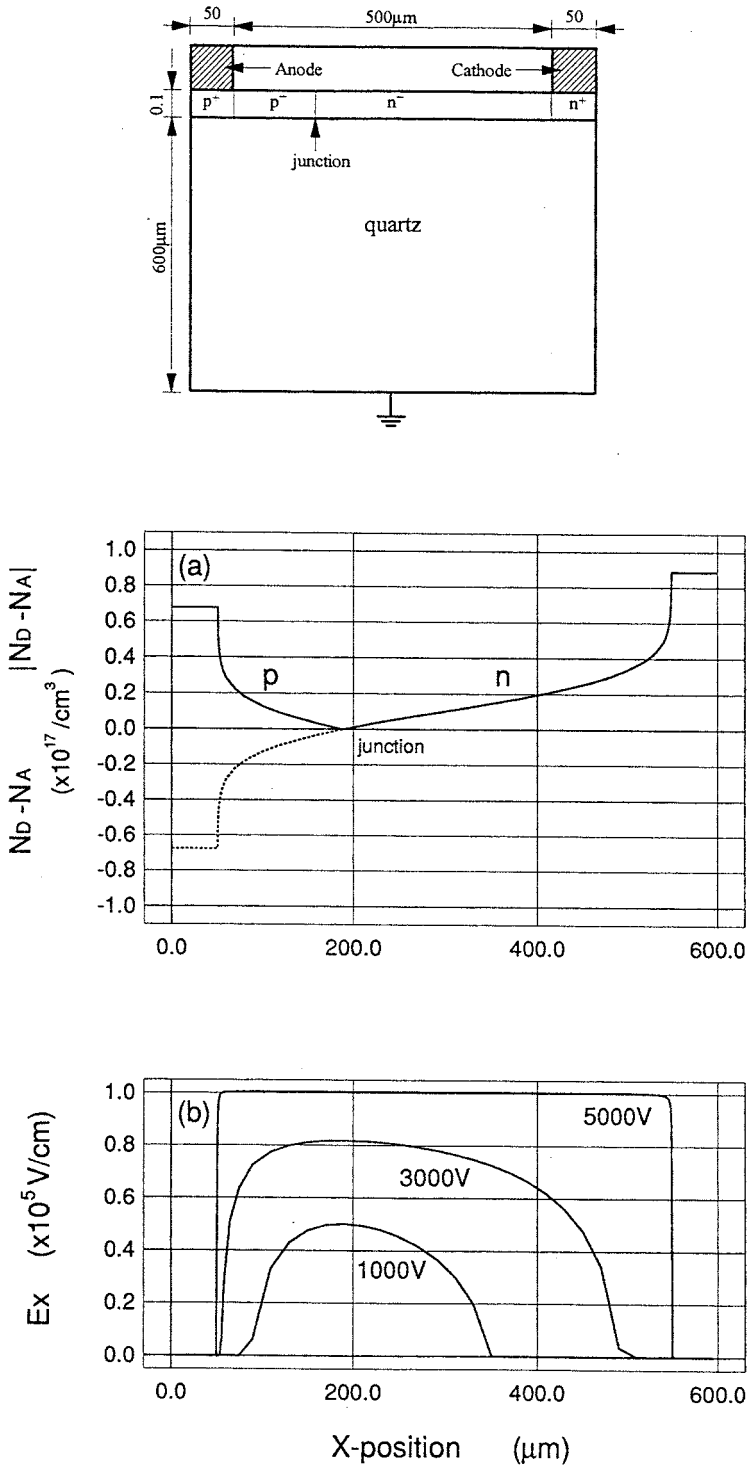

FIGURE 8.21 Calculated ideal profile for a lateral diode on thin SOI.

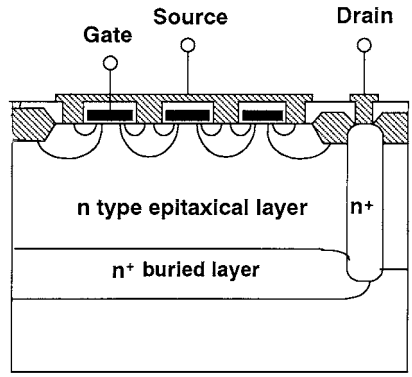

FIGURE 8.22 Vertical DMOS structure with upside surface drain contact.

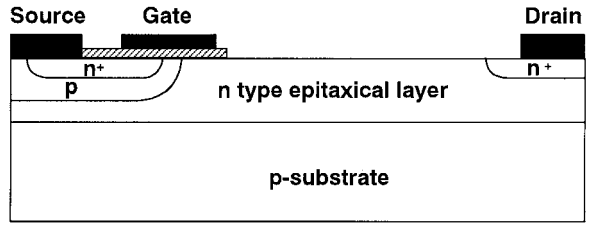

FIGURE 8.23 Lateral DMOS (LDMOS) structure.

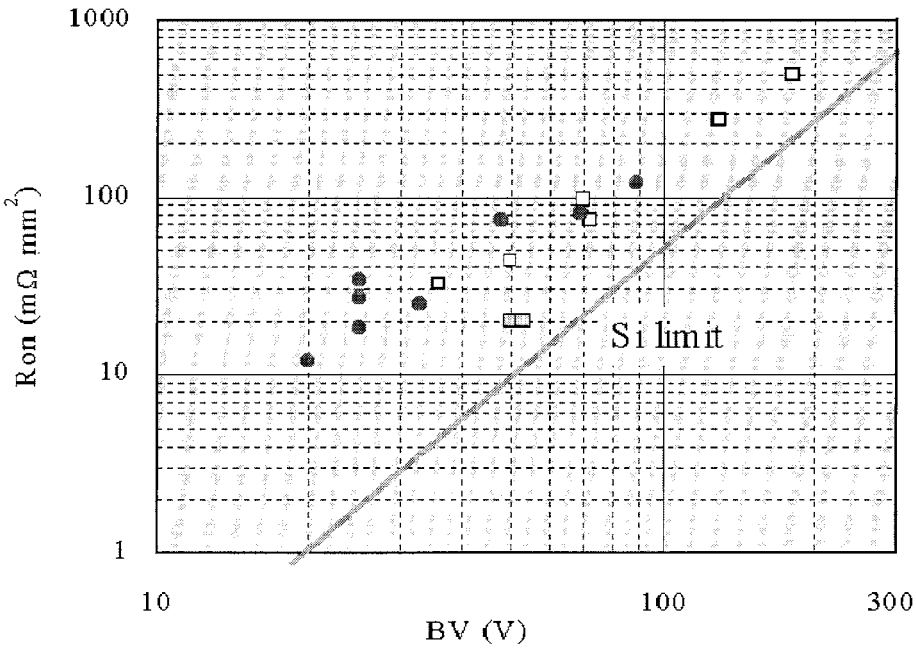

FIGURE 8.24 State-of-the-art lateral DMOS and vertical trench MOSFET on-resistance as a function of breakdown voltage (black circles show lateral DMOS, and open squares show trench MOSFETs).

lateral DMOS and vertical trench MOSFETs are almost the same. This implies that power ICs with a vertical DMOS output will be replaced by power ICs with a lateral DMOS output, if current capacity is small — for example, less than 10 A.

High-side switching operation is an important function in automotive applications, especially in case of H-bridges for motor control. The on-resistance of conventional junction-isolated, high-voltage MOSFETs, shown in Fig. 8.23, is significantly influenced by the source to substrate bias,[26] because the drift layer is depleted. However, in the SOI MOSFETs shown in Fig. 8.25, the drift layer is not depleted, but a hole inversion layer is formed. Thus, the substrate bias influence of SOI LDMOS is small.[26]

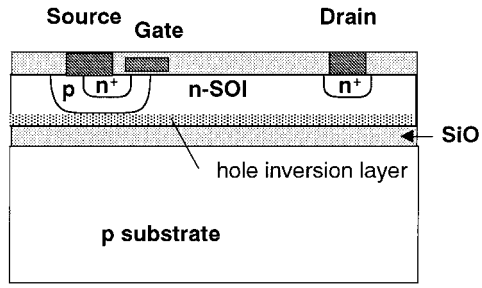

FIGURE 8.25 SOI MOSFET at high-side operation.

Figure 8.26 shows a 60-V DMOS in a 2-μm thick p-type SOI. The fabrication process is completely compatible with the CMOS process. The threshold voltage is controlled by channel implant. The experimentally obtained specific on-resistance of the 60-V LDMOS is 100 $m\Omega \cdot mm^2$.The developed power MOSFET is completely free from substrate bias influence.[27] This is because the hole accumulation layer is induced on the buried oxide, leaving the n-drift layer unchanged. These results indicate that this device can be used for high-side switches without on-resistance increase.

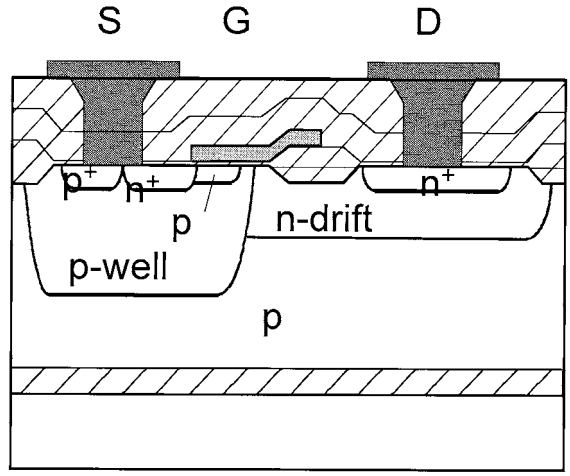

FIGURE 8.26 60-V DMOS in 5-μm thick p-type SOI.

Lateral IGBTs on SOI

IGBTs are suitable for high-voltage, medium current power ICs because of large current capability, as shown in Fig. 8.27. IGBT can be recognized as a pnp transistor driven by an n-channel MOSFET for a

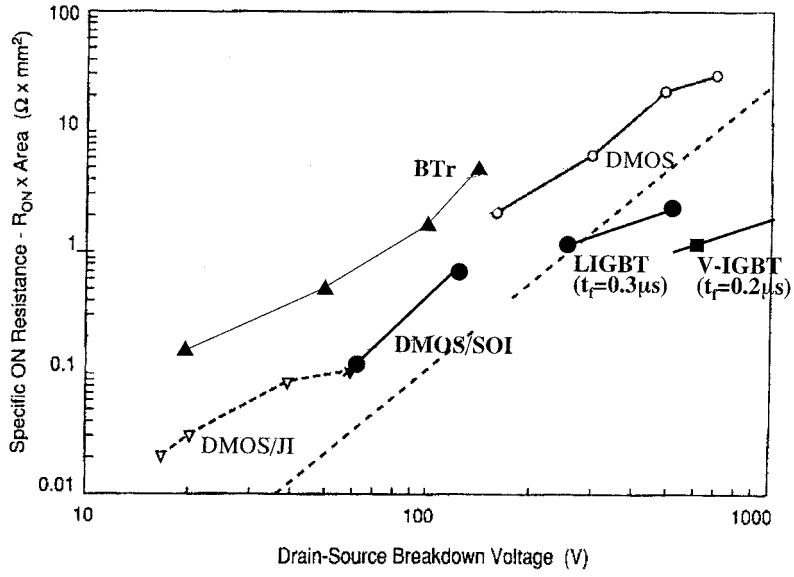

FIGURE 8.27 On-resistance versus breakdown voltage for bipolar transistor, DMOS, LIGBT, and VIGBT (discrete IGBTs).

first order approximation. IGBTs should be fabricated by conventional CMOS-compatible processes so that conventional CMOS circuit libraries can be utilized without changes.

The switching speed of bipolar power devices is conventionally controlled by introduction of a lifetime killer. However, the lifetime control process is not compatible with a conventional CMOS process. There are two ways to control the switching speed of power devices. One way is to use thin SOI layers. The switching speed of IGBTs improves as the SOI thickness decreases,[28] because the carrier lifetime is effectively decreased by the influence of large carrier recombination at the silicon dioxide interfaces.[29] The other way is to reduce the emitter efficiency of the p^+ drain or collector. The effective methods are (1) emitter short, (2) low-dose emitter,[30] (3) high-dose n buffer, and (4) forming an n^+ layer in the p^+ emitter.[31]

Figure 8.28 shows a cross-section of large current lateral IGBTs. Large current capability has been realized by adopting multiple surface channels. Figure 8.29 shows typical current voltage curves of the multi-channel LIGBT. The current is an exponential function of the drain bias (collector bias) for the low-voltage range. The current-voltage curves seem to have a 0.8-V offset voltage, just like a diode. The typical switching speed of the developed LIGBTs is 300 ns.

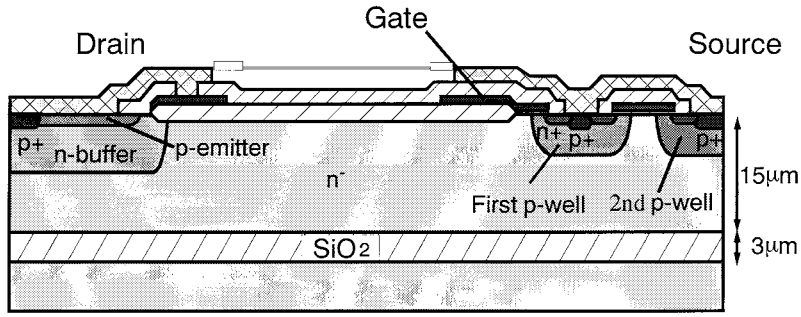

FIGURE 8.28 Cross-section of large current lateral IGBT.[30] (Copyright (1997) IEEE. With permission.)

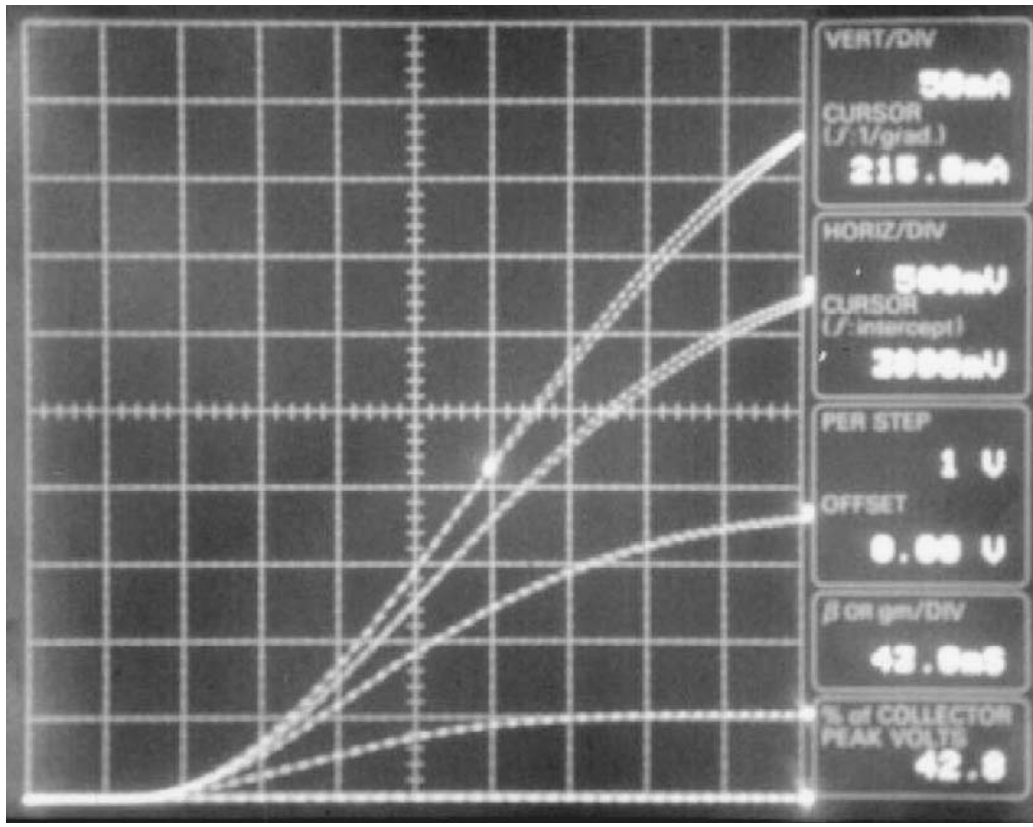

FIGURE 8.29 Typical current-voltage curves of a multi-channel LIGBT (Vertical scale: 50 mA/Div, Horizontal scale: 0.5 V/Div).

It is extremely important to increase the operating current density of LIGBTs in order to reduce chip size. This is because output devices occupy most of the chip area and the cost of the power ICs depends significantly on the size of the power devices. The current density of the developed LIGBT is 175 A/cm^2 for 3-V forward voltage.

8.7 Sense and Protection Circuit

Power ICs have a significant advantage over discrete devices in terms of power switch protection because the protection circuit can be integrated on the same chip. Figure 8.30(a) shows the over-temperature sense circuit. In this circuit, the junction temperature dependence of diode forward voltage drop is utilized to sense the temperature. The series diodes are located close to the power switches so that the junction temperature of the diodes responds to the temperature at the power switches. Comparing the forward voltage drop across the diodes with the reference voltage, the circuit senses the over-temperature at the power switches and the fault signal is fed back to the gate control logic.

Figure 8.30(b) shows the over-current sense circuit for bipolar power transistors. The magnitude of the current through the main transistor is reflected to the current through the sense transistor with the current mirror circuit configuration. Therefore, the voltage drop across the resistor in the collector of the sense transistor is proportional to the current through the main transistor. Comparing the voltage drop with the reference voltage, the circuit detects the over-current. Figure 8.30(c) shows the over-current sense circuit for IGBTs or MOSFETs, which has a similar configuration with Fig. 8.30(b). In this circuit, the over-current is detected by the voltage drop across the resistor in the sense IGBT (MOSFET) emitter (source).

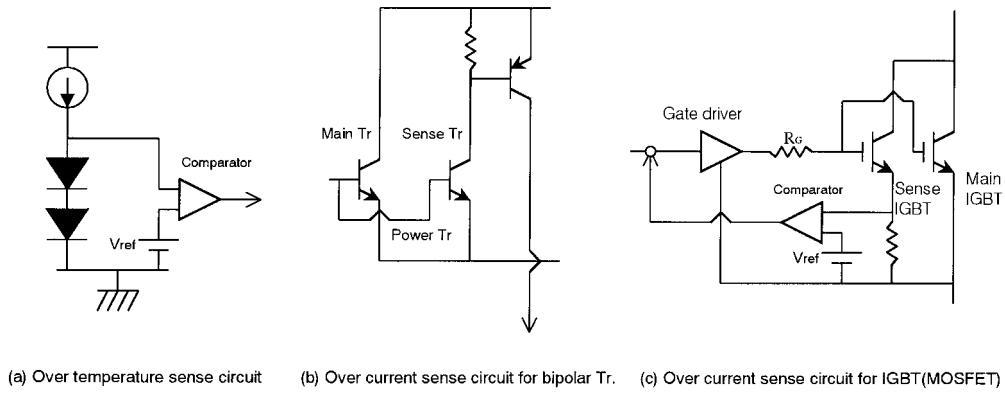

FIGURE 8.30 Sense circuits for over-temperature and over-current.

In short-circuit protection, the collector current should be squeezed or terminated as soon as the short-circuit operation is detected. For this purpose, the protection circuit directly draws down the gate voltage with the short feedback loop. Figure 8.31 shows a typical short-circuit protection circuit for IGBTs. When high current flows through the IGBT, the voltage drop across the emitter resistor of the sense IGBT directly drives the npn transistor. The transistor draws down the gate voltage so that the collector current is reduced to the level of a safe turn-off operation.

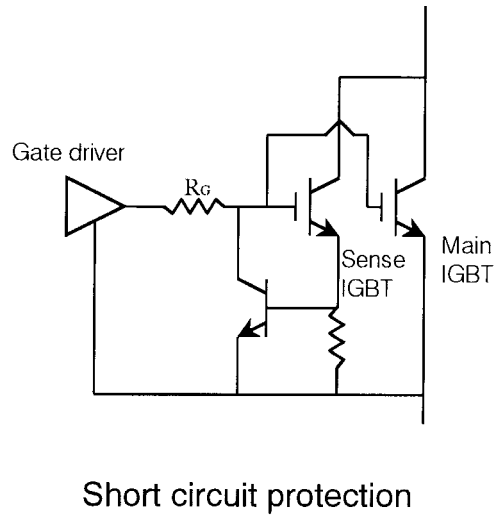

FIGURE 8.31 Typical short-circuit protection method for IGBTs.

8.8 Examples of High-Voltage SOI Power ICs with LIGBT Outputs

Current main applications of high voltage SOI power ICs are dc motor control and flat-panel display drivers. Recently, technologies for color plasma display panels have been greatly improved, and demands for PDP driver ICs have increased. There are several reports[32,33] on the development of such ICs using SOI wafers. Flat-panel display drivers have to integrate a large number of high-voltage devices. Trench isolation and LIGBTs are key techniques for reducing chip size and resultant cost.

Another large market is the motor control field. Home-use appliances use a number of small motors, which are directly controlled by a ac source line. Single-chip inverter ICs are able to reduce system size and increase system performance. Figure 8.32 shows a 500-V, 1-A, single-chip inverter IC[34] for dc brushless motors. It integrates six 500-V, 1-A LIGBTs, six 500-V diodes, control protection, and logic circuits.

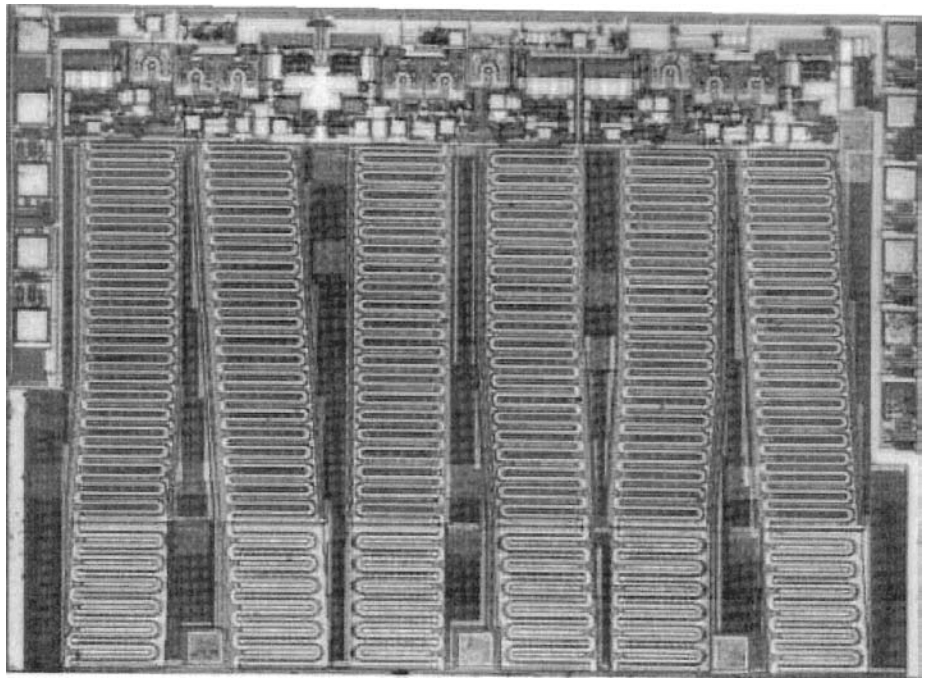

FIGURE 8.32 Photograph of a 500-V, 1-A single-chip inverter.

8.9 SOI Power ICs for System Integration

Another prospective application of SOI technology is in the automotive field, which requires large current DMOS outputs. Conventional pn junction-isolated power ICs are frequently used for these applications; however, the reliability of junction isolation is not sufficient. SOI DMOS power ICs will be used where high reliability is required.

For less than 100-V applications, the required thickness of the buried oxide layer is less than 1 μm. The warpage of the SOI wafers is very small; thus, fine lithography can be applied. The same CMOS circuit library can be used without changes because the same CMOS fabrication process can be applied without modification if a relatively thick SOI layer is used.

This section shows the possibility of integration of an MPU, together with BiCMOS analog circuits and 60-V power LDMOS. 4-bit MPUs, vertical npn, pnp, and 60-V power DMOS were fabricated on 2-μm SOI wafers by a conventional 0.8-μm BiCMOS process.[27] The 60-V DMOS used CMOS p-well without using self-alignment.

The fabricated 4-bit MPU, consisting of 30,000 FETs for the core, 6000 FETs for the cache, and 120,000 FETs for the ROM, operated at a 20% faster clock speed of 50 MHz at 25°C, as compared to 42 MHz of the bulk version MPU, and even operated at over 200°C. It was found that the clock speed could be improved and that a large latch-up immunity at high temperature was realized even if the MOSFETs were not isolated by trenches. The maximum operating temperature was more than 300°C. It was found that the yield of the MPU fabricated on SOI was the same as that on bulk wafers, verifying that the crystal

quality of the currently available SOI wafers was sufficiently good. It was also found that both SOI and bulk MPUs could be operated at 300°C if MPUs consisted of pure CMOS, although the power consumption of the bulk MPU was larger than that of the SOI MPUs.

One of the characteristic features of the SOI power IC structure, shown in Fig. 8.33, is that there are no buried layers for bipolar transistors. It was found that vertical npn and pnp transistors fabricated on the n-well and p-well layers exhibited sufficiently good characteristics, and the typical current gains h_{FE} for the vertical npn and pnp transistors were 80 and 30, respectively.

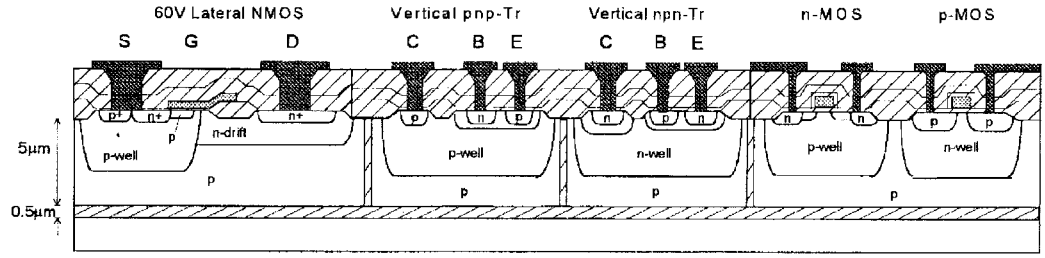

FIGURE 8.33 SOI power IC system integration.

All these results show that system integration including power LDMOS will be a reality in SOI wafers.

8.10 High-Temperature Operation of SOI Power ICs

The leakage current of SOI devices simply reduces as the SOI layer becomes thinner, as seen in Fig. 8.34.[35] Small leakage current enables high-temperature operation of SOI power ICs. It was experimentally shown

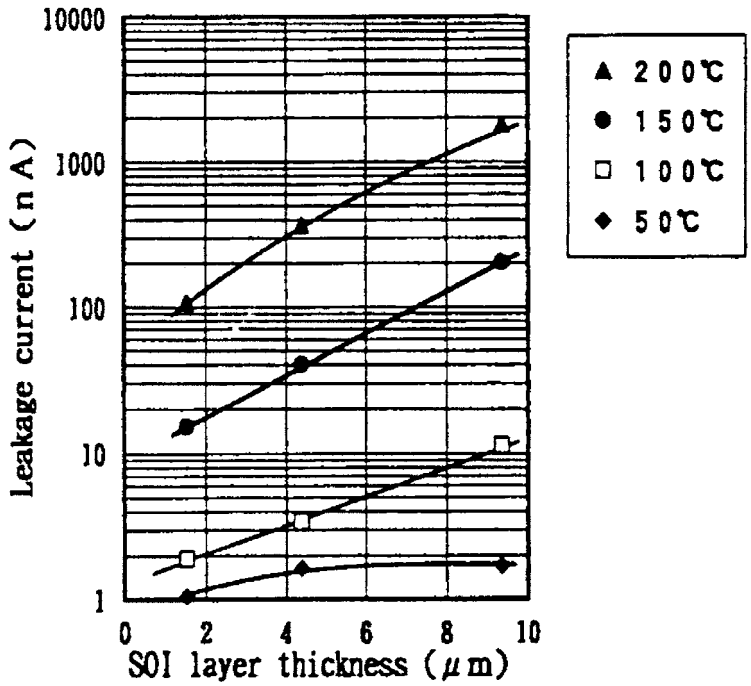

FIGURE 8.34 Leakage current vs. SOI layer thickness. (Copyright (1994) IEEE. With permission.)

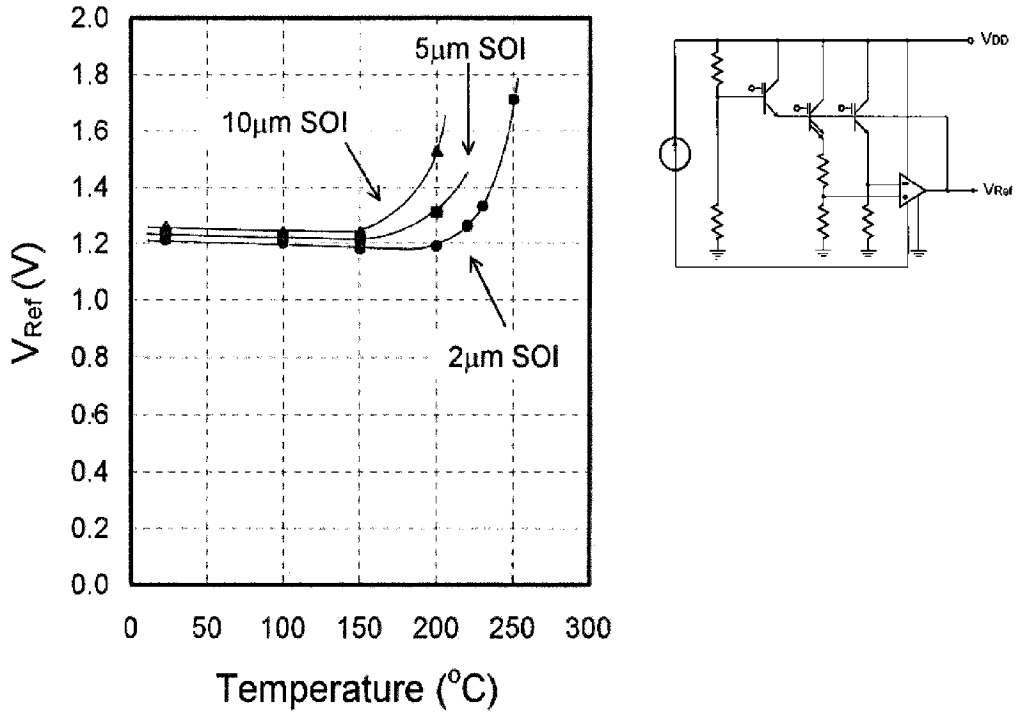

FIGURE 8.35 Output voltage of a bandgap reference circuit as a function of operation temperature. (Copyright (1995) IEEE. With permission.)

that IGBTs can be operated at a switching frequency of 20 kHz at 200°C if they are fabricated in thin SOI of less than 5 μm. The maximum operating temperature of analog circuits in SOI increases as the SOI layer becomes thinner. Figure 8.35 shows the output voltage of bandgap reference circuits as a function of temperature with SOI thickness as a parameter. In the circuits, each device was not trench-isolated. If all the devices are trench-isolated, much higher temperature operation can be expected.

The 200°C operation of 250-V, 0.5-A, three-phase, 1-chip inverter ICs fabricated in a 5-μm thick SOI layer was demonstrated.[36] CMOS circuits on SOI were found to be capable of operating at 300°C. CMOS-based analog circuits with a minimum number of bipolar transistors were adopted. It was found that the bandgap reference circuit operated at 250°C, which was higher than that expected from Fig. 8.34. This was probably because each device was trench-isolated. A DC brushless motor was successfully operated by the single-chip inverter IC at 200°C. The carrier frequency was 20 kHz.

Lucent Technologies

9.1 Introduction

The progress of VLSI technologies is a result of an intimate interaction between improvements in IC chip design and in device properties of the underlying process technologies. The semiconductor roadmap following Moore's law is responsible for an exponential decrease of minimum feature size of devices. The associated increase of device speed and decrease of supply voltage have strong implications for the available noise margin of a VLSI chip. This chapter addresses the main issues relevant for noise in VLSI technologies at various levels as indicated schematically in Fig. 9.1. At the microscopic level, the fundamental sources of noise associated with carrier transport are derived with emphasis on semiconductors. The next level deals with the noise properties of active devices and passive components. Three classes of active devices are chosen for illustration: bipolar junction transistors (BJTs), field effect transistors (FETs), and two terminal junction devices (diodes). Although the treatment of these device classes implies silicon-based technologies (Si-BJT, Si-MOSFET, Si-diode), it can generally be applied to other device classes as well (HBT, MESFET, etc.). Finally, the chip level noise is presented in terms of the major contributions being amplifier noise, oscillator noise, timing jitter, and interconnect noise. The evolution of VLSI technologies into the deep-sub-micron regime has significant implications for the treatment of fundamental noise mechanisms, which are briefly outlined in the last section of the chapter.

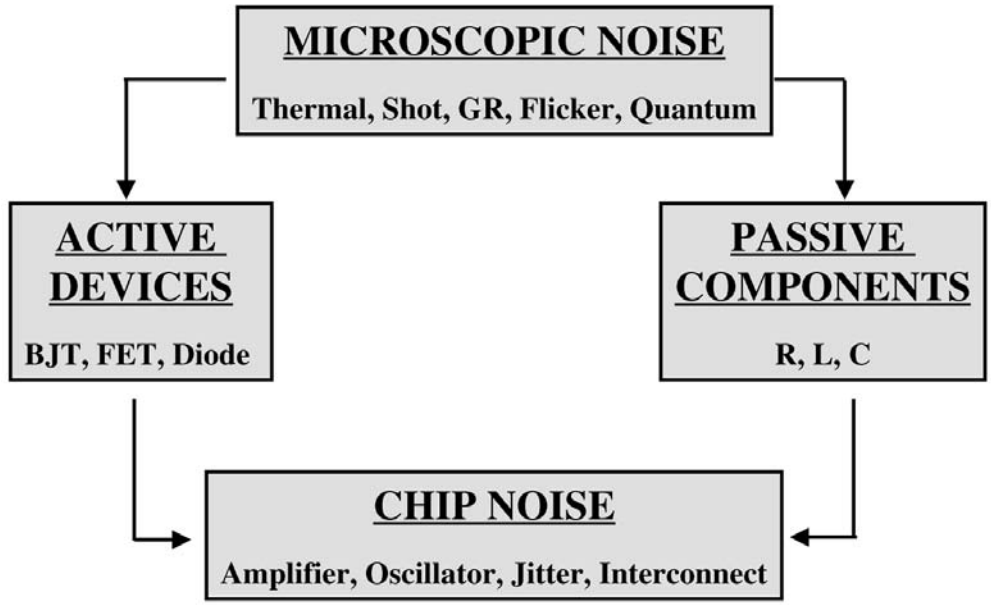

FIGURE 9.1 Schematic describing the various levels of noise studied in this chapter and their causal relationship.

9.2 Microscopic Noise

Thermal Noise

Thermal noise is, in general, associated with random motion of particles in a force-free environment. Since the mean available energy per degree of freedom is proportional to temperature, the resulting noise is referred to as thermal noise. Specifically, carrier transport in semiconductors is treated by considering energy distribution functions, such as the Fermi-Dirac distribution. The effect of local fields and scattering of carriers in position and momentum space is described by a change in the distribution function. This is expressed by the Boltzmann transport equation. Noise is a stochastic process and is characterized in terms of time-averaged quantities, as the instantaneous value cannot be predicted. The fundamental origins of thermal noise in semiconductors are microscopic velocity fluctuations. Velocity fluctuations occur due to various mechanisms, such as electron-phonon scattering, electron-electron scattering, etc. Since the same mechanisms give rise to macroscopic resistivity of a material, noise can be viewed as the microscopic property of transport. Consequently, noise is intimately related to bulk transport in a semiconductor. The voltage noise spectral density is given by:

$$S_{\Delta v}(\omega) = 2 \cdot \int_{-\infty}^{\infty} \langle \Delta v(t) \Delta v(t+\tau) \rangle e^{j\omega\tau} d\tau \tag{9.1}$$

In the above expression, $\Delta v(t)$ denotes the instantaneous velocity fluctuation, ω the frequency, and S the spectral density of noise. Velocity fluctuations can also be viewed as the driving force for diffusion, where the diffusion coefficient is given by:

$$D(\omega) = \int_0^{\infty} \langle \Delta v | \Delta v(t+\tau) \rangle e^{-j\omega\tau} d\tau \tag{8.2}$$

Therefore, the voltage noise spectral density can be directly related to the real part of the frequency-dependent diffusion function as:

$$S_{\Delta v}(\omega) = 4 \cdot \mathrm{Re}[D(\omega)] \tag{9.3}$$

The current noise spectral density due to a charge q in a slab of material of length L can be derived from the carrier velocity fluctuation as:

$$S_{\Delta i}(\omega) = \frac{q^2}{L^2} \cdot S_{\Delta v}(\omega) \tag{9.4}$$

The current noise spectral density of the whole slab of material of area A is then obtained by integrating the carrier density n(x) and the diffusion coefficient over the length of the sample, as given by:

$$S_I(\omega) = \frac{4q^2 A}{L^2} \cdot \int_0^L n(x) \mathrm{Re}[D(\omega, x)] dx \tag{9.5}$$

In the limit of uniform carrier density, thermal equilibrium, and neglecting quantum effects, the diffusion coefficient can be expressed in terms of the carrier mobility using the Einstein relation:

$$D = \frac{kT}{q}\mu \tag{9.6}$$

and the current noise spectral density is given by:

$$S_I(\omega) = 4kT \cdot \left(nq\mu \cdot \frac{A}{L} \right) \tag{9.7}$$

The above expression leads to the well-known Johnson thermal noise of a conductance $G = \sigma A/L$, where the conductivity is $\sigma = nq\mu$ and the carrier mobility is denoted by μ:

$$S_I(\omega) = 4kT \cdot G(\omega) \tag{9.8}$$

In general, the conductance is the real part of the frequency-dependent admittance of the material as indicated above. Note that the thermal noise expression given here is valid only when the mean scattering time of the carriers is negligible with respect to the inverse of the frequency at which the noise is measured. This assumption is true for most studies of semiconductors where the mean scattering times are on the order of 1 ps. The generalized expression for finite scattering times is discussed in a later section. The thermal noise expression also provides a direct relation between the microscopic noise and the bulk resistance (conductance), indicating the nature of noise as being due to the same type of scattering mechanisms as those causing resistance in a sample. A prominent feature of thermal noise is its direct dependence on temperature, giving rise to the possibility of measuring a thermodynamic quantity with noise.

Shot Noise

The discrete nature of particles undergoing an average flow in space, together with their velocity distribution, results in a random arrival at a fixed plane of incidence. The corresponding fluctuations of the flow are referred to as *shot noise*. Specifically, the discrete flow of charge in a field yields shot noise of current in semiconductors. Shot noise can be derived as being due to a random train of pulses corresponding to events, such as carrier emission from an electrode, carrier injection across a semiconductor junction, etc. The power spectral density of the resulting time-dependent waveform is given by:

$$S(\omega) = 2\nu \cdot \langle a^2 \rangle \cdot |F(\omega)|^2 \tag{9.9}$$

Here, $F(\omega)$ is the Fourier transform of the impulse function, ν the mean rate of the events, and $\langle a^2 \rangle$ the mean square amplitude of the pulses. For a current pulse $\delta i(t)$ due to the transit of a charge q through a sample, the Fourier transform is given by:

$$F(\omega) = \frac{1}{q} \cdot \int_0^{\tau_T} \delta i(t) \cdot e^{-j\omega\tau} dt \tag{9.10}$$

At sufficiently low frequencies, the transit time τ_T can be neglected with respect to $1/\omega$, and the current pulse can be considered a delta function. The Fourier transform function then becomes unity. The mean rate of current pulses is $\nu = I/q$, where I is the mean value of the current, and the mean pulse amplitude $\langle a \rangle = q$, so that the power spectral density of shot noise current is given by:

$$S_I(\omega) = 2qI \tag{9.11}$$

Note that the above expression is valid only for negligible transmit times of the carriers through a sample region with respect to the inverse of the frequency at which the noise is measured. The shot noise for non-negligible transit times and scattering times is treated in more detail later. One of the most significant properties of shot noise is its dependence on the mean current flow or bias in a semiconductor, in contrast to thermal noise which is dependent only on the temperature and resistivity of the material. Shot noise can also be measured only when the energy distribution function of the carriers can be probed by a reference plane of incidence, such as a p-n junction in a semiconductor.

Generation-Recombination Noise

The generation and recombination of charge carriers due to traps in semiconductors results in fluctuations of the current flow through the semiconductor. The temporal change in the carrier number N from a rate of generation g(t) and a rate of recombination r(t) is given by:

$$\frac{d(\Delta N)}{dt} = -\frac{\Delta N}{\tau} + \Delta g(t) - \Delta r(t) \tag{9.12}$$

Here, τ is the mean lifetime of the carriers. The noise spectral density of the carrier number fluctuations is found to be:

$$S_N(\omega) = 4\langle \Delta N^2 \rangle \cdot \frac{\tau}{1 + \omega^2\tau^2} \tag{9.13}$$

A current fluctuation is related to a carrier number fluctuation through $\Delta I/I = \Delta N/N$. The current noise spectral density from generation and recombination of carriers is then given by:

$$S_I(\omega) = 4\frac{I_0^2}{N_0^2}\langle \Delta N^2 \rangle \cdot \frac{\tau}{1+\omega^2\tau^2} \tag{9.14}$$

Here, I_0 denotes the mean current and N_0 the mean carrier number. The form of the above expression implies a constant noise power below a characteristic frequency $\omega_c = 1/\tau$, and a $1/\omega^2$ dependence (Lorentzian) at higher frequencies. This type of noise is observed in systems with a single well-defined trapping time constant or energy level of traps. The most significant feature of GR noise is its explicit frequency dependence, in contrast to the "white" spectral densities of thermal and shot noise. This frequency dependence has strong implications for semiconductors, since the characteristic frequency is well within the frequency range of most applications.

Flicker Noise

Flicker noise is, in general, a phenomenon observed in many systems with an inverse frequency dependence of the noise spectral density over a wide frequency regime. In semiconductors, the presence of energy traps can lead to generation and recombination of carriers and a corresponding frequency-dependent noise of the flicker noise type. A phenomenological approach for deriving the frequency dependence of flicker noise is to consider the expression for generation-recombination noise given by:

$$S_I^{\tau}(\omega) = A(I) \cdot \frac{\tau}{1+\omega^2\tau^2} \tag{9.15}$$

Here, A(I) summarizes the current-dependent pre-factor given earlier. A distribution of characteristic time constants given by a probability density $P(\tau)d\tau$ would result in a current noise spectral density of the form:

$$S_I(\omega) = A(I) \cdot \int_{\tau_0}^{\tau_1} \left(\frac{\tau}{1+\omega^2\tau^2} \cdot P(\tau)d\tau \right) \tag{9.16}$$

In the case of MOSFETs, the tunneling of carriers from the channel through an oxide to a trap at a distance x from the channel/oxide interface produces a probability distribution of time constants:

$$P(\tau) \propto \frac{1}{\tau} \tag{9.17}$$

Such a distribution of time constants yields the flicker noise expression for the current noise spectral density:

$$S_I(\omega) \propto \frac{A(I)}{\omega} \tag{9.18}$$

Note that the inverse frequency dependence of the noise is obtained from the integral above with the approximation: $1/\tau_1 < \omega < 1/\tau_0$. The most important characteristic of flicker noise is its explicit inverse frequency dependence, like GR noise. Another feature is the dependence of flicker noise magnitude on material properties such as trap densities, carrier mobility, etc. Consequently, no general form can be given for the flicker noise of semiconductors, but specific devices need to be considered.

Although the overall frequency dependence of flicker noise is universally found to be inversely proportional to frequency in semiconductors, the expression for the amplitude of flicker noise is strongly dependent on device technology. In general, for Si-BJTs and Si-MOSFETs, the flicker noise power is found to increase with bias current according to a power-law as given by:

$$S_I(\omega) = K \cdot \frac{I^{\gamma}}{\omega^{\alpha}} \tag{9.19}$$

The bias exponent γ has typical values between 1 and 2, and the frequency exponent α varies around unity by about 20%.

Quantum Limit

Quantum effects become relevant for noise processes for sufficiently high frequencies and low temperatures, such that a quantum of energy is comparable to or larger than the thermal energy:

$$\hbar\omega \geq kT \tag{9.20}$$

Consequently, the treatment of thermal or shot noise power requires modifying the mean available energy for each degree of freedom, which results in the following generalized expression for the spectral density of current noise:

$$S_I^Q(\omega) = S_I^C(\omega) \cdot \left(\frac{1}{2}\frac{\hbar\omega}{kT} + \frac{\hbar\omega/kT}{[e^{\hbar\omega/kT} - 1]} \right) \tag{9.21}$$

Here, the quantum correction (denoted by Q) to the classical noise power (denoted by C) is given by the expression in the parentheses, which includes both the Planck distribution function and the zero-point energy term. In the limit of low frequencies or high temperatures ($\hbar\omega << kT$); the expression in parentheses reduces to unity and the classical form for the noise is recovered.

A further implication of quantum effects is a fundamental lower limit on the noise power of a linear amplifier, which is given by:

$$\frac{\Delta P_{min}}{\Delta f} = \frac{(G-1)}{G} \cdot \hbar\omega_0 \tag{9.22}$$

Here, P denotes the noise power G of the amplifier gain and Δf is a frequency interval centered around the signal frequency ω_0. This limit on the noise is a result of the uncertainty principle applied to the number of photons and the corresponding phase of an electromagnetic wave.

9.3 Device Noise

The microscopic noise mechanisms described in the previous section are responsible for producing macroscopic noise in active semiconductor devices as well as passive components. This section briefly outlines the major noise contributions in several device technologies relevant for IC design. The intrinsic noise sources are related to measurable noise parameters and to properties suitable for device modeling.

Passive Components

The most relevant contribution to noise from passive components is the thermal noise of a resistance R given by:

$$S_v^t = 4kTR \tag{9.23}$$

The thermal noise is determined by the magnitude of the resistance and its equilibrium temperature only. It exhibits a "white" (constant) noise spectral density as function of frequency and becomes

frequency dependent at high frequencies, either due to the reactive components of a real resistor or fundamentally due to non-equilibrium effects.

Besides the thermal noise of resistors, the reactive components (inductors and capacitors) also play a major role in affecting noise in VLSI chips. The ideal reactive components are not associated with any noise sources. However, non-ideal properties such as series resistance in inductors and leakage currents in capacitors give rise to thermal and shot noise, respectively. Moreover, the reactive components introduce the frequency dependence of noise or cause phase shifts between voltage and current noise sources. Finally, the thermal noise bandwidth of a resistance R or a conductance G is limited by the series inductance L or the shunt capacitance C, respectively. The resulting integrated thermal noise powers are given by:

$$\langle i_n^2 \rangle = \frac{kT}{L} \tag{9.24a}$$

$$\langle v_n^2 \rangle = \frac{kT}{C} \tag{9.24b}$$

Here, i_n and v_n denote the noise current and noise voltage, respectively, integrated over the whole frequency bandwidth.

Diodes

A p-n junction is characterized by a depletion region and an energy barrier. The depletion region can be modeled by a frequency-dependent admittance, comprised of a diffusion plus depletion conductance $G_J(\omega)$ and a diffusion plus depletion capacitance $C_J(\omega)$. In the presence of a bias across the junction, the current-voltage characteristic is given by:

$$I_D = I_S \cdot \left\{ \exp\left(\frac{qV}{kT}\right) - 1 \right\} \tag{9.25}$$

Here, I_D is the total current through the diode, I_S the reverse saturation current, and V the forward voltage across the diode. The junction noise is shown to be arising from the shot noise due to current across the junction, and the thermal noise from the conductance of the junction:

$$S_I(\omega) = 2q(I_D + 2I_S) + 4kT[G_J(\omega) - G_J(0)] \tag{9.26}$$

Here, the frequency-dependent junction conductance is denoted by $G_J(\omega)$ and the low-frequency junction conductance is given by:

$$G_J(0) = \frac{q}{kT} \cdot (I_D + I_S) \tag{9.27}$$

Note that the general expression for the diode noise (Eq. 9.26) reduces to the pure shot noise form 2qI at low frequencies and to the thermal noise form 4kTG at zero bias.

Bipolar Junction Transistors

Figure 9.2 shows a schematic of a bipolar junction transistor (BJT) in a conventional device layout. The macroscopic noise sources in such a BJT are thermal noise from all resistive regions (especially from the

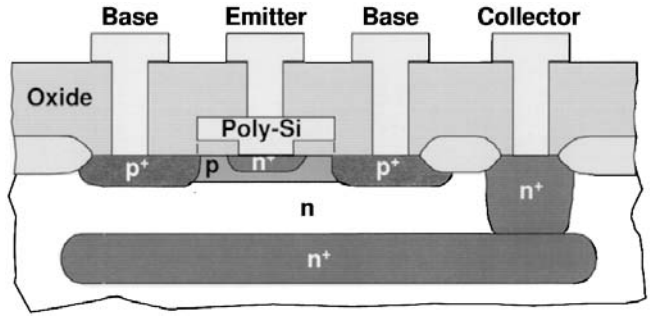

FIGURE 9.2 Schematic cross-section of an npn bipolar junction transistor in a conventional device layout.

extrinsic base region), shot noise from the base–emitter and base–collector junctions, and flicker noise from base and collector currents. These noise sources can be summarized as:

$$S^t_{R_x} = 4kTR_x \tag{9.28a}$$

$$S^s_{I_B} = 2qI_B \tag{9.28b}$$

$$S^s_{I_C} = 2qI_C \tag{9.28c}$$

$$S^f_{I_B} = K_B \cdot \frac{I_B^\gamma}{f^\alpha} \tag{9.28d}$$

$$S^f_{I_C} = K_C \cdot \frac{I_C^\gamma}{f^\alpha} \tag{9.28e}$$

The flicker noise magnitudes are strongly dependent on device processing and technology, and are summarized in the pre-factors K for each term. Note that, in general, the flicker noise exponents α and γ are different for base and collector currents. The resistor R_x denotes the total of base, emitter, and collector resistances, and the individual thermal noise terms need to be included appropriately within the device model. Since the noise sources are distributed in various regions of the device, it is useful to refer the noise either at the input or the output in order to estimate their contributions to the overall noise performance of the device. Here, we choose to refer the noise to the input of the device. The total input referred noise is given by taking into account the transconductance g_m:

$$S^{IN}_{tot} = S^t_{R_x} + (S^s_{I_B} + S^f_{I_B}) \cdot R_x^2 + (S^s_{I_C} + S^f_{I_C}) \cdot \frac{(R_x + Z_\pi)^2}{g_m^2 Z_\pi^2} \tag{9.29}$$

In the above expression, the input impedance relevant for noise is denoted as Z_π, indicating a π-model for the small-signal equivalent circuit of the device. For high gain BJTs, the general expression can be simplified and separated to obtain the voltage and current noise terms.

The input referred voltage noise is given by:

$$S^{IN}_v = 4kTR_B + \left(2qI_B + K_B \cdot \frac{I_B^\gamma}{f^\alpha}\right)R_B^2 + 2qI_C \frac{[|R_B + Z_\pi|^2]}{g_m^2 |Z_\pi|^2} \tag{9.30}$$

The input referred current noise is given by:

$$S_i^{IN} = 2qI_B + K_B \cdot \frac{I_B^{\gamma}}{f^{\alpha}} + \left(2qI_C + K_C \cdot \frac{I_C^{\gamma}}{f^{\alpha}}\right) \cdot \frac{1}{g_m^2 |Z_{\pi}|^2} \tag{9.31}$$

The input referred voltage and current noise expressions can be used to completely characterize the noise properties of an individual device. The circuit noise performance is obtained by deriving the noise parameters from the above expressions, as described in the next section. Note that all types of bipolar devices (heterojunction bipolar transistors, etc.) can be treated in a manner similar to that given here. The overall frequency dependence of noise in BJTs is discussed, together with that of MOSFETs, at the end of the next section.

Field Effect Transistors

Figure 9.3 shows a schematic of an n-channel MOSFET with a conventional device layout. The macroscopic noise sources in a MOSFET are thermal noise from resistive regions (especially from the gate resistance), shot noise from gate leakage current, dynamic channel thermal noise from drain current, and flicker noise from drain and gate currents. These noise sources can be summarized as:

$$S_{R_x}^{t} = 4kTR_x \tag{9.32a}$$

$$S_{I_G}^{s} = 2qI_G \tag{9.32b}$$

$$S_{I_D}^{t} = \beta \cdot 4kTg_{\mu} \tag{9.32c}$$

$$S_{I_G}^{f} = K_G \cdot \frac{I_G^{\gamma}}{f^{\alpha}} \tag{9.32d}$$

$$S_{I_D}^{f} = K_D \cdot \frac{I_D^{\gamma}}{f^{\alpha}} \tag{9.32e}$$

Note that, except for the channel thermal noise of the drain current, the intrinsic noise sources in a MOSFET are very similar to that of a BJT. The pre-factor β to the channel thermal noise was introduced

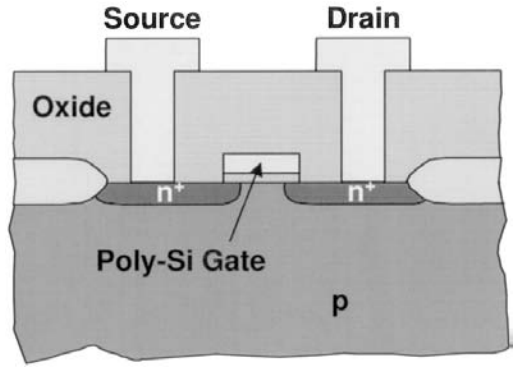

FIGURE 9.3 Schematic cross-section of an n-channel MOSFET in a conventional device layout.

to account for the specific operation of FETs in general. It was shown to have a value of 2/3 for MOSFETs and a value between 1/3 and 2/3 for JFETs. For sub-micron MOSFETs, high field effects are known to increase its value to well above 2/3. In a manner similar to that used for BJTs, one can express the noise at the input by taking into account the transconductance of the device, and then separate into voltage and current contributions.

The total input referred noise is given by:

$$S_{tot}^{IN} = S_{R_x}^{t} + (S_{I_G}^{s} + S_{I_G}^{f}) \cdot R_x^2 + (S_{I_D}^{t} + S_{I_D}^{f}) \cdot \frac{(R_x + Z_\pi)^2}{g_m^2 Z_\pi^2} \tag{9.33}$$

The input referred voltage noise is given by :

$$S_v^{IN} = 4kTR_G + \left(2qI_G + K_G \cdot \frac{I_G^\gamma}{f^\alpha}\right) \cdot R_G^2 + \left(\beta \cdot 4kTg_m + K_D \cdot \frac{I_D^\gamma}{f^\alpha}\right) \frac{[|R_G + Z_\pi|^2]}{g_m^2 |Z_\pi|^2} \tag{9.34}$$

The input referred current noise is given by :

$$S_i^{IN} = 2qI_G + K_G \cdot \frac{I_G^\gamma}{f^\alpha} + \left(\beta \cdot 4kTg_m + K_D \cdot \frac{I_D^\gamma}{f^\alpha}\right) \frac{1}{g_m^2 |Z_\pi|^2} \tag{9.35}$$

The overall frequency behavior of the noise in FETs is similar to that of BJTs; however, the contributions from the device parameters are different in each case specific to the device properties. In the above expressions, the flicker noise becomes predominant below a "corner" frequency f_{c1}; whereas above a second "corner" frequency f_{c2}, the noise increases with frequency. Figure 9.4 illustrates this behavior schematically, where the high-frequency increase of noise is referred to as being due to impedance coupling. In this region, the thermal or shot noise from one region of the device is coupled into other regions due to the reactive components and gives rise to frequency dependence. Figure 9.5 also illustrates the overall behavior of noise figure vs. frequency measured on devices from different technologies. The

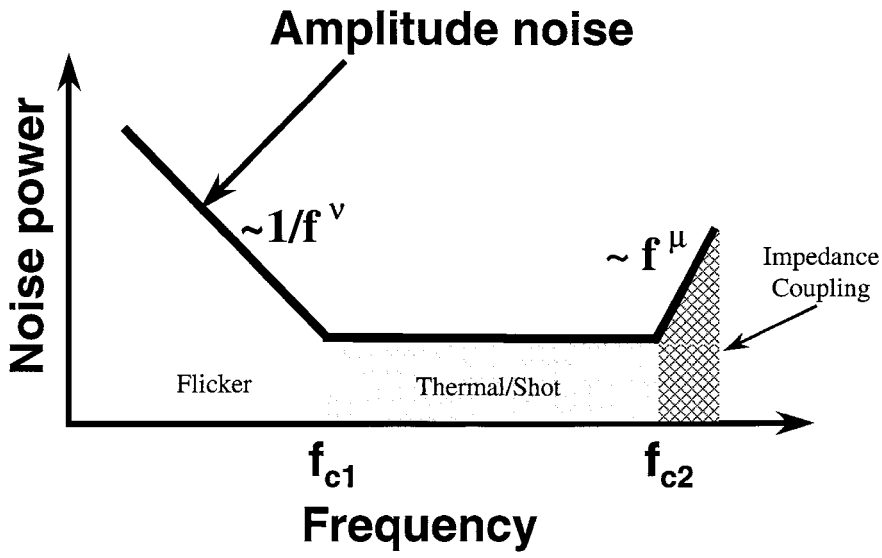

FIGURE 9.4 Schematic of amplitude noise as function of frequency, indicating the three distinct regions of noise (flicker, thermal/shot, and impedance coupling).

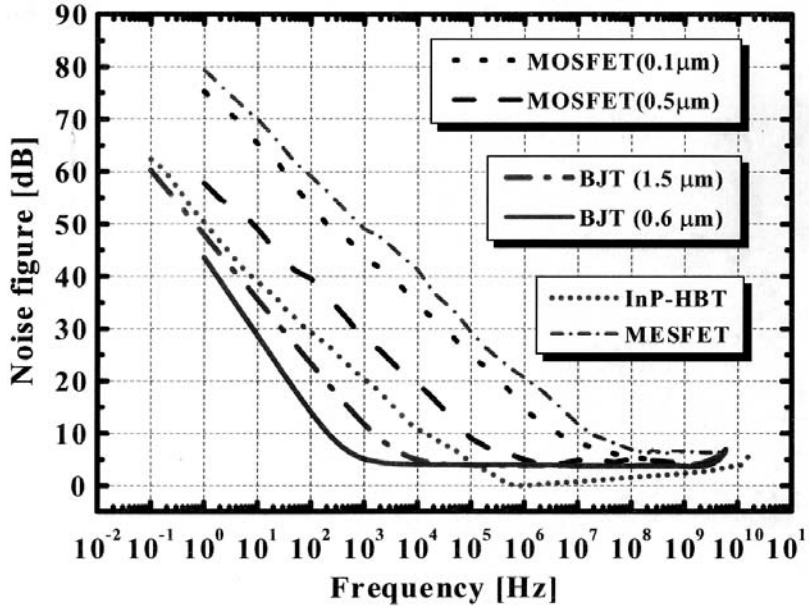

FIGURE 9.5 Measured noise figure vs. frequency for various device technologies. The plot indicates the relative magnitude of the three noise regions shown schematically in Fig. 9.4. The plot also presents the wide range of noise behavior found in device technologies.

bias-dependent behavior of noise in the low-frequency flicker noise regime is illustrated in Fig. 9.6, where measured output current noise power at 10 Hz is plotted as function of drain current for n-channel MOSFETs, with different gate lengths as given in the legend of the figure. Note that although all devices exhibit power law behavior, the exponent increases with decreasing gate length.

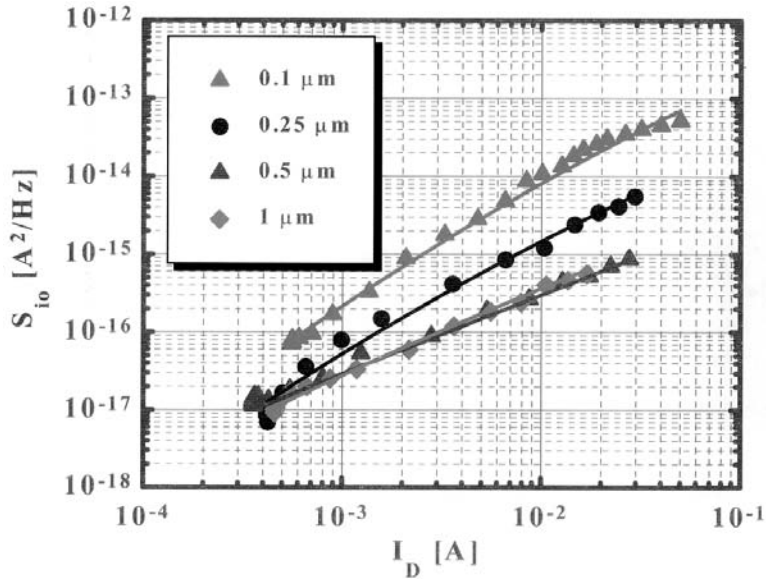

FIGURE 9.6 Output current noise spectral density vs. drain current for a set of n-channel MOSFETs with equal gate widths and different lengths, as given in the legend. Note that all devices exhibit power-law bias dependence, but the exponent increases with decreasing gate length.

9.4 Chip Noise

The device noise mechanisms discussed in Section 9.3 give rise to noise at the chip level in a number of ways. This section outlines the principal noise mechanisms encountered in amplifiers, oscillators, as well as timing jitter and interconnect noise in VLSI circuits.

Amplifier Noise

Amplifier noise is a small-signal phenomenon and can thus be treated by a linear approximation. It is directly determined by the noise and gain of the devices used in the design. The noise figure of an amplifier can be computed from the noise parameters of the active devices used in the circuit. The noise parameters are a set of four quantities that characterize the noise of any 2-port (e.g., active device, amplifier, etc.) completely. They are derived from the input referred voltage and current noise sources of the 2-port in the following manner. For a noise voltage v_n and a noise current i_n at the input of a 2-port, the corresponding noise correlation matrix is given by:

$$\hat{C} = \frac{1}{2B} \cdot \begin{bmatrix} \langle v_n^2 \rangle & \langle v_n i_n^* \rangle \\ \langle v_n^* i_n \rangle & \langle i_n^2 \rangle \end{bmatrix} \tag{9.36}$$

Here, B denotes the frequency bandwidth. The voltage and current noise sources used in the expression above are related to the noise spectral densities derived in the previous sections as follows:

$$S_v^{IN} = \frac{\langle v_n^2 \rangle}{B} \tag{9.37a}$$

$$S_i^{IN} = \frac{\langle i_n^2 \rangle}{B} \tag{9.37b}$$

The noise parameters are the minimum noise figure F_{min}, the complex optimum source impedance Z_{opt}, and the noise conductance g_n. They are expressed in terms of the input referred noise voltage and current as follows:

$$F_{min} = 1 + \frac{[v_n + Z_{opt} \cdot i_n]^2}{4kTBZ_{opt}} \tag{9.38a}$$

$$Z_{opt} = \sqrt{\frac{\langle v_n^2 \rangle}{\langle i_n^2 \rangle}} \tag{9.38b}$$

$$g_n = \frac{\langle i_n^2 \rangle}{4kTB} \tag{9.38c}$$

The correlation matrix expressed in terms of the four noise parameters is given by:

$$\hat{C} = 2kT \cdot \begin{bmatrix} g_n |Z_{opt}|^2 & \left[\frac{(F_{min} - 1)}{2} - g_n Z_{opt}\right] \\ \left[\frac{(F_{min} - 1)}{2} - g_n Z_{opt}^*\right] & g_n \end{bmatrix} \tag{9.39}$$

The noise parameters are directly measurable quantities for an active device or circuit and, thus, the noise correlation matrix can be evaluated quantitatively. The overall noise figure of a linear 2-port depends not only on its four noise parameters, but also on the source impedance as given by:

$$F = F_{min} + \frac{g_n}{R_s} \cdot |Z_s - Z_{opt}|^2 \tag{9.40}$$

Here, R_s is the real part of the source impedance Z_s. For a cascade of amplifiers with individual noise figures F_i and gain G_i ($i = 1, 2, \ldots$), the total noise figure is given by:

$$F = F_1 + \frac{(F_2 - 1)}{G_1} + \frac{(F_3 - 1)}{G_1 G_2} + \ldots \tag{9.41}$$

The above expression shows that the primary contribution to the total noise figure of any amplifier comprised of several stages is from the initial stages. A quantity that takes into account both noise figure and gain of an amplifier is the noise measure given by:

$$M = \frac{F - 1}{1 - (1/G)} \tag{9.42}$$

The noise measure can be used as a figure-of-merit for the overall noise–gain performance of a linear amplifier for analog applications. As described by Eq. 9.41, the primary contribution to amplifier noise can be attributed to the noise of the input active device. Hence, an experimental study of noise in devices provides valuable information for optimum design of low noise amplifiers.

For the purpose of illustrating the main features of amplifier noise, we show measured RF noise behavior of an active device. Figure 9.7 shows the frequency dependence of minimum noise figure, input

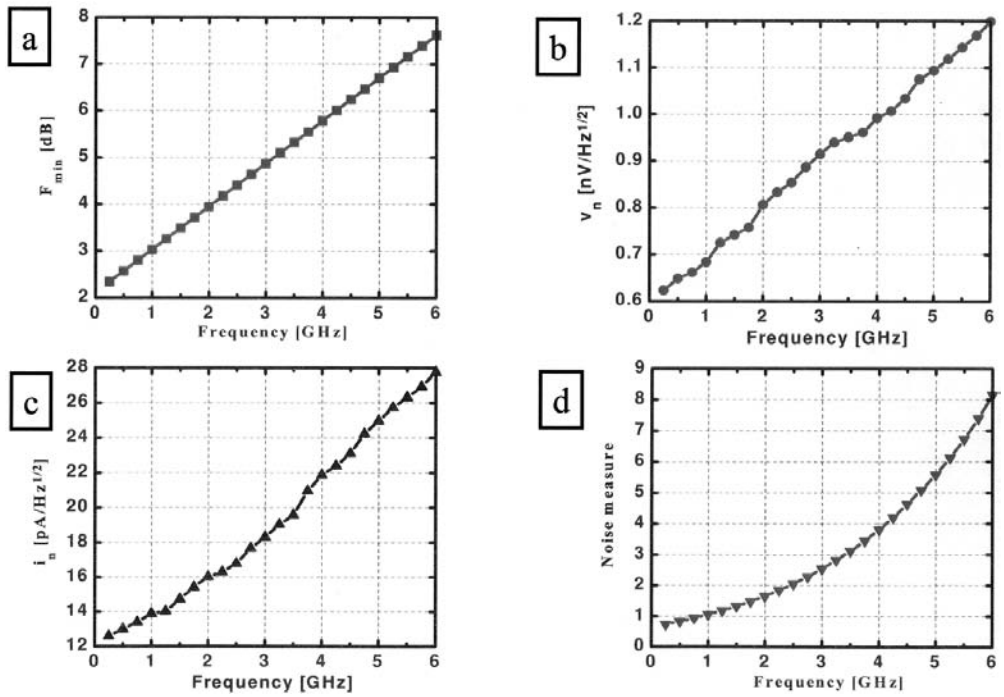

FIGURE 9.7 Plots of minimum noise figure, input referred voltage noise, input referred current noise, and noise measure vs. frequency for an npn BJT with an emitter width of 0.5 μm technology. The plots show the increase of noise with frequency in the impedance coupling regime.

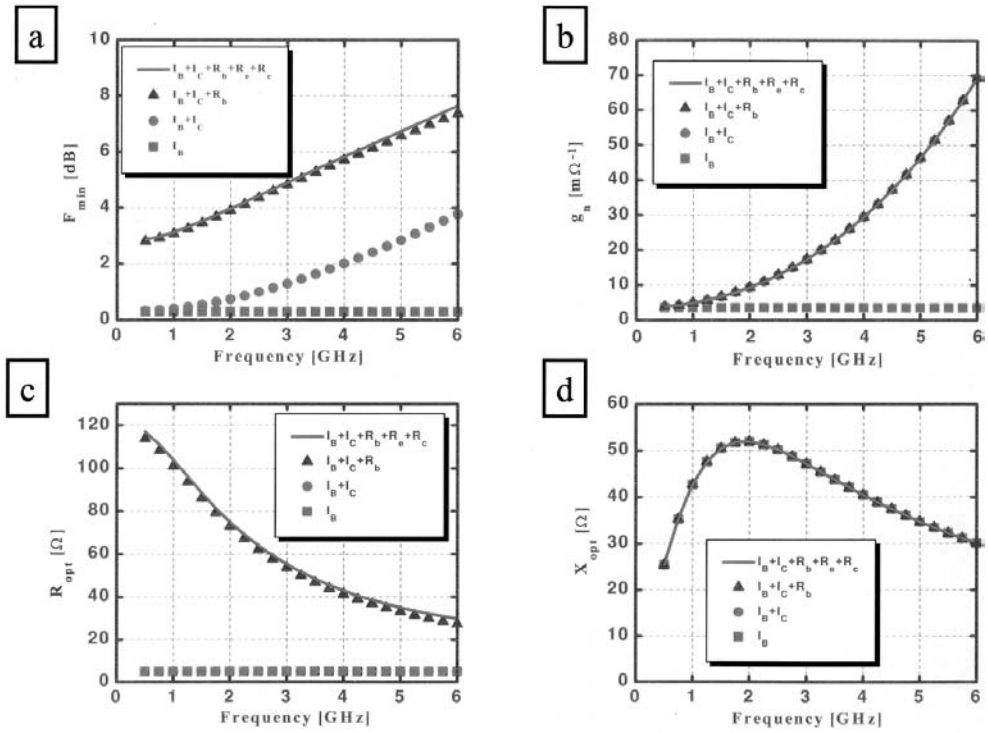

FIGURE 9.8 Plots of the four RF noise parameters vs. frequency obtained from fitting measured data on an npn BJT to a small-signal model of the device. The different curves in each plot indicate the individual contributions from the various regions of the device, as discussed in the text.

referred voltage noise, input referred current noise, and noise measure for a BJT. Note that in the frequency range shown in the figure, all quantities increase with frequency corresponding to the impedance coupling regime. The voltage noise is a measure of the thermal noise of the input resistance, and the current noise is a measure of the input referred shot noise. In order to optimize the device technology for low noise applications, it is important to study the relative contributions from the various regions of an active device to the total noise power. This is done most conveniently by extracting a small-signal noise model of the device from measured data. After successively removing the noise contributions from various regions, the resulting noise parameters can be plotted and compared. Figure 9.8 shows the results of such noise modeling of a BJT. The four noise parameters are plotted vs. frequency, with the individual contributions from the various regions of the device illustrated in the figure. Here, it is seen that the major contribution to the minimum noise figure is the base resistance, followed by the base–collector shot noise at higher frequencies. The noise conductance is primarily determined by the base–collector shot noise. The optimum source resistance is given by the thermal noise of the base resistance. Finally, the optimum source reactance is not explicitly determined by any of the noise sources, but by the input impedance of the device.

Oscillator Noise

The major noise source in oscillators is phase noise caused by mixing of device noise (flicker, shot, thermal) with the carrier frequency due to the nonlinear operation of the circuits. In general, noise in oscillators is a large-signal phenomenon and, hence, linearization techniques have limited applicability. Several approaches have been published for calculating the phase noise. The simplest is that of Leeson, which estimates the phase noise of oscillators due to nonlinear mixing of device flicker noise, and finite bandwidth of the oscillator. More advanced approaches include both analytical and numerical studies,

as given in the references. Here, we briefly outline the fundamental features of noise in a negative conductance LCR oscillator driven by an external current source (e.g., an active device). In the presence of small-signal noise, the output voltage of the oscillator with an intrinsic amplitude v_0 and frequency ω_0 is given by:

$$v(t) = v_0 \cdot [1 + a(t)] \cdot \cos\{\omega_0 t - \varphi(t)\} \tag{9.43}$$

The amplitude fluctuations a(t) and phase fluctuations $\phi(t)$ can be evaluated to first order by just taking into account the mixing of the noise with the free oscillations. The spectral density of the amplitude fluctuations (AM noise) is given by:

$$S_a(\Delta\omega) = \frac{S_I(\omega)}{2v_0^2(G_L - G_0)^2 \cdot \left[1 + Q_0^2\left(\frac{\Delta\omega}{\omega_0}\right)^2\right]} \tag{9.44}$$

Here, G_L is the loss conductance, G_0 the lowest-order term of an expansion of the nonlinear negative conductance, and Q_0 the Q-factor of the oscillator. The frequency offset from the fundamental oscillator is denoted by $\Delta\omega$. The spectral density of the phase fluctuations (PM noise) is given by:

$$S_\varphi(\Delta\omega) = \frac{2S_I(\omega)}{v_0^2(G_L - G_0)^2 \cdot Q_0^2\left(\frac{\Delta\omega}{\omega_0}\right)^2} \tag{9.45}$$

Both amplitude and phase noise exhibit a $\propto 1/\Delta\omega^2$ dependence as a function of frequency offset from the oscillation frequency. Note that the phase noise is always larger than the amplitude noise and is therefore of most relevance to chip design. Moreover, a frequency-dependent current noise $S_I(\omega) \propto 1/\omega$ (flicker noise of device) gives rise to a $\propto 1/\Delta\omega^3$ dependence of phase noise. Figure 9.9 shows schematically a simplified case of oscillator noise with two typically encountered types of phase noise frequency dependencies. For small offset frequencies, the phase noise is caused by up-conversion of the device flicker noise. At larger offset frequencies, the phase noise shows a behavior depending on the value of the flicker noise corner frequency with respect to that of the oscillator bandwidth.

Timing Jitter

In digital circuits, the timing of pulses exhibits a random fluctuation as a function of time, which is referred to as *jitter*. Jitter is fundamentally caused by the noise of individual components of the circuit (active devices, resistors, interconnect delays, etc.) and is of primary concern to the design of low-noise oscillators. As signal levels decrease and clock frequencies increase, jitter becomes a serious noise phenomenon in VLSI circuits. Jitter can be expressed in terms of fluctuations of the fundamental period of oscillation. The distribution of these fluctuations has a standard deviation that is used as a measure of jitter:

$$\sigma_T = \frac{\sqrt{\langle T^2\rangle - \langle T\rangle^2}}{\langle T\rangle} \tag{9.46}$$

For example, the thermal noise of collector load resistors in a differential pair stage of a ring oscillator is shown to result in jitter given by:

$$\sigma^t_{R_C} = \sqrt{2kTC_C} \cdot f(I_E, R_C) \tag{9.47}$$

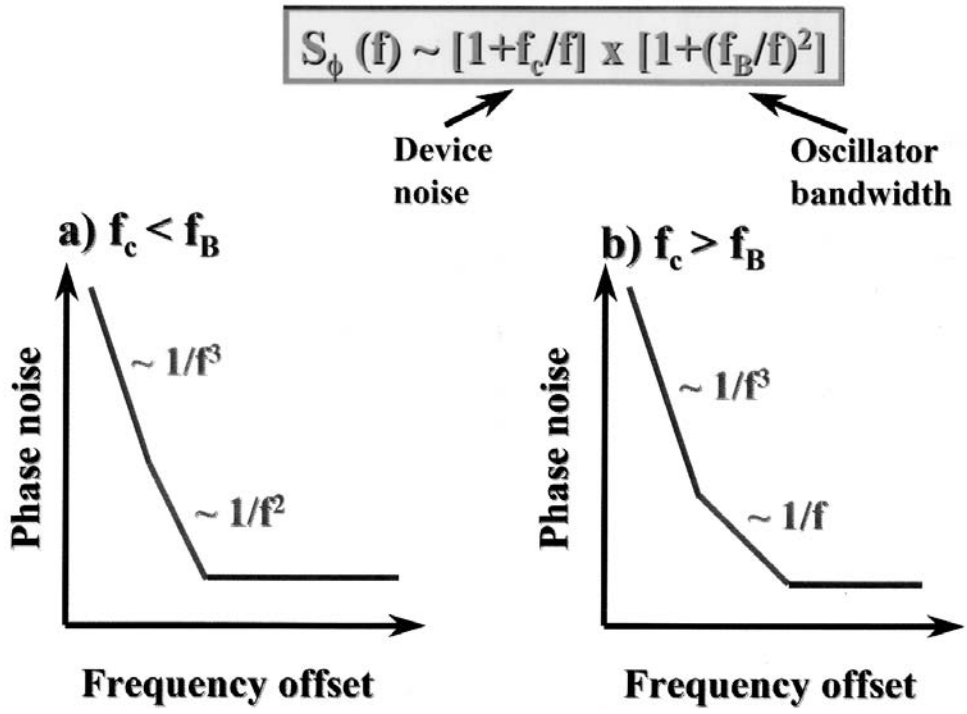

FIGURE 9.9 Schematic of frequency dependence of phase noise vs. offset from the fundamental frequency. In a simplified model, the phase noise can be treated as a product of two terms resulting from device noise and oscillator bandwidth. The two cases shown relate the flicker noise corner frequency f_c to the oscillator bandwidth f_B.

Note that the above expression contains the voltage noise fluctuations from the collector resistance R_C and shunt capacitance C_C. The thermal noise of transistor input resistances (e.g., base or gate resistance) is shown to give rise to a jitter of the form:

$$\sigma^t_{R_X} = \sqrt{4kTR_X} \cdot f(I_E, C_C) \tag{9.48}$$

Note that here the thermal noise of the input resistance R_x directly affects the jitter of the circuit. Similarly, other noise sources at the oscillator input will modulate the fundamental frequency and contribute proportionally to jitter.

Interconnect Noise

Interconnects in VLSI chips are a source of noise referred to as crosstalk, which originates from capacitive and inductive coupling of signals between transmission lines. A quantitative treatment of crosstalk requires an appropriate modeling of the impedance of the transmission lines. At sufficiently high frequencies, the wavelength of the propagating electromagnetic wave becomes comparable to the length scales of the transmission lines. In this regime, the transmission needs to be treated as a distributed entity. The electrical properties of a distributed transmission line can be characterized by the characteristic impedance Z_0 and the propagation coefficient γ. For a "quasi-TEM" mode of propagation along the line, these quantities are given by:

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}} \tag{9.49a}$$

$$\gamma = \sqrt{(R + j\omega L)(G + j\omega C)} \tag{9.49b}$$

Here, the transmission line is characterized by a lateral resistance per unit length R, a lateral inductance per unit length L, a perpendicular conductance per unit length G, and a perpendicular capacitance per unit length C. The magnitude of the crosstalk between two lines is determined by their mutual capacitance C_m and mutual inductance L_m. Since the capacitive noise is proportional to $C_m \cdot dV/dt$, and the inductive noise is proportional to $L_m \cdot dI/dt$, the crosstalk can be treated as being proportional to V_{DD}/τ and proportional to I_{sat}/τ, where τ is a pulse rise or fall time.

Another more fundamental source of noise in VLSI interconnects is the thermal noise of transmission lines. It can be shown that by treating the interconnect as a distributed transmission line, the thermal noise can be expressed as:

$$S_v^t = 4kTR \cdot f(\gamma, l) \tag{9.50}$$

In the above expression, the thermal noise due to the resistance R of the interconnect is modified by a function of only the propagation coefficient γ and the total length l of the interconnect.

9.5 Future Trends

Scaling

The scaling of silicon technology with decreasing minimum feature size is associated with changes in active device parameters as well as changes in passive components and interconnect dimensions. The effect of technology scaling on noise in VLSI chips can be estimated by considering the dependence of the noise of the individual components of the chip on their scaled properties. It turns out that general expressions for technology scaling of noise cannot be formulated, since device dimensions are chosen specific to the chip design. However, one can observe certain trends for active devices. It is found that in MOSFETs, the flicker noise scaling is primarily determined by changes in the gate-oxide quality (trap density in the oxide) and roughness of the oxide–channel interface (carrier mobility in the channel). At RF frequencies, the noise is dependent on device dimensions (base resistance of BJT, gate resistance of MOSFET, etc.) and on small-signal properties (base-collector capacitance, gate-channel capacitance, etc.). Although the specific choice of device dimensions primarily determines its noise, the trend of increasing cutoff frequencies results in improvement of RF noise at a given frequency due to decreased device parasitics. However, the thermal noise of interconnects increases as the technology is scaled to smaller dimensions, due to the associated decrease of cross-sectional area.

Processing

Process development in VLSI technologies is intimately related to device performance. As described above, the RF noise in BJTs is significantly determined by thermal noise in the base resistance and by shot noise from the base–collector junction. These contributions can be minimized by utilizing super-self-aligned device layouts, as shown schematically in Fig. 9.10. In this case, the extrinsic base region is significantly reduced to decrease the base thermal noise. The effect of the shot noise from the base–collector junction is minimized by reducing the base–collector capacitance that acts as a feedback capacitance and couples the collector current shot noise into the base. In MOSFETs, a reduction of the gate resistance is achieved through the use of higher conducting gate stacks (Fig. 9.11) or a multi-finger layout. Moreover, the coupling of channel thermal noise into the gate region can be minimized by reducing the gate–channel capacitance. In general, processing has a strong influence on the flicker noise of semiconductor devices. In BJTs, the passivation of the base–emitter junction region improves flicker noise substantially. In MOSFETs, the quality of the gate-oxide and its interface with the channel

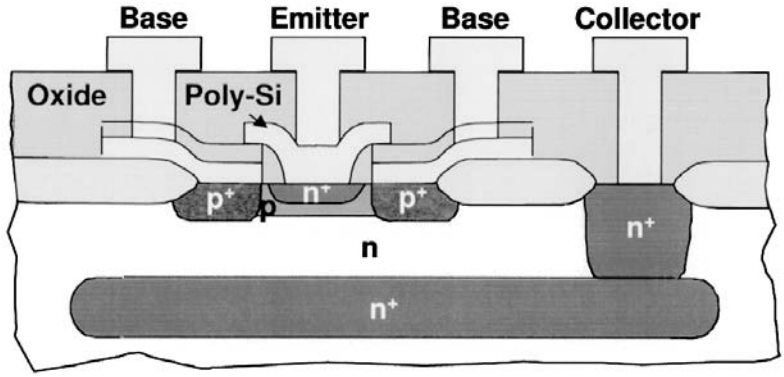

FIGURE 9.10 Schematic of a super-self-aligned BJT layout used to reduce base thermal noise and the effect of base–collector shot noise.

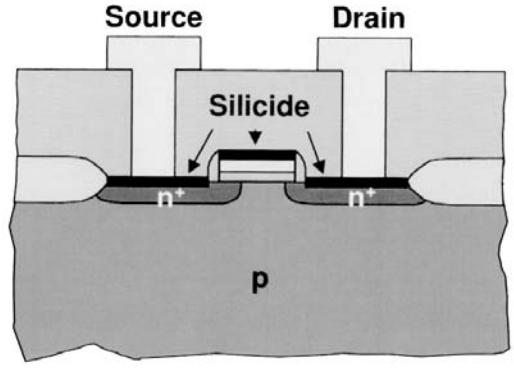

FIGURE 9.11 Schematic of a silicide-gate MOSFET used to reduce the thermal noise from the gate resistance.

affects flicker noise and can be improved through annealing treatments. One of the approaches being studied presently for reducing RF noise in MOSFETs is the use of silicon-on-insulator substrates instead of conducting substrate material, in order to reduce parasitic elements of the device.

Non-equilibrium Transport

In deep-submicron devices at high electric fields, the assumption of thermal equilibrium between carriers and lattice is not valid. Here, we briefly indicate the type of corrections required for estimating the noise in non-equilibrium transport.

The diffusion coefficient in non-equilibrium transport can be modified by approximating it to be a simple frequency-dependent quantity of the form:

$$D(\omega) = \frac{D(0)}{1 + (\omega\tau)^2} \tag{9.51}$$

The resulting thermal noise is then given by:

$$S_I(\omega) = \frac{S_I(0)}{1 + (\omega\tau)^2} \tag{9.52}$$

In the above expression, the quantity τ is the mean scattering time of the carriers. A further effect of non-equilibrium transport are velocity-velocity correlations, which modify the macroscopic values of the noise spectral densities and need to be considered in detail.

The general expression for shot noise in semiconductors needs to include finite carrier transit times and is given by:

$$S_I(\omega) = 2qI \cdot \left[\frac{\langle N^2\rangle - \langle N\rangle^2}{\langle N\rangle}\right] \cdot f(\omega, \tau, \tau_T) \tag{9.53}$$

Here, N is the number of carriers, τ the mean scattering time, and τ_T the carrier transit time. We can consider several limiting cases of the above expression. For sufficiently low frequencies and small transit times, such that $\omega << 1/\tau << 1/\tau_T$, the shot noise is given by:

$$S_I(\omega) = 2qI \cdot \left[\frac{\langle N^2\rangle - \langle N\rangle^2}{\langle N\rangle}\right] \tag{9.54}$$

The above expression is the full shot noise in a semiconductor sample where all the carriers are traversing the sample along the field direction. For a Poisson distribution function of carrier number, the variance of the fluctuations is equal to the mean of the distribution, and then the simple expression 2qI is recovered for the shot noise. For sufficiently small scattering times, such that $\tau << \tau_T$, the shot noise is given by:

$$S_I(\omega) = 2qI \cdot \left[\frac{\langle N^2\rangle - \langle N\rangle^2}{\langle N\rangle}\right] \cdot \left\{\frac{2\tau}{\tau_T} \cdot \frac{1}{1 + (\omega\tau)^2}\right\} \tag{9.55}$$

The above expression indicates that the shot effect is reduced by the randomizing due to scattering of carriers. At high frequencies, the shot noise also shows a decrease due to effective acceleration of carriers along the field direction.

9.6 Conclusions

In this chapter, the issue of noise in VLSI technologies was treated by introducing the microscopic noise mechanisms from fundamental carrier transport in semiconductors. The noise properties of active semiconductor devices and passive components were given in a general form and certain approximations relevant for most applications were outlined. The noise at the chip level was presented in terms of specific circuits where noise-critical applications are realized. Finally, trends in future VLSI technologies and their implications for noise were briefly mentioned.

10 Micromachining

Peter J. Hesketh
The Georgia Institute of Technology

10.1 Introduction

There has been a tremendous growth in activity over the past seven years in exploring the use of micromachining for the fabrication of novel microstructures, microsensors, and microdevices and also their integration with electronic circuits. Specific application areas have developed to such an extent that there are specialist meetings on the following topics: sensors and actuators,[1] microelectromechanical system (MEMS),[2] microchemical analysis systems (μTAS),[3] optical-MEMS,[4] MEMS-electronics,[5] chemical sensors,[7] and microstructures and microfabricated systems.[7] Early examples of MEMS devices and innovations are reviewed in Peterson's[8] classic paper. Up until recently, the MEMS micromachining processes were developed outside the realm of a CMOS line although the advantages of IC fabrication processes and the economies of batch fabrication have been used for production of microdevices at low

cost and high volume. The tremendous successes of microfabricated silicon pressure sensors used for blood pressure monitoring and automotive air intake manifold pressure sensing, ink-jet printer heads, and the air bag accelerometer sensors, and most recently projection overhead display systems, demonstrate the tremendous success of this technology. There are several important differences between MEMS processing and IC processing that make this an exciting and rapidly evolving field:

- Wider range of materials
- Wider range of fabrication processes utilized
- Use of three-dimensional structures
- Material properties are not fully characterized
- Interdisciplinary expertise necessary for successful technology implementation
- CAD tools are not yet fully developed for integrated thermal/mechanical, magnetic, optical, and electronic design

In keeping with the general philosophy of this volume, I will emphasize the fundamental principles and discuss CMOS-compatible processing methods. Selected examples of MEMS devices will be given to illustrate some of exciting applications of this technology. The reader is referred to the comprehensive survey by Göpel et al.[9] and the vast diversity of micromachining and micromanufacturing methods described in recent books by Kovacs,[10] Madou,[11] and Sze.[12] In addition, reference materials include a collection of classic papers by Trimmer,[13] texts on sensors by Middlehoek and Audet,[14] Ristic,[15] Gardener,[16] and bio and chemical sensors texts by Janata,[17] Madou and Morrison,[18] Moseley et al.,[19] and Wilson et al.[20]

10.2 Micromachining Processes

There are a wide range of MEMS processing methods for 2-D and 3-D structures, many of which are incompatible with CMOS fabrication. Micromachining is the process of forming such structures by processes of chemical etching, physical machining, and layering of materials by a diverse range of processes, as listed in Table 10.1. A range of processes for material removal has been developed, including chemical etching,[21] laser ablation,[22] precison machining,[23] focused ion beam etching,[24] ultrasonic drilling and electrodischarge machining,[25] and others. Historically, surface and bulk micromachining have developed independently to produce novel structures and microdevices in two different ranges of dimensional scales. A great deal of work has addressed hybrid approaches that combine bulk and surface processes in novel ways, which will be discussed in the next section. A major obstacle to the further development of MEMS devices is the compatibility of micromachining processes with CMOS circuit processing if integration of electronics is desired. A recent review of micromachining methods for a range of materials of interest is given by Williams and Muller.[26]

10.3 Bulk Micromachining of Silicon

Bulk machining involves etching the bulk single-crystal silicon wafer with respect to a patterned insoluble masking layer that defines the structure on the wafer surface. These methods are either isotropic-independent of direction, or anisotropic-crystal plane selective. Silicon has a diamond lattice as shown in Fig. 10.1(a). The dimensions of the structure in the bulk of the wafer are defined by the crystal plane locations. In particular, the etch rate of the (111) planes are slower than other crystalline directions by typically 35 to 50 times.[27] An SiO_2 or Si_3N_4 mask is used in on etching solution, as shown in Fig. 10.1(b).

Anisotropic etching which is a function of the crystal planes of the Si substrate, occurs in strong bases. The (111) close-packed silicon lattice plane etches slower than other directions of the crystal. Examples of commonly used formulations are given in Table 10.2. This process has been extremely successful for the fabrication of diaphragms for pressure sensors and other devices, aligning the [110] flat of a (100) wafer to a mask opening a rectangular opening which is produced. Etching into the

bulk of the silicon crystal the dimensions of the resulting structure is defined by the slow etching {111} planes (see Fig. 10.1c), which are parallel and perpendicular to the [011] flat on a (100) silicon wafer. Alternatively, on a (110) silicon wafer, a slot is produced, as shown in Fig. 10.1(d). Note here that the shape is bounded by the {111} crystal planes in the vertical direction and the {100} planes or {311} planes at the base of the groove. There is insufficient space here to describe the mechanism of etch chemistry, and the reader is referred to the work of Seidel,[28] Kendall,[29] Palik et al.,[30] Hesketh et al.,[31] and Allongue et al.,[32] the recent review given by Kovacs et al.,[33] and a recent workshop of Wet Chemical Etching of Silicon.[34]

KOH is perhaps the most widely used bulk micromachining wet chemical etchant, although it is a strong ionic contaminant to the CMOS process. Despite these difficulties, it has been demonstrated in post- and pre-processing formalisms with stringent chemical cleaning. The etch has been charac-

terized extensively.[35–37] Table 10.2 lists the plane selectivity of useful concentrations that in additon to the surface roughness, are a function of the solution composition. However, roughness appears to be related to hydrogen bubble release from the surface, and work by Bressers et al.[38] has demonstrated that the addition of ferricyanide ions reduces hillock formation. Note that selectivity to oxide masking layers is not as high as CsOH and TMAH. Alcohol can be added to the etch to improve the surface finish and uniformity.[39]

CsOH etchant has been characterized,[40–42] and the results are summarized in Table 10.2. It has high selectivity to silicon dioxide and is dopant selective, producing smooth membranes at high concentrations. Surface roughness is often a key parameter in device design and is of key importance for technologically useful etches to obtain controlled surface conditions.

FIGURE 10.2 (a) Schematic diagram of isotropic etching, indicating undercut of mask and definition of isotropy; (b) effect of isotropic etching on grooves sawed into silicon wafer. The etching has rounded the tops of the grooves. (Kasapbasioglu, H. et al., *J. Electrochem. Soc.*, 140, 2319, 1993. With permission.)

EDP has been demonstrated as compatible with CMOS processing. It has high selectivity to dielectic and metallization layers and contains no ionic contaminants. Etch has been characterized by Reisman et al.[43] and Finne and Klein.[44] The popular formulations are as follows: Type-S is 1000 ml ethylenediamine, 160 g pyrocatechol, 133 ml water, and 6 g pyrazine; Type-F is 1000 ml ethylenediamine, 320 g pyrocatechol, 320 ml water, and 6 g pyrazine. These solutions etch thermal oxide at about 55 Å/h at 115°C, there is no detectable attack of LPCVD silicon nitride, and the following metals — Au, Cr, Ag, and Cu — are resistant to EDP. The plane selectivity is listed in Table 10.2.

TMAH has been studied extensively due to its low ionic contamination with CMOS. The early work on etch characterization was carried out by Tabata.[45] Characteristics are listed in Table 10.2 and the plane selectivity is markedly lower than KOH; however, selectivity to SiO_2 is quite high. The solution also passivates aluminum surfaces when the pH is adjusted into a suitable range.[46] This makes it a strong candidate for CMOS post-processing; however, the etch rate is reduced with silicon doping and there are unresolved issues regarding the solution stability. Ammonium persulphonate was added to the TMAH bath to reduce surface roughness by limiting the formation of hydrogen bubbles, specifically for a 5 wt % solution, 40 g/l silicic acid, and 5 to 10 g/l ammonium persulphate.[47] Changes in the surface morphology and high index plane selectivity are observed with the addition of alcohol[48] and hillock formation has been studied.[49]

Isotropic etching in a mixtures of hydrofluoric acid (HF) and nitric acid (HNO_3) produces typically rounded profiles.[50] Figure 10.2 shows a schematic diagram of the profile produced during isotropic etching. The etching takes place in a two-step process, the first being oxidation of the silicon by the HNO_3, and the second being dissolution of the oxidized layer into a soluble H_2SiF_6 silicate. These two processes have different reaction rates and, hence, polishing occurs at low concentrations of HF where it defines the rate-limiting step in the reaction. The etchant can be stabilized by the addition of acetic acid, which helps prevent the dissociation of the nitric acid into NO_3^- and NO_2^-. The etch is dopant selective, having a lower etch rate for lightly doped region ($<10^{17}/cm^3$) of silicon relative to heavier doping regions.[21] Figure 10.2(b) shows the application of this etching mixture to the rounding of pins that have been produced by mechanical sawing of the silicon.

Etch Stop Methods

There are various methods that have been developed for membrane fabrication at a defined doped layer as shown in Fig. 10.3(a). The heavily doped etch stop occurs when the doping level of p-type silicon is greater than $2–5 \times 10^{19}/cm^3$ for all of the principle etching solutions listed in Table 10.2. It is believed that the etch mechanism is related to the availability of electrons at the surface, which is a participant in the silicon dissolution process. Thus, high p^+ doping results in electron-hole recombination. Doping and etch back has been very successful in producing capacitive pressure sensors and neural recording probes.[52] The etch rate of the heavily doped material has an n^4 dependence on the concentration of the dopant; however, there are some differences in the abruptness of this dependence as indicated in Fig. 10.3(b). This is in agreement with the four electrons per silicon atom dissolution process. The mechanism for dopant-selective behavior is discussed by Collins.[53]

Other methods are listed in Table 10.3. The electrochemical etch stop relies on the formation of an anodic oxide on the silicon, which stops the etching process. The process was first demonstrated by Waggener and has been developed for silicon microstructures by Jackson et al.[54] and Kloeck et al.[55] Figure 10.4 shows a typical experimental set-up in which an n/p junction is reverse-biased in the etching tank and protected in a Teflon holder so that only the p-type surface is exposed to the solution. Because the junction is reverse-biased, the potential on the silicon is close to the open-circuit potential and so etching continues uninhibited. However, once the n-type material is reached, the potential becomes that applied by the external circuit. Care must be taken to ensure that the reverse-bias leakage current is not high enough to allow the potential on the exposed silicon to reaching a point more positive than the passivation potential, as indicated in the figure by the operating potential for the silicon surface. The passivation potential is the potential at which oxide forms rather than dissolution

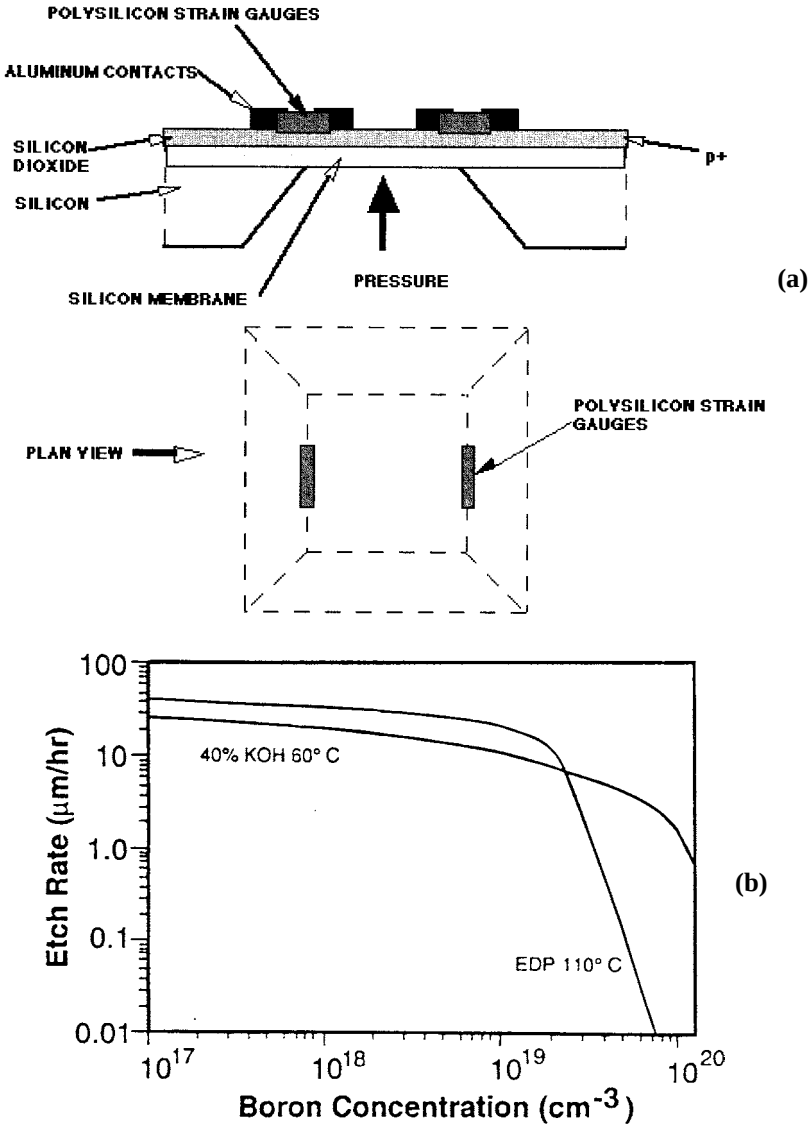

FIGURE 10.3 (a) Schematic diagram of a heavily doped layer diaphragm formation; (b) etch stop of heavily doped silicon for KOH and EDP anisotropic etching solutions. (Collins, S. D., *J. Electrochem. Soc.*, 144, 2242, 1997. With permission.)

TABLE 10.3 Silicon Membrane Fabrication Methods

Method	Thickness Range	Process	Comments	Ref.
Timed etch	5–100s μm	Observation of diaphram thickness as a function of time	Inaccurate	53
p^+ heavy doping	0.1–5 μm	Boron doping of ion implant to define location of membrane	Membrane is highly compressive state	52,53
Electrochemical etch stop	0.1–100 μm	p/n junction location of membrane	Electrical contact is necessary to wafer so special fixturing is required	53–55
Buried oxide layer	0.1–1 μm	SIMOX implant of O_2 dose above $10^{18}/cm^3$	Expensive; annealing damage from surface region after implant critical	53
Si-Si bonding			Alignment of two wafers is required	117–119

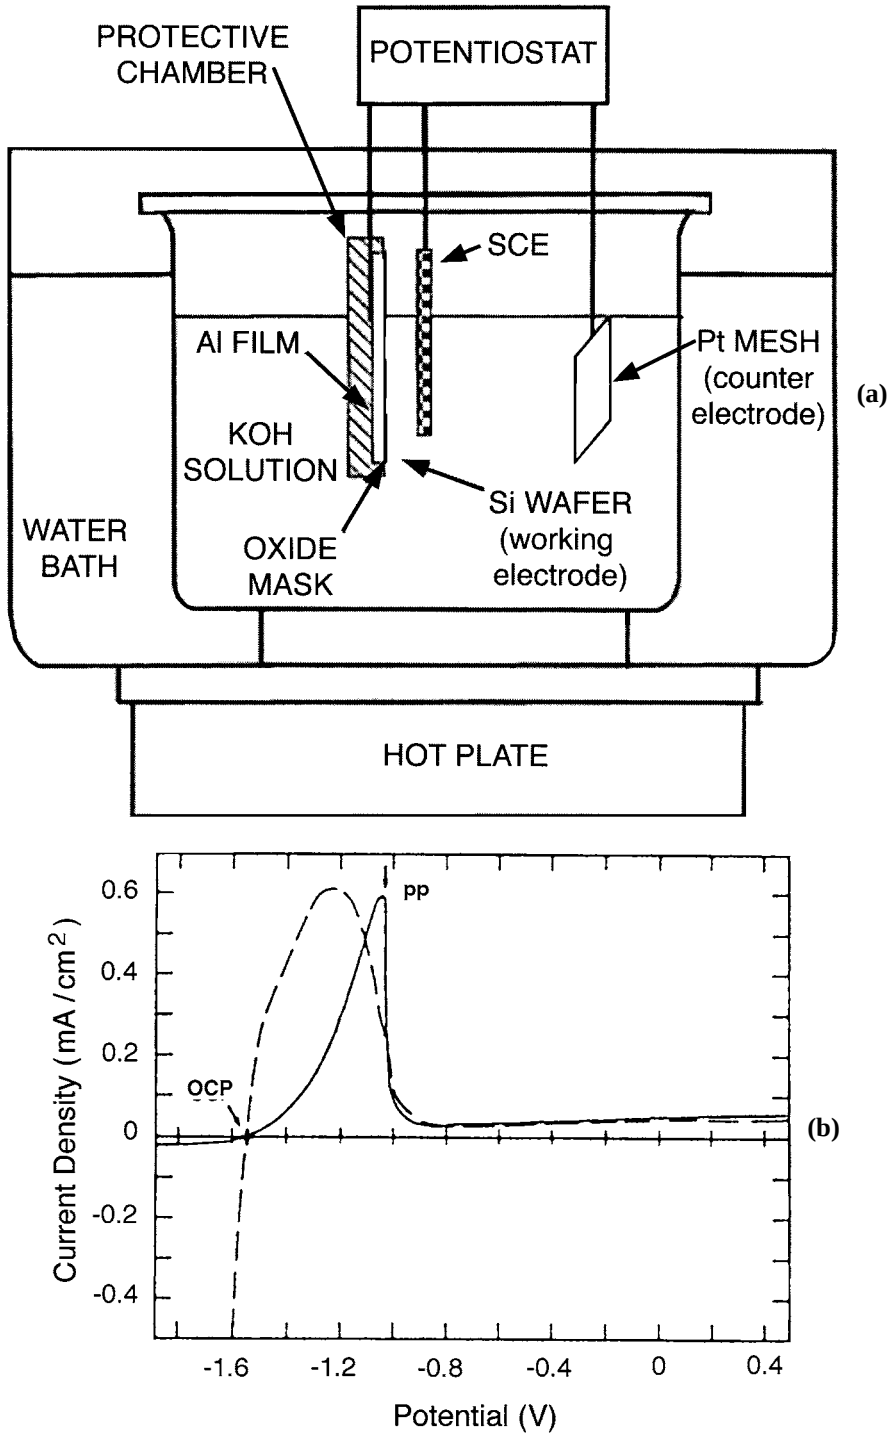

FIGURE 10.4 (a) Typical experimental set-up for electrochemical etch stop method for formation of thin silicon diaphragms (SCE is the Standard Calomel Electrode); (b) current–voltage characteristics of the p-type (solid line) and n-type (dashed line) silicon in 40 wt. % KOH solution at 60°C, where OCP is the open circuit potential and PP passivation potential. (Kloeck, B., et al., *IEEE Trans. Electron. Dev.*, 36, 663, 1989. With permission.)

takes place. The current is used as a diagnostic to indicate when the layer is removed in practical etching procedures because a current peak occurs when the oxidation reaction occurs due to the additional electrons required by the reaction. Once a passivating layer of oxide has formed, the current drops to a low level of leakage current through the oxide layer. The oxide dissolution process is slow in these solutions, and hence, if the bias is removed, after a finite time the oxide layer is removed and etching of the silicon continues.

Electrochemical Machining and Porous Silicon

Tuller and Mlcak[56] have demonstrated that anodic dissolution of silicon offers a controllable method for the fabrication of cantilever beams, membranes, and other structures. Dopant-selective etch stop can be achieved because p-type Si etches in HF solutions under anodic bias, whereas the n-type is stable. However, under strong illumination, porous silicon is formed on the n-type material. Hence, the etch rate and surface morphology are a function of the doping level, current density, and illumination level. The anodic current is a direct measure of the dissolution rate and, by defining an optically opaque insoluble mask on the silicon surface, high aspect ratio structures have been defined in the surface. Porous silicon is under investigation as a MEMS material as discussed by Schöning et al.[57] for its extremely high surface area.

Xenon Difluoride Etching

This dry gas-phase isotropic etch process relies on sublimation of solid XeF_2 at room temperature into a vapor that selectively attacks Si over SiO_2, Si_3N_4, and several metals.[58] Hoffman et al.[59] demonstrated its use for sensors and for CMOS-compatible processing. Chu et al.[60] later confirmed the minimal etch rate of Al, Cr, TiN, and SiC. Alternatively, gas-phase isotropic etching in xenon difluoride, or reactive ion etching methods may be selected. Tea et al.[61] has studied several of these methods and concluded that EDP can attach the Al bonding pads, whereas XeF_2 shows excellent compatibility. Microheaters for chemical sensors and microwave transmission lines were successfully fabricated; however, there was a lack of compatibility with catalytic metals such as Pt, Ir, and Au.

RIE Etching

Dry etching offers the advantages of controlled dimensions independent of the crystal planes in the substrate, in addition to higher dimensional control to sub-micron over wet chemical methods. The process utilized either a dc, RF, microwave, or inductively coupled energy to excite a plasma of reactive ions and accelerate them to the substrate. Depending on the ion acceleration potential utilized and the gas pressure, there are very different process characteristics. Figure 10.5 shows the different processes of (a) sputtering by physical bombardment of the surface, (b) chemical etching which is isotropic, and (c) reactive ion etching in which the ion bombardment enhances the chemical etching rate. This ion-assisted mechanism provides anisotropy, which is useful technologically for the fabrication of high aspect ratio structures. Ion milling represents the processes at high potentials where sputtering is dominant and at the other extreme at low substrate bias plasma etching where chemistry plays the dominant role. The reader is referred to excellent texts on dry etching equipment and processing methods.[62,63] Key factors in the design of dry etching processes for films are the selectivity with respect to the masking layer and with respect to the substrate material. The etch rate, uniformity, and anisotropy are other key process parameters.

Deep-RIE Etching

Deep-RIE etching was developed by the application of a novel etch chemistry and high-density plasmas created by either microwave or inductively coupled sources. Mixed gas chemistries can be utilized to provide sidewall passivation and further increase the anisotropy of the process. Selectivities with respect to a photoresist mask of 200:1 can be reached, allowing one to etch completely through a silicon wafer. Bhardwaj et al.[64] have demonstrated deep reactive ion etching by alternating between deposition of a

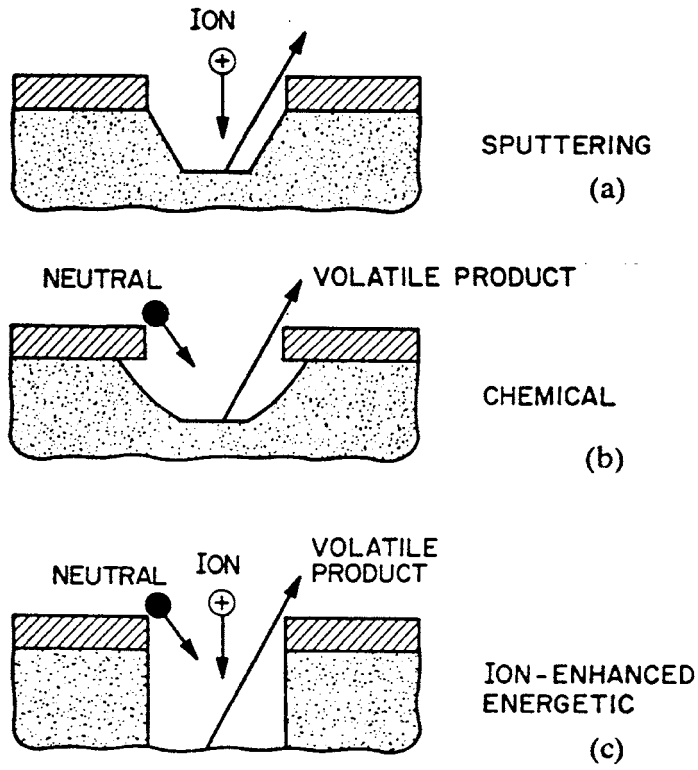

FIGURE 10.5 (a) Sputtering, (b) plasma etching, and (c) reactive ion etching.

passivating film and etch chemistry. The surface is coated with a Teflon-like material and the material remains on the sidewalls; however, ion bombardment removes it from the horizontal surfaces. Typically, a low bias voltage is utilized so that the mask erosion rate is minimized. An example of grooves etched with this process is given in Fig. 10.6.

Corner Compensation

Corner compensation of the bulk etched structure is important to maintain the shape of a micromachined structure. For example, microchambers for DNA sequencing by hybridization have been fabricated with corner compensation structures oriented in the [110] direction.[65] A great deal of work has examined the compensation of exposed corners for etching in KOH solutions under different conditions.[66] The shape of the compensation structure is shown in Fig. 10.7. There are several commercially available CAD tools for silicon bulk etching. Figure 10.7(c) is an example of a etched cantilever in CsOH solution. The CAD simulation shows the faceting high-index planes and the general features of the structure.

10.4 Surface Micromachining

Surface micromachining involves depositing thin layers of polysilicon as a structural layer and phosphosilicate glass as a sacrificial layer (see Fig. 10.8), as first demonstrated by Howe and Muller.[67] These layers are typically less than 2 μm in thickness, and etching away the PSG layer in a HF-based etching process. Undercut etch rates have been characterized, and the maximum dimensions of the thin polysilicon beams are limited due to internal stresses and the mechanical strength of the polysilicon.[68] Fine-grained polysilicon deposited at 580°C is subsequently annealed for surface micromachining to

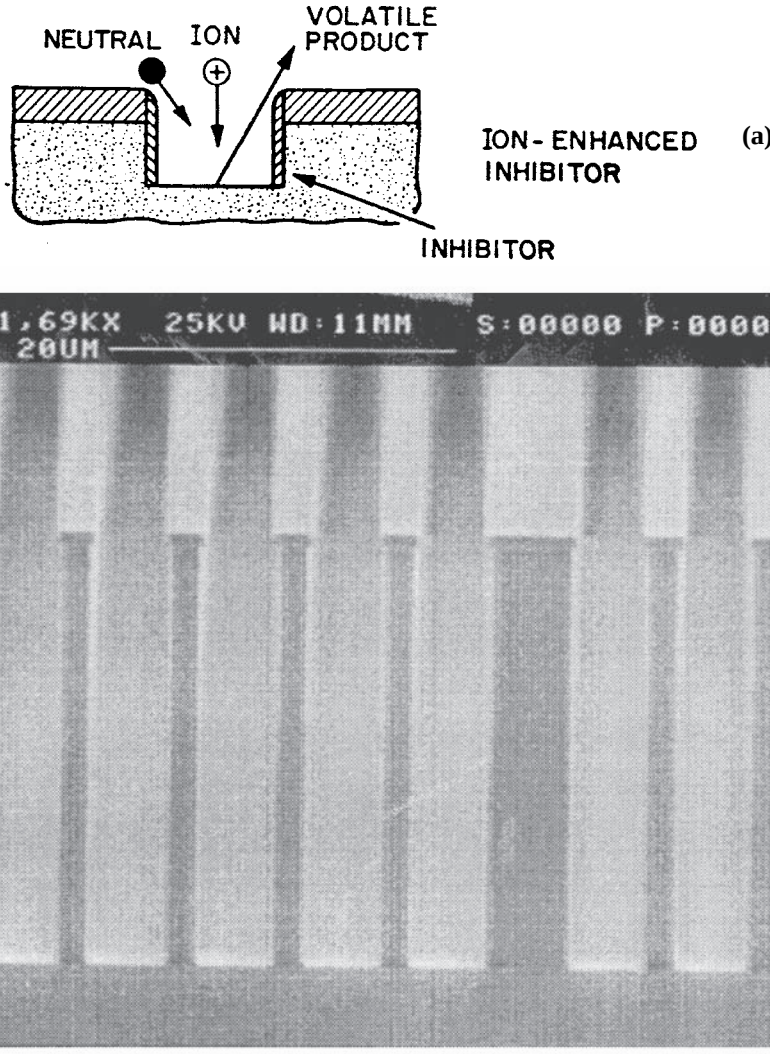

FIGURE 10.6 (a) Method of side-wall passivation during RIE etching; (b) slot produced by deep RIE etching process. (Bhardwaj, J. et al. in *Microstructures and Microfabricated Systems-III, Proceedings of the Electrochemical Society*, 97-5, 118, 1997. With permission.)

produce low stress polysilicon. Guckel et al.[69] have demonstrated that post-deposition anneal conditions are key to defining the low stress characteristics of polysilicon, as shown in Fig. 10.9. Conductive regions are defined by ion implantation. An alternative process is to carry out *in situ* doping with phosphourus and a relatively rapid deposition rate, followed by an RTA at 950°C to produce a low tensile stress film with a small stress gradient through the film.[70] Polysilicon is an extremely stable and good-quality material for producing micromechanical elements, as demonstrated by the success of these devices (examples are given in the next section). Sealing of surface micromachined structures has been developed for absolute pressure sensors by reactive sealing of small openings in the surface or by dry deposition of another layer of material like silicon nitride.[71] Surface micromachining is not limited to poly-Si and PSG. A wide range of material combinations have been studied.[15] Machining with aluminum as the structural layer and a photoresist as the sacrificial layer is discussed by Westerberg et al.[72]

Stiction

Stiction in surface micromachined structures is an issue that must be addressed due to the very small gaps present between surfaces. Tas et al.[73] investigated the origins of stiction in surface micromachined devices

and found that roughness plays an important role. The critical dimensions for the mechanical force to snap back a cantilever beam against the stiction force was investigated. The energy of adhesion by liquid bridging found that if the tip touches the substrate, the surface energy plus the deformation energy has a minimum for a detachment length smaller than the beam length. Stiction can occur during processing or during device operation. Various methods have been developed to avoid stiction during processing. Carbon dioxide drying is used because, below the critical temperature of the supercritical carbon dioxide, no liquid vapor interface exists that could cause contact. During device operation, the fail-safe requires that these surfaces do not make contact or an adequate release force can be applied. Surface energy is only partially successful in modifying these interactions and it is important to limit the contact area. Specifically, dimples, bumps, sidewall spacers, or increased surface roughness can define smaller contact areas.

Materials Properties of Thin Films

The properties of thin films differ from bulk material, and measurement techniques have been developed for *in situ* determination of these properties on a silicon wafer. Properties of interest are Young's modulus, Poisson ratio, residual stress, tensile strength, fracture toughness, thermal conductivity, density, and optical aborbance and optical reflectivity. Finding mechanical properties of thin films as a function of deposition conditions has been cataloged for many materials in a properties database available from Intellisense Inc.[74] Table 10.4, summarizes properties of thin-film CMOS and MEMS materials. However, this information should be used with caution given that there is considerable variation in materials properties as a function of the specific growth conditions due to variations in the microstructure and the film thickness. Low-stress polysilicon has been deposited in an epitaxy reactor in a process compatible with bipolar electronics by Gennissen et al.[75] In addition, more recent work by Wenk[76] has demonstrated thick low-stress polysilicon films grown in an epitaxial growth reactor from DCS at 1000°C for a microfabricated accelerometer and inertial gyroscope. Figure 10.9(b) shows a typical biaxial stress plot for the 3-μm polysilicon tested from the MUMPS process by Sharpe et al.[77] Other studies include those of Kahn et al.,[78] Maier-Schneider et al.,[79] and Biebl et al.[80]

Silicon Nitride

Stoichiometric silicon nitride has high tensile stress and this limits the maximum film thickness that can be fabricated on a wafer.[81] Stress relaxation occurs in silicon-rich nitride as a function of the film stoichiometry and has been characterized by Gardemoers et al.,[82] Chu et al.,[83] French et al.,[84] and Habermehl.[85] Figure 10.10(a) shows the intrinsic stress as a function of deposition conditions for silicon-rich nitride growth at several different temperatures and pressures and Fig. 10.10(b) for PECVD material.[86] Other materials have been studied, including SiC[87] and diamond like carbon.[88]

10.5 Advanced Processing

We have discussed both surface and bulk machining processes and these offer certain advantages and limitations, as contrasted by French and Sarro.[89] Due to the space limitation, there is only an opportunity to mention a few examples of mixed-technology processes that have combined aspects of surface and bulk machining with other processes like chemical mechanical polishing for planarization.

Chemical Mechanical Polishing

Chemical mechanical polishing is well-known in the lapping and polishing of wafers prior to fabrication. It has been recently demonstrated as a key process for achieving multilayers of polysilicon and metallization by Rogers and Sniegowski.[90] They have achieved up to five levels of polysilicon fabrication for micromechanical actuators, linkages, gears, and mechanisms. Examples of interconnected gears, locking pins, and movable elements are shown in Fig. 10.11. The key to this process is planarization of the surface between polysilicon layer deposition processes by chemical mechanical polishing.[91] In this process, planarization is

TABLE 10.4 Materials Properties of LPCVD Deposited MEMS Materials

achieved by depositing a thick layer of silicon dioxide over the polysilicon layer and polishing back to achieve planarization.[92] The process flow is shown schematically in Fig. 10.12. The key advantages of this process are: (1) the removal of stringers without the necessity for an over-etch; (2) improvement in line width control given that topographic features are removed; (3) removal of mechanical protrusions between layers that can cause interference; and (4) the possibility to carry out integration by placing the mechanical elements in a etched well in the silicon substrate (as discussed in the next section). Finally, these processing improvements lead to higher process yield.

SCREAM processing utilizes the advantages of the properties of single-crystal silicon for producing a wide range of elegant devices.[93] This method was derived from a process to make isolated islands of submicron silicon by local oxidation. Suspended high aspect ratio structure are fabricated by SF_6 RIE step, followed by sidewall oxidation and isotropic silicon etch to undercut the structure (see Fig. 10.13). Both suspended structures and structures with metallized sides for electrostatic drives can be realized by varying the width of the structure and processes, each with high out-of-plane stiffness, as defined by the ratio of beam height to length, $[h^3/l^3]$. Examples of devices realized by this elegant process include tip-on-tip sensors, microaccelerometers, electrostatic drives, torsional actuators, microloading machines, and STM tips with integrated drive. In addition, beams filled with spin on glass isolation have been demonstrated with high thermal isolation. The planarity of large aspect ratio structures has been investigated by Saif and MacDonald.[94]

HEXSIL is an RIE-etched channel and fill process that utilizes polishing for planarization.[95] The trench with controls the material that fills the grooves defined by RIE process. After the groove is coated with an oxide layer, the body of the device is made from undoped polysilicon, followed by a doped layer, and finally, Ni is electrolytically deposited into grooves to define highly conducting regions (see Fig. 10.14 for a process overview). The different groove width provide discrimination between different materials; hence, three types of material combinations are defined. Once the sacrificial oxide is removed, the HEXIL structure is released, micro-tweezers, and other structures have been defined by this method, as shown in Fig. 10.14(b).

Electroplating into Molds

A variety of materials have been utilized for a mold into which metals can be electroplated. These include the LIGA process, thick photoresists, polyimide,[96] and SU-8.[97] Photoresists often have a limited sidewall profile; however, polyimide structures with vertical wall profiles can be processed up to 100 μm in thickness.[98] The process flow is shown in Fig. 10.15 that utilizes a standard optical mask and standard UV exposure system. A spiral inductor structure produced by Ahn et al.[99] is shown in Fig. 10.15(b). A 30-μm thick nickel-iron permalloy magnetic core is wrapped with 40-μm thick multilevel copper conductor lines. [The magnetic circuit consists of an inductor $4 \times 1 \times 0.13$ mm^3 having 33 turns, with an inductance of 0.4 μH at 1 kHz to 1 MHz.] Applications of inductive components are for microsensors, microactuators, and magentic power devices such as dc-to-dc converters. Layers of copper conductor and high-permeability NiFe are electroplated to form a high-value inductance with parallel and spiral coils.[100] The process SU-8 is a negative-acting epoxy resin that has been fabricated up to 100 μm thick layers in a standard alignment system (see example in Fig. 10.16). Multiple levels of metallization have been developed of ULSI copper plating by the metal is formed by the Damascene process with a photoresist mold. Planarization is achieved by chemical mechanical polishing, which relies on the materials (metals and dielectics) having similar abrasion rates.

LIGA Process

LIGA is an acronym from the German Lithographie, Galvanoformung, und Abformung, denoting the use of X-ray lithography from a synchrotron source, in thick PMMA layers to define structures with very high aspect ratios, followed by nickel electroplating, and subsequent replication by injection molding.[101] Because LIGA is based on X-ray radiation, it is not compatible with CMOS processing. The intensity of

the X-rays produces damage in the dielectric components of the CMOS circuit. An excellent review of recent development in LIGA processing is given by Friedrich et al.[51] Optical gratings have been made by the LIGA process by Cox et al.[102]; specifically, infrared tunable filters driven by magnetic actuators, features 30 μm in height and a filter period of 8 to 17 μm. (See Fig. 10.17.)

GaAs Micromachining

The properties of GaAs as a MEMS material have been investigated by Hjort et al.[103] The key advantages of GaAs are that it is a direct-bandgap semiconductor also having high electron mobility, so that optoelectronic devices can be realized, and the piezoelectric properties are comparable to that of quartz. Finally, electronic devices can be operated at temperatures up to 350°C. Although the mechanical strength of the material is lower than silicon, the material can be bulk micromachined with HNO_3/HF solutions. Surface-type micromachining processes have also been developed, based on the advanced state-of-the-art in modulated material doping and selective etching of AlGaAs. Interdigitated electrostatic actuators have been realized in addition to surface acoustic wave sensors (SAW) optical sensors, and piezoelectric sensors (see later section on optical devices).

10.6 CMOS and MEMS Fabrication Process Integration

One of the key challenges in micromachining processes is combining the electronic devices with the mechanical, optical, or chemical function of the MEMS device. Although most work has utilized a hybrid approach in which the MEMS device is fabricated independently of the interface electronics, there are several examples of integrated sensors and other devices. The early work of Parameswaran et al.[104] demonstrated a post-CMOS processing anisotropic etching in KOH solutions that was feasible under limited conditions. The circuit elements and the MEMS devices were defined by a standard CMOS process and then the structures were released from the substrate or thermally isolated from the silicon substrate by a post-processing step. Requirements for such an etch are that it is compatible with exposed silicon dioxide, and silicon nitride, on the chip. Other etching chemistry may be more suitable such as XeF_2 or TMAH. Another issue is ionic contamination which leads to failure of the CMOS devices through mobile ions present in the gate dielectric,[105] producing instability in threshold voltages.

There have been several approaches for combining CMOS circuits with MEMS structures, summarized as follows:

- Post-processing : protecting the CMOS circuit with a chemically resistant film(s) and carrying out the micromachining after the circuits are complete and avoiding any high-temperature steps.
- Combined processing: integration in a custom MEMS/CMOS process or utilizing the CMOS layers themselves for MEMS devices.

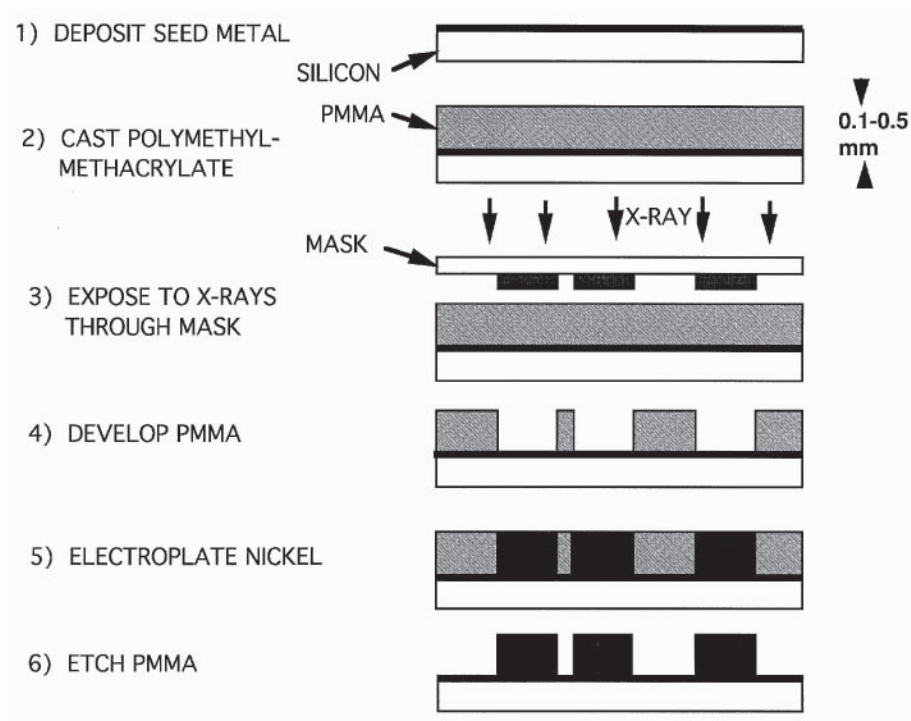

FIGURE 10.17 Schematic diagram of the LIGA process modified for MEMS.

- Pre-processing: etching wells in the wafer of a depth equal to the total height for the formation of the MEMS device. Fabrication of MEMS devices and protection with an encapsulation layer that is planar with the silicon surface. CMOS circuit fabrication then follows, and removal of the encapsulating film releases the MEMS structure.

Post-processing

Micromachined thermally isolated regions have been developed by Parameswaran et al.[106] in a CMOS-compatible process for infrared emitter arrays. Post-processing was carried out following a commercial Northern Telecom Canada Ltd. COMS3 DLM (3-μm 13 mask) process. Openings are defined in layers so that the silicon surface is exposed for the EDP etching. The active devices, both p-MOS and n-MOS, were tested after etching and there was no change in device performance.

Fedder et al.[107] have demonstrated the fabrication of intricate structures with a standard CMOS process. Structures are designed in the metal and polysilicon layers and aligned so that a post-processing dry etch step defines the dimensions and a post-processing etch undercuts the structure. Releasing it from the substrate is carried out by RIE etching (see Fig. 10.18). Electrostatic comb drives actuate microstructures that are 107 μm wide and 109 μm long show a resonance amplitude of 1 μm with an ac drive voltage of 11 V. The effective Young's modulus of the structure was found to be 63 GPa. The design rules are as follows. The scaling factor for the 0.8-μm process is $\lambda = 0.4$ μm. The minimum beam width is 3λ (1.2 μm), and the minimum gap is 3λ (1.2 μm); however, for holes, a minimum dimension of 4 μm is required for release. The CMOS circuit is protected by metal-3 to prevent etching. The metal-1 and -2 collar is inserted underneath the break in metal-3 to prevent the etch from reaching the surface and facilitating electrical interconnects to the MEMS structure.

Finally, planarization techniques have been developed by Lee et al.[108] to prepare a foundry-fabricated chip for post-processing by other low-temperature methods, including electroforming, LIGA, and reactive ion etching.

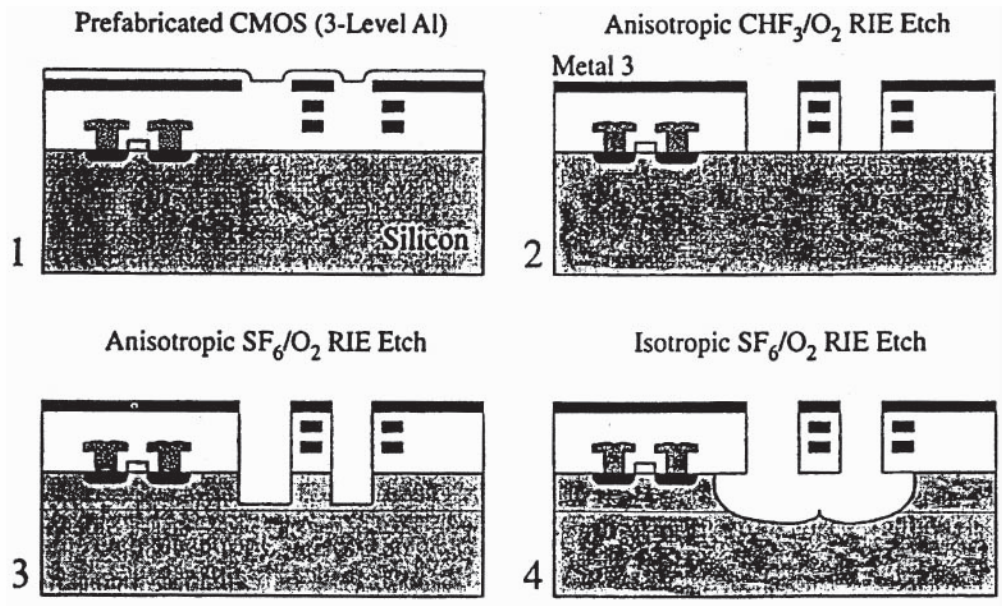

FIGURE 10.18 Example of the use of variable anisotropy dry etch on prefabricated CMOS integrated circuit using the upper level of metallization as the mask: (1) CMOS cross-section, (2) anisotropic CHF_3/O_2 RIE process, (3) anisotropic SF_6/O_2 RIE process, and (4) isotropic SF_6/O_2 RIE process. (Fedder, G. K. et al., in *Proceedings of the International Meeting on MicroElectroMechanical Systems*, IEEE, p. 13, 1996. With permission.)

Mixed Processing

The surface micromachined accelerometer manufactured at analog devices utilizes an integrated process. The BiCMOS process is interleaved with the micromachining so that the higher-temperature steps are completed first; then the lower temperature steps and metallization complete the device fabrication.

A different approach has been taken by the group at the Univesity of California at Berkeley, using high-temperature metallization of tungsten and titanium silicide and TiN barrier layers to replace the aluminum.[109] A double polysilicon single metal, n-well CMOS technology is fabricated first, encapsulated with PSG and low-stress nitirde, as shown schematically in Fig. 10.19.

Pre-processing

Smith et al.[110] pioneered the pre-processing of fabricating the MEMS device in a buried well and then encapsulation with a protective passivation film, which is later be removed once the CMOS process is complete. The key to this process is the use of CMP to planarize the surface after MEMS device fabrication and before the CMOS fabrication is begun. The release etch must be highly selective to materials in the MEMS structure and not damage the CMOS outer layers of material (see Fig. 10.19). This process has been very successful in fabricating structures such as pressure sensors, electronic oscillators, microaccelerometers, and gyroscopes. Also, Gianchandani et al.[111] have demonstrated pre-processing integration of thick polysilicon microstructures with a CMOS process. Silicon-to-silicon bonding has been utilized for sensor integration with a pre-etched sealed cavity process,[112] shown in Fig. 10.19(b). The thin membrane formed undergoes plastic deformation, and as a result, the proper design of the cavity geometry is critical to control the gas pressures during bonding. Pressure sensors, accelerometers, and gas flow shear stress sensors have been demonstrated with and without integrated electronics. Lowering the bonding temperature is of key interest to allow more widespread use of this bonding method — because of its incompatibility with many materials and processes.

With permission.)

10.7 Wafer Bonding

Anodic bonding was first demonstrated by Wallis and Pemerantz[113] and can be carried out between a range of glass/metal sealing combinations. The key to obtaining a reliable to bond is to minimize the stress; thus, the glass must be selected very carefully to match the expansion coefficient with the silicon. For example, the expansion coefficient of silicon is a function of temperature and that of Pyrex glass is much less so (Fig. 10.20). Sodium ions that become mobile at elevated temperatures (>300°C) produce a depletion layer at the silicon/glass interface.[114] The resulting electrostatic attraction between these two charge layers brings the surfaces into intimate contact, and a chemical bonding takes place that is irreversible and strong. This bond is hermetic and is widely used in microsensor technology for pressure sensors and other devices, such as fluid pumps and valves.[115] The process compatibility with CMOS is

TABLE 10.5 Wafer Bonding Techniques

Bonding Technique	Materials	Surface Treatment	Process	Time	Bond Strength/Comments	Ref.
Anodic bonding	Silicon/7740 Pyrex glass	Clean	350–450°C ~500-1000V	~1-10 min	1-3 MPa[a]/uniform reliable hermetic bond formed	113,116
Silicon-silicon	Si-Si SiO_2-Si and SiO_2/SiO_2	Hydrophobic Hydrophilic	500–1100	Hrs	Difficult to avoid voids unless processed at higher temperatures	117,118

Solder	SiO_2-Pb/Sn/Ag-SiO_2	Needs solder flux	250–400	min	Large difference in thermal expansion coefficient can lead to mechanical fracture	119
Glass frit	SiO_2-glass Ag mixture-SiO_2	Clean	~350	<hr	Difficult to form thin layers	121

under investigation.[116] The circuit is protected from the large electrostatic fields by shorting the gate regions together with a polysilicon strip. After bonding, regions were opened up in this area to facilitate etching. In addition, cavities were drilled ultrasonically in the Pyrex wafer to reduce the electric field over the active circuits.

The key advantage of silicon-silicon direct bonding is that the same material is used so there are minimal thermal stresses after bonding. The wafers must be flat, scrupulously clean, and in prime condition to achieve a reliable bond. First, the wafers are chemically cleaned and surface-activated in a nitric acid solution. Then the wafers are bonded at room temperature in a special jig that has been demonstrated to improve the bonding yield, as shown in Fig. 10.21.[117] A subsequent anneal step increases the bonding strength through a chemical reaction that grows a very thin silicon dioxide layer at the interface (Fig. 10.21(b)). The wafers can be inspected for voids utilizing an infrared microscope or an ultrasonic microscope. High yield has been achieved and the community that develop silicon-on-insulator technology have published conference proceedings on these methods.[118]

Other bonding methods are listed in Table 10.6; these include eutectic,[119] low-temperature glass,[120] glass frit,[121] and borosilicate glass.[122] Materials are selected to minimize the stresses in the bond by selecting a match in the thermal expansion coefficients, or a compliant layer is utilized at the interface.

10.8 Optical MEMS

There is great interest in taking advantage of MEMS devices for the manipulation of optical beams for which they are naturally suited, because of the ease of batch fabrication into large arrays, the small forces required, and the high speed of operation. Examples of devices that have been demonstrated include chopper beam steering, diffraction gratings, optical scanners, Fabre-Perot interferometer, sensors, and spectrometers on a chip. This demonstrates the high speed of operation that is achievable with MEMS technology. A recent excellent review of MEMS devices is given by Wu[123] and an earlier paper by Motamedi.[124]

Components

In the first generation of microfabricated optical components, hybrid assembly into optical devices was carried out rather than integrated functionality. Various optical components were reviewed by Motamedi et al.,[125] including diffractive optical components integrated with infrared detectors, refractive micro-optics,

(Parameswaran L. et al., in *Meeting Abstracts of the 194th Meeting of the Electrochemical Society*, Boston, Nov. 1-6th, Abst #1144, 1998. With permission.)

and microlenses. However, the integration of optical components into a micro-optical bench offers several advantages over guided wave approaches; in particular, high spatial bandwidth, independent optical routing 3-D interconnects, and optical signal processing. Moving the individual optical elements out of the plane has greatly expanded the utility of this method.[126] Micro-electrostatic deformable mirrors have also been demonstrated as an effective method for reducing aberrations.[127]

Tunable semiconductor laser diodes have been demonstrated by Uenishi et al.[128] with anisotropically etched (110) silicon substrates and hybrid assembly. A cantilever 1.7 mm long and 8 μm wide defines a (111) surface reflecting mirror normal to the substrate provided modulation from 856 to 853 nm, with a drive of 12.5 V. The etching conditions in KOH solutions were optimized for minimum surface roughness of the (111) surface.

External mirrors for edge emitting lasers can also be produced in GaAs by micromachining. Larson et al.[129] have demonstrated a Fabry-Perot mirror interferometer by combining a GaAs-AlAs vertical cavity laser VCSEL with a suspended movable top mirror membrane. The bottom mirror is a 12.5 period GaAs/AlAs distributed Bragg reflector of 640 Å/775 Å thickness with a center wavelength of 920 nm. The GaAs laser had a center wavelength of 950 nm and a cavity of 2580 Å thick GaAs layer. The top electrode was 2230 Å SiN_xH_y with a nominal 200-Å Au reflector. The air gap thickness is modulated around 3λ/4 with electrostatic means to provide a 40-nm tuning range with an 18-V drive. Figure 10.22(b) shows the reflectance spectra from the device.

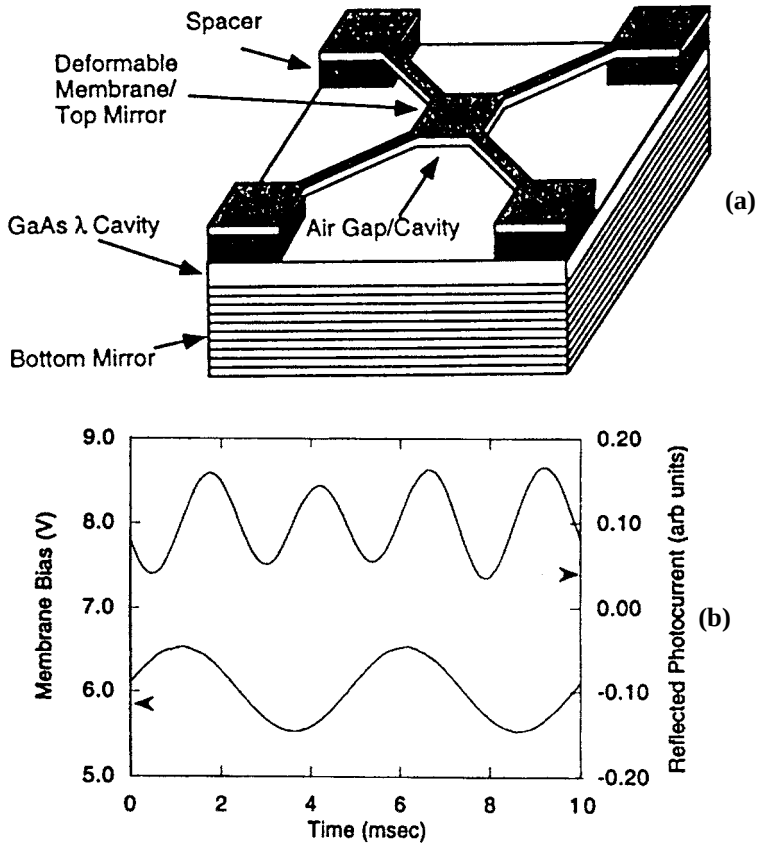

FIGURE 10.22 (a) Schematic diagram of coupled-cavity microinterferometer; (b) membrane voltage and reflected photocurrent traces for the device acting as an intensity modulator for an active wavelength of 933 nm. (Larson, M. C. et al., *IEEE Phot. Tech. Lett.*, 7, 382, 1995. With permission.)

Fabry-Perot tuning was also applied to a photodiode detector by Wu et al.[123] A DBR mirror is defined on top of a movable cantilever. A 30-nm tuning range was achieved with a 7-V drive and 17-dB extinction ratio. The DBR comprised a top reflector of 18 pairs n-doped $Al_{0.6}Ga_{0.4}As$-$Al_{0.1}Ga_{0.9}$ As and a fixed portion was two pairs p^+-doped $Al_{0.6}Ga_{0.4}As$-$Al_{0.1}Ga_{0.9}As$. The bottom DBR was 13 pairs of n-doped AlAs-GaAs mirror grown onto an n^+-doped GaAs substrate.

Modulators and Active Gratings

Micromechanical optical modulators offer certain advantages over traditional means, specifically, maintenance of wavelength coherence, reliability, and temperature insensitivity. Goossen et al.[130] have developed a silicon mechanical antireflectance switch based on a silicon nitride membrane. The thickness of the nitride membrane can be defined precisely so that an antireflection condition occurs when $\lambda/4$ film is brought into contact with no gap. The air gap defines a second coupled cavity at $m\lambda/4$. High transmission is achieved for m even and reflection for m odd. Contrast ratios of 24 dB were obtained with maximum response times of 250 ns.

Sene et al.[131] developed a grating light modulator based on a surface micromachined polysilicon layer. Each polysilicon beam in the array is individually addressed and deflected electrostatically. When the grating is moved, it diffracts the optical beam from the zero order to the +/- first order (see Fig. 10.23). The design incorporates drive plates at the edges of the grating so that the grating lines are not part of the electrostatic actuation. Two anti-sag support lines keep the grating lines parallel during actuation. There are also 0.75-μm deep dimples in the upper electrode to prevent stiction. Thermally actuated beams are used to assemble these structures (see Section 10.9).

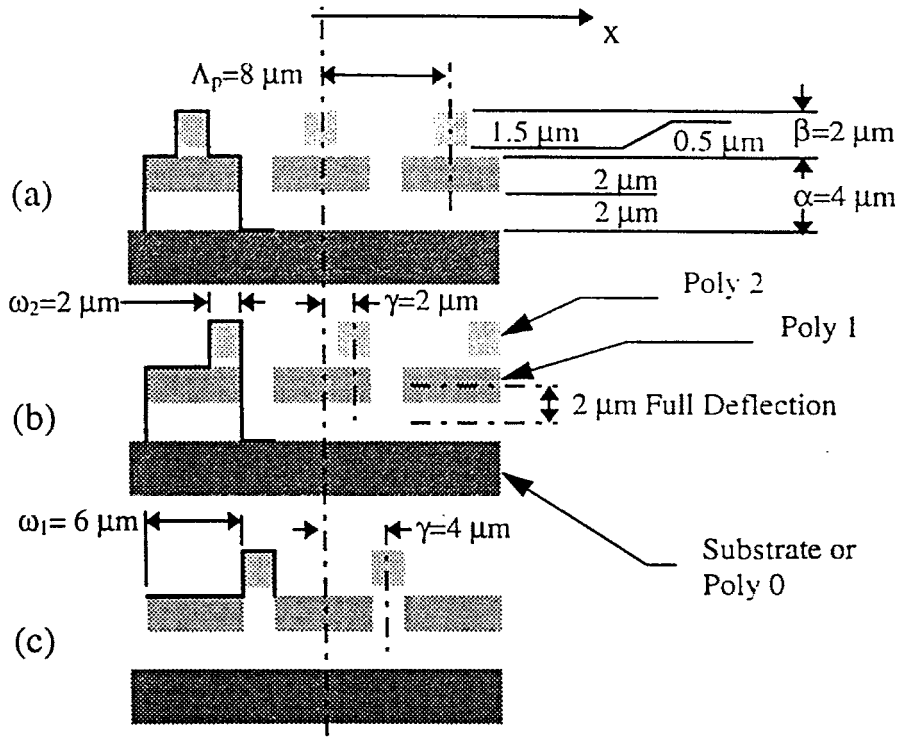

FIGURE 10.23 Schematic representation of variable diffraction grating. The value of γ will depend on the position of the upper, poly-2 grating and the three positions span a full period as indicated by the solid lines, for the following values of γ: (a) $\gamma = 0$, (b) $\gamma = 2$ μm, and (c) $\gamma = 4$ μm. (Sene, D. E. et al., in *Proceedings of the Ninth Annual International Workshop on Micro Electro Mechanical Systems*, San Diego, CA, February 1996, 222. With permission.)

Burns and Bright[132] have developed microelectromechanical variable blaze gratings operated by adjusting the blaze angle of each slat so that specular reflection of the incident light matches a particular grating diffraction order. Figure 10.24 shows a grating element that was fabricated with polysilicon using the MUMPS process surface micromachining available at MCNC.[45] Both electrostatic and thermal actuators were studied. Light beams of diameters greater than 1 mm and power levels of 1 W have been directed. Measurements with 20 mW HeNe (632.8 nm) produced diffraction efficiency in the far field of 55%, which agreed with model results. Devices with gold metallization demonstrate improved reflectivity; however, they are not fully compatible with CMOS processing.

Scanning Mirrors

Miller et al.[133] fabricated a magnetically actuated scanner with a 30-turn coil on an 11-μm thick permalloy layer. The external magnetic field provided deflection while the coil provided fine control and/or fast motion. Asada et al.[134] fabricated optical scanners with bulk micromachining and a magnetic drive. The electroplated copper used photoresist mold with period of 50 μm. Coils formed on the *x*-axis and *y*-axis plate of the Pyrex glass plate. Spring constants were evaluated for the *x*- and *y*-axes at 6.48×10^{-4} Nm and 12.8×10^{-4} Nm, respectively, and resonant frequencies of 380 Hz and 1450 Hz, respectively. Judy and Muller[135] demonstrated a torsional mirror scanner moved with a magnetic field. They electroplated a nickel mirror 450-μm square on a polysilicon flexure over a 10-turn coil. With a current of 500 mA and field of ~5 kA/m, the mirror moved more than 45°. Micromachined electromagnetic scanning mirrors have also been fabricated and demonstrated by Miller and Tai.[136] One advantage of magnetic actuators is that both attractive and repulsive forces can be generated. The mirrors are permalloy coated ($Ni_{90}Fe_{10}$) and formed on a silicon substrate with a 20-μm thick epitaxial layer for etch stop. Copper coils are electroplated into a photoresist mold. The mirror is shown schematically in Fig. 10.25(a), and the deflection as a function of the external magnetic field in Fig. 10.25(b). Utilizing these mirrors, holographic data storage has been demonstrated. Scanners are widely used in printers, display devices, graphic storage systems, and bar code readers.

Kiang et al.[137] have developed polysilicon hinged structures for scanners which utilized an electrostatic drive. The 200 × 250-μm mirror was rotated 12° with a drive voltage of 20 V, and the device had a resonant frequency of 3 kHz.

Fischer et al.[138] have utilized electrostatic means for mirror deflection with integrated p-well CMOS drive circuits. Two types of torsional mirrors, comprising a polysilicon layer with double-beam suspension and a reflecting area of 75×41 μm^2, have been realized. The mirrors were integrated by post-processing a layer of polysilicon at 630°C, implanting with phosphorus, dose 5×10^{15}/cm^2, and annealing at 900°C, resulting in a resistivity of 100Ω/sq. The electronics included a demultiplexer circuit for addressing the mirrors and a drive circuit producing 30 V for the electrostatic deflection. Bühler et al.[139] have also developed an electrostatically driven mirror made of aluminum in arrays for low-cost applications. The CMOS-compatible process consisted of modifying the second metal layer deposited process into two successive passes. The first, of 1.1 μm, established a thick metal layer for the mirror plate and the second, of 0.3 μm, a thin metal layer for the hinges. Deposition was carried out by sputtering at 250°C for improved step coverage; however, a roughness of ~53 nm resulted. Smooth reflecting surface room-temperature depositions were preferred, resulting in roughness ~12.5 nm. The mirrors were released by sacrificial aluminum and oxide etching. They were deflected with a drive voltage of 11 V for a pixel area of 30×40 μm^2.

Ikeda et al.[140] fabricated a scanning system that had a two-dimensional array with integrated photodetectors and piezoresistors. A bulk piezoelectric actuator moves the silicon nitride bridges with a torsional spring scanning angle of 40° and 30° bending and twisting and a resonant frequency of 577 Hz in bending and 637 Hz in torsional motion.

Huang et al.[141] have demonstrated piezoelectrically actuated ZnO cantilevers for application in projection displays, as shown in Fig. 10.26. One of the key advantages of piezoelectrically controlled motion is that the displacement is linearly proportional to the applied voltage. Although sputtered ZnO films have a lower piezoelectric coefficient than PZT, the fabrication process is compatible with CMOS

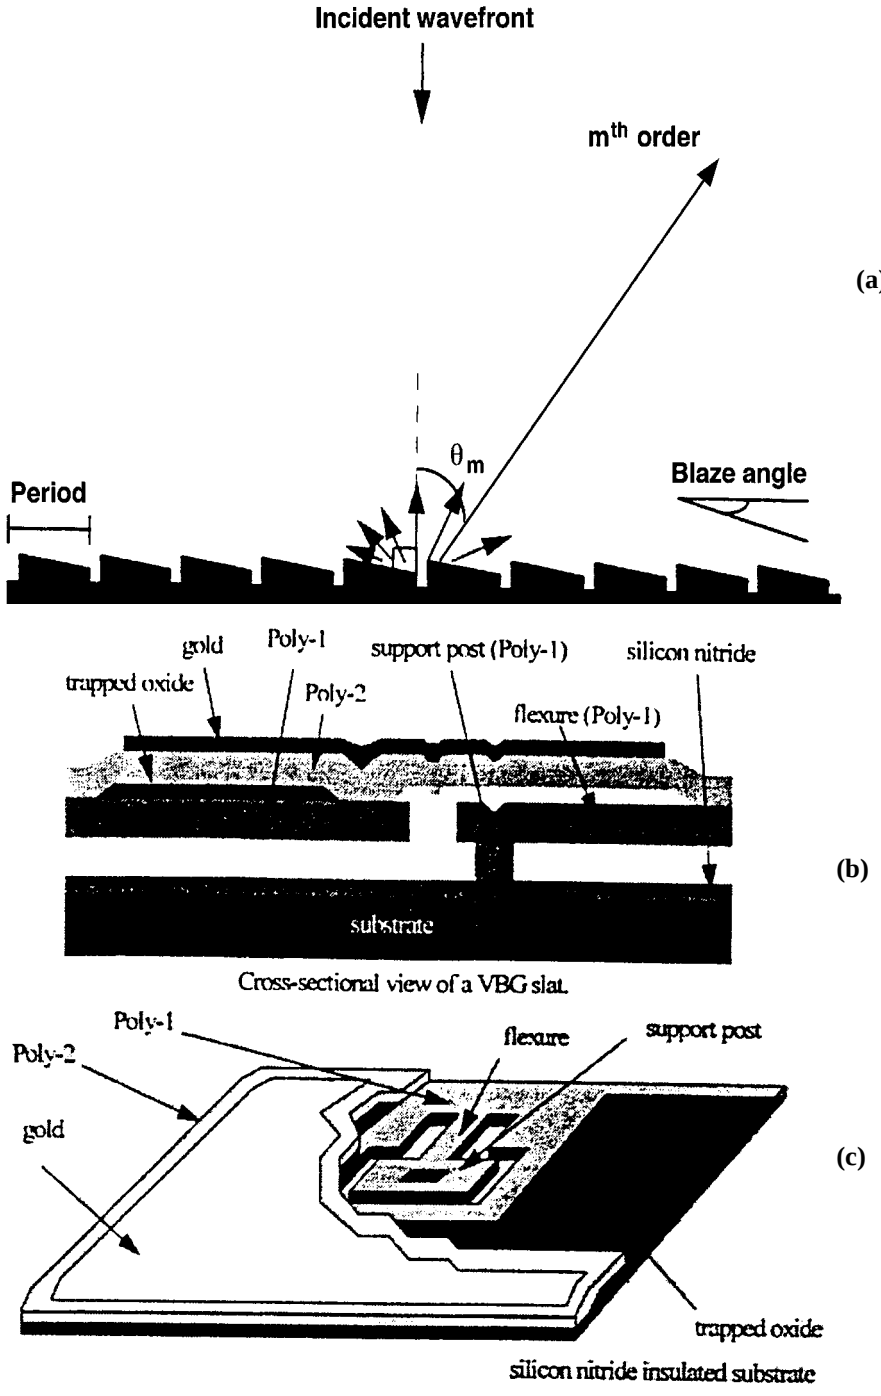

FIGURE 10.24 (a) Schematic diagram of reflective blazed grating illuminated at normal incidence; (b) cross-sectional view of the slat support posts and flexure used in the electrostatically actuated variable blaze grating; (c) the embossing present in the cross-section view of the gold layer. FIGURE 10.25 (a) Schematic diagram and cross-section of the deflected magnetic micromirror; (b) change in deflection angle from bias position for a variable coil current with external field of 994 Oe. (Miller, R. and Tai, Y.-C., *Opt. Eng.*, 36, 1399, 1997. With permission.)

processing. Calculations show that for a beam length of 150 μm, the tip deflection is 0.06°/V or 0.12 μm/V. The ZnO is fabricated with a sacrificial spin-on-glass process, the upper and lower electrodes formed from aluminum. The release step involves a HF vapor etch at low concentration to avoid attack of the Al and ZnO thin film. Tip displacements were measured with a laser interferometer and, in order

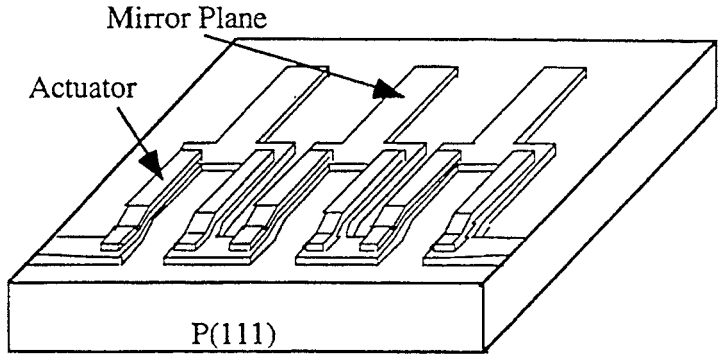

FIGURE 10.26 Perspective view of the ZnO-driven cantilever array. (Huang, Y. et al., in *Digest of Technical Papers, Solid-State Sensor and Actuator Workshop*, Hilton Head, South Carolina, June 1996, 191. With permission.)

to distinguish between any thermal contribution to the measured deflections, a drive waveform of unbiased square wave was selected. The frequency response was over 80 Hz with a 1 μm air gap and limited to about 10 Hz with a 0.5-μm air gap, indicating the dominance of squeeze film damping. The thermal deflection was bout 2 to 3 orders of magnitude less than the piezoelectric response.

Spectrometer on a Chip

Surface micromachining has been demonstrated by Lin et al.[142] for out-of-plane assembly of optical elements. The hinge mechanism allows the plate to be moved to a vertical position and locked into place with a spring latch (see Fig. 10.27(a)). Micro-Fresnel lenses with a 280-μm diameter and an optical axis 254 μm above the plane of the silicon have been realized. The slide latch precisely defines the angle of the element (see Fig. 10.27(b)). It has a 'V' shape 2 μm wide in the center. In addition, rotating structures can be realized, such as a rotating mirror. Surface micromachined free space optical components have been demonstrated by Lee et al.[143] for the collimation and routing of optical beams. Micrograting with 5-μm pitch are fabricated on flip-up structures metallized with a thin layer of aluminum. A diffraction pattern was imaged with a CCD camera and beams directed to a second grating into the zero-order beam. Recent progress in micro-optical systems is reviewed by Bright et al.,[144] including mirrors, Fresnel lenses, gratings, and larger systems. All of these structures were fabricated by surface micromachining in the MCMC processes[145] using electrostatically actuated gold surfaced mirror.

Micromechanical Displays

Miniature display systems have been commercialized by Texas Instruments in projection television systems.[146] They offer the advantage of cold operation and high contrast (>100:1) compared to the cathode-ray tube (CRT). A CMOS-like process over a CMOS memory element defined aluminum mirrors, each $16 \times 16\ \mu m^2$ in area, that can reflect light in two directions. The hinges and support structure are positioned under the reflector element. The display element can be moved by up to +/-10° and at speeds up to 10 μs, which make them suitable for standard rate NTSC video. Figure 10.28 shows the structure of one element in the 124×124 elements. The underlying memory cell operates on 5 V. Eight-bit pulse width modulation of the mirror state produces a gray scale or color image. The fabrication process is compatible with CMOS processing; however, to date, only the display has been fabricated on chip, and hybrid packaging is used for the drive electronics.

Optical Disk Pick-up Head

The technology for fabrication of optical pick-up heads is currently limiting the track access speed and maximum data rate. Ukita et al.[147] developed a flying optical head consisting of a laser diode and a

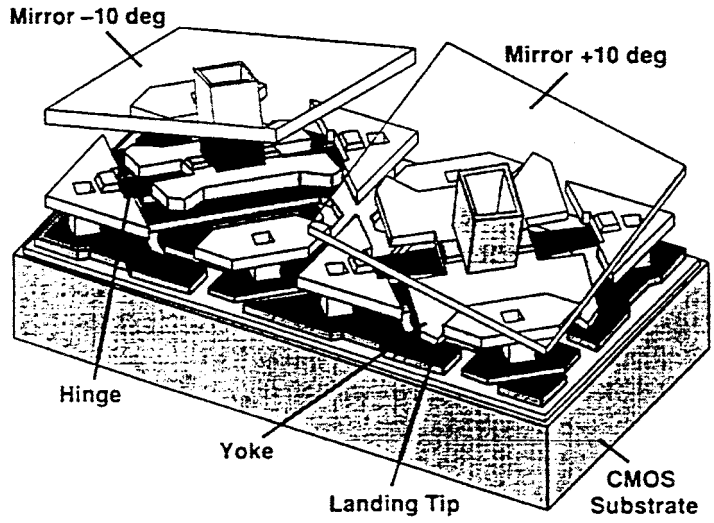

FIGURE 10.28 A two digital micro-mirror device pixels mirrors are shown as transparent for clarity in the diagram. (Hornbeck, L. J, in *Symposium Micromachining and Microfabrication, Proceedings of SPIE,* Vol. 2783, Austin, TX, 1996, 2. With permission.)

photodiode. The recording medium was a phase change material SbTeGe on a 130-mm diameter glass substrate. The read/write head was mounted on a gold electrode on the slider. Light reflected from the medium was fed back into the active region, with head-to-disk spacing of typically <1 μm. The 1.3-μm wavelength InGaAsP laser diode has a spot diameter constrained by the ridged waveguide shape. The reflection of the recording medium was reduced by an antireflection coating of 0.24-μm SiN_xH_y. Recording was achieved by producing a change in the reflectivity of the phase change medium, based on crystalline to amorphous states of the film, typically at a power of 20 mW and data rates of up to 1 MHz. Reading is achieved at lower power and higher rates. A single chip which integrates a photodetector, several Fresnel lenses, and a semiconductor laser has been demonstrated by Lin et al.[148] Surface micromachining allows the integration of a 45° reflector, Fresnel lens, rotary beam splitter, and photodetector on a chip. A 980-nm laser source was attached to the surface with an optical axis 245 μm above the silicon surface. The beam splitter has a 20-nm gold layer and the reflectors and mirrors have a thicker layer of gold. The focusing lens, with a NA of 0.17, results in a spot with FWHM of 6.1 μm in the *x*-direction and 2.6 μm in *y*-direction. The advantages of this system are small size, light weight, and potentially low-cost integration of actuation on chip to achieve track-to-track alignment.

10.9 Actuators for MEMS Optics

A variety of actuation principles have been demonstrated that are compatible with optical elements on chip. A limited number of these are compatible with CMOS processing. Further developments in integration of miniature optical components with functional optical MEMS devices is expected in the near future.[149]

Electrostatic Comb Drive Actuators

The electrostatic force generated between two conductive plates provides a compact, efficient actuation principle. These actuators are often limited to small displacements, and the force depends on the capacitance of the electrode. Interdigitated comb drives provide increased force and extended linear range, compared to parallel plate design. Recently, a large displacement actuator has been designed at Sandia National Laboratories using multiple stages of gearing (see Fig. 10.29). In general, high voltages of ~100 V

are required to drive electrostatic actuators. Circuits have been designed to work in conjunction with micromachining processes to integrate the actuators and drive circuit on the same chip.[150]

Linear Microvibromotor

The linear microvibromotor is based on impact momentum to produce small displacements. Each impact from the comb drive produces a step of typically 0.27 μm. Although this is an impulsive drive, the standard deviation between steps is 0.17 μm. A maximum speed to 1 mm/s has been demonstrated and used for a slide-tilt mirror and alignment of beams in a fiber coupler.[151]

Scratch Drive

The scratch drive is based on applying pulses to a plate and allowing the successive bending and release to produce lateral motion of the bushing to move out.[152] During release, the none-symetric functional forces produce an incremental motion DX. Microactuators and XYZ stages have been developed for a micro-optical bench.[153] A comb drive is used to drive the torsional *z* actuator with displacements up to 140 μm. Figure 10.29(b) is a schematic diagram of the microactuator stage. The lower 45° mirror is moved to achieve lateral adjustment of the beam. The translation stages are defined in the first (poly-1) layer, and the second (poly-2) layer defines the optical elements. The scratch drive actuator is particularly suited for this application because of the high forces and small step size (~10 nm) at moderate drive voltages of 87 V. Two-dimensional optical beam scanning has been demonstrated of several mm in the far field at a distance of 14 cm utilizing a HeNe laser source. A micro-Fresnel lens has been integrated into the actuator with eight scratch drive actuators.

With permission.); (c) schematic diagram of the lateral thermal actuator. Typical dimensions are given in the text. (Comtois, J. H., and Bright, V. M., in *Digest of Technical Papers, Solid-State Sensor and Actuator Workshop*, Hilton Head, South Carolina, June 1996, 152. With permission.)

Thermal Actuator

Thermal actuator arrays for positioning surface micromachined elements have been demonstrated, as well as automated assembly of polysilicon mirrors and other elements with thermal actuators.[154–156] The thermal actuator was designed for vertical and horizontal motions. The horizontal actuator is shown schematically in Fig. 10.29(c). These structures were fabricated with MUMPS processes.[145] It comprises a hot and a cold arm of polysilicon. Initially, the components are on the surface of the substrate; however when current is passed, one side becomes hotter than the other. The deflection of up to 16 μm is produced at moderate power levels of 16 mW and forces of 7 μN. In a second mode of operation if the actuator is heated above that for maximum deflection the hot arm becomes shorter than before and a negative deflection results with power off condition (see Fig. 10.29). The vertical actuator consists of two polysilicon beams separated by a 0.75-μm air gap. The lower arm is wider than the top one. When current is applied, the upper arm becomes hotter, providing higher electrical and higher thermal resistance, and thus a higher temperature driving the arm downward toward the substrate. Back-bending of the vertical actuator is particularly useful for clamping components in automatic assembly operations without the continuous application of current. These actuators are suitable for forming arrays of devices; designs of linear motors have been described. A self-engaging locking mechanism is also described which takes advantage of a tether from the upper polysilicon layer interacting with a key hole on a movable plate. When the movable plate is rotated out of the plane of the wafer, the tether slides into the wide section of the opening, which is wider than the tether. For example, the assembly of a polysilicon mirror 104 × 108 μm is achieved with two vertical actuators and a linear motor. Bending of the actuators is achieved with current levels of 4.2 mA at a voltage of ~14 V and the linear motor is operated with 24 mA at 5.5 V.[156]

Magnetically Driven Actuators

Magnetically driven micromirrors have been developed by Shen et al.[157] and one key advantage of magnetic drive is that actuation can be achieved in two directions by reversing the current flow, unlike electrostatic drive. A CMOS-compatible process was utilized to fabricate a suspended plate approximately 200 × 200 μm on a side. The deflection of the plate was ±1.5° with a single suspension; however, with multiple suspension arms, up to ±27° was observed at a drive current of 20 mA. Other work on magnetically driven mirrors was discussed in the previous section.

10.10 Electronics

For electronic applications of MEMS, the compatibility of the micromachining processes with IC processing is key for integration with active electronic components. There has been considerable work on fabrication of passive components by micromachining, specifically capacitors, inductors, and microwave transmission lines, and other components. The key advantages for passive component integration are ease of manufacturability for the higher frequency range of 100 to 1000 GHz where characteristic dimensions are mm to sub-mm range compatible with micromachining. This offers the opportunity to fabricate components and packaging in an integrated approach. Applications include test instruments, communications systems, radar, and others.

RF and Microwave Passive Components

Large suspended inductors were fabricated by Chang et al.[158] to demonstrate the integration of such components with electronic circuits. A 100-nH spiral with a self-resonance at 3 GHz integrated with a balanced cascade tuned amplifier with gain of 14 dB centered at 770 MHz, implemented with standard digital 2-μm CMOS process. The amplifier had a noise figure of 6 dB and a power dissipation of 7 mW, operated from a 3-V supply.

A 1-GHz CMOS RF front end has been demonstrated by Rofougaran et al.[159] The application is for direct conversion wireless receiver, or zero RF, and frequency shift-keying receivers. The building blocks

TABLE 10.6 Microrelays

Application	Fabrication Process	Drive	Contact On-Resistance	Maximum Current	Off- Resistance/ Breakdown voltage	Switching Time	Insertion Loss	Ref.
			Electrostatic					
Automated test equipment	Bulk micromachining and anodic bonding	<100V	<3 Ω	—	—	<20 μs		172
Switching	CMOS compatible	1-10V with DC bias of 30-54 V	—	—	—	<1 ms		176
RF to microwave	Surface micromachining	28V at >50 nA	~0.22 Ω	200 mA	—	—	0.1 db at 4 GHz	173
RF to microwave	Surface micromachining on GaAs	~30 V	—	—	—	—	0.3 dB at 20 GHz	174
Switching	Electroplated metal films	24 V	0.05 Ω (initial)	5 mA (single contact); 150 mA (multiple contacts)	>100 V	—	—	170–171
Small-signal RF	Surface micromachining	20–100 V [10 μW]	10–80 Ω	1 mA	—	2.6– 20μs	-	175
			Thermal					
Switching	MUMPS	7-12 V	2.4 Ω	80 mA	—	—	—	178

			Magnetic					
Electrical control circuits	Polyimide mold and electroplated metals	180 mA (33 mW)	0.022 Ω	1.2 A	—	0.5-2.5 ms	—	179

consist of low-noise RF amplifier, down-conversion mixer, and the contact pad is modified to reduce electric noise by connecting metal layer-1 to RF ground and metal-2 to RF input. The MEMS aspects are in the tuned amplifier's 50-nH spiral inductor, which would normally self-resonate at 700 MHz due to capacitive coupling to the substrate through the 1-μm field oxide, so that the use of standard CMOS inductors is generally limited to 5 to 10 nH. In this work, a gas-phase isotropic etch provides removal of the substrate from under the coil, allowing 50 nH to be realized.

López-Villegas et al.[160] have studied integrated RF passive components fully integrated with CMOS processing. Spiral inductors of 10 to 20 turns with 10-μm line width were characterized over the frequency range 50 MHz to 40 GHz. The influence of the material was key to defining the self-resonance of the structure, typically 1 to 6 GHz. Interdigitated capacitors were also fabricated with values of 0.5 to 1.35 pF and had self-resonances of 6 to 7 GHz.

Microwave Waveguides

Rectangular waveguides have been fabricated by McGrath et al.[161] by a bulk micromachining process and characterized over the frequency range 75 to 110 GHz. Slots are formed in a (110) silicon wafer, which were subsequently coated with 250 Å Cr and 5000 Å Au to form a plating base for a further 3 μm of electroplated Au. Losses measured in a 2.5-cm guide were comparable to commercial waveguides at about 0.024 dB/m. Active and passive components could be integrated into these structures.

Circuit components have also been fabricated by bulk micromachining with the added advantage of an integrated package by Franklin-Drayton et al.[162,163] and Katehi et al.[164] A series open-end tuning stub and a stepped impedance low-pass filter were realized for the frequency range 10 to 40 GHz. The method of design is based upon a quasi-static model utilizing TEM or quasi-TEM approximation, following this with a finite difference time-domain technique to evaluate the performance. The mesh was carefully selected to reduce truncation errors and grid dispersion errors, typically less than 1/20 of the shortest wavelength. Electrical conductors are assumed perfect conductors and, at dielectric interfaces, the average of the two permitivities was taken. Metallization comprised Ti/Au/Ti with subsequent electroplating to a final thickness of 3 μm Au. Alignment between cavities and waveguide structures was achieved via windows etched through the wafer thickness. Figure 10.30(a) shows a five-section, stepped impedance low-pass filter in which the 100- and 20-ohm impedance steps are formed by conductor widths of 20 μm and 380 μm, with slot widths of 210 μm and 30 μm, respectively. Figure 10.30(b) shows the integrated packaging topology and micrographs of the fabricated structures.

Microwave transmission lines have also been fabricated by Milanovíc et al.[165] with a commercial CMOS process with post-processing micromachining. The transmission lines were designed to operate in TEM mode

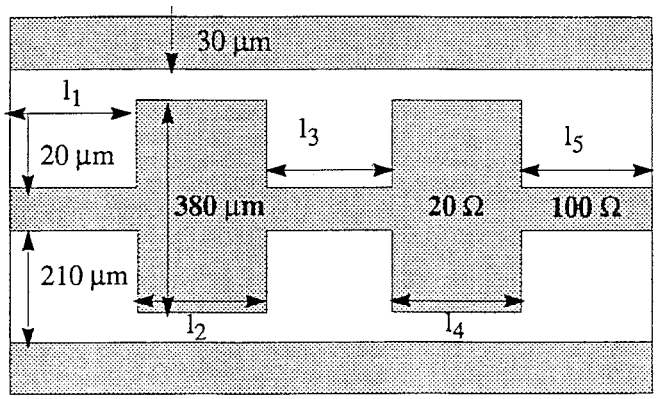

FIGURE 10.30(a) Integrated packaging. (Drayton, R. F. et al., *IEEE Trans. Microwave Theory and Tech.*, 46, 900, 1998. With permission.)

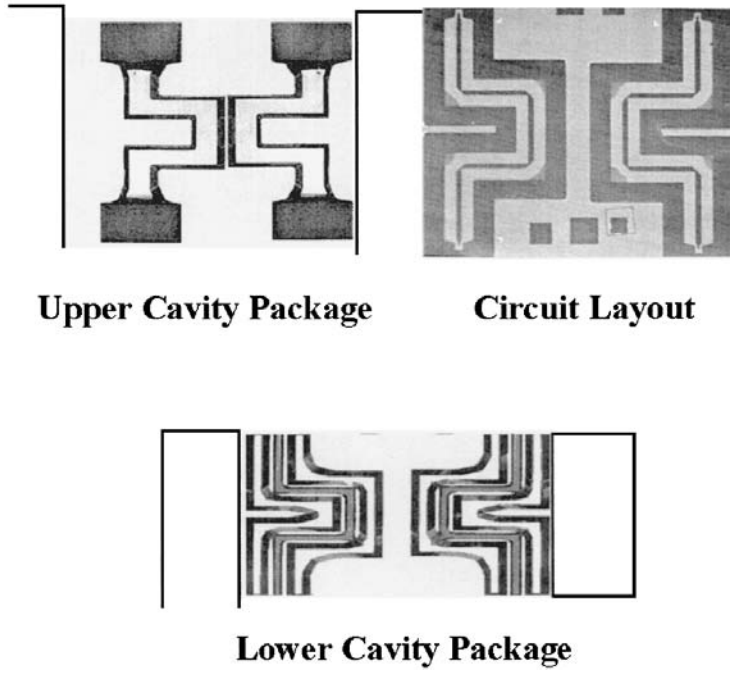

FIGURE 10.30(b) Microfabricated two-stage coupler. Chip measures 7.6 × 10 cm. Upper cavity shows probe windows as dark region. Conductor is dark region in circuit layout. with 50 and 120 Ω nominal characteristic impedance with standard layout tools. The post-processing etch was used to remove the silicon from underneath the conductive aluminum transmission lines to lower the losses. Figure 10.30(c) shows the simplified layout of the co-planar waveguides where the open areas are shaded in black. The open areas are first etched with a xenon difluoride, followed by anisotropic chemical etching with EDP. The cavities connect beneath the aluminum conductors, but enough material remains for mechanical stability. A fully formed trench also lowers electromagnetic coupling to the substrate. Measurements for test chip with three different lengths, 0.8 to 3.7 mm, with open and short stubs were made between 1 and 40 GHz. Insertion loss was calculated based on transmission line measurements, as shown in Fig. 10.30(d).

Tuning Fork Oscillator

A tuning fork-based oscillator has been fabricated by surface micromachining in polysilicon with integrated electronics by Roessig et al.[166] The device has an output frequency of 1.0022 MHz and exhibits a noise floor of –88 dBc/Hz at a distance of 500 Hz from the carrier. Previous surface micromachined oscillators used resistors to detect motion — which limits the noise floor. In this device, the capacitive detection is employed and, hence, the large impedance at the sensing node introduces a smaller input current noise than the resistive method. Figure 10.31 shows the integrated device with a double-ended tuning fork with tines 2 μm wide, 60 μm long, and 2 μm thick. These are fabricated in an etched well prior to the CMOS circuit, as discussed in the Section 10.6.

Thermal Devices

A great deal of progress has been made in the integration of thermal sensors, infrared sensors, and gas flow sensors with on-chip CMOS electronics. Baltes et al.[167] describe the fabrication and operation of a thermoelectric air-flow sensor and an infrared sensor, in addition to measurements of the thermophysical properties of material components of CMOS electronics.

Bandgap Voltage Reference

Reay et al.[168] have demonstrated thermally isolated bandgap voltage reference temperature sensors. The reference has a 5300°C/W thermal resistance isolation from the substrate silicon, a 2.5-ms thermal time constant, and uses 1.5 mW at 25°C ambient temperature. This regulation achieved a reduction of the temperature coefficient from 400 to 9 ppm/°C for an ambient temperature range of 0 to 80°C. A schematic of the circuit is shown in Fig. 10.32(a). The servo-amplifier adjusts the reference voltage until the currents in the two branches are equal and thus generate the bandgap voltage.

RMS Converter

Measurement of true RMS voltage is complicated by the fact that the waveform shape is important and the peak value is only utilized the waveform shape must be known. Commercial true RMS meters utilize thermal heat to evaluate the power in the signal with specialized components. Klassen et al.[169] has developed a CMOS fabrication process in which a suspended, thermally isolated platform is utilized for this purpose. On the platform, a resistive heater and diode-connected vertical BJT are formed; temperature sensitivity of 2 mV/K. The beams, 85 to 225 μm in length, are defined in an oxide-nitride diaphragm and undercut with a bulk-silicon etch in TMAH, as shown in Fig. 10.32(b). The beams had a maximum thermal resistance of 37,000 K/W in air. The cascade CMOS operational amplifier, followed by a source follower to provide up to 50 mA of current for the heating element, operated from a 5-V supply. The quiescent power consumption of the amplifier was 950 μW and the –3-dB frequency was 415 MHz. With a sinusoidal input signal at 1 kHz, the measured dynamic range of the system was from 2.4 mV to 1.1 V r.m.s. (53 dB). Measurements of nonlinearity were 4% compared to a Hewlett-Packard HP3478A, which had a specified nonlinearity of 0.2% for low-frequency inputs.

Microrelays

An important illustrative example of MEMS process integration in which electronic and mechanical function are combined is the microrelay. There has been considerable interest in relays and switches for high-impedance isolation of circuit components, and for RF and microwave switching. There is insufficient space in this chapter to give a comprehensive overview of these activities; however, Table 10.6 summarizes some of the work that has been directed toward the success of these microdevices — grouped by actuation method. These devices typically have lifetimes of greater than 10^6 cycles. Zavracky et al.[170] and McGruer et al.[171] have built electrostatic relays with multiple contacts to increase the maximum current-carrying capacity. Micrographs of the electroplated thick film of the relay are shown in Fig. 10.33. Other electrostatic designs demonstrate low power consumption, [172–175] and CMOS-compatible microrelays have been demonstrated by Grétillat et al.[176] Novel latching a surface micromachined devices have been demonstrated and an example[177] is shown in Fig. 10.34(a).[178] Alternative actuation schemes are thermal and magnetic. Finite element modeling of the actuator and the magnetic circuit has been carried out by Taylor et al.[179] to provide improved design methods for these devices (see Fig. 10.34(b)). The thickness of the permalloy layer must be large enough to avoid saturation of the magnetic field. Minimum switching current and optimum coil spacing for operation at under 100 mA were achieved in these devices. The hold force is high — to provide low contact resistance. Contact resistance is a critical issue and has been studied in macroscopic relays by Holm[180] and Schimkat[181] with forces in the μN range.

Integrated Ink-Jet Printers

Integration of fluidic elements with a drive circuit on a single chip have been demonstrated by Krause et al.[182] Figure 10.35 shows the integrated structure. The fluid cavity is bulk micromachined from the back of the wafer, while the (2 μm-process) CMOS electronics are fabricated on the front side. The devices were fabricated on 4 in. dia. p-type 30-50 Ω-cm, 400 μm thick (110) silicon to achieve high aspect ratio slots. The heating elements for bubble formation are integrated into the structure with 30 μJ required to eject each ink droplet. The heaters have a possible output of 1 GW/m^2, but in this

application, generate 7.5 W in a 50-nozzle array firing at 5 kHz. The chip is covered with an electroplated layer, shielding the device from mechanical, chemical, and electric damage comprising 4-μm nickel and 1 μm gold on a Ti/Cu adhesion layer.

10.11 Chemical Sensors

There has been great success in developing chemical sensors, however, one of the key stumbling blocks is the compatibility of chemically sensitive layers with IC processes, thus limiting the possibilities for

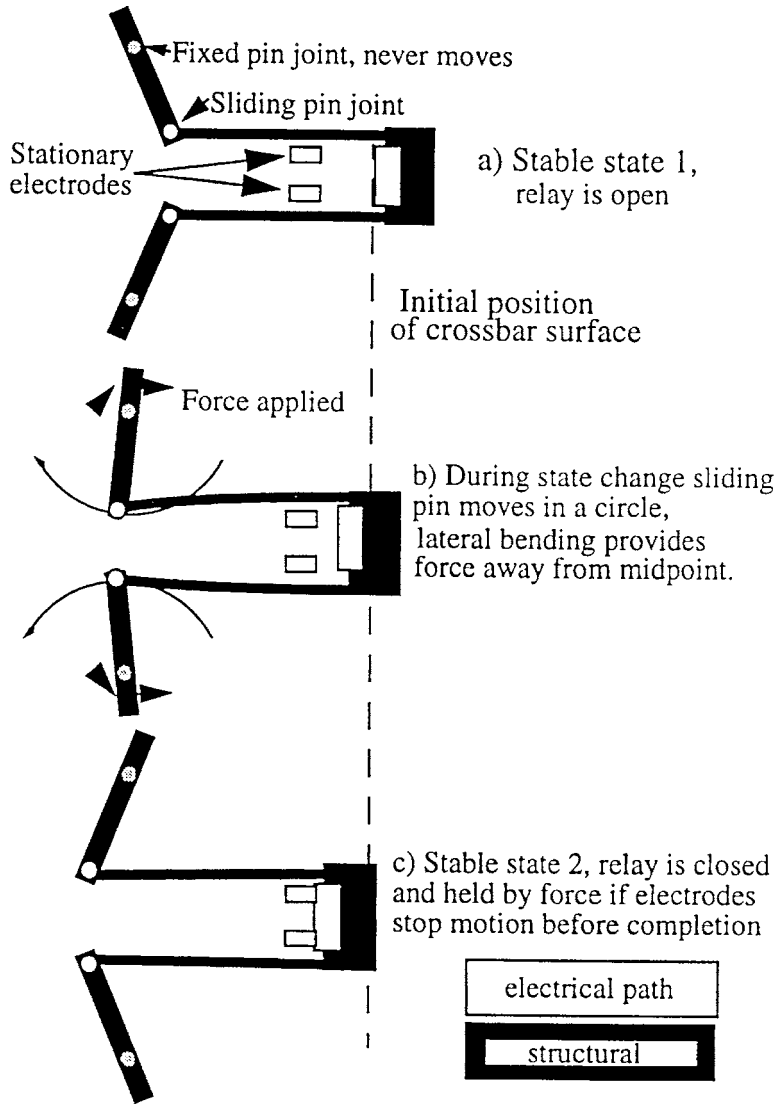

FIGURE 10.34(a) Bistable action in the relay frame hold the device in the open or closed state without actuation: (Kruglick, E. J. J. and Pister, K. S. J., in *Digest of Technical Papers, IEEE Solid-State Sensor and Actuator Workship*, Hilton Head, SC, 1998, 333. With permission.)

process integration. When one considers it the processing complexity required to integrate the electronics and chemically sensitive layers on chip is justified, there are a number critical issues:

- Is the cost per packaged functional sensor lowered by integration?
- Does the application requires integration (i.e., is small size essential?)?
- Is the sensing function improved by integration?

An excellent review of recent work on chemical sensors has been published by Janata et al.[183] Most work has focused on hybrid designs in which the electronics and chemical sensor arrays are fabricated separately and then interconnected. The work of Madou et al.[184] in a blood gas sensor for the measurement of pH, CO_2, and O_2 *in vivo* is an example of this approach. Here, the device was fabricated by bulk micromachining on a thin silicon piece approximately 350 μm wide and bonded to an associated interface circuit chip that was made at an IC foundry.

ISFET

The chemically selective FET developed by Janata[185] and Bergveld[186] demonstrates specific analyte selectivity based on an FET structure with the gate coated with a chemically sensitive layer exposed to the solution. The sensing mechanism is based on a variety of surface-specific interactions.[187] These devices may be configured as gas-sensitive devices, for hydrogen detection,[188] ion-selective devices,[189] enzyme FETs, and most recently, suspended gate structures. Figure 10.36 shows a schematic diagram of an ISFET. The important characteristic of these sensors is that the gate potential and, hence, the channel threshold voltage are defined by the potential applied at the reference electrode and the interfacial potentials. This potential is related to the activities of participating ions rather than their concentrations. Hydrogen ion sensitivity is intrinsic to the dielectric material coating the gate. Bousse[190] has developed an OH site-binding theory to account for the pH dependence of the FET for oxide and nitride gates. The most stable gate dielectric choices are TaO_2 and Al_2O_3. Advanced concepts for back-side contact FETs are reviewed by Cane et al.[191] One of the advantages of ISFET technology is that it can be made compatible with CMOS processing. An integrated CHEMFET, demonstrated by Domanský et al.[192] is capable of measurement of work function and bulk resistance changes. Here, a carbon black/organic polymer composite film for the detection of solvents covers the gate, as shown in Fig. 10.36(b).

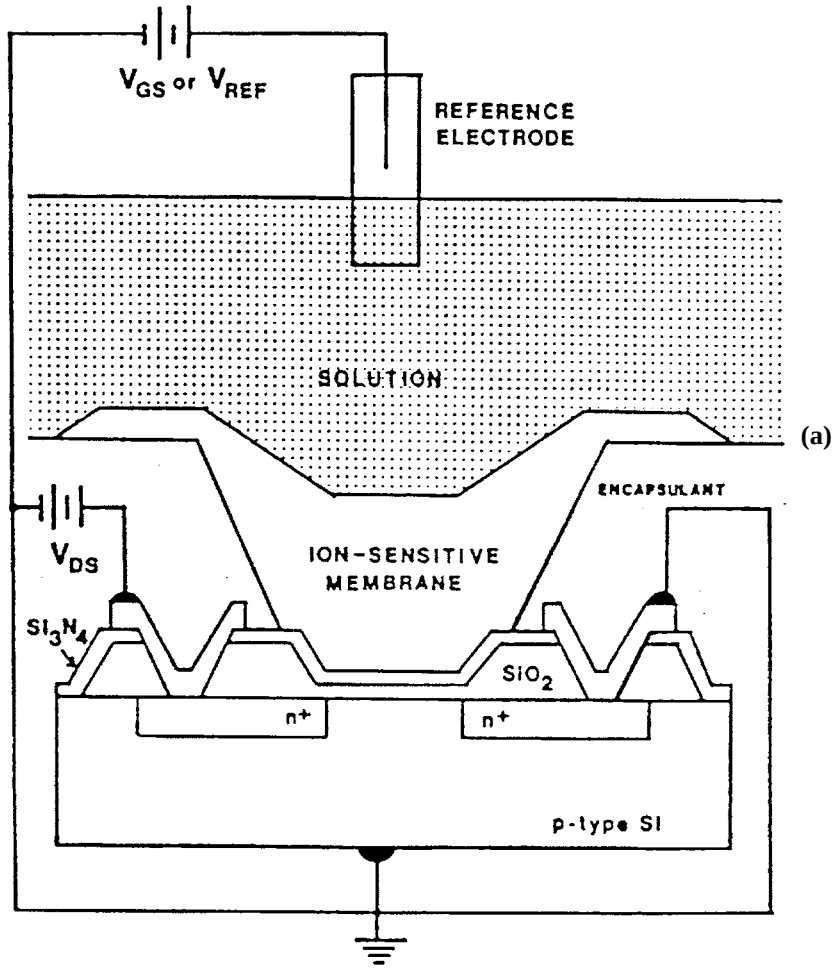

FIGURE 10.36(a) Schematic diagram of an ISFET. (Janata, J., in *Solid State Chemical Sensors*, J. Janata and R. J. Huber, Eds., Academic Press, New York, 1985. With permission.)

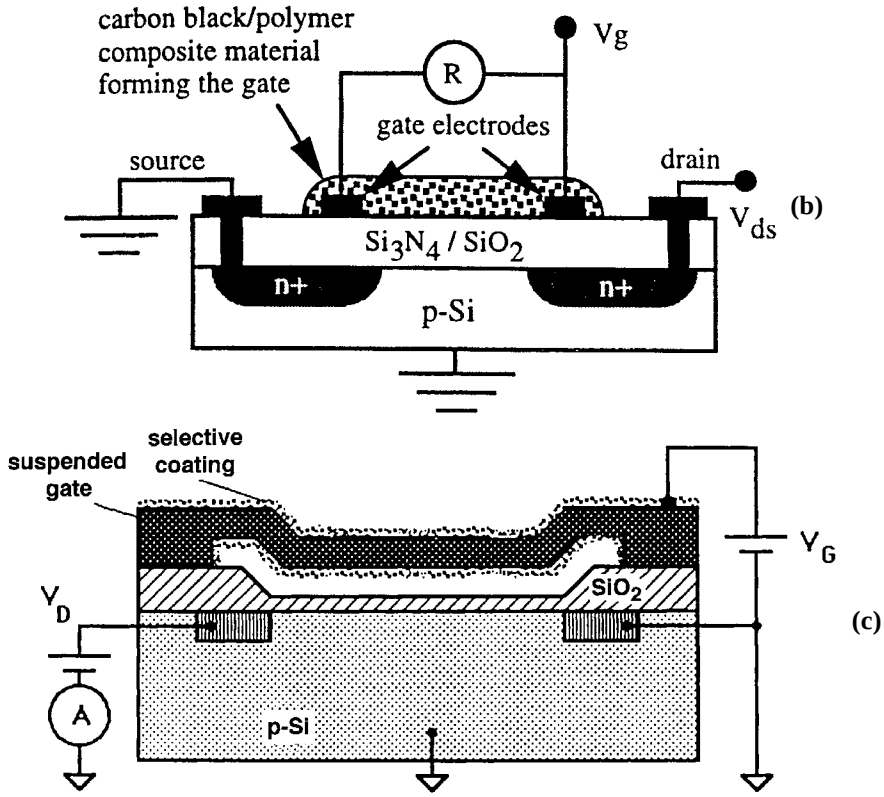

FIGURE 10.36(b-c) (b) Carbon black impregnated gate FET. (Domanský, K. et al., in *Digest of Technical Paper, IEEE Solid-State Sensors and Actuators Workshop,* Hilton Head, NC, 1998, 187. With permission.); and (c) suspended gate FET. (Mosowicz, M., and Janata, J., in *Chemical Sensor Technology,* T. Seiyama, Ed., Elsevier, New York, 1988. With permission.)

Chemically sensitive layers are, in general, not process compatible with CMOS circuit fabrication. Approaches that have been made in this area include fabrication of the electronics first, followed by deposition of the chemically sensitive membranes while the CMOS circuit is covered with a passivation coating.

Hydrogen Sensor

The Pd gate MOS hydrogen sensitive FET was invented by Lundström et al.[188] The device is shown schematically in Fig. 10.37(a). Upon exposure to hydrogen, dipoles are created at the SiO_2/Pd interface producing a shift in the threshold voltage. A hydrogen chemical sensor has been successfully integrated with electronics components at Sandia National Laboratories (Rodriguez et al.[193]). This sensor utilizes two Pd/Ni layers, one as a chemiresistor and the second as the gate of an FET. Figure 10.37(b) shows a picture of the sensor with integrated heaters and temperature sensors. The FET shown in Fig. 10.37(b) is more sensitive at low concentration ranges and has a logarithmic response, however, the conductimetric sensor has a square-root dependence on the hydrogen concentration. The sensors are operated at elevated temperature of approximately 100°C to increase the reaction kinetics and improve reversibility. Typical response data is shown in Fig. 10.37(c) with a 1% hydrogen concentration, resulting in a response time of a few seconds. The sensor combination has an exceptionally wide dynamic range of six orders of magnitude, and response time was within 5 seconds. Heating is achieved through two power transistors and temperature monitoring with an array of nine p/n junction diodes. Typical die size is 270 × 120 mils. Devices have been demonstrated with stabilities of over 60 days and show reversible behavior. Sensors are being commercialized for detection of hydrogen in aerospace applications. Advanced versions of this sensor have also been produced with fully

integrated op-amps and control electronics, including analog capacitors, high-value polysilicon resistors, current mirrors, and operational amplifiers.

Gas Sensors

Microhotplates have been developed by Suehle et al.[194] for tin oxide chemical sensors. These devices are conductimetric sensors for reducing gases and operate at elevated temperatures, typically ~350°C. A suspended sandwich structure of CVD oxides, encapsulating a polysilicon heater, and integrated with an aluminum layer to provide thermal diffusion, is shown in Fig. 10.38. Post-processing was carried out after a standard CMOS process by EDP etching with added aluminum hydroxide to ensure passivation of any exposed Al conductors. Heating current (mA) was provided to the polysilicon layer and temperature sensing from van der Pauw aluminum layer with a temperature coefficient of resistance typically 0.003667/°C. The hotplates were effectively thermally isolated, showing efficiency of 8°C/mW in air, thermal time constant of 0.6 ms, and maximum operating temperature of 500°C. SnO_2 was deposited onto the hotplate by reactive sputter deposition in ultrahigh vacuum; and by heating the platform during deposition, selective control of the local material properties was achieved (such as grain size and the conductivity). After deposition, annealing was also carried out selectively *in situ* on the hotplates. The selectivity of these devices can be further modified by addition of catalytic metals such as Pt, Pd, or Ir. Semancik and Cavicchi[195] have demonstrated kinetic sensing on microhotplates by modulation of the sensor temperature to enhance analyte discrimination. Microhotplates were also fabricated with tungsten metallization so they could operate up to 800°C. The response of a Pt-doped SnO_2 sensor operating at 130°C to CO gas is shown in Fig. 10.38(b). The stability of high-temperature micromachined TiO_x gas sensors has been investigated by Patel et al.[196] for measurements of hydrogen and propylene in the presence of oxygen. The temperature played a key role in defining the sensor response to hydrogen at 100°C and propylene when above 350°C.

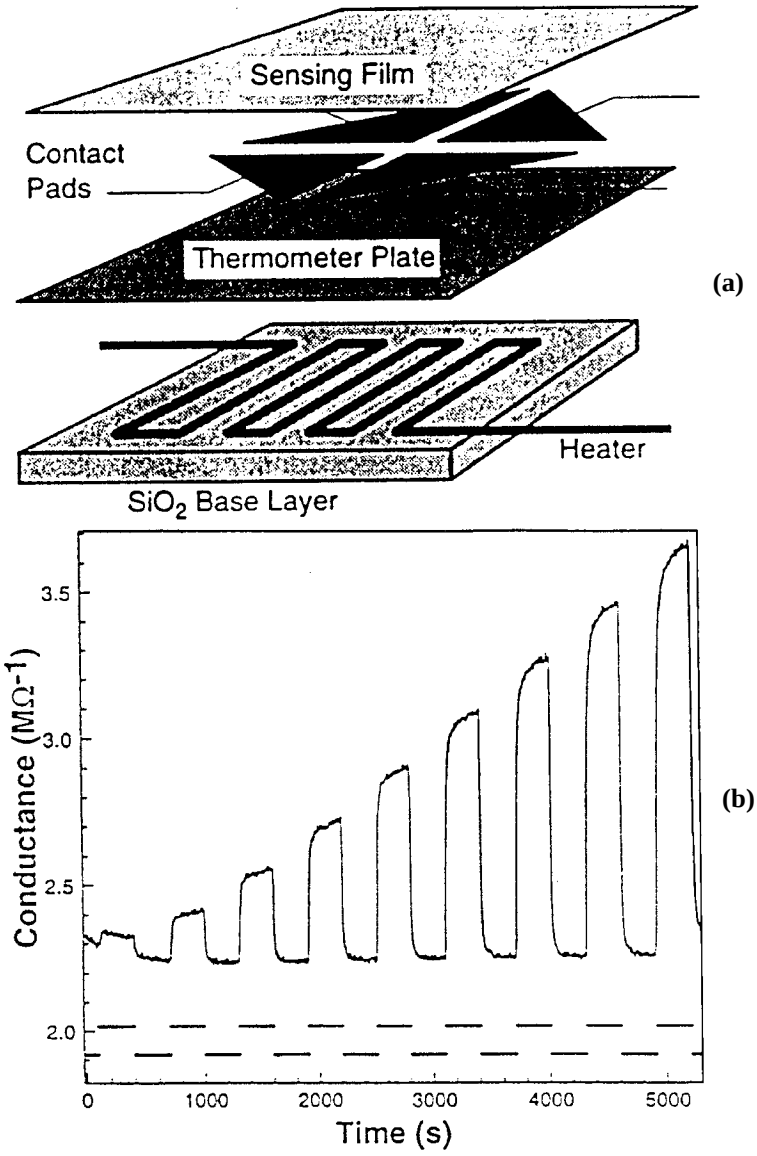

FIGURE 10.38 (a) Schematic diagram of a single micro-hot plate and functional cross-section of component parts; (b) static response at 130°C of a Pt/SnO_2 microsensor to on/off CO exposures, into dry air, of increasing concentrations from 5 to 45 ppm. (Suehle, J. S. et al., *IEEE Elec. Dev. Lett.*, 14, 118 1993. With permission.)

Artifical Nose

Microfabrication technology lends itself to the construction of arrays of sensors with differing chemical selectivities. Capacitive-based gas sensors having selectivity to different classes of chemical species[197] along with pattern recognition[198] have been demonstrated as a viable scheme for the realization of the electronic nose. The polymer coatings produce characteristic dielectric constant, mass, or conductivity changes when the analyte is adsorbed. This work on chemiresistor arrays has also been integrated with CMOS interface circuits for applications in food quality and odor identification.

With permission.); (b) schematic diagram of the neural interface structure. (Akin, T. and Najafi, K., *IEEE Trans. Biomed. Eng.*, 41, 305, 1994. With permission.)

Neural Probes

Najafi[199] has reviewed his extensive work on neural probes with integrated electronics. The early design involved four masks and had a high yield. A boron diffusion defined the thickness of the structure. Three-dimensional multielectrode systems were later developed to improve electrode positioning. Each array of neural probes is inserted into a silicon machined substrate and electrical connections are made between the probe and support chip by electroplating nickel. On the chip, preamplifiers are followed by analog multiplexers and a broad-band output buffer to drive the external data line. Later developments included a NMOS and CMOS integrated circuit with ten recording sites of gold electrodes on 100-μm centers. The circuit operated with a 5-V supply and consumes 5 mW. A 32-electrode version also has an integrated multiplexing for 32-to-8 switching array. Preamp specifications were 150 to 300 V/V, –3 dB bandwidth

100 Hz to 10 kHz. Akin and Najafi[200] have developed novel sieve structures for stimulation electrodes. They include a silicon ribbon cable that allows connections with minimal mechanical hindrance of the implant while maintaining electrical connections. Neural probes for recording brain activity have also been fabricated by Kewley et al.,[201] with integration of the buffer electronics with the probe tip electrode. The advantage of a dry-etch process is a small, well-defined tip radius of 0.25 μm in this case. He integrated 18-channel preamplifiers in a MOSIS 2-μm, low-noise analog process, each having a total gain of 150 V/V. Probe tips of iridium were fabricated with PECVD layers of silicon nitride low-stress material over the electrodes, achieving a parasitic capacitance of 20 pF and an electrode capacitance of 40 pF; stable, low-leakage current of less than 0.25 pA at a 5-V bias in buffered saline solutions, in addition to maintaining a well-adhered film necessary to maintain the tip electrode integrity.

Microelectronics Packaging

Krishna Shenai
Pankaj Khandelwal
University of Illinois at Chicago

11.1 Introduction

Packaging of electronic circuits is the science and the art of establishing interconnections and a suitable operating environment for predominantly electrical circuits. It supplies the chips with wires to distribute signals and power, remove the heat generated by the circuits, and provides them with physical support and environmental protection. It plays an important role in determining the performance, cost, and reliability of the system. With the decrease in feature size and increase in the scale of integration, the delay in on-chip circuitry is now smaller than that introduced by package. Thus, the ideal package would be one that is compact, and should supply the chips with a required number of signal and power connections, which have minute capacitance, inductance, and resistance. The package should remove the heat generated by the circuits. Its thermal properties should match well with semiconductor chip to avoid stress-induced cracks and failures. The package should be reliable, and it should cost much less than the chips it carries[1] (See Table 11.1).

TABLE 11.1 Electronic Packaging Requirements

Speed	Size
• Large bandwidth	• Compact size
• Short inter-chip propagation delay	
Thermal & Mechanical	Test & Reliability
• High heat removal rate	• Easy to test
• A good match between the thermal coefficients of the dice and the chip carrier	• Easy to modify • Highly reliable • Low cost
Pin Count & Wireability	Noise
• Large I/O count per chip	• Low noise coupling among wires
• Large I/O between the first and second level package	• Good-quality transmission line • Good power distribution

11.2 Packaging Hierarchy

The semiconductor chip is encapsulated into a package, which constitutes the first level of packaging. A printed circuit board is usually employed because the total circuit and bit count required might exceed that available on a single first-level package. Further, there may be components that cannot be readily integrated on a chip or first-level package, such as capacitors, high power resistors, inductors, etc. Therefore, as a general rule, several levels of packaging will be present. They are often referred to as a packaging hierarchy. The number of levels within a hierarchy may vary, depending on the degree of integration and the totality of packaging needs[2] (see Fig. 11.1).

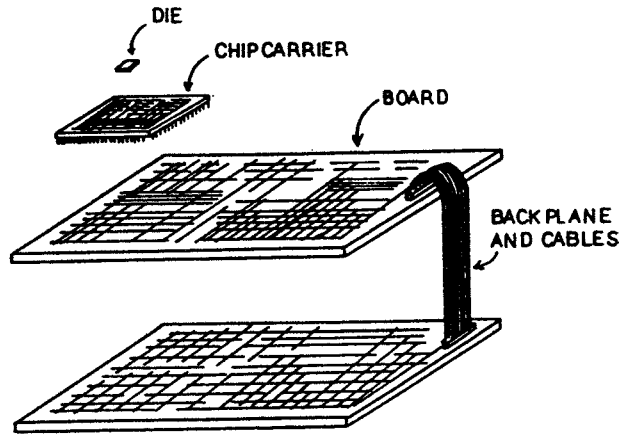

FIGURE 11.1 Packaging hierarchy of a hypothetical digital computer.

In the past, the packaging hierarchy contained more levels. Dies were mounted on individual chip carriers, which were placed on a printed circuit board. Cards then plugged into a larger board, and the boards were cabled into a gate. Finally, the gates were connected to assemble the computer. Today, higher levels of integration make many levels of packaging unnecessary, and this improves the performance, cost, and reliability of the computers. Ideally, all circuitry one day may be placed on a single piece of semiconductor. Thus, packaging evolution reflects the integrated circuits progress.[3,4]

11.3 Package Parameters

A successful package design will satisfy all given application requirements at an acceptable design, manufacturing, and operating expense. As a rule, application requirements prescribe the number of logic

circuits and/or bits of storage that must be packaged, interconnected, supplied with electric power, kept within a proper temperature range, mechanically supported, and protected against the environment. Thus. IC packages are designed to accomplish the following three basic functions[5]:

- Enclose the chip within a protective envelope to protect it from the external environment
- Provide electrical connection from chip to circuit board
- Dissipate heat generated by the chip by establishing a thermal path from a semiconductor junction to the external environment

To execute these functions, package designers start with a fundamental concept and, using principles of engineering, material science, and processing technology, create a design that encompasses:

1. Low lead capacitance and inductance
2. Safe stress levels
3. Material compatibility
4. Low thermal resistance
5. Seal integrity
6. High reliability
7. Ease of manufacture
8. Low cost

Success in performing the functions outlined depends on the package design configuration, the choice of encapsulating materials, and the operating conditions.[6,7] Package design is driven by performance, cost, reliability, and manufacturing considerations. Conflicts between these multiple criteria are common. The design process involves many tradeoff analyses and the optimization of conflicting requirements.

While designing the package for an application, the following parameters are considered.

Number of Terminals

The total number of terminals at packaging interfaces is a major cost factor. Signal interconnections and terminals constitute the majority of conducting elements. Other conductors supply power and provide ground or other reference voltages.

The number of terminals supporting a group of circuits is strongly dependent on the function of this group. The smallest pinout can be obtained with memory ICs because the stream of data can be limited to a single bit. Exactly the opposite is the case with groups of logic circuits which result from a random partitioning of a computer. The pinout requirement is one of the key driving parameters for all levels of packaging: chips, chip carriers, cards, modules, cables, and cable connectors.

Electrical Design Considerations

Electrical performance at the IC package level is of great importance for microwave designs and has gained considerable attention recently for silicon digital devices due to ever-increasing speed of today's circuits and their potentially reduced noise margins.[8] As a signal propagates through the package, it is degraded due to reflections and line resistance. Controlling the resistance and the inductance associated with the power and ground distribution paths to combat ground bounce and the simultaneous switching noise has now become essential. Controlling the impedance environment of the signal distribution path in the package to mitigate the reflection-related noise is becoming important. Reflections, in addition, cause an increase in the transition time, and may split the signal into two or more pulses with the potential of causing erroneous switching in the subsequent circuit and thus malfunction of the system. Controlling the capacitive coupling between signal traces in the signal distribution path to reduce crosstalk is gaining importance. Increased speed of the devices demands that package bandwidth be increased to reduce undue distortion of the signal. All these criteria are related through geometric variables, such as conductor cross-section and length, dielectric thickness, and the dielectric constant of the packaging body. These problems are usually handled with transmission line theory.[9]

Thermal Design Considerations

The thermal design objective is to keep the operating junction temperature of a silicon chip low enough to prevent triggering the temperature-activated failure mechanisms. Thus, the package should provide a good medium for heat transfer from junction to the ambient/heat sink. It is generally recommended to keep the junction temperature below 150°C to ensure proper electrical performance and to contain the propensity to fail.[10,11]

Thermal expansion caused by heating up the packaging structure is not uniform — it varies in accordance with the temperature gradient at any point in time and with the mismatches in the thermal coefficient of expansion. Mechanical stresses result from these differences and are one of the contributors to the finite lifetime and the failure rate of any packaging structure.[12]

In a simplistic heat transfer model of a packaged chip, the heat is transferred from the chip to the surface of the package by conduction, and from the package surface to the ambient by convection and radiation.[13,14] Typically, the temperature difference between the case and ambient is small, and hence radiation can be neglected. This model also neglects conduction heat transfer out of the package terminals, which can become significant. A multilayer example, which models the heat transfer from a region in the silicon device to the ambient, is shown in Fig. 11.2. The total thermal resistance from the junction to the ambient is given by:

$$R_{\theta ja} = R_{\theta jc} + R_{\theta cs} + R_{\theta sa} \tag{11.1}$$

The resulting junction temperature, assuming a power dissipation of P_d, is

$$T_j = P_d(R_{\theta jc} + R_{\theta cs} + R_{\theta sa}) + T_a \tag{11.2}$$

in analogy with electric circuits. If there are parallel paths for heat flow, the thermal resistances are combined in exactly the same manner as electrical resistors in parallel.

$R_{\theta cs}$, the conductive thermal resistance, is mainly a function of package materials and geometry. With the higher power requirements, one must consider the temperature dependence of materials selected in design. T_j depends on package geometry, package orientation in the application, and the conditions of the ambient in the operating environment. The heat sink is responsible for getting rid of the heat of the environment by convection and radiation. Because of all the many heat transfer modes occurring in a finned heat sink, the accurate way to obtain the exact thermal resistance of the heat sink would be to measure it. However, most heat sink manufactures today provide information about their extrusions concerning the thermal resistance per unit length.

Reliability

The package should have good thermomechanical performance for better reliability. A variety of materials of widely differing coefficients of thermal expansion (CTEs) are joined to create interfaces. These interfaces are subject to relatively high process temperatures and undergo many temperature cycles in their useful life as the device is powered on and off. As a result, residual stresses are created in the interfaces. These stresses cause reliability problems in the packages.[15,16]

Testability

Implicit in reliability considerations is the assumption of a flawless product function after its initial assembly — a zero defect manufacturing. Although feasible in principle, it is rarely practiced because of the high costs and possible loss of competitive edge due to conservative dimensions, tolerances, materials, and process choices. So, several tests are employed to assess the reliability of the packages.[17,18]

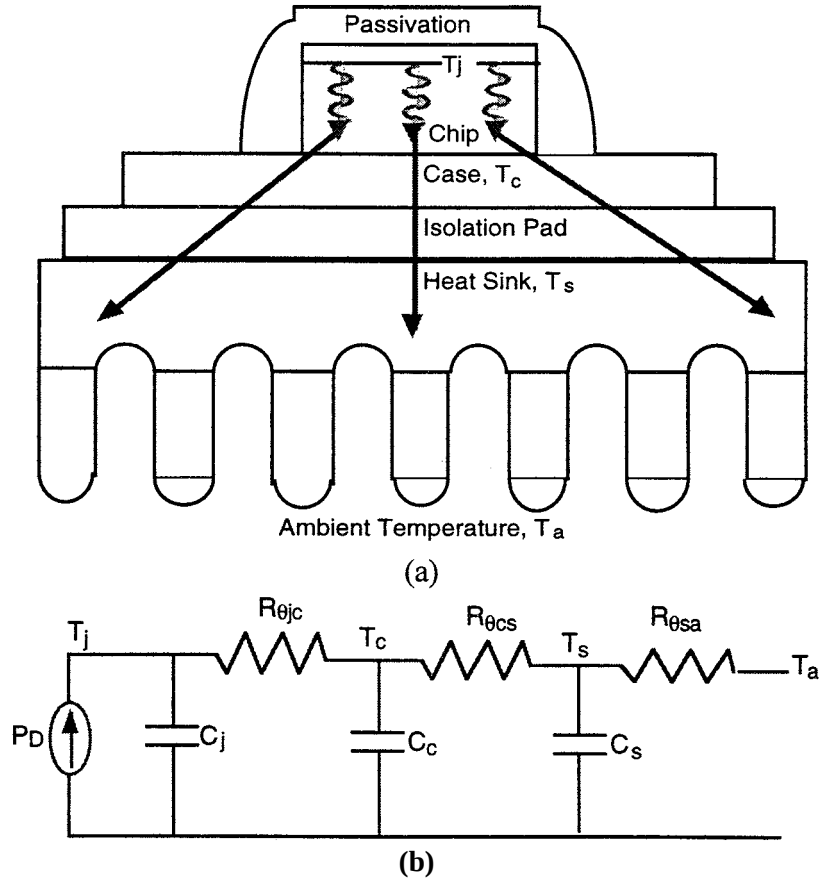

FIGURE 11.2 Steady-state heat flow and thermal resistance in a multilayer structure (a) path of heat flow; (b) equivalent electrical circuit based on thermal resistance.

11.4 Packaging Substrates

An IC package falls into two basic categories. In the first, a single-layer type, the package is constructed around the IC chip on a lead frame. In the second, a multilayer type, the IC chip is assembled into a prefabricated package.

In a single-layer technology, the IC chip is first mechanically bonded to a lead frame, and then electrically interconnected with fine wires from the chip bond pads to the corresponding lead-frame fingers. The final package is then constructed around the lead-frame subassembly. Two single-layer technologies are used in the industry: molded plastic and glass-sealed pressed ceramic.

Plastic Packaging

Plastic is a generic term for a host of man-made organic polymers. Polymer materials are relatively porous structures, which may allow absorption or transport of water molecules and ions.[19] The aluminum metallization is susceptible to rapid corrosion in the presence of moisture, contaminants, and electric fields. So, plastic packages are not very reliable. Impurities from the plastic or other materials in the construction of the package can cause threshold shifts or act as catalysts in metal corrosion. Fillers can also affect reliability and thermal performance of the plastic package.

Ceramic Packaging

Pressed ceramic technology packages are used mainly for economically encapsulating ICs and semiconductor devices requiring hermetic seals. Hermeticity means that the package must pass both gross and fine leak tests and also exclude environmental contaminants and moisture for a long period of time. Further, any contaminant present before sealing must be removed to an acceptable level before or during the sealing process.[20] Silicon carbide (SiC), aluminum nitride, beryllia (BeO), and alumina (Al_2O_3) are some of the ceramics used in electronic packaging. In comparison with other ceramics, SiC has a thermal expansion coefficient closer to silicon, and as a result less stress is generated between the *dice* and the substrate during temperature cycling. In addition, it has a very high thermal conductivity. These two properties make SiC a good packaging substrate and a good heat sink that can be bonded directly to silicon *dice* with little stress generation at elevated temperatures. Its high dielectric constant, however, makes it undesirable as a substrate to carry interconnections. Alumina and BeO have properties similar to SiC.[21]

TABLE 11.2A Thermal and Electrical Properties of Materials Used in Packaging

Metals	Coefficient of Thermal Expansion (CTE) (10^{-6} K^{-1})	Thermal Conductivity (W/cm-K)	Specific Electrical Resistance $10^{-6}\Omega$-cm
Aluminum	23	2.3	2.8
Silver	19	4.3	1.6
Copper	17	4.0	1.7
Molybdenum	5	1.4	5.3
Tungsten	4.6	1.7	5.3

Insulating Substrates	Coefficient of Thermal Expansion (CTE) (10^{-6} K^{-1})	Thermal Conductivity (W/cm-K)	Dielectric Constant
Alumina (Al_2O_3)	6.0	0.3	9.5
Beryllia (BeO)	6.0	2.0	6.7
Silicon carbide (SiC)	3.7	2.2	42
Silicon dioxide (SiO_2)	0.5	0.01	3.9

Semiconductors	Coefficient of Thermal Expansion (CTE) (10^{-6} K^{-1})	Thermal Conductivity (W/cm-K)	Dielectric Constant
Silicon	2.5	1.5	11.8
Germanium	5.7	0.7	16.0
Gallium arsenide	5.8	0.5	10.9

TABLE 11.2B Some Properties of Ceramic Packaging Materials

Property	BeO	AlN	Al_2O_3 (96%)	Al_2O_3 (99.5%)
Density (g/cm^3)	2.85	3.28	3.75	3.8
CTE (ppm/K)	6.3	4.3	7.1	7.1
TC (W/cm-K)	285	180	21	25.1
Dielectric const.	6.7	10	9.4	10.2
Loss tangent	0.0001	0.0005	0.0001	0.0001

11.5 Package Types

IC packages have been developed over time to meet the requirements of high speed and density. The history of IC package development has been the continuous battle to miniaturize.[22,23] Figure 11.3 illustrates the size and weight reduction of IC package over time.

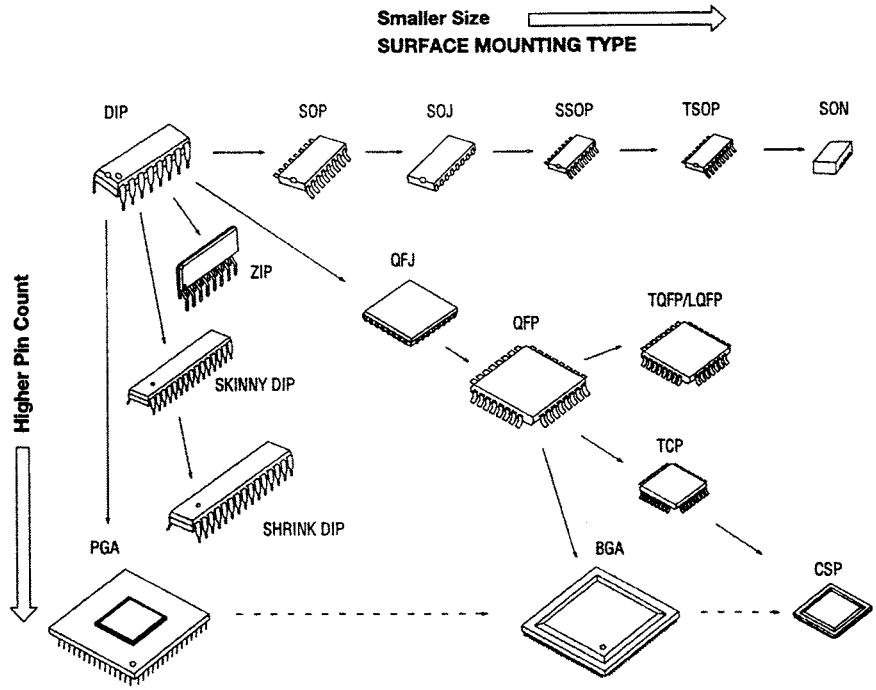

FIGURE 11.3 Packaging trends.

Several packages can be classified as follows.

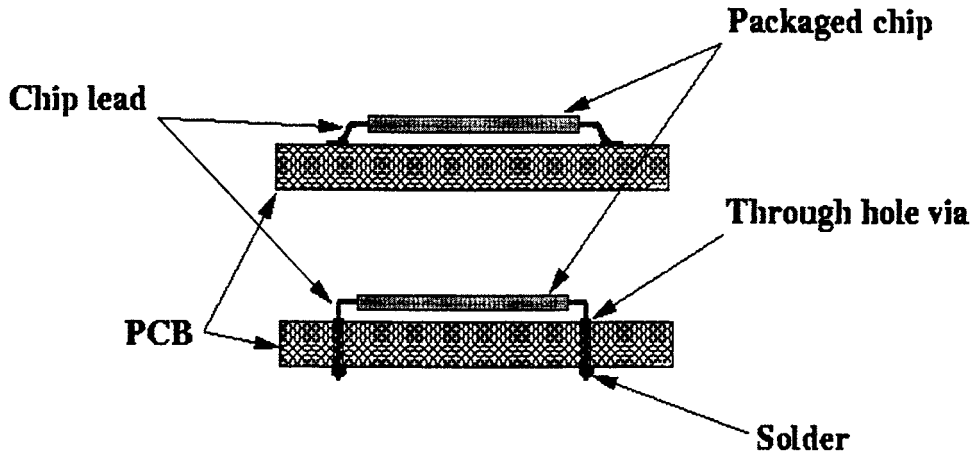

FIGURE 11.4 A generic schematic diagram showing the difference between the surface-mount technology (upper) and through hole mounting (lower).

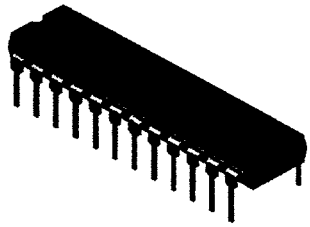
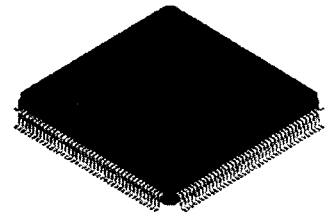
Through Hole Packages

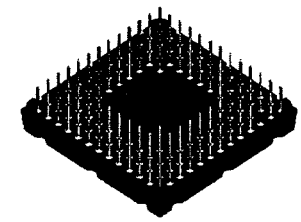
Through-the-board hole mounting technology uses precision holes drilled through the board and plated with copper. This copper plating forms the connections between separate layers. These layers consist of thin copper sheets stacked together and insulated by epoxy fiberglass. There are no dedicated via structures to make connections between wiring levels; through holes serve that purpose. Through holes form a sturdy support for the chip carrier and resist thermal and mechanical stresses caused by the variations in the expansions of components at raised temperatures. Different types (see Fig. 11.5) of through hole packages can be further classified as:



(a) Dual in-line package (DIP).



(b) Quad flat package (QFD).



(c) Pin grid array package (PGA).

FIGURE 11.5 Different through mount packages.

Dual-in-Line Packages (DIPs)

A dual-in-line package is a rectangular package with two rows of pins in its two sides. Here, first the die is bonded on the lead frame and in the next step, chip I/O and power/ground pads are wire-bonded to the lead frame, and the package is molded in plastic. DIPs are the workhorse of the high-volume and general-purpose logic products.

Quad Flat Packages (QFPs)

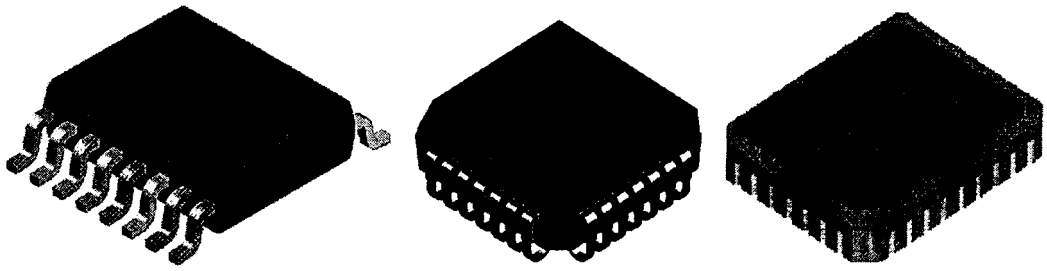
With the advances in VLSI technology, the lower available pin counts of the rectangular DIP became a limiting factor. With pins spaced 2.4 mm apart on only two sides of the package, the physical size of the DIP has become too great. On the other hand, the physical size of an unpackaged microelectronic circuit (bare die) has been reduced to a few millimeters. As a result, the DIP package has become up to 50 times larger than the bare die size itself, thus defeating the objective of shrinking the size of the integrated circuits. So, one solution is to provide pins all around. In QFPs, pins are provided on all four sides. Thin QFPs are developed to reduce the weight of the package.

Pin Grid Arrays (PGA)

A pin grid array has leads on its entire bottom surface rather than only at its periphery. This way it can offer a much larger pin count. It has cavity-up and cavity-down versions. In a cavity-down version, a die is mounted on the same side as the pins facing toward the PC board, and a heat sink can be mounted on its backside to improve the heat flow. When the cavity and the pins are on the same side, the total number of pins is reduced because the area occupied by the cavity is not available for brazed pins. The mounting and wire bonding of the dice are also more difficult because of the existence of the pins next to the cavity. High pin count and larger power dissipation capability of PGAs make them attractive for different types of packaging.

Surface-Mounted Packages

Surface mounting solves many of the shortcomings of through-the-board mounting. In this technology, a chip carrier is soldered to the pads on the surface of a board without requiring any through holes. The smaller component sizes, lack of through holes, and the possibility of mounting chips on both sides of the PC board improve the board density. This reduces package parasitic capacitances and inductances associated with the package pins and board wiring. Various types of surface-mount packages are available on the market and can be divided into the following categories (see Fig. 11.6):



(a) Small outline package (SOP). **(b) Plastic-leaded chip carriers (PLCC).** **(c) Leadless ceramic chip carriers (LCCC).**

FIGURE 11.6 Different surface-mount packages.

Small-Outline Packages (SOPs)

The small-outline package has gull-wing shaped leads. It requires less pin spacing than through-hole-mounted DIPs and PGAs. SOP packages usually have small lead counts and are used for discrete, analog, and SSI/MSI logic parts.

Plastic-leaded Chip Carriers (PLCCs)

Plastic-leaded chip carriers, such as gull-wing and J-leaded chip carriers, offer higher pin counts than SOP. J-leaded chip carriers pack denser and are more suitable for automation than gull-wing leaded carriers because their leads do not extend beyond the package.

Leadless Ceramic Chip Carriers (LCCCs)

Leadless ceramic chip carriers take advantage of multilayer ceramic technology. The conductors are left exposed around the package periphery to provide contacts for surface mounting. *Dice* in leadless chip carriers are mounted in cavity-down position, and the back side of the chip faces away from the board, providing a good heat removal path. The ceramic substrate also has a high thermal conductivity. LCCCs are hermetically sealed.

Flip-Chip Packages

The length of the electrical connections between the chip and the substrate can be minimized by placing solder bumps on the *dice*, flipping the chips over, aligning them with the contacts pads on the substrate, and reflowing the solder balls in a furnace to establish the bonding between the chips and the package. This method provides electrical connections with minute parasitic inductance and capacitance. In addition, contact pads are distributed over the entire chip surface. This saves silicon area, increases the maximum I/O and power/ground terminals available with a given die size, and provides more efficiently routed signal and power/ground interconnections on the chips.[24] (see Fig. 11.7.)

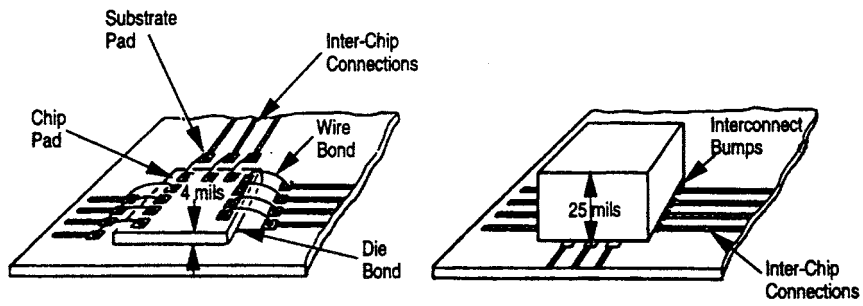


FIGURE 11.7 Flip-chip package and its interconnections.

Chip Size Packages (CSPs)

To combine the advantages of both packaged chip and bare chip in one solution, a variety of CSPs have been developed.[25,26] CSPs can be divided into two categories: the fan-in type and the fan-out type.

Fan-in type CSPs are suitable for memory applications that have relatively low pin counts. This type is further divided into two types, depending on the location of bonding pads on the chip surface; these are the center pad type and the peripheral pad type. This type of CSP keeps all the solder bumps within the chip area by arranging bumps in area array format on the chip surface.

The fan-out CSPs are used mainly for logic applications: because of the die size to pin count ratio, the solder bumps cannot be designed within the chip area.

Multi-Chip Modules (MCMs)

In a multi-chip module, several chips are supported on a single package. Most multi-chip packages are made of ceramic. By eliminating one level of packaging, the inductance and capacitance of the electrical connections among the *dice* are reduced. Usually, the *dice* are mounted on a multilayer ceramic substrate via solder bumps, and the ceramic substrate offers a dense interconnection network.[27,28] (See Fig. 11.8.) There are several advantages of multi-chip modules over single-chip carriers. The multi-chip module minimizes the chip-to-chip spacing and reduces the inductive and capacitive discontinuities between the chips mounted on the substrate by replacing the die-bump-interconnect-bump-die path. In addition, narrower and shorter wires on the ceramic substrate have much less capacitance and inductance than the PC board interconnections.

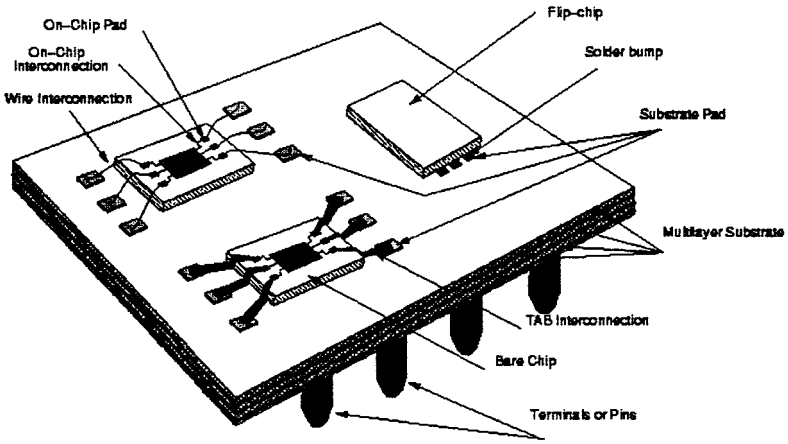

FIGURE 11.8 A generic schematic diagram of an MCM, showing how bare *dice* are interconnected to an MCM substrate using different interconnection technologies.

3-D VLSI Packaging

The driving forces behind the development of three-dimensional packaging technology are similar to the multi-chip module technology, although the requirements for the 3-D technology are more aggressive. These requirements include the need for significant size and weight reductions, higher performance, small delay, higher reliability, and potentially reduced power consumption.

Silicon-on-Silicon Hybrid

A silicon substrate can also be used as an interconnection medium to hold multi-chips as an alternative to ceramic substrates. This is called silicon-on-silicon packaging or, sometimes, hybrid wafer-scale

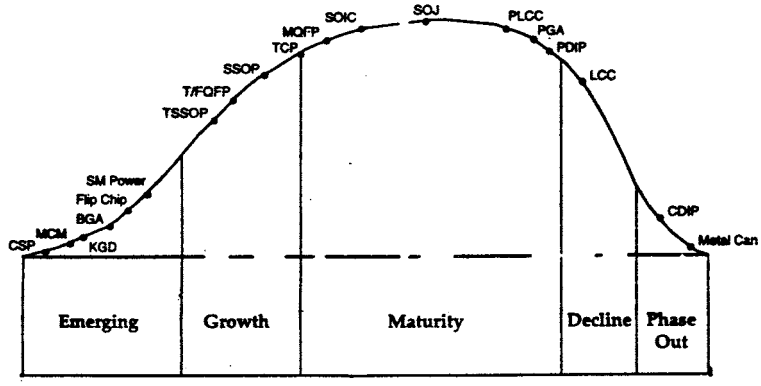

FIGURE 11.9 IC packaging life cycle.

integration. Thin-film interconnections are fabricated on a wafer and separately processed, and test dice are mounted on this silicon substrate via wire bonding, TAB, or solder bumps. Using this technique, chips fabricated in different technologies can be placed on the same hybrid package. The silicon substrate can also potentially contain active devices that serve as chip-to-chip drivers, bus and I/O multiplexers, and built-in test circuitry.[29]

11.6 Hermetic Packages

In hermetic packages, the packaged cavity is sealed in such a way that all external chemical species are permanently prevented from entering into it. In practice, however, a finite rate of leakage occurs through diffusion and permeation. Moisture is the principal cause of device failures. Moisture by itself does not cause electronic problems when trapped in an electronic package, because it is a poor electrical conductor. However, water can dissolve salts and other polar molecules to form an electrolyte, which together with the metal conductors and the potential difference between them, can create leakage paths as well as corrosion problems. Moisture is contributed mainly by the sealing ambient, the absorbed and dissolved water from the sealing materials, lid and the substrate and the leakage of external moisture through the seal. No material is truly hermetic to moisture. The permeability to moisture of glasses, ceramics, and metals, however, is very low and is orders of magnitude lower than for any plastic material. Hence, the only true hermetic packages are those made of metals, ceramics, and glasses. The common feature of hermetic packages is the use of a lid or a cap to seal in the semiconductor device mounted on a suitable substrate. The leads entering the package also need to be hermetically sealed.

11.7 Die Attachment Techniques

To provide electrical connections between the chip pads and package, different bonding techniques are used. These can be classified as follows.

Wire Bonding

Wire bonding (see Fig. 11.10) is a method used to connect a fine wire between an on-chip pad and a substrate pad. This substrate may simply be the ceramic base of a package or another chip. The common materials used are gold and aluminum. The main advantage of wire bonding technology is its low cost; but it cannot provide large I/O counts, and it needs large bond pads to make connections. The connections have relatively poor electrical performance.

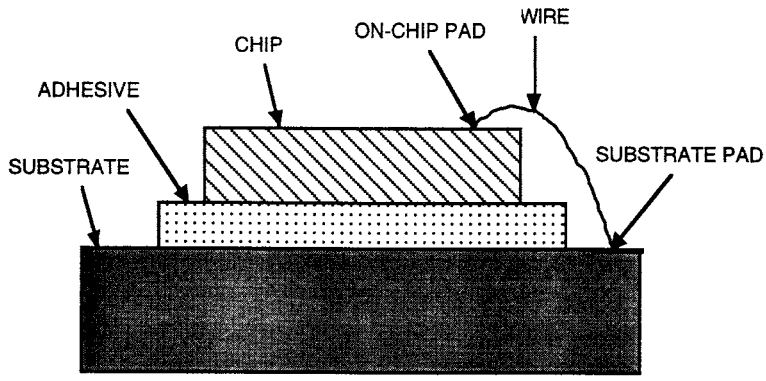

FIGURE 11.10 Wire bonding assembly.

Tape-Automated Bonding

In tape-automated bonding (TAB) technology, a chip with its attached metal films is placed on a multilayer polymer tape. The interconnections are patterned on a multilayer polymer tape. The tape is positioned above the "bare die" so that the metal tracks (on the polymer tape) correspond to the bonding sites on the die (Fig. 11.11). TAB technology provides several advantages over wire bonding technology. It requires a smaller bonding pad, smaller on-chip bonding pitch, and a decrease in the quantity of gold used for bonding.[30] It has better electrical performance, lower labor costs, higher I/O counts and lighter weight, greater densities, and the chip can be attached in a face-up or face-down configuration. TAB technology includes time and cost of designing and fabricating the tape and the capital expense of the TAB bonding equipment. In addition, each die must have its own tape patterned for its bonding configuration. Thus, TAB technology has typically been limited to high-volume applications.

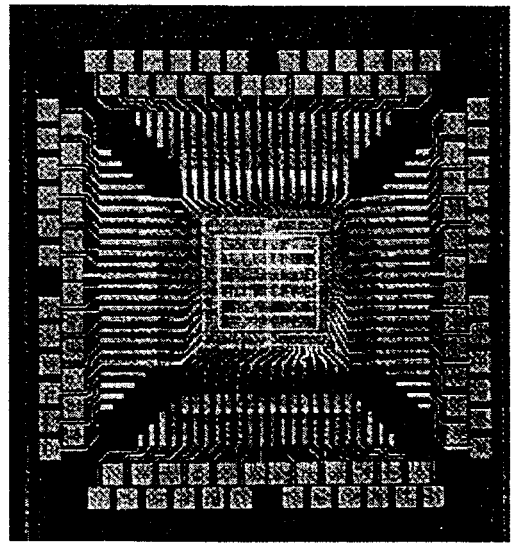

FIGURE 11.11 Tape-automated bonded die.

Solder Bump Bonding

Solder bumps are small spheres of solder (solder balls) that are bonded to contact areas or pads of semiconductor devices and subsequently used for face-down bonding. The length of the electrical

connections between the chip and the substrate can be minimized by placing solder bumps on the die, flipping the die over, aligning the solder bumps with the contact pads on the substrate, and re-flowing the solder balls in a furnace to establish the bonding between the die and the substrate[31] (Fig. 11.12). This technology provides electrical connections with minute parasitic inductances and capacitances. In addition, the contact pads are distributed over the entire chip surface rather than being confined to the periphery. As a result, the silicon area is used more efficiently, the maximum number of interconnects is increased, and signal interconnections are shortened. But this technique results in poor thermal conduction, difficult inspection of the solder bumps, and possible thermal expansion mismatch between the semiconductor chips and the substrate.

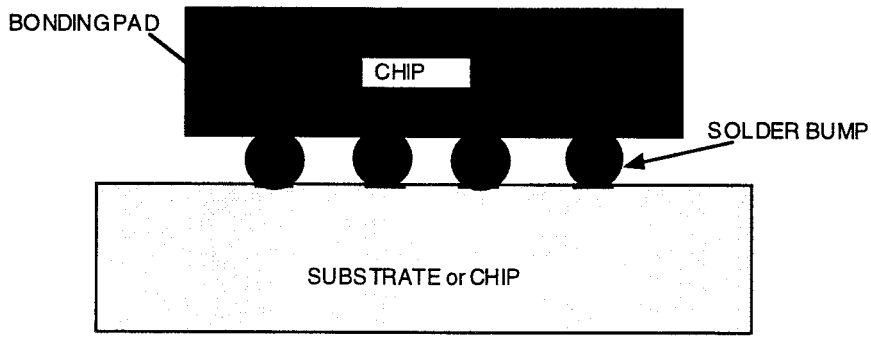

FIGURE 11.12 Flip-chip method using solder bumps.

11.8 Package Parasitics

Typically, the electrical interconnection of a chip in a package consists of chip-to-substrate interconnect, metal runs on the substrate, and finally, pins from the package. Associated with these are the electrical resistance, inductance and capacitance — referred to as package parasitics. The electrical parasitics are determined by the physical parameters such as interconnect width, thickness, length, spacing, and resistivity; by the thickness of the dielectric; and by the dielectric constant.

Resistance refers to both dc and ac. The dc resistance of an interconnect is a property of its cross-sectional area, length, and material resistivity. In addition, the ac resistance depends on the frequency of the signal and is higher than the dc resistance because of the skin effect. Resistance in the power distribution path results in attenuation of input signals to the device and output signals from the device. This has the effect of increasing the path delay.

Capacitance of an interconnect is a property of its area, the thickness of the dielectric separating it from the reference potential, and the dielectric constant of the dielectric. It is convenient to consider this as two parts: capacitance with respect to ground, and capacitance with respect to other interconnections. The capacitance with respect to ground is referred to as the *load capacitance*. This is seen as part of the load by the output driver and thus can slow down the rise time of the driver. Interlead capacitance couples the voltage change on the active interconnect to the quiet interconnect.[32] This is referred to as *crosstalk*.

Inductance can be defined only if the complete current path is known. In the context of component packages, the inductance of an interconnect should be understood as part of a complete current loop. Thus, if the placement of the package in the system alters the current path in the package, the package inductance will vary. Total inductance consists of self-inductance and mutual inductance. Mutual inductance between two interconnects generates a voltage in one when there is current change in the other. Inductive effects are the leading concern in the design of power distribution path in high-performance packages. They are manifested as “ground bounce” noise and “simultaneous switching” noise.

11.9 Package Modeling

As the complexity of devices increases, design and development efforts for packages become comparable to design and development efforts for chips. Many package design concepts must be simulated to assess their associated performance parameters.[33,34] Computer-aided design software and test chips are becoming indispensable design tools. Computer-aided design tools are extensively used to analyze the thermal, thermomechanical, mechanical, and electrical parameters of packages[35]; for example, electrical modeling extracts an equivalent electrical circuit that describes the physical structure of the package and, hence, the equivalent electrical circuit of the package can be used in circuit simulation programs to evaluate the overall performance of a packaged circuit. Until now, the equivalent electrical circuit incorporated only lumped electrical parameters; but as frequency of operation of the circuits is increasing, the distributed model of the package needs to be developed for high-frequency simulations.[36]

11.10 Packaging in Wireless Applications

Wireless applications typically involve RF, high-frequency digital, and mixed-mode circuits. Wireless packaging requires minimal electrical parasitic effects that need to be well-characterized.

In wireless applications, the trend is to integrate multiple modules on a single chip.[37] So, the thermal management of the whole chip becomes crucial. The IC package must have good thermal properties. Metal as a material shows optimal properties concerning thermal conductivity, electromagnetic shielding, mechanical and thermal stability. For thermal expansion, best match to semiconductor and ceramic material can be achieved with molybdenum, tungsten, or special composites like kovar. Ceramic materials are applied, both as parts of the package as well as for subsystem carrying RF transmission lines. To this end, and to provide electromagnetic shielding, these materials partly have to be metallized. Aluminum nitride, beryllia, aluminum silicon carbide, and CVD diamond show best thermal conductivity and are therefore applied in high-power applications,[38,39] while alumina is well known for standard microwave applications.[40]

Integration of passive components is a major challenge in wireless packages. More and more efforts are being made to integrate passive components, power devices on a chip with the other mixed signal circuits.[41] The size of the package becomes an issue. Micromachining technology provides a way to make miniature packages that conform to RF circuits, while providing physical and electrical shielding. Conformal packages made by applying micromachining technology provide the capability to isolate individual circuit elements and improve circuit performance by eliminating the radiation and cross-coupling between the adjacent circuits.[42,43]

At high frequencies, interconnections need to be carefully designed. Microstrip interconnects, coplanar waveguide are mostly used for microwave packaging.[44] Flip-chip packaging has tremendous potential for future RF packaging.[45]

11.11 Future Trends

Packaging is the bridge between silicon and electronics system. Packaging design and fabrication are increasingly important to system applications. Consideration of factors affecting waveform integrity for both power and signal (i.e., timing, cross-talk, and ground bounce) will affect device layout on the chip, chip layout on the package, and interconnect.

Conventional surface mount packages will dominate in the region of low pin count and low clock frequency. Ball-grid array packages and chip-scale packages will be used for medium pin counts. Technically bare chip solutions can cover the whole area, but have a reliability versus cost tradeoff. Bare chip solutions could be very competitive with packaged solutions, as they can accomplish very high density and very good electrical performance.

Packaging needs are driven as much by market application requirements as by silicon technology. Cost drives technology tradeoffs for all market segments. As the complexity of package technology continues to increase, new materials will be needed to meet design and performance challenges. Significant engineering development will be needed for power increases at each technology generation.

An integrated design environment of physical, electrical, thermal, thermo-mechanical, chip, package, and system design needs to be evolved. Most of these integrated solutions will provide modeling and simulation capabilities that will be embodied in packaging computer aided design systems. Design tools are required to manage the complexity of packaging that is being pushed to its performance limits.

12.1 Introduction

From the pioneering days to its current renaissance, the electronics industry has become the largest and most pervasive manufacturing industry in the developed world. Electronic products have the hallmark of innovation, creativity, and cost competitiveness in the world market place. The way the electronics are packaged, in particular, has progressed rapidly in response to customers' demands in general for diverse functions, cost, performances, and robustness of different products. For practicing engineers, there is a need to access the current state of knowledge in design and manufacturing tradeoffs.

Thus arises a need for electronics technology-based knowledge to optimize critical electronic design parameters such as speed, density, and temperature, resulting in performance well beyond PC board design capabilities. By removing discrete component packages and using more densely packed interconnects, electronic circuit speeds increase. The design challenge is to select the appropriate packaging technology, and to manage any resulting thermal problems.

The expanding market for high-density electronic circuit layouts calls for multi-chip modules (MCMs) to be able to meet the requirements of fine track and gap dimensions in signal layers, the retention of accurately defined geometry in multilayers, and high conductivity to minimize losses. Multi-chip module technologies fill this gap very nicely. This chapter provides engineers/scientists with an overview of existing MCM technologies and briefly explains similarities and differences of existing MCM technologies. The text is reinforced with practical pictorial examples, omitting extensive development of theory and details of proofs.

The simplest definition of a multi-chip module (MCM) is that of a single electronic package containing more than one integrated circuit (IC) die.[1] An MCM combines high-performance ICs with a custom-designed common substrate structure that provides mechanical support for the chips and multiple layers of conductors to interconnect them.

One advantage of this arrangement is that it takes better advantage of the performance of the ICs than it does interconnecting individually packaged ICs because the interconnect length is much shorter. The really unique feature of MCMs is the complex substrate structure that is fabricated using multilayer ceramics, polymers, silicon, metals, glass ceramics, laminates, etc. Thus, MCMs are not really new. They have been in existence since the first multi-chip hybrid circuit was fabricated. Conventional PWBs utilizing chip-on-board (COB), a technique where ICs are mounted and wire-bonded directly to the board, have also existed for some time. However, if packaging efficiency (also called silicon density), defined as the percentage of area on an interconnecting substrate that is occupied by silicon ICs, is the guideline used to define an MCM, then many hybrid and COB structures with less than 30% silicon density do not qualify as MCMs. In combination with packaging efficiency, a minimum of four conductive layers and 100 I/O leads has also been suggested as criteria for MCM classification.[1]

A formal definition of MCMs has been established by the Institute for Interconnecting and Packaging Electronic Circuits (IPC). They defined three primary categories of MCMs: MCM-L, MCM-C, and MCM-D.

It is important to note that these are simple definitions. Consequently, many IC packaging schemes, which technically do not meet the criteria of any of the three simple definitions, may incorrectly be referred to as MCMs. However, when these simple definitions are combined with the concept of packaging efficiency, chip population, and I/O density, there is less confusion about what really constitutes an MCM. The fundamental (or basic) intent of MCM technology is to provide an extremely dense conductor matrix for the interconnection of bare IC chips. Consequently, some companies have designated their MCM products as high-density interconnect (HDI) modules.

12.2 Multi-Chip Module Technologies

From the above definitions, it should be obvious that MCM-Cs are descended from classical hybrid technology, and MCM-Ls are essentially highly sophisticated printed circuit boards, a technology that has been around for over 40 years. On the other hand, MCM-Ds are the result of manufacturing technologies that draw heavily from the semiconductor industry.

MCM-L

Modules constructed of plastic laminate-based dielectrics and copper conductors utilizing advanced forms of printed wiring board (PWB) technologies to form the interconnects and vias are commonly called "laminate MCMs," or MCM-Ls.[2]

Advantages	
Economic	Ability to fabricate circuits on large panels with a multiplicity of identical patterns. Reduces manufacturing cost. Quick response to volume orders.

Disadvantages	
Technological	More limited in interconnect density relative to advanced MCM-C and MCM-D technologies. Copper slugs and cut-outs are used in MCM-Ls for direct heat transfer. This degrades interconnection density.

MCM-L development has involved evolutionary technological advances to shrink the dimensions of interconnect lines and vias. From a cost perspective, it is desirable to use conventional PWB technologies for MCM-L fabrication. This is becoming more difficult as the need for multi-chip modules with higher interconnect density continues.

As MCM technologies are being considered for high-volume consumer products applications, a focus on containing the cost of high-density MCM-Ls is becoming critical.

The most usefull charateristic in assessing the relative potential of MCM-L technology is interconnection density,[3,4] which is given by:

$$\text{Packaging efficiency (\%)} = \text{Silicon chip area/Package area} \tag{12.1}$$

The above formula measures how much of the surface of the board can be used for chip mounting pads versus how much must be avoided because of interconnect traces and holes/pads.

MCM-C

These are modules constructed on co-fired ceramic or glass-ceramic substrates using thick-film (screen printing) technologies to form the conductor patterns using fireable metals. The term "co-fired" implies that the conductors and ceramic are heated at the same time. These are also called thick-film MCMs.

Ceramic technology for MCMs can be divided into four major categories

- Thick-film hybrid process
- High-temperature co-fired alumina process (HTCC)
- Low-temperature co-fired ceramic/glass based process (LTCC)
- High T_c aluminum nitride co-fired substrate (AIN)

Thick-film hybrid technology produces by the successive deposition of conductors, dielectric, and/or resistor patterns onto a base substrate.[5] The thick-film material, in the form of a paste, is screenprinted onto the underlying layer, then dried and fired. The metallurgy chosen for a particular hybrid construction depends on a number of factors, including cost sensitivity, conductivity requirements, solderability, wire bondability, and more. A comparative summary of typical ceramic interconnect properties is compiled in Table 12.1.

TABLE 12.1 A Comparative Summary of Typical Ceramic Interconnect Properties

Item	Thick Film	HTCC	LTCC
Line width (μm)	125	100	100
Via diameter (μm)	250	125	175
Ave. No. conductor layers	1–6	1–75	1–75
Conductor res. (mohm/sq)	2–100	8–12	3–20
ε (dielectric)	5–9	9–10	5–8
CTE	4–7.5	6	3–8
T_c Dielectric (W/mC)	2	15–20	1–2
Relative cost (low volume)	Medium	High	High
Tooling costs	Low	High	High
Capital outlay	Low	High	Medium

12.3 Materials for HTCC Aluminum Packages

Metal conductors of tungsten and molybdenum are used for compatibility in co-firing to temperatures of 1600°C. Materials compatibility during co-firing dictates that raw materials of alumina with glass used for densification and any conductor metal powders (W, Mo) must be designed to closely match onset, rate, and volume shrinkage; promote adhesion; and minimize thermal expansion mismatch between conductor and dielectric.

Processing HTCC Ceramics

The raw materials used in fabrication of aluminum substrates include aluminum oxide, glass, binder, plasticizer, and solvent. Materials specifications are used to control alumina particle size, surface area, impurity, and agglomeration. Glass frit is controlled through composition, glass transition and softening point, particle size, and surface area. Molecular weight, group chemistry, and viscosity controls are used for the binder and plasticizer.

Metal Powder and Paste

A thick-film paste often uses metal powder, glass powder, organic resins, and solvents. Compositions are varied to control screening properties, metal shrinkage, and conductivity. Paste fabrication begins with batch mixing, dispersion, and deagglomeration, which are completed on a three-roll mill.

Thick-Film Metallization

The greensheet is cast, dried, stripped from the carrier film, and blanked into defect-free sheets, typically 200 mm^2. The greensheet is then processed through punching, screening, and inspection operations.

HTCC in Summary

- Electrical performance characteristics include 50-ohm impedance, low conductor resistance, ability to integrate passive components such as capacitors and inductors, the ability to achieve high wiring density (ease of increasing the number of wiring at low cost), the ability to support high-speed simultaneous switching drivers, and the ease of supporting multiple reference voltages.
- Inherent thermal performance characteristics superior to MCM-L and MCM-D.
- Time-demonstrated reliability.

12.4 LTCC Substrates

The use of glass and glass-ceramics in electronic packaging goes back to the invention of semiconductors. Glasses are used for sealing T-O type packages and CERDIPs, as crossover and inter-level dielectrics in hybrid substrates. The success of co-fired alumina substrates spurred the development of the multilayer glass-ceramic substrates. These advantages derive from the higher electrical conductivity lines of copper, silver, or gold; the lower dielectric constant of the glass ceramic; and the closer CTE match of the substrate to silicon.

Two approaches have been used to obtain glass-ceramic compositions suitable for fabricating self-supporting substrates.[6–8] In the first approach, fine powder of a suitable glass-composition is used that has the ability to sinter well in the glassy state and simultaneously crystallize to become a glass-ceramic. More commonly, mixtures of ceramic powders are used, such as alumna and a suitable glass in nearly equal proportions, to obtain densely sintered substrates.[9,10] Because many glass and ceramic powders can be used to obtain densely sintered glass-ceramic, the actual choice is often made on the basis of other desirable attributes in the resulting glass-ceramic — such as low dielectric constant for lowering the signal propagation delay and coefficient of thermal expansion (CTE) closely matched to the CTE of

silicon to improve the reliability of solder interconnections. Unlike the case of a crystallizing glass, the mixed glass and ceramic approach allows for a much wider choice of materials.

12.5 Aluminum Nitride

Aluminum nitride products are used in a variety of commercial and military applications.

Thermal management with solutions such as AlN can provide superior cooling to ensure reliable system operation. AlN packages typically offer a thermal conductivity of 150 to 200 W/mK, a level which can be compared with many metals or other high thermal conductive materials such as berillia (BeO) or silicon carbide (SiC). AlN has a thermal coefficient of expansion of 4.4 ppm, which is better matched to silicon than to alumina or plastics. Table 12.2 provides a comparison of AlN properties.

TABLE 12.2 AlN Properties Comparison

Item	ALN	HTCC	LTCC	BeO	Si	Cu
Thermal conductivity (W/mK)	175	25	2	260	150	394
Density (g/cm)		3.3	3.9	2.6	2.8	8.9
Dielectric constant (Mhz)	8.9	9.5	5.0	6.7		
Dissipation factor	0.0004	0.0004	0.0002	0.0004		
Bending strength (MaP)	320	420	210	220		

Source: From Ref. 2.

12.6 Materials for Multi-layered AlN Packages

Aluminum nitride is a synthetic compound manufactured by two processes: the carbothermal reduction of alumina (Eq. 12.2) and/or direct nitridation of aluminum metal (Eq. 12.3):

$$Al_2O_3 + 3C + N_2 \rightarrow 2AlN + 3CO \tag{12.2}$$

$$2Al + N_2 \rightarrow 2AlN \tag{12.3}$$

MCM-D

Modules are formed by the deposition of thin-film metals and dielectrics, which may be polymers or inorganic dielectrics. These are commonly called thin-film MCMs.

Here, the focus will be on materials to fabricate the high-density MCM-D interconnect. The materials of construction can be categorized as the thin-film dielectric, the substrate, and the conductor metallization.

12.7 Thin-Film Dielectrics

Dielectrics for the thin-film packaging are polymeric and inorganic. Here, we will try to be brief and informative about those categories. Thin-film packages have evolved to a much greater extent with polymeric materials. The capability offered by polymers include a lower dielectric constant, the ability to form thicker layers with higher speeds, and lower cost of deposition. Polymer dielectrics have been used as insulating layers in recent microelectronics packaging.

12.8 Carrier Substrates

The thin-film substrate must have a flat and polished surface in order to build upon. The substrate should be inert to the process chemicals, gas atmospheres, and temperatures used during the fabrication of the interconnect. Mechanical properties are particularly important because the substrate must be strong

enough to withstand handling, thermal cycling, and shock. The substrate must also meet certain CTE constraints because it is in contact with very large silicon chips on one side and with the package on the other side.[11,12] Thermal conductivity is another important aspect when heat-generating, closely spaced chips need that heat conducting medium. It is informative to state that high-density, large-area processing has generated interest in glass as a carrier material.

Metallic substrates have been used to optimize the thermal and mechanical requirements while minimizing substrate raw material and processing costs. Metallic sandwiches such as Cu/Mo/Cu can be tailored to control CTE and thermal properties. 5%Cu/Mo/5%Cu is reported to have a thermal conductivity (TC) of 135 W/mK, a CTE of 5.1 ppm, an as-manufactured surface finish of 0.813 μm, and a camber of 0.0005 in/in.

12.9 Conductor Metallization

In MCM, fabrication materials chosen will depend on the design, electrical requirements, and process chosen to fabricate the MCM. It is important to note that the most critical requirements for conductor metallization are conductivity and reliability.

Aluminum

Aluminum is a low-cost material that has adequate conductivity and can be deposited and patterned by typical IC techniques. It is resistant to oxidation. It can be sputtered or evaporated, but cannot be electroplated.

Copper

Copper has significant conductivity over aluminum and is more electromigration-resistant. It can be deposited by sputtering, evaporation, electroplating, or electroless plating. Copper rapidly oxidizes, forming a variety of oxides that can have poor adhesion to polymer dielectrics and copper itself.

Gold

Gold is used in thin-film structures to minimize via contact resistance problems caused by oxidation of Cu and Al. Gold can be deposited by sputtering, evaporation, electroplating, or electroless plating. Cost is high with excellent resistivity characteristic. Adhesion is poor and so it requires a layer (50 to 200 nm) of Ti or Ti/W.

12.10 Choosing Substrate Technologies and Assembly Techniques

The MCM designer has the freedom of choosing/identifying substrate and assembly technologies[13–15] from many sources.[16,17] If you are about to start a design and are looking for guidelines, finding a good source of information could be Internet access. In addition to designing to meet specific performance requirements, it is also necessary to consider ease of manufacture. For example, Maxtek publishes a set of design guidelines, that inform the MCM designer of preferred assembly materials and processes, process flows, and layout guidelines.

Substrate Technologies	Assembly Techniques
Chip-on-board	Surface mount
Chip-on-flex	Chip-and-wire
Thick-film ceramic	Mixed technology
Cofired ceramic	Special module
Thin-film ceramic	

Under Substrate Technologies and Assembly techniques it will be very informative to look at some pictorial examples, a primary source of which is Maxtek. The pictorial examples, followed by a brief description of technology or assembly technique shown, will serve as a quick guideline for someone who would like to get a feel of what technologies are viable in the MCM technology domain. Here, it is important to mention that a lot of current space electronic flight projects use MCM technologies for their final deliverables. Project Cassini, for example, used MCM hybrids in telecommunication subassemblies. On this note, take a look at some of the examples of MCM technologies currently on the market.

Chip-on-Board

Chip-on-board substrate technology (Fig. 12.1) has low set-up and production costs and utilizes Rigid FR-406, GETEK, BT Epoxy, or other resin boards.[3] Assembly techniques used are direct die attach/wire bonding techniques, combined with surface-mount technologies.

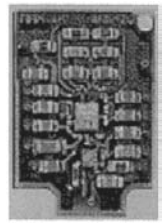

FIGURE 12.1 Chip-on-board.

Chip-on-Flex

Chip-on-Flex substrate technologies[18,19] (Fig. 12.2) are excellent for high-frequency, space-constrained circuit implementation. In creating this particular technology, the manufacturer needs Kapton or an equivalent flex-circuit base material with board stiffeners. Here, the die can be wire-bonded, with "glob-top" protection, while other discretes can be surface mounted. Integral inductors can be incorporated (e.g., for load matching).

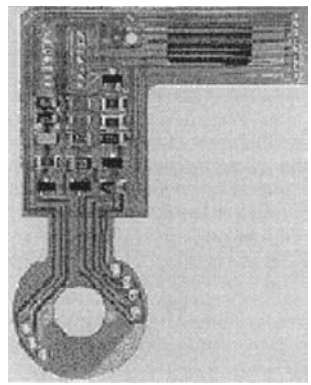

FIGURE 12.2 Chip-on-flex.

Thick-Film Ceramic

This technology is the most versatile technology, with low-to-medium production costs. The 1-GHz attenuator above demonstrates the versatility of thick film on ceramic substrate technology (Fig. 12.3),

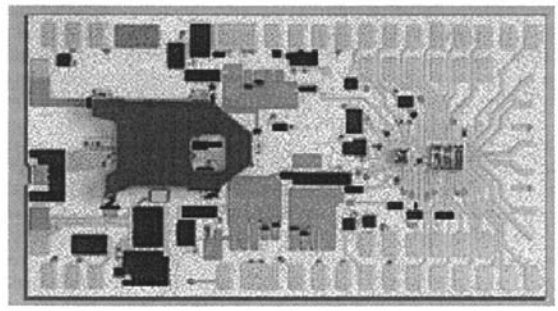

FIGURE 12.3 Thick-film ceramic.

which utilizes both standard and custom ICs, printed resistors and capacitors actively trimmed to 0.25% with extremely stable capacitors formed between top plate and ground plane on the other side of substrate. Thick-film thermistor here senses overheating resistor and protects the remainder of the circuit.

Co-fired Ceramic

Co-fired ceramic MCM substrate technologies (low- or high-temperature co-fired multilayer ceramic) (Fig. 12.4) are particularly suited for high-density digital arrays. Despite its high set-up and tooling costs, up to 14 co-fired ceramic layers are available from this particular manufacturer. In this technology, many package styles are available, including DIP, pin-grid array, and flat pack.

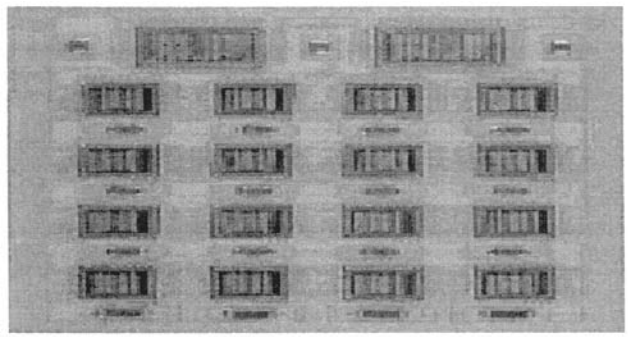

FIGURE 12.4 Co-fired ceramic.

Thin-Film Ceramic

For thin-film ceramic technologies (see Fig. 12.5), here is the outlined technology features include:

- High-performance MCMs, offset by high set-up and tooling costs
- Alumina or BeO (as shown here) substrate
- Both sides of substrate can be used, the back side typically being a ground plane, with access through plated-through holes
- Chip-and-wire assembly with epoxied capacitors
- Many packaging styles available, including Kovar or ceramic package and lid
- Primarily used for high-frequency circuits requiring thin-film inductors or controlled impedance lines

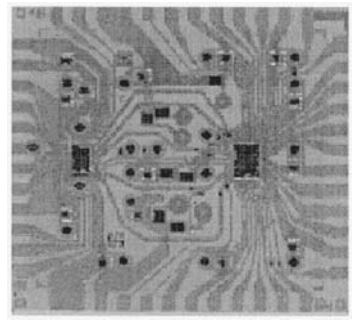

FIGURE 12.5 Thin-film ceramic.

For quick reference, some specifications and MCM technology information are summarized in Tables 12.3 and 12.4.

TABLE 12.3 Thick-Film Specifications

Printed Component	Sheet Resistivity per square	Typical Values	Comments
Conductor, Gold	3–5 mohm		Lowest resistivity, 5-mil min. line/space
Etched thick-film	3–5 mohm		2 mil min. line/space
Conductor, Pd-Ag	<50 mohm		Lowest cost, solderable, 10-mil min. line/space
Resistor	3 ohm–1 Mohm		<±100 ppm/°C, laser trimmable to ±0.25%
Capacitor		10, 50, 100, 1500	Untrimmed ±30%, may be actively trimmed dielectric constant
Inductor		4–100 nH	Untrimmed ±10%

Source: Ref. 19.

TABLE 12.4 MCM Substrate Technologies

Technology	Material	Line/Space (mils min.)	Dielectric Constant	Integral R	Integral C	Integral L
Chip-on-board	Glass-epoxy (FR-4), polyimides	4	4.3-5.0 4.0-4.6	Y	Y	
Chip-on-flex	Kapton or equiv. with stiffeners	3 inner, 5 outer	3.2-3.9	Y	Y	
Thick-film ceramic	Alumina	5	9.26.3	Y	Y	Y
	BeO	5		Y	Y	
Multilayer ceramic	Lo-fire alumina	5	5.8-9.0	Y	Y	
	Hi-fire alumina	5	9.0-9.6	Y	Y	
Thin-film ceramic	Alumina	1	9.9	Y	Y	Y
	BeO	1	6.3			
Etched thick-film	Alumina	2	9.2	Y	Y	Y

Other thick-film components are available, such as thermistors and spark gaps. In many applications, both sides of a substrate can be used for printed components.

12.11 Assembly Techniques

Surface-Mount Assembly

The surface-mount assembly technique can be categorized under lowest-cost, fastest turnaround assembly method, using pre-packaged components soldered to glass-epoxy board, flex circuit, or thick-film ceramic substrate. Many package styles are available, such as SIP, DIP. Pins may be attached as in-line leads, 90° leads, etc.[19]

Chip-and-Wire Assembly

In order to minimize interconnect electronic circuit parasitics, a high-density layout is one of the assembly techniques recommended as a solution. The highlight of this technique is epoxy attachment/wire bonding of integrated circuits and components (e.g., capacitors) to a glass-epoxy board (chip-on-board). Of course, another way is attachment to a thick- or thin-film ceramic substrate. Currently, many package styles are available and can be listed as follows[19,20]:

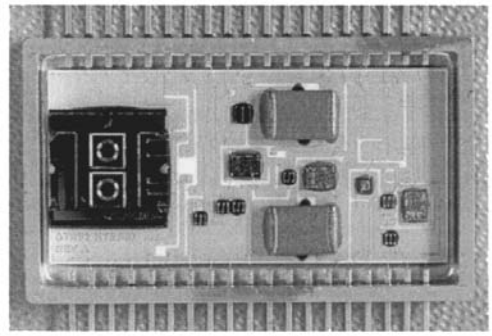

FIGURE 12.6 JPL STRV-2 project: tunneling accelerometer.

- Epoxy seal, using a B-stage ceramic lid epoxies to the substrate (quasi-hermetic seal)
- Encapsulation, in which bare semiconductor die are covered with a "glob top" (low-cost seal)
- Metal (typically Kovar) package with Kovar lid either welded or soldered to the package (hermetic seal)
- Leads are typically plug-in type, SIP, DIP, PGA, etc.

Mixed Technologies

Another category of assembly technique recognized as "mixed technologies" combines chip-and-wire with surface-mount assembly techniques on a single substrate, which may be a glass-epoxy board or ceramic substrate. Heat sink/heat spreaders are available in a variety of materials.

The Maxtek module shown in Fig. 12.7 includes a 4-layer, 20-mil-thick glass-epoxy board mounted to a beryllium copper heat spreader.

Selectively gold plated for wire bonding pads and pads at each end for use with elastomeric connectors,

- Three methods of IC die attach
- Epoxied directly to glass-epoxy board
- Epoxied directly to the BeCu heat spreader through a cutout in the board
- Epoxied to the head spreader, through a cutout, via a thermally conductive submount, to electrically isolate the die from the heat spreader

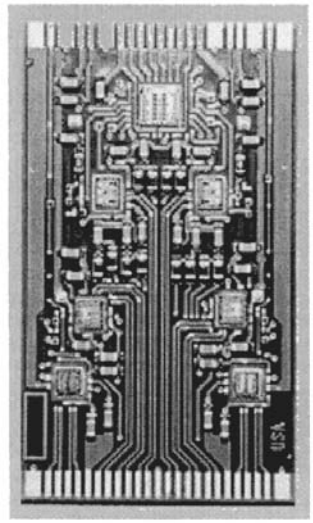

FIGURE 12.7 Example of a mixed-technology assembly technique.

- Solder-mounted resistors and capacitors
- 50-ohm differential signal lines
- IC die may be "glob topped" or covered in either a ceramic or plastic lid for protection

Special Modules

Under special modules we can emphasize and highlight technologies of complex assemblies of mixed-technology substrates, flexible circuits, and/or electromechanical components. (See Fig. 12.8.) Complex assemblies of mixed-technology substrates often utilize a B-stage epoxy lid or glob top over chip-and-wire circuitry. These technologies enable designers to provide an integrated solution complex system problems like in a module shown on page 22 which is CRT Driver System capable of displaying 4 million pixels with 1.5-ns rise and fall times. The circuit incorporates a thin-film MCM connected by a special high-frequency connector to an FR-4 board with thick-film ceramic low-inductance load resistor and flex circuit with an integral impedance-matching inductor, connecting directly to the CRT.[19,20]

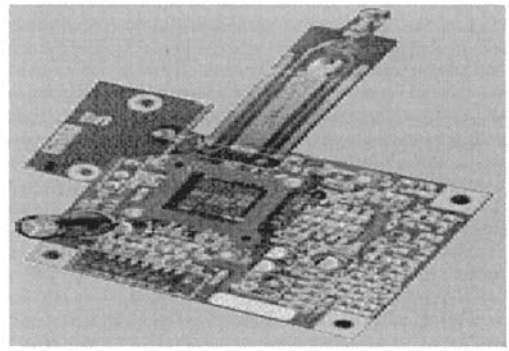

FIGURE 12.8 Example of a special module.

The design engineer of an MCM chip should work with customer to partition the circuit and optimize the design to be implemented in MCM technology. Application of technologies for placement, routing, via minimization, tree searching, and layer estimation will be important to assess at this point. The general function, purpose, and configuration of the active elements, interconnects, and assembly technology should also be assessed, along with key materials and critical properties, representative manufacturing-process flows, potential failure mechanisms, qualification procedures, and design for testability.

Note that two concepts must be carefully examined for successful MCM production. An MCM design is initiated by selecting appropriate technologies from the many options available. The basic choices are for substrate technology and assembly techniques. Design trade-offs are analyzed, and a preliminary specification is completed. Following circuit simulation, prototypes are produced and tested. When the application requires it, an ASIC can be designed to be included in the MCM.

12.12 Summary

In summary, it is customary to give an answer to the fundamental question: What multi-chip modules do for you?… and here is the answer …

MCMs optimize critical design parameters such as speed, density, and temperature, resulting in performance well beyond PC board design capabilities. By removing discrete component packages and using more densely packed interconnects, circuit speeds increase. The design challenge is to select the appropriate packaging technology, and to manage any resulting thermal problems.[20]

MCM technologies found their way and are utilized in the wireless, fiber, and instrumentation markets; space and military programs; and in the real world, they stand in the forefront of best merchant-market technology .

13.1 Introduction

Hydrogen-related degradation by hot electrons in MOS transistors has been long known and is well documented.[1] It has recently been discovered that the degradation exhibits a giant isotope effect if hydrogen is substituted by deuterium.[2–4] The isotope effect can delay the channel hot-electron degradation by factors of 10 to 100 and, with the current definition of lifetime, even much beyond that. It therefore must be an effect different to the known kinetic isotope effect and the standard changes in reaction velocity of a factor of three or so when hydrogen is substituted by deuterium.

Deuterium is a stable and abundantly available isotope of hydrogen. It is contained at a level larger than 10^{-4} in all natural water sources. Its mass is roughly twice that of hydrogen, while all its electronic energy levels and the related chemistry are identical to that of hydrogen.

The difference in channel hot-electron degradation and lifetime must therefore be due to the mass difference. There are several possible explanations of the giant isotope effect in degradation.[4] The most probable explanation at low supply voltages ($V_{DD} < 3.3$ V) is the one first advanced in Ref. 5. This explanation concerns the dynamics of hydrogen (deuterium) desorption from an Si-H (Si-D) bond at the silicon–silicon dioxide interface under extreme non-equilibrium conditions — which is the central cause of the particular degradation discussed here. There are other forms of degradation known that show no, or a much lesser, isotope effect and are not discussed here. According to Ref 5, the heated electrons (with a typical energy of several electron volts) excite local vibrations of the Si–H bond. These vibrations have a very long lifetime of the order of nanoseconds or longer because the vibrational energy of the Si–H is mismatched to the bulk vibrations in both silicon and silicon dioxide. Therefore, a high probability exists that other hot electrons will collide with the Si–H and cause further vibrational excitation until, finally, desorption is accomplished. One vibrational mode

of Si–D, on the other hand, virtually matches a bulk silicon vibrational energy. Therefore, the local Si–D vibrations are short lived and it is much less likely that Si–D is excited so much that deuterium will desorb. The basic science of these processes has meanwhile been investigated (e.g., by scanning tunneling microscopy) and is consistent with the above description.[4] Similar desorption processes are known from photochemistry, where the energy is provided by photons, and the new aspect here is only the energy supply by the channel electrons and the extent of the isotope effect due to the special interface properties. While these considerations apply only under extreme nonequilibrium conditions, there are also in-equilibrium isotopic differences between the Si–H and Si–D bond, again due to their vibrational differences.

The question that appears under the initial equilibrium conditions, before the degradation occurs, is the following. Since many processing steps in MOS technology introduce hydrogen in one form or another, and since hydrogen densities in the silicon dioxide will be of the order of 10^{18} cm^{-3} whether desired or not, how can the hydrogen be effectively replaced by deuterium? An elementary proof[6] shows that the equilibrium population of the silicon bond by H or D also depends on the vibrational properties. Because of the higher vibrational energy of some of the Si-H vibrational modes (compared to deuterium), hydrogen is less likely to saturate the bond. In fact, if H and D are present at the same density at the interface, then (around the usual anneal temperature of 425°C) the deuterium is about 10 times more likely to populate the silicon bond than hydrogen.[6]

From these facts, it is evident that a relatively simple substitution of hydrogen by deuterium can lead to very beneficial delays of hot-electron degradation. In the following, we first describe the necessity to anneal the silicon–silicon dioxide interface with H or D; then we describe the advantages of D for hot electron degradation and the introduction of D by post-metal anneal procedures. Finally, we describe confirmations and extensions to more complex introductions of D.

13.2 Post-Metal Forming Gas Anneals in Integrated Circuits

Low-temperature post-metal anneals (350–450°C) in hydrogen ambients have been successfully used in MOS fabrication technologies to passivate the silicon dangling bonds and consequently to reduce the Si/SiO_2 interface trap charge density.[7–11] This treatment is imperative from a fabrication standpoint since silicon dangling bonds at the Si/SiO_2 interface are electrically active and lead to the reduction of channel conductance and also result in deviations from the ideal capacitance–voltage characteristics. Electron spin resonance (ESR) measurements performed in conjunction with deep-level transient spectroscopy (DLTS) and capacitance–voltage (C-V) measurements have elucidated the role of hydrogen in this defect annihilation process. The passivation process is described by the equation

$$P_b + H_2 \rightarrow P_bH + H \tag{13.1}$$

where P_bH is the passivated dangling bond. These measurements indicate that for the oxides grown on Si-<111>, the density of the interface trap states in the middle of the forbidden gap decreases from 10^{11}–10^{12} cm^{-2} eV^{-1} to about 10^{10} cm^{-2} eV^{-1} after the post-metal anneal process step. The Si-<100>/SiO_2 material system, which is technologically more significant, exhibits the same qualitative behavior. The necessity of post-metallization anneal processing for CMOS technologies is demonstrated in Figs. 13.1 and 13.2 where the measured NMOS threshold voltage (V_{th}) and transconductance (g sub m) distributions of a wafer annealed in forming gas (10% H_2) is compared with an untreated wafer. The high mean value and variation of the threshold voltage and reduced channel mobility across the untreated wafer is a clear indication of the unacceptable levels of interface trap density for CMOS circuit operation and stability. As described above, MOS transistors under bias can degrade as a result of channel hot (large kinetic energy) carriers (electrons and holes) stimulating the desorption of the hydrogen that is passivating the dangling bonds at the Si/SiO_2 interface. These concerns are exacerbated with the ever-ongoing scaling efforts for high-performance transistors and added dielectric/metallization (and hence plasma process damage) layers in integrated circuits.

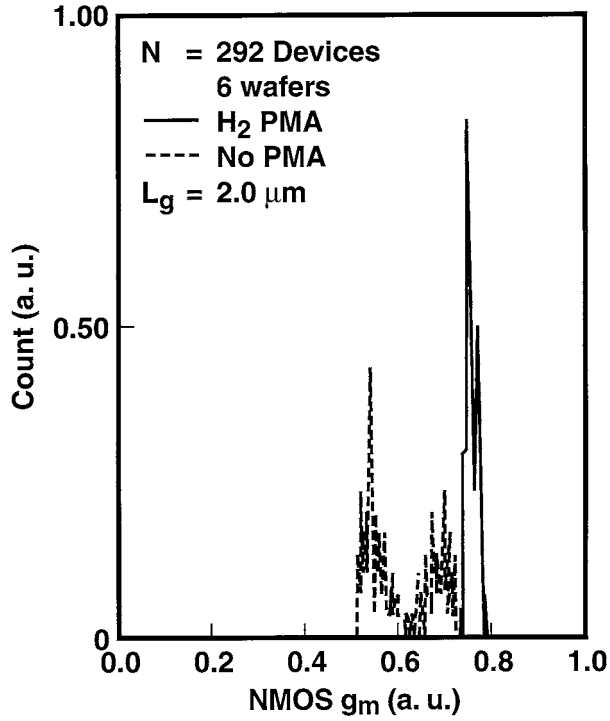

FIGURE 13.2 Same as Fig. 13.1 but for the transconductance g_m.

13.3 Impact of Hot Electron Effects on CMOS Development

The current industry practice for evaluating the intrinsic hot carrier related reliability of a MOS transistor involves two distinct accelerated electrical stress test methodologies (including certain intermediate methodologies). Although it is unlikely that the physical mechanisms responsible for gate oxide wear-out are identical in each of these cases, hydrogen appears to play some role in both modes of degradation. In the first stress configuration, the Si/SiO_2 system is degraded via large electrical fields across the gate oxide (e.g., $|V_G| >> V_D$).[12] Threshold voltage shifts in MOS capacitor structures are observed. The damage induced in this degradation mode is due to both charge trapping within the oxide and the creation of Si/SiO_2 interface trap states. Our initial studies have not identified a clear isotope effect for this mode of stress test. In this article, only the second stress configuration, namely the *channel hot carrier aging of NMOS transistors,* where we have discovered the large isotope effect, is discussed. In this mode of accelerated stress, threshold voltage instability and channel transconductance degradation in MOS transistors[13] is induced with the aid of hot carriers (electrons and holes with large kinetic energy) using the source-drain electric field. That is, the Si/SiO_2 interface is degraded by hot carriers that are traversing the device while they gain kinetic energy from the source-drain electric field. The device is biased to maximize the substrate current (e.g., $V_G \approx 1/2V_D$). The transistor aging is accelerated by stressing the device using a drain voltage (V_D) which is much larger than the intended operating voltage. The hot carrier lifetime of the transistor is estimated by extrapolating the accelerated stress test results to operating voltage (peak substrate current specification) conditions. DC, AC, or pulsed DC waveforms are most commonly used. This mode of accelerated stress tests performed on NMOS transistors typically results in localized oxide damage, which has been identified as Si/SiO_2 interface trap states.[14,15] The asymmetry of the current–voltage characteristics under source-drain reversal indicates that the damaged region is located near the drain end of the transistor where the electric fields are the largest due to the the pinch-off effect. Moreover, it has been suggested that the generation of the interface trap states is due to hot carrier-stimulated hydrogen desorption and depassivation of the silicon dangling bonds. Channel hot-carrier degradation in MOS transistors manifests itself in the form of threshold voltage (V_{th}) instability, transconductance ($g_m = dI_{DS}/dV_{GS}$) degradation, and a change in the subthreshold slope ($S_I = d \ln I_{DS}/dV_{GS}$ at $V_{GS} < V_{th}$) over time.

Various technological advances have been made to address the problem of MOS transistor degradation due to channel hot carriers. Most significant and lasting progress in fabrication technology to alleviate the channel hot carrier problem has been the development of lightly doped source-drain (LDD) and gate sidewall spacer processes.[15–17] The lightly doped drain region is used to reduce the strength of the electric field at the gate-end of the drain. Such advances have been integrated in all submicron CMOS technologies at the cost of added process complexity and intricate device design.[18] Unfortunately, processing requirements for good short channel behavior and high performance, namely, shallow source-drain junctions, reduced overlap capacitance, and low source-access resistance, are all at odds with hot carrier immune device design.

A reasonable argument (now it appears that this was merely wishful thinking) had been that the hot carrier degradation effect can be scaled away by reducing the supply voltage (constant field scaling). However, this does not appear to be the case since device feature size scaling accompanies supply voltage scaling in VLSI CMOS technologies to achieve improved performance and increased packing density. Gate oxide thickness is also reduced to maintain the device current density at low supply voltage operation. Takeda et al. have observed device degradation in a no-LDD NMOS transistor structure with gate lengths of 0.3 μm at 2.5 V.[19] Chung et al. observed hot carrier degradation for a 0.15-μm gate length transistor (with no LDD regions) at 1.8 V.[20] Current state-of-the-art high-performance 1.5- and 1.8-V sub-0.18-μm CMOS technology with good quality gate oxide exhibits hot carrier degradation effects and requires precise drain engineering.[21,22] Circuit solutions to alleviate hot carrier degradation effects in transistors, although proposed, involve further circuit design and layout complications.[23] Hot carrier-induced transistor degradation will continue to be a major roadblock for satisfying market demand for high-performance CMOS circuits such as the Lucent-DSP shown in Fig. 13.3 with transistor gate lengths phase-shifted down to 0.1 μm and operated at a large range of supply voltages (1.0 to 1.8 V).

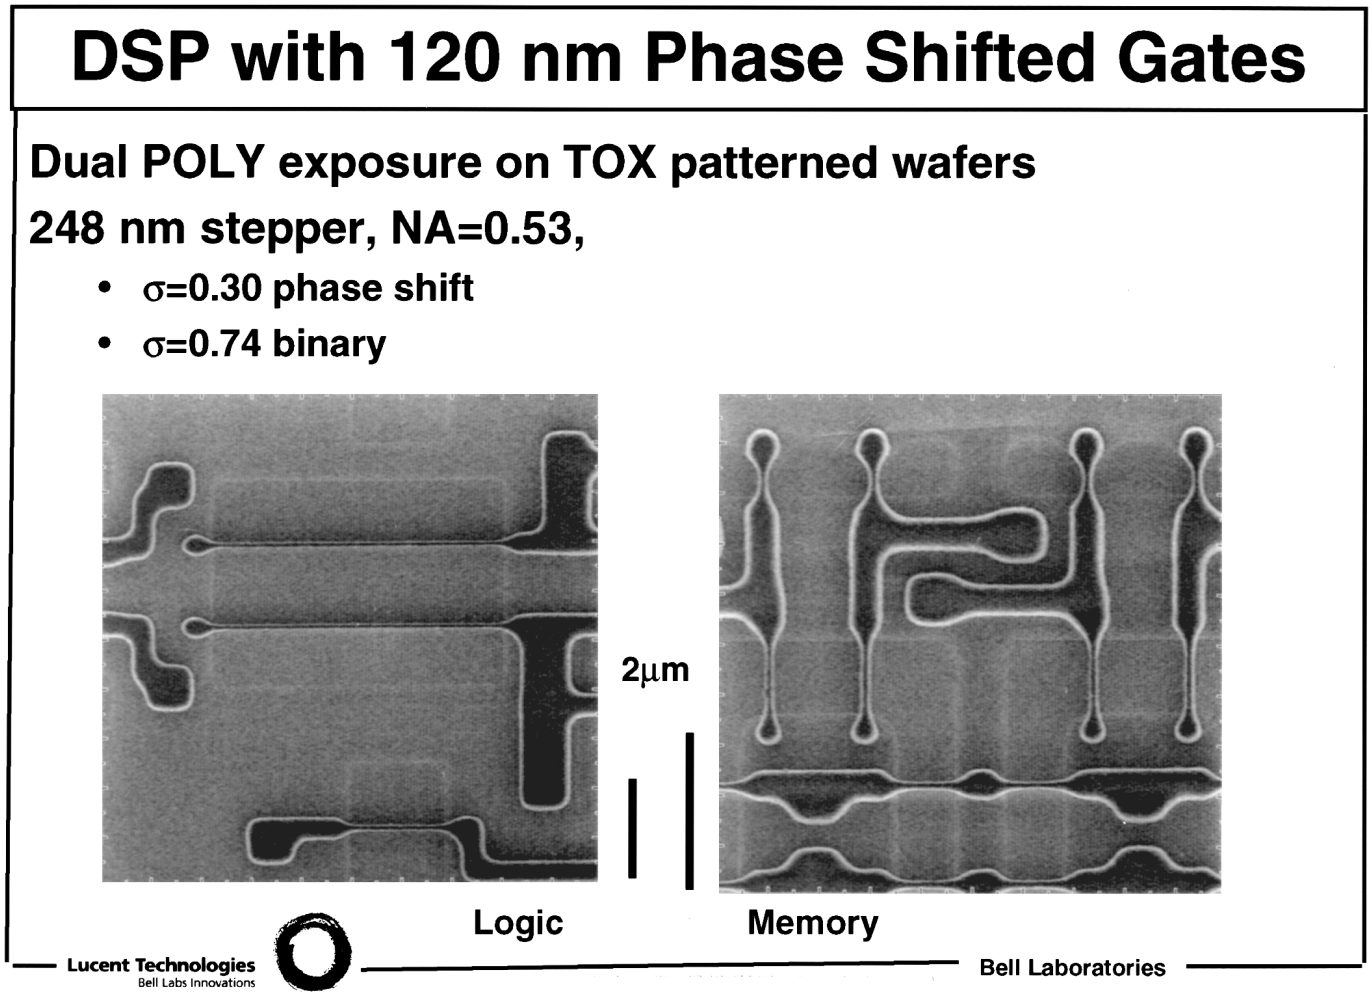

FIGURE 13.3 High-performance CMOS circuit with 0.1-μm gate length operated in a range of 1.0 V to 1.8 V of supply voltages.

13.4 The Hydrogen/Deuterium Isotope Effect and CMOS Manufacturing

As noted above, the major reliability limitation for the miniaturization CMOS technologies is the NMOS transistor hot carrier lifetime. A breakthrough in integrated circuit manufacturing is needed where reliable CMOS scaling is enabled by eliminating the undesirable effects of channel hot carriers. The giant hydrogen/deuterium isotope effect that has been discovered and reported by Lyding, Hess, and Kizilyalli[2,3] in NMOS transistors is the extremely significant increase in time-dependent channel hot carrier transistor (reliability) lifetime in devices that have been annealed with deuterium instead of hydrogen, as shown in Figs. 13.4 and 13.5. In the fabrication sequence, deuterium is introduced, instead of hydrogen, to the Si/SiO_2 interface via a low-temperature (400–450°C) post-metallization anneal process. Figure 13.6 shows the transfer characteristics of uncapped NMOS and PMOS transistors annealed in deuterium and hydrogen ambients at 400°C and 1 hour. Prior to hot electron stress, transistors annealed in either ambient are electrically identical. This results in indistinguishable device function prior to hot carrier stress. Indistinguishable device function prior to hot carrier stress is also demonstrated in two experiments shown in Table 13.1. This is an expected result since the chemistry of deuterium and hydrogen is virtually identical. These results prove that deuterium and hydrogen are equally effective in reducing the interface trap charge density which results in equivalent device function. Deuterium can be substituted for hydrogen (at least in post-metal anneal processes) in semiconductor manufacturing.

Although devices annealed either in deuterium or hydrogen appear to be identical in pre-stress electrical tests, they exhibit markedly different degradation dynamics. The observed improvement in the degradation rates (lifetimes) in the transistors is a result of the large difference in the desorption rates of the two isotopes, as described in the introduction and in detail in Refs. 4 and 5.

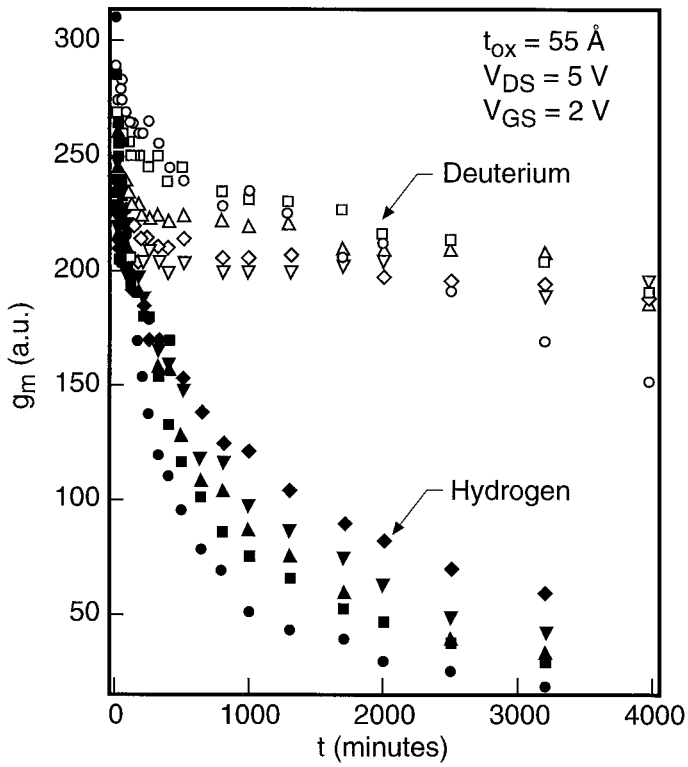

FIGURE 13.4 Transconductance channel hot-electron accelerated stress degradation with hydrogen and deuterium anneal and a significant degradation delay due to the presence of deuterium.

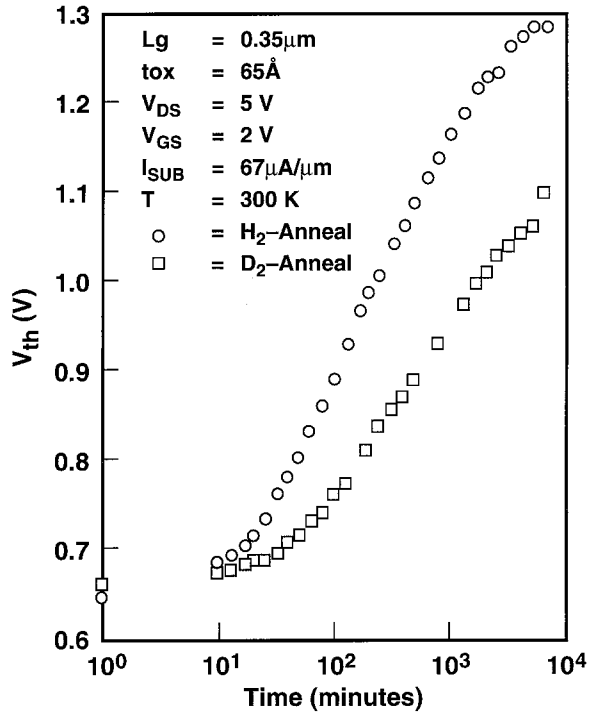

FIGURE 13.5 Same as Fig. 13.4 but for the threshold voltage.

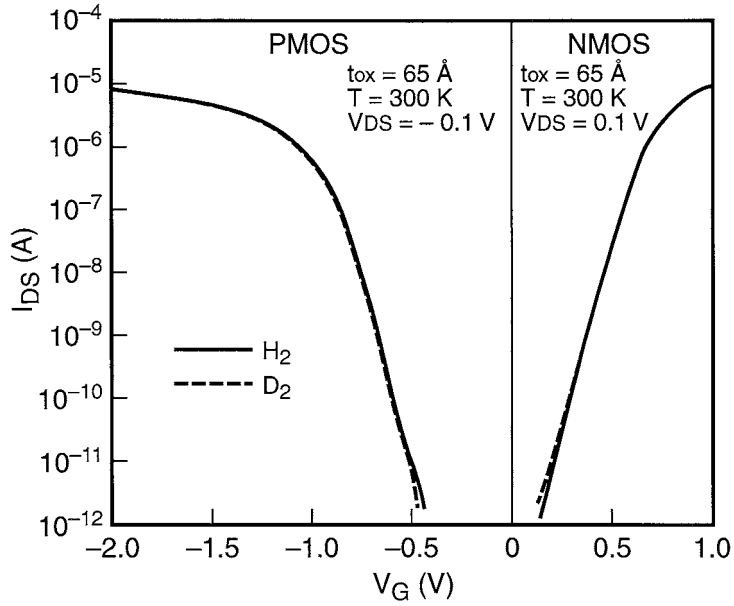

FIGURE 13.6 Subthreshold current I_{DS} as a function of gate voltage V_G for both hydrogen and deuterium anneal before degradation. No difference is shown within the experimental accuracy.

TABLE 13.1 Anneal Process and Threshold Voltage

Process	$V_{th,N}$	σ-$V_{th,N}$	$V_{th,P}$	σ-$V_{th,P}$
10%-H_2	0.51V	2.7 mV	0.983 V	2.8 mV
50%-D_2	0.51V	2.4 mV	0.986 V	4.5 mV
100%-D_2	0.51V	1.7 mV	0.987 V	1.1 mV

The large hydrogen/deuterium isotope effect in NMOS transistors has been subsequently observed and verified by other laboratories.[24–27] Studies also indicate that transistors annealed in deuterium are much more resilient against plasma process-induced damage (as quantified by Si/SiO_2 interface trap generation and gate oxide leakage).[28] Furthermore, stability of PMOS transistors;[29] hydrogenated (deuterated) amorphous silicon-based solar cells and TFTs;[30–32] hydrogen (deuterium) terminated, porous-silicon light-emitting devices;[33] and ultra-thin oxides for non-volatile memory devices[34] have been found to improve with the isotopic substitution against degradation due to light and field exposure.

For reasons outlined above, there is a strong motivation to introduce the deuterium anneal process to CMOS manufacturing. However, two further obstacles need to be removed for transfer of process to the factory floor. First, all modern CMOS technologies require a minimum of three levels of dielectric/metal interconnect process. Anneal processes that are found to be effective for improving channel hot carrier reliability in one-level of metal/dielectric structures (e.g., 400°C for 0.5 hr and 10% D_2/90% N_2) may be ineffective for multi-level metal/dielectric structures. The deuterium anneal process needs to be (and in some cases has been) optimized for multi-level interconnect. Second, the benefits of the deuterium anneal should be still evident subsequent to the final SiN cap wafer passivation process.

The test vehicle used for the experiments to surmount these challenges is a development version of Lucent Technologies 0.35 μm 3.3 V transistors with a 65 Å gate oxide, very shallow arsenic implanted MDD regions, TEOS spacers, and three dielectric (doped and undoped plasma enhanced TEOS) and metal levels (Ti/TiN/AlCuSi/TiN).[35] The deuterium (5–100% D_2) anneal process was performed after the third layer of metal had been patterned. The deuterium anneal temperatures vary between 400 to 450°C and anneal times of 1/2 to 5 hours are considered. Accelerated hot carrier DC stress experiments are performed on NMOS transistors at peak substrate current conditions. In Fig. 13.7, the time-dependent deviation of V_{th} is shown with the deuterium anneal conditions as a parameter. Table 13.2 summarizes the results of all stress experiments (V_{DS} = 5 V and V_{GS} = 2 V), assuming a degradation criteria of δV_{th} = 200 mV. The degradation dynamics of S_i and $I_{D,SAT}$ are plotted in Figs. 13.8 and 13.9. Degradation in the transistor I–V characteristics is accompanied by an increase in the interface trap density (D_{it}) as extracted (Fig. 13.10) from charge-pump current measurements. Figure 13.11 shows hot electron degradation lifetime versus substrate current with 20% g_m (transconductance) degradation as the lifetime criteria. For a peak substrate current specification of I_{SUB} = 2000 nA/μm, the extrapolated lifetime for the hydrogen and deuterium annealed device is 0.06 years and 4 years, respectively. The hot carrier lifetime (reliability) of transistors increases continuously and dramatically with increases in deuterium anneal times and temperatures. Negligible improvement is observed for short (1/2 hour) and low concentration (<10% D_2) anneal conditions. The 400°C, 2-hour process results in a four-fold improvement in lifetime over the standard hydrogen process, while the 450°C, 3-hour deuterium anneal process yields nearly a factor of 50 improvement. Hence, whenever the deuterium content in the wafer is increased, large corresponding improvements in transistor lifetimes are measured. For longer (450°C, and 5-hour) anneals, the lifetime improvement asymptotically reaches a factor of about 80 to 100 over the standard process, corresponding to similar findings in basic experiments using scanning tunneling microscopy.[4] In Fig. 13.12, it is demonstrated that the benefits of the deuterium anneal are still observed even if the post-metal anneal is followed by an SiN caps process. Similar findings for higher levels of metallization were made by other groups (see Ref. 27). For ultimate stability against further processing, and to avoid the complicated diffusion through many layers of metallization, it may be necessary to introduce the deuterium in a layer close to the device that can act as a reservoir and is activated in any temperature increase (anneal). A convincing proof of this possibility has been given.[36]

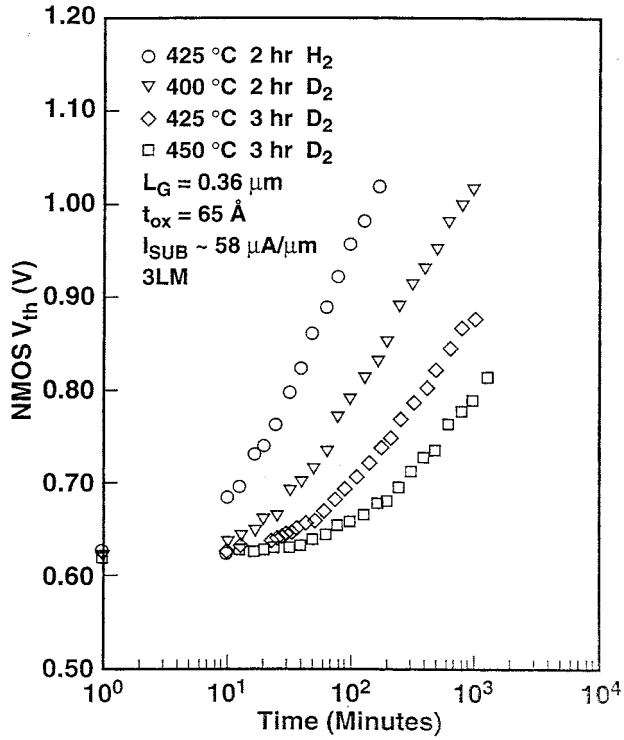

FIGURE 13.7 Degradation improvements by deuterium anneal after three levels of metallization for various temperatures and times. Only one hydrogen curve is shown; annealing with hydrogen gives identical results over wide ranges of temperature and time.

TABLE 13.2 Relative Hot Carrier Reliability (Lifetime) Improvement and D_2 Anneals

Temperature	Time	Ambient	N_2 Pre-anneal	Lifetime
425°C	2 hr	10%H_2/90%N_2	No	1.0
400°C	1/2 hr	5%D_2/95%N_2	No	1.0
400°C	1 hr	5%D_2/95%N_2	No	1.0
400°C	1 hr	10%D_2/90%N_2	No	1.0
400°C	2 hr	100%D_2	Yes	3.8
400°C	3 hr	100%D_2	No	5.5
425°C	3 hr	100%D_2	No	12.5
450°C	2 hr	100%D_2	Yes	36.0
450°C	3 hr	20%D_2/80%N_2	No	37.5
450°C	3 hr	100%D_2	No	62.5
450°C	5 hr	100%D_2	No	80.0

Figure 13.13 shows a hydrogen and deuterium profile as measured by surface ion mass spectroscopy for a successfully treated transistor. A deuterium peak concentration at the interface is a typical necessity for successful anneal. The absolute concentrations may vary according to experimental conditions.

These experiments prove that one can substitute deuterium for hydrogen in a CMOS manufacturing process with no penalty, yet with a 50 to 100-fold improvement in channel hot carrier lifetime. For completeness, other transistor structures with varying design considerations have been evaluated and summarized elsewhere.[37,38] Transistor parameters that were explored include: (1) gate oxide thickness t_{ox} = 50–115 Å, (2) LDD implant species arsenic and phosphorus and (3) gate stack structure of n^+-polysilicon and polycide (n^+-polysilicon/WSi), and (4) an experimental 0.25-μm 3.3-V CMOS[39] process

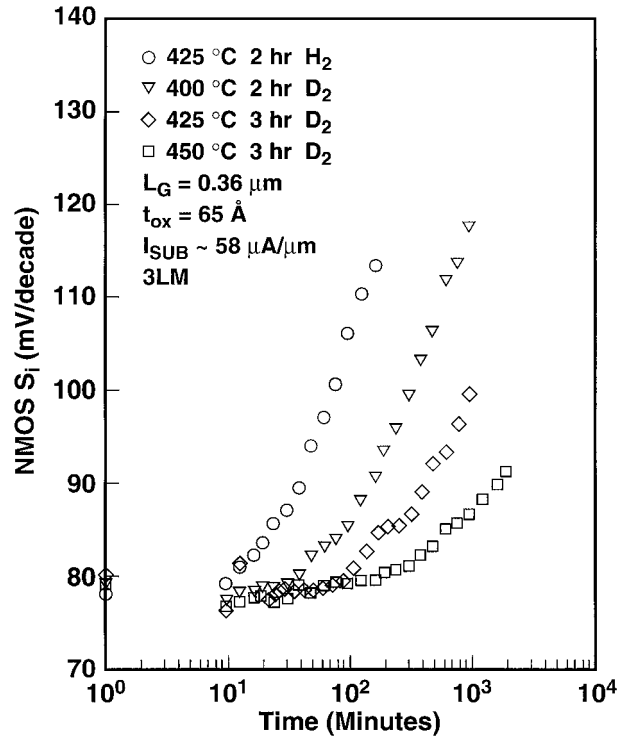

FIGURE 13.8 Degradation dynamics as in Fig. 13.7 but for S_I.

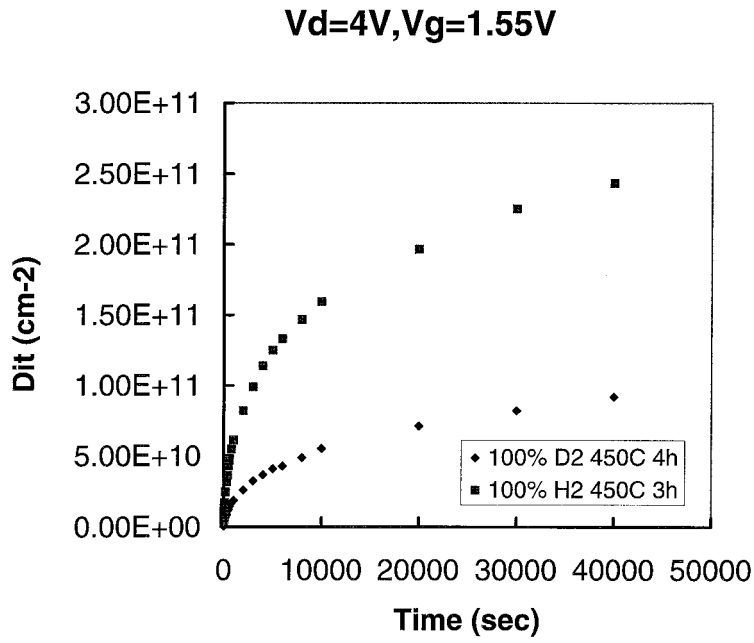

FIGURE 13.10 Interface trap density D_{it} extracted from charge-pump current measurements vs. stress time with hydrogen and deuterium anneal as indicated.

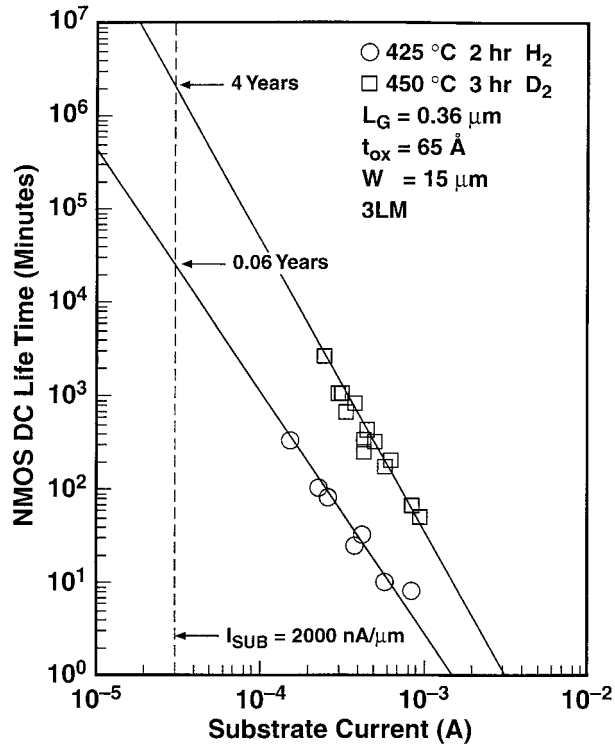

FIGURE 13.11 Channel hot electron lifetime (20% g_m degradation as lifetime limit) vs. substrate current for both hydrogen and deuterium anneal with extrapolations to actual operating conditions (dashed vertical line).

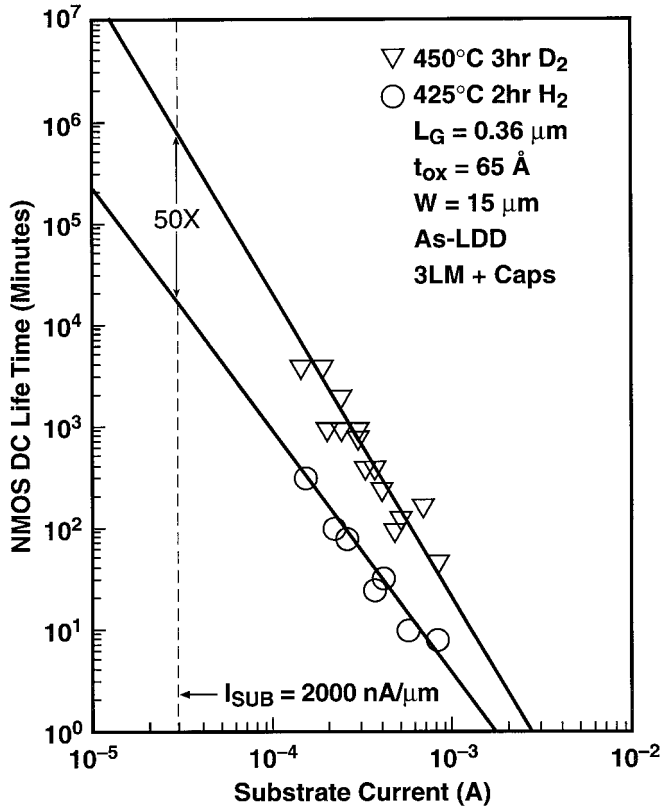

FIGURE 13.12 As in Fig. 13.11 but after final SiN cap process.

with 4 levels of metal. In all cases, the large isotope effect is observed. Clearly, the hydrogen/deuterium isotope effect is a general property of the semiconductor device wear-out.

It is important to correlate the observed improved hot carrier reliability to the location and quantity of deuterium in the wafer. Secondary ion mass spectroscopy (SIMS) analysis through the first interlevel oxide and silicon was performed on two uncapped (it is well known that $Si_x N_y$ is a barrier for deuterium) samples as shown in Fig. 13.13. The first wafer was annealed in forming gas (10% molecular hydrogen), while the other sample was annealed in forming gas comprising 10% molecular deuterium. A Cameca IMS-2f system with oxygen primary beam 60 μm^2 was used for analysis. $^{18}0^+$ was monitored to locate the SiO_2/Si interface. The $^2D^+$ concentration is inferred from the difference between the $^2H^+$ profiles for wafers annealed in deuterium and hydrogen. Deuterium was not detected under large areas of (200 times 200 μm^2) polysilicon in wafers that were annealed in deuterium and were not capped with Si_xN_y. This indicates the finite lateral diffusion length of deuterium in the transistor gate oxide and channel region. Deuterium is detected in the interlevel oxide at concentrations of 10^{19} cm^{-3} and was found to accumulate at Si/SiO_2 interfaces with a surface concentration of 10^{14} cm^{-2}. This SIMS study suggests that deuterium diffuses rapidly through the interlevel oxides and the gate sidewall spacers to passivate the interface states in the transistor channel region. However, the exact lateral spread (reach) of diffused deuterium in the transistor-channel and gate-oxide region is not certain.

The question still remains regarding the purity, specification limits, as well as cost for the implementing deuterium gas in semiconductor manufacturing. Deuterium is a stable isotope of hydrogen and is present as D_2O. Deuterium gas is produced by electrolysis of pure D_2O. Tritium is a radioactive isotope of hydrogen and has a lifetime of 12.3 years. Because of the nature of the electrolysis, the molar concentration of tritium in the gas will be essentially the same as the feed heavy water with the tritium

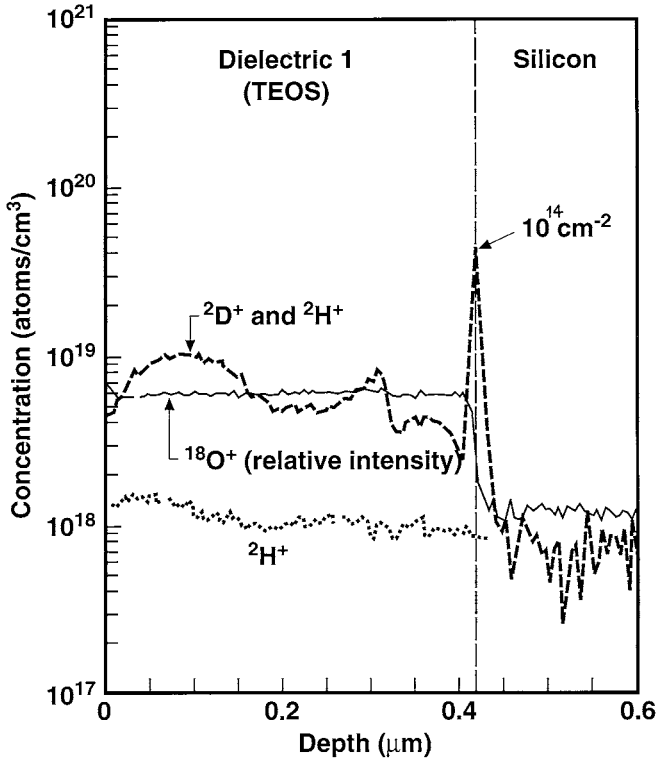

FIGURE 13.13 Typical results for hydrogen and deuterium concentrations measured after anneals by secondary ion mass spectroscopy (SIMS).

gas being in the form of DT rather than pure T_2. If the tritium content in the feed water is 50 nCi/kg, the expected concentration in the gas would be about 45 pCi/L (1.65 Bq/L). The tritium content in heavy water varies from 5 nCi/kg (virgin heavy water) to 50 Ci/kg (heavy water used in nuclear reactors). The limit of tritium in deuterium gas suitable for CMOS manufacturing is estimated as follows. When 10^{14} deuterium atoms are placed in a single chip, 3×10^{-9} Bq/L of tritium are also incorporated. This implies that one tritium decay event would occur approximately every 370 days, much below the rate of other radioactive events occurring in chip technology and operation. In addition, this is only a β-decay with usually negligible consequences. Since it is very difficult to measure tritium gas at these low concentrations, specifications should be placed on the tritium content for the heavy water used in the electrolytic production process (which is straightforward). A suggested upper limit could be 6000 nCi/kg that results in 1 tritium event/month per chip.[40] The substitution of deuterium for hydrogen adds 0.1% to the total wafer cost.

13.5 Summary

It has been demonstrated that the replacement of hydrogen by deuterium in CMOS technology can lead to significant delays in channel hot electron degradation. Increases in hot electron lifetime of a factor of 10 to 100 and beyond have been shown by simple post-metal anneals in deuterium atmosphere for several levels of metallization. Deuterium has also been proven beneficial for the reliability of other devices such as deuterated amorphous thin-film silicon devices of various kinds. Since deuterium and hydrogen have the same electronic energy levels, deuterium- and hydrogen-treated devices are indistinguishable in terms of their normal pre-stress electronic characteristics. Deuterium only delays degradation due to its higher mass and different vibrational properties.

Bipolar Junction Transistor (BJT) Circuits

David J. Comer
Donald T. Comer
Brigham Young University

14.1 Introduction

The *bipolar junction transistor* (or BJT) was the workhorse of the electronics industry from the 1950s through the 1990s. This device was responsible for enabling the computer age as well as the modern era of communications. Although early systems that demonstrated the feasibility of electronic computers used the vacuum tube, the element was too unreliable for dependable, long-lasting computers. The invention of the BJT in 1947[1] and the rapid improvement in this device led to the development of highly reliable electronic computers and modern communication systems.

Integrated circuits, based on the BJT, became commercially available in the mid-1960s and further improved the dependability of the computer and other electronic systems while reducing the size and cost of the overall system. Ultimately, the microprocessor chip was developed in the early 1970s and the age of small, capable, personal computers was ushered in. While the metal-oxide-semiconductor (or MOS) device is now more prominent than the BJT in the personal computer arena, the BJT is still important in larger high-speed computers. This device also continues to be important in communication systems and power control systems.

Because of the continued improvement in BJT performance and the development of the heterojunction BJT, this device remains very important in the electronics field, even as the MOS device becomes more significant.

14.2 Physical Characteristics and Properties of the BJT

Although present BJT technology is used to make both discrete component devices as well as integrated circuit chips, the basic construction techniques are similar in both cases, with primary differences arising in size and packaging. The following description is provided for the BJT constructed as integrated circuit devices on a silicon substrate. These devices are referred to as "junction-isolated" devices.

The cross-sectional view of a BJT is shown in Fig. 14.1.[2]

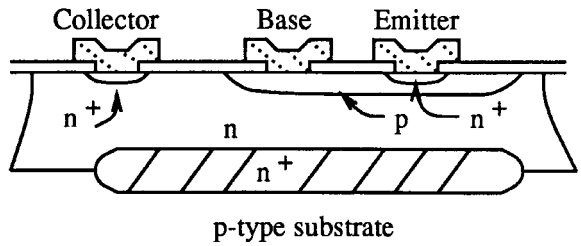

FIGURE 14.1 An integrated npn BJT.

This device can occupy a surface area of less than 1000 μm^2. There are three physical regions comprising the BJT. These are the emitter, the base, and the collector. The thickness of the base region between emitter and collector can be a small fraction of a micron, while the overall vertical dimension of a device may be a few microns.

Thousands of such devices can be fabricated within a silicon wafer. They may be interconnected on the wafer using metal deposition techniques to form a system such as a microprocessor chip or they may be separated into thousands of individual BJTs, each mounted in its own case. The photolithographic methods that make it possible to simultaneously construct thousands of BJTs have led to continually decreasing size and cost of the BJT.

Electronic devices, such as the BJT, are governed by current–voltage relationships that are typically nonlinear and rather complex. In general, it is difficult to analyze devices that obey nonlinear equations, much less develop design methods for circuits that include these devices. The basic concept of modeling an electronic device is to replace the device in the circuit with linear components that approximate the voltage–current characteristics of the device. A model can then be defined as a collection of simple components or elements used to represent a more complex electronic device. Once the device is replaced in the circuit by the model, well-known circuit analysis methods can be applied.

There are generally several different models for a given device. One may be more accurate than others, another may be simpler than others, another may model the dc voltage–current characteristics of the device, while still another may model the ac characteristics of the device.

Models are developed to be used for manual analysis or to be used by a computer. In general, the models for manual analysis are simpler and less accurate, while the computer models are more complex and more accurate. Essentially, all models for manual analysis and most models for the computer include only linear elements. Nonlinear elements are included in some computer models, but increase the computation times involved in circuit simulation over the times in simulation of linear models.

14.3 Basic Operation of the BJT

In order to understand the origin of the elements used to model the BJT, we will discuss a simplified version of the device as shown in Fig. 14.2. The device shown is an npn device that consists of a p-doped material interfacing on opposite sides to n-doped material. A pnp device can be created using an n-doped central region with p-doped interfacing regions. Since the npn type of BJT is more popular in present construction processes, the following discussion will center on this device.

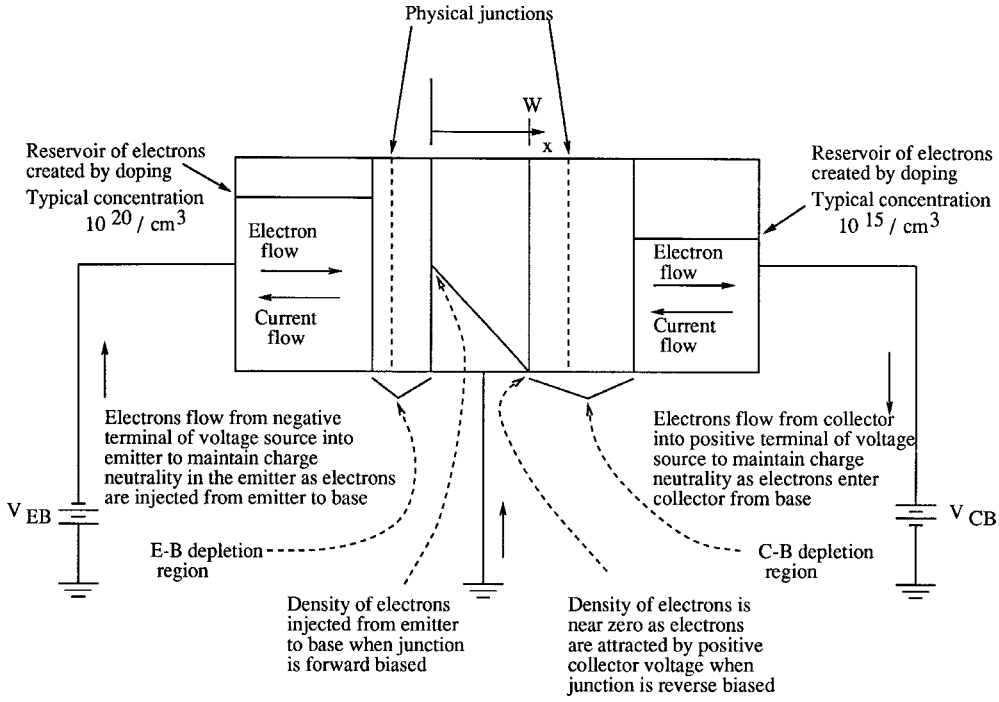

FIGURE 14.2 Distribution of electrons in the active region.

The geometry of the device implied in Fig. 14.2 is physically more like the earlier alloy transistor. This geometry is also capable of modeling the modern BJT (Fig. 14.1) as the theory applies almost equally well to both geometries. Normally, some sort of load would appear in either the collector or emitter circuit; however, this is not important to the initial discussion of BJT operation.

The circuit of Fig. 14.2 is in the active region, that is, the emitter–base junction is forward-biased, while the collector–base junction is reverse-biased. The current flow is controlled by the profile of electrons in the p-type base region. It is proportional to the slope or gradient of the free electron density in the base region. The well-known diffusion equation can be expressed as[3]:

$$I = qD_nA\frac{dn}{dx} = -\frac{qD_nAn(0)}{W} \tag{14.1}$$

where q is the electronic charge, D_n is the diffusion constant for electrons, A is the cross-sectional area of the base region, W is the width or thickness of the base region, and $n(0)$ is the density of electrons at the left edge of the base region. The negative sign reflects the fact that conventional current flow is opposite to the flow of the electrons.

The concentration of electrons at the left edge of the base region is given by:

$$n(0) = n_{bo}e^{qV_{BE}/kT} \tag{14.2}$$

where q is the charge on an electron, k is Boltzmann's constant, T is the absolute temperature, and n_{bo} is the equilibrium concentration of electrons in the base region. While n_{bo} is a small number, $n(0)$ can be large for values of applied base to emitter voltages of 0.6 to 0.7 V. At room temperature, this equation can be written as:

$$n(0) = n_{bo}e^{V_{BE}/0.026} \tag{14.3}$$

In Fig. 14.2, the voltage $V_{EB} = -V_{BE}$..

A component of hole current also flows across the base–emitter junction from base to emitter. This component is rendered negligible compared to the electron component by doping the emitter region much more heavily than the base region.

As the concentration of electrons at the left edge of the base region increases, the gradient increases and the current flow across the base region increases. The density of electrons at $x = 0$ can be controlled by the voltage applied from emitter to base. Thus, this voltage controls the current flowing through the base region. In fact, the density of electrons varies exponentially with the applied voltage from emitter to base, resulting in an exponential variation of current with voltage.

The reservoir of electrons in the emitter region is unaffected by the applied emitter-to-base voltage as this voltage drops across the emitter–base depletion region. This applied voltage lowers the junction voltage as it opposes the built-in barrier voltage of the junction. This leads to the increase in electrons flowing from emitter to base.

The electrons injected into the base region represent electrons that were originally in the emitter. As these electrons leave the emitter, they are replaced by electrons from the voltage source, V_{EB}. This current is called emitter current and its value is determined by the voltage applied to the junction. Of course, conventional current flows in the opposite direction to the electron flow.

The emitter electrons flow through the emitter, across the emitter–base depletion region, and into the base region. These electrons continue across the base region, across the collector–base depletion region, and through the collector. If no electrons were "lost" in the base region and if the hole flow from base to emitter were negligible, the current flow through the emitter would equal that through the collector. Unfortunately, there is some recombination of carriers in the base region. When electrons are injected into the base region from the emitter, space charge neutrality is upset, pulling holes into the base region from the base terminal. These holes restore space charge neutrality if they take on the same density throughout the base as the electrons. Some of these holes recombine with the free electrons in the base and the net flow of recombined holes into the base region leads to a small, but finite, value of base current. The electrons that recombine in the base region reduce the total electron flow to the collector. Because the base region is very narrow, only a small percentage of electrons traversing the base region recombine and the emitter current is reduced by a small percentage as it becomes collector current.

In a typical low-power BJT, the collector current might be $0.995I_E$. The current gain from emitter to collector, I_C/I_E, is called α and is a function of the construction process for the BJT. Using Kirchhoff's current law, the base current is found to equal the emitter current minus the collector current. This gives:

$$I_B = I_E - I_C = (1-\alpha)I_E \tag{14.4}$$

If $\alpha = 0.995$, then $I_B = 0.005I_E$. Base current is very small compared to emitter or collector current. A parameter β is defined as the ratio of collector current to base current resulting in:

$$\beta = \frac{\alpha}{1-\alpha} \tag{14.5}$$

This parameter represents the current gain from base to collector and can be quite high. For the value of α cited earlier, the value of β is 199.

14.4 Use of the BJT as an Amplifier

Figure 14.3 shows a simple configuration of a BJT amplifier. This circuit is known as the *common emitter configuration.*

A voltage source is not typically used to forward-bias the base–emitter junction in an actual circuit, but we will assume that V_{BB} is used for this purpose. A value of V_{BB} or V_{BE} near 0.6 to 0.7 V would be appropriate for this situation. The collector supply would be a large voltage, such as 12 V. We will assume that the value of V_{BB} sets the dc emitter current to a value of 1 mA for this circuit. The collector current entering the BJT will be slightly less than 1 mA, but we will ignore this difference and assume that I_C = 1 mA also. With a 4-kΩ collector resistance, a 4-V drop will appear across R_C, leading to a dc output voltage of 8 V. The distribution of electrons across the base region for the steady-sate or quiescent conditions is shown by the solid line of Fig. 14.3(a).

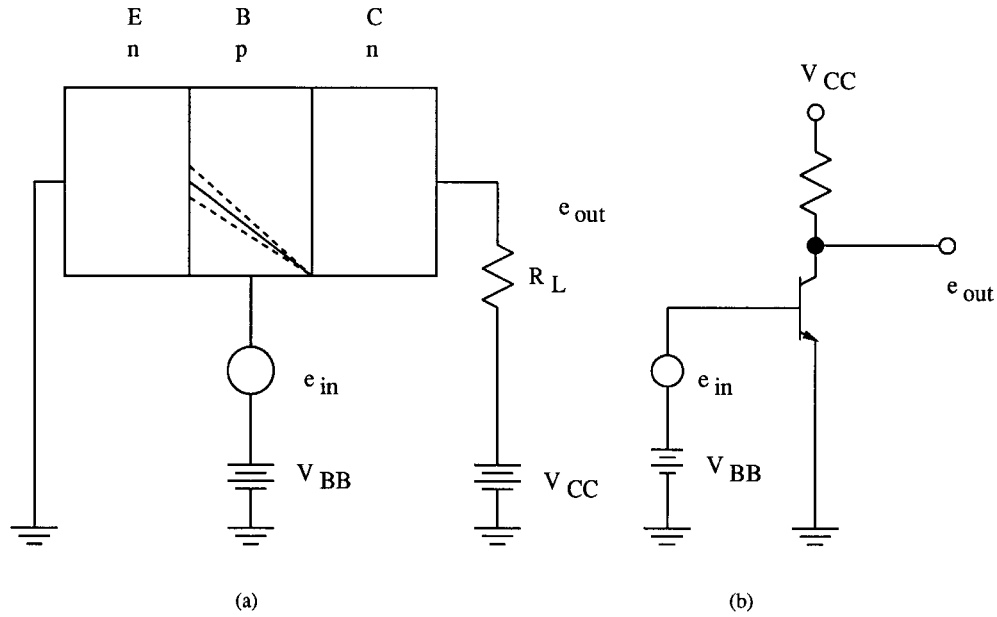

FIGURE 14.3 A BJT amplifier.

If a small ac voltage now appears in series with V_{BB}, the injected electron density at the left side of the base region will be modulated. Since this density varies exponentially with the applied voltage (see Eq. 14.2), a small ac voltage can cause considerable changes in density. The dashed lines in Fig. 14.3(a) show the distributions at the positive and negative peak voltages. The collector current may change from its quiescent level of 1 mA to a maximum of 1.1 mA as e_{in} reaches its positive peak, and to a minimum of 0.9 mA when e_{in} reaches its negative peak. The output collector voltage will drop to a minimum value of 7.6 V as the collector current peaks at 1.1 mA, and will reach a maximum voltage of 8.4 V as the collector current drops to 0.9 mA. The peak-to-peak ac output voltage is then 0.8 V. The peak-to-peak value of e_{in} to case this change might be 5 mV, giving a voltage gain of A = –0.8/0.005 = –160. The negative sign occurs because when e_{in} increases, the collector current increases, but the collector voltage decreases. This represents a phase inversion in the amplifier of Fig. 14.3.

In summary, a small change in base-to-emitter voltage causes a large change in emitter current. This current is channeled across the collector, through the load resistance, and can develop a larger incremental voltage across this resistance.

14.5 Representing the Major BJT Effects by an Electronic Model

The two major effects of the BJT in the active region are the diode characteristics of the base–emitter junction and the collector current that is proportional to the emitter current. These effects can be modeled by the circuit of Fig. 14.4.

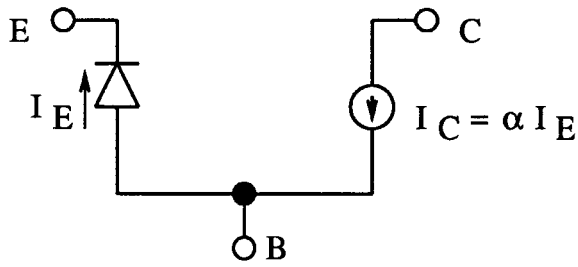

FIGURE 14.4 Large-signal model of the BJT.

The simple diode equation represents the relationship between applied emitter-to-base voltage and emitter current. This equation can be written as

$$I_E = I_1(e^{qV_{BE}/kT} - 1) \tag{14.6}$$

where q is the charge on an electron, k is Boltzmann's constant, T is the absolute temperature of the diode, and I_1 is a constant at a given temperature that depends on the doping and geometry of the emitter-base junction.

The collector current is generated by a dependent current source of value $I_C = \alpha I_E$.

A small-signal model based on the large-signal model of Fig. 14.4 is shown in Fig. 14.5. In this case, the resistance, r_d, is the dynamic resistance of the emitter-base diode and is given by:

$$r_d = \frac{kT}{qI_E} \tag{14.7}$$

where I_E is the dc emitter current.

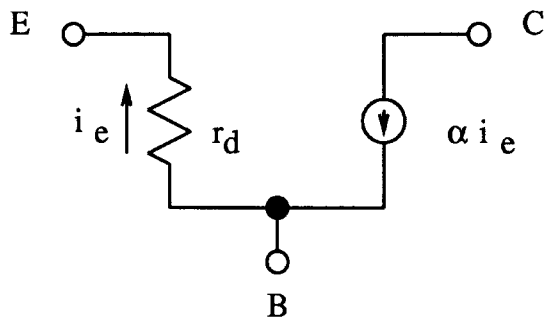

FIGURE 14.5 A small-signal model of the BJT.

14.6 Other Physical Effects in the BJT

The preceding section pertains to the basic operation of the BJT in the dc and midband frequency range. Several other effects must be included to model the BJT with more accuracy. These effects will now be described.

Ohmic Effects

The metal connections to the semiconductor regions exhibit some ohmic resistance. The emitter contact resistance and collector contact resistance is often in the ohm range and does not affect the BJT operation in most applications. The base region is very narrow and offers little area for a metal contact. Furthermore, because this region is narrow and only lightly doped compared to the emitter, the ohmic resistance of the base region itself is rather high. The total resistance between the contact and the intrinsic base region can be 100 to 200 Ω. This resistance can become significant in determining the behavior of the BJT, especially at higher frequencies.

Base-Width Modulation (Early Effect)

The widths of the depletion regions are functions of the applied voltages. The collector voltage generally exhibits the largest voltage change and, as this voltage changes, so also does the collector–base depletion region width. As the depletion layer extends further into the base region, the slope of the electron distribution in the base region becomes greater since the width of the base region is decreased. A slightly steeper slope leads to slightly more collector current. As reverse-bias decreases, the base width becomes greater and the current decreases. This effect is called *base-width modulation* and can be expressed in terms of the Early voltage,[4] V_A, by the expression:

$$I_C = \beta I_B\left(1 + \frac{V_{CE}}{V_A}\right) \tag{14.8}$$

The Early voltage will be constant for a given device and is typically in the range of 60 to 100 V.

Reactive Effects

Changing the voltages across the depletion regions results in a corresponding change in charge. This leads to an effective capacitance since

$$C = \frac{dQ}{dV} \tag{14.9}$$

This depletion region capacitance is a function of voltage applied to the junction and can be written as[4]:

$$C_{dr} = \frac{C_{Jo}}{(\phi - V_{app})^m} \tag{14.10}$$

where C_{Jo} is the junction capacitance at zero bias, ϕ is the built-in junction barrier voltage, V_{app} is the applied junction voltage, and m is a constant. For modern BJTs, m is near 0.33. The applied junction voltage has a positive sign for a forward-bias and a negative sign for a reverse-bias. The depletion region capacitance is often called the *junction capacitance*.

An increase in forward base–emitter voltage results in a higher density of electrons injected into the base region. The charge distribution in the base region changes with this voltage change, and this leads to a capacitance called the *diffusion capacitance*. This capacitance is a function of the emitter current and can be written as:

$$C_D = k_2 I_E \tag{14.11}$$

where k_2 is a constant for a given device.

14.7 More Accurate BJT Models

Figure 14.6 shows a large-signal BJT model used in some versions of the popular simulation program known as SPICE.[5] The equations for the parameters are listed in other texts[5] and will not be given here.

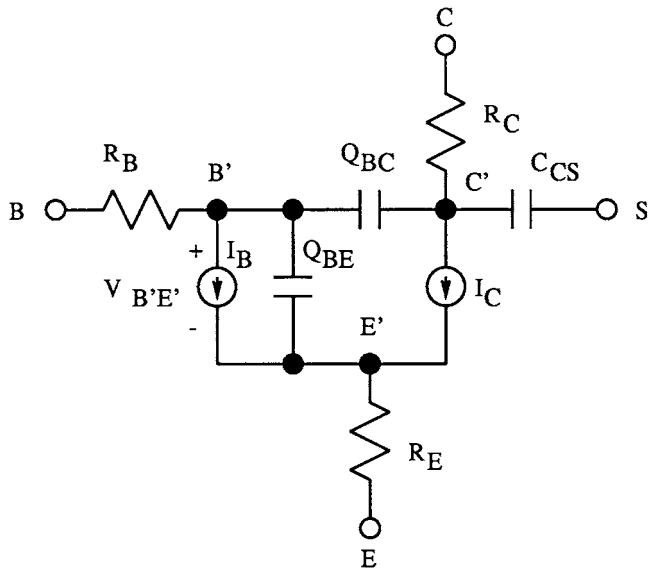

FIGURE 14.6 A more accurate large-signal model of the BJT.

Figure 14.7 shows a small-signal SPICE model[5] often called the hybrid-π equivalent circuit. The capacitance, C_π, accounts for the diffusion capacitance and the emitter–base junction capacitance. The collector–base junction capacitance is designated C_μ. The resistance, r_π, is equal to $(\beta + 1)r_d$. The transductance, g_m, is given by:

$$g_m = \frac{\alpha}{r_d} \tag{14.12}$$

The impedance, r_o, is related to the Early voltage by:

$$r_o = \frac{V_A}{I_C} \tag{14.13}$$

R_B, R_E, and R_C are the base, emitter, and collector resistances, respectively. For hand analysis, the ohmic resistances R_E and R_C are neglected along with C_{CS}, the collector-to-substrate capacitance.

14.8 Heterojunction Bipolar Junction Transistors

In an npn device, all electrons injected from emitter to base are collected by the collector, except for a small number that recombine in the base region. The holes injected from base to emitter contribute to emitter junction current, but do not contribute to collector current. This hole component of the emitter

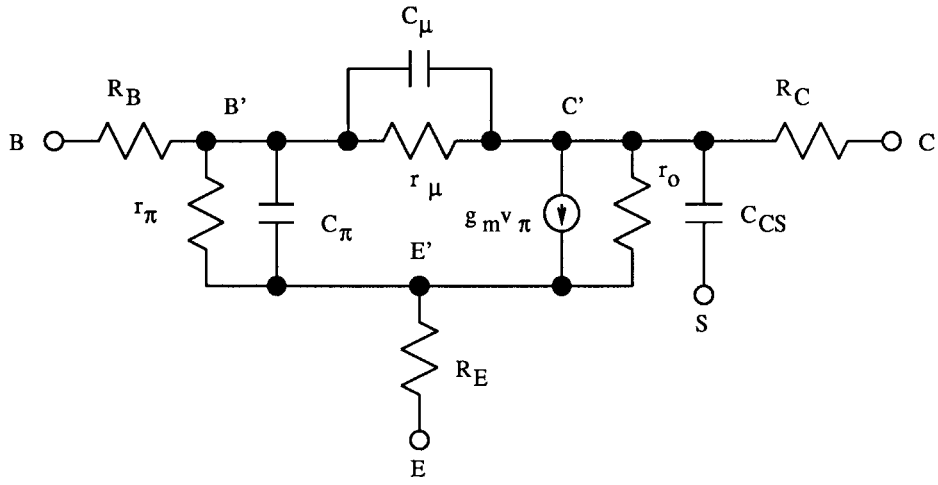

FIGURE 14.7 The hybrid-π small-signal model for the BJT.

current must be minimized to achieve a near-unity current gain from emitter to collector. As α approaches unity, the current gain from base to collector, β, becomes larger.

In order to produce high-β BJTs, the emitter region must be doped much more heavily than the base region, as explained earlier. While this approach allows the value of β to reach several hundred, it also leads to some effects that limit the frequency of operation of the BJT. The lightly doped base region causes higher values of base resistance, as well as emitter–base junction capacitance. Both of these effects are minimized in the *heterojunction BJT* (or HBJT). This device uses a different material for the base region than that used for the emitter and collector regions. One popular choice of materials is silicon for the emitter and collector regions, and a silicon/germanium material for the base region.[6] The difference in energy gap between the silicon emitter material and the silicon/germanium base material results in an asymmetric barrier to current flow across the junction. The barrier for electron injection from emitter to base is smaller than the barrier for hole injection from base to emitter. The base can then be doped more heavily than a conventional BJT to achieve lower base resistance, but the hole flow across the junction remains negligible due to the higher barrier voltage. The emitter of the HBJT can be doped more lightly to lower the junction capacitance. Large values of β are still possible in the HBJT while minimizing frequency limitations. Current gain-bandwidth figures exceeding 60 GHz have been achieved with present industrial HBJTs.

From the standpoint of analysis, the SPICE models for the HBJT are structurally identical to those of the BJT. The difference is in the parameter values.

14.9 Integrated Circuit Biasing Using Current Mirrors

Differential stages are very important in integrated circuit amplifier design. These stages require a constant dc current for proper bias. A simple bias scheme for differential BJT stages will now be discussed.

The diode-biased current sink or *current mirror* of Fig. 14.8 is a popular method of creating a constant-current bias for differential stages.

The concept of the current mirror was developed specifically for analog integrated circuit biasing and is a good example of a circuit that takes advantage of the excellent matching characteristics that are possible in integrated circuits. In the circuit of Fig. 14.8, the current I_2 is intended to be equal to or "mirror" the value of I_1. Current mirrors can be designed to serve as sinks or sources.

The general function of the current mirror is to reproduce or mirror the input or reference current to the output, while allowing the output voltage to assume any value within some specified range. The current mirror can also be designed to generate an output current that equals the input current multiplied by a scale factor *K*. The output current can be expressed as a function of input current as:

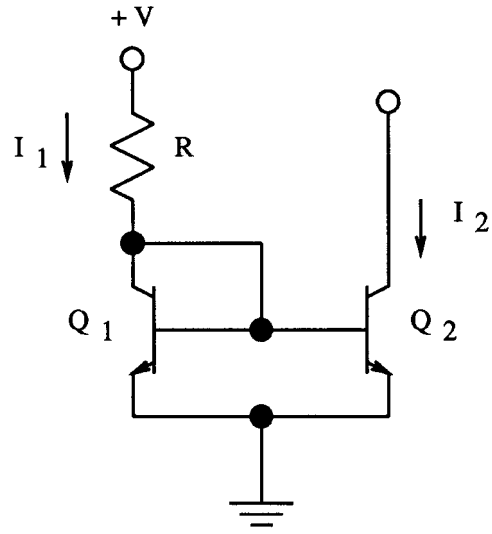

FIGURE 14.8 Current mirror bias stage.

$$I_O = KI_{IN} \tag{14.14}$$

where K can be equal to, less than, or greater than unity. This constant can be established accurately by relative device sizes and will not vary with temperature.

Figure 14.9 shows a multiple output current source where all of the output currents are referenced to the input current. Several amplifier stages can be biased with this multiple output current mirror.

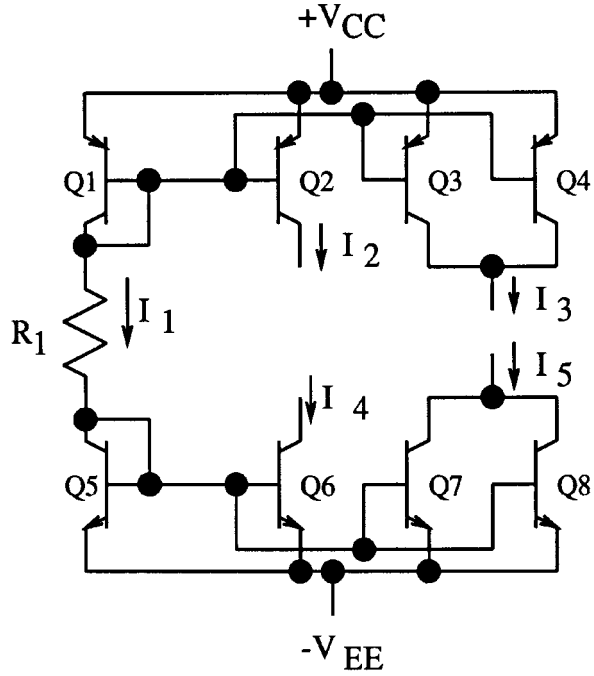

FIGURE 14.9 Multiple output current mirror.

Current Source Operating Voltage Range

Figure 14.10 shows an ideal or theoretical current sink in (a) and a practical sink in (b). The voltage at node A in the theoretical sink can be tied to any potential above or below ground without affecting the value of *I*. On the other hand, the practical circuit of Fig. 14.10(b) requires that the transistor remain in the active region to provide a current of:

$$I = \alpha \frac{V_B - V_{BE}}{R} \tag{14.15}$$

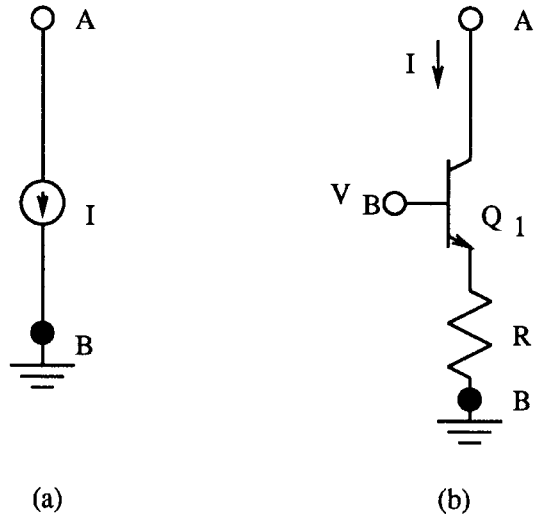

FIGURE 14.10 Current sink circuits: (a) ideal sink, (b) practical sink.

This requires that the collector voltage exceed the voltage V_B at all times. The upper limit on this voltage is determined by the breakdown voltage of the transistor. The output voltage must then satisfy:

$$V_B < V_C < (V_B + BV_{CE}) \tag{14.16}$$

where BV_{CE} is the breakdown voltage from collector to emitter of the transistor. This voltage range over which the current source operates is called the *output voltage compliance range* or the *output compliance*.

Current Mirror Analysis

The current mirror is again shown in Fig. 14.11. If devices Q_1 and Q_2 are assumed to be matched devices, we can write:

$$I_{E1} = I_{E2} = I_{EO} e^{V_{BE}/V_T} \tag{14.17}$$

where $V_T = kT/q$, $I_{EO} = AJ_{EO}$, A is the emitter area of the two devices, and J_{EO} is the current density of the emitters. The base currents for each device will also be identical and can be expressed as:

$$I_{B1} = I_{B2} = \frac{I_{EO}}{\beta + 1} e^{V_{BE}/V_T} \tag{14.18}$$

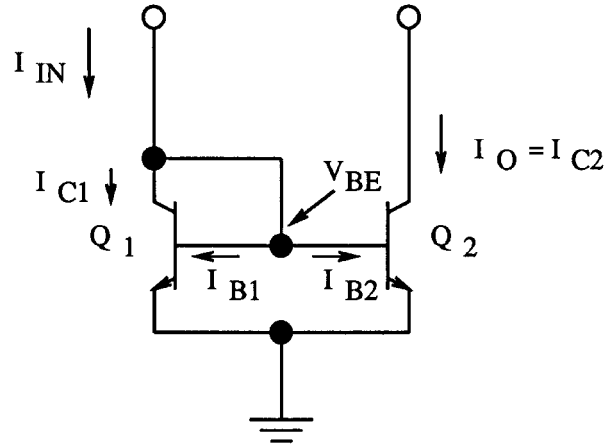

FIGURE 14.11 Circuit for current mirror analysis.

Device Q_1 operates in the active region, but near saturation by virtue of the collector–base connection. This configuration is called a *diode-connected transistor*. Since the collector-to-emitter voltage is very small, the collector current for device Q_1 is given by Eq. 14.8, assuming $V_{CE} = 0$. This gives:

$$I_{C1} = \beta I_{B1} \approx \frac{\beta}{\beta + 1} I_{EO} e^{V_{BE}/V_T} \tag{14.19}$$

The device Q_2 does not have the constraint that $V_{CE} \approx 0$ as device Q_1 has. The collector voltage for Q_2 will be determined by the external circuit that connects to this collector. Thus, the collector current for this device is:

$$I_{C2} = \beta I_{B2}\left(1 + \frac{V_{C2}}{V_A}\right) \tag{14.20}$$

where V_A is the Early voltage. In effect, the output stage has an output impedance given by Eq. 14.13. The current mirror more closely approximates a current source as the output impedance becomes larger.

If we limit the voltage V_{C2} to small values relative to the Early voltage, I_{C2} is approximately equal to I_{C1}. For integrated circuit designs, the voltage required at the output of the current mirror is generally small, making this approximation valid.

The input current to the mirror is larger than the collector current and is:

$$I_{IN} = I_{C1} + 2I_B \tag{14.21}$$

Since $I_{OUT} = I_{C2} = I_{C1} = \beta I_B$, we can write Eq. 14.21 as:

$$I_{IN} = \beta I_B + 2I_B = (\beta + 2) I_B \tag{14.22}$$

Relating I_{IN} to I_{OUT} results in:

$$I_{OUT} = \frac{\beta}{\beta + 2} I_{IN} = \frac{I_{IN}}{1 + 2/\beta} \tag{14.23}$$

For typical values of β, these two currents are essentially equal. Thus, a desired bias current, I_{OUT}, is generated by creating the desired value of I_{IN}. The current I_{IN} is normally established by connecting a resistance R_1 to a voltage source V_{CC} to set I_{IN} to:

$$I_{IN} = \frac{V_{CC} - V_{BE}}{R_1} \tag{14.24}$$

Control of collector/bias current for Q_2 is then accomplished by choosing proper values of V_{CC} and R_1.

Figure 14.12 shows a multiple-output current mirror.

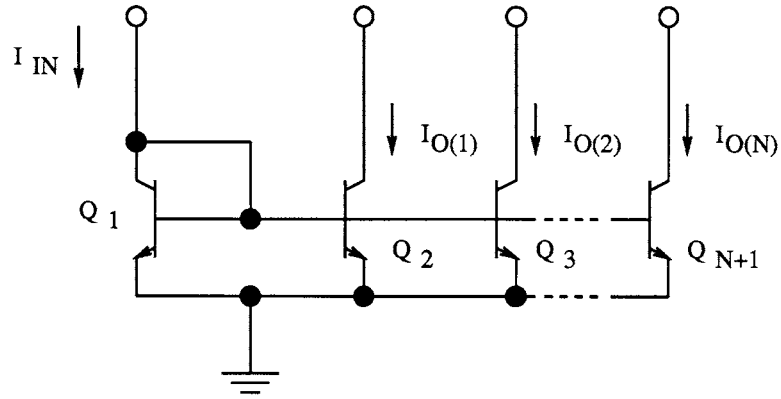

FIGURE 14.12 Multiple-output current mirror.

It can be shown that the output current for each identical device in Fig. 14.12 is:

$$I_O = \frac{I_{IN}}{1 + \dfrac{N+1}{\beta}} \tag{14.25}$$

where N is the number of output devices.

The current sinks can be turned into current sources by using pnp transistors and a power supply of opposite polarity. The output devices can also be scaled in area to make I_{OUT} be larger or smaller than I_{IN}.

Current Mirror with Reduced Error

The difference between output current in a multiple-output current mirror and the input current can become quite large if N is large. One simple method of avoiding this problem is to use an emitter follower to drive the bases of all devices in the mirror, as shown in Fig. 14.13.

The emitter follower, Q_0, has a current gain from base to collector of $\beta + 1$, reducing the difference between I_O and I_{IN} to:

$$I_{IN} - I_O = \frac{N+1}{\beta+1} I_B \tag{14.26}$$

The output current for each device is:

$$I_O = \frac{I_{IN}}{1 + \dfrac{N+1}{\beta(\beta+1)}} \tag{14.27}$$

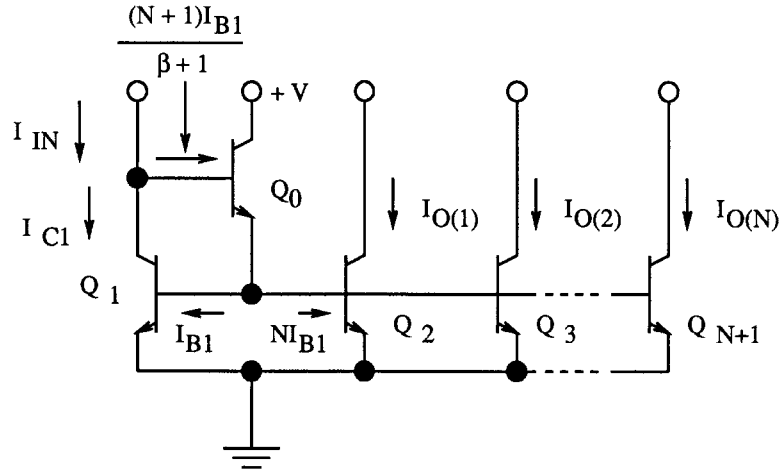

FIGURE 14.13 Improved multiple output current mirror.

The Wilson Current Mirror

In the simple current mirrors discussed, it was assumed that the collector voltage of the output stage was small compared to the Early voltage. When this is untrue, the output current will not remain constant, but will increase as output voltage (V_{CE}) increases. In other words, the output compliance range is limited with these circuits due to the finite output impedance of the BJT.

A modification of the improved output current mirror of Fig. 14.13 was proposed by Wilson[7] and is illustrated in Fig. 14.14.

The Wilson current mirror is connected such that $V_{CB2} = 0$ and $V_{BE1} = V_{BE0}$. Both Q_1 and Q_2 now operate with a near-zero collector–emitter bias although the collector of Q_0 might feed into a high-voltage point. It can be shown that the output impedance of the Wilson mirror is increased by a factor of β /2 over the simple mirror. This higher impedance translates into a higher output compliance. This circuit also reduces the difference between input and output current by means of the emitter follower stage.

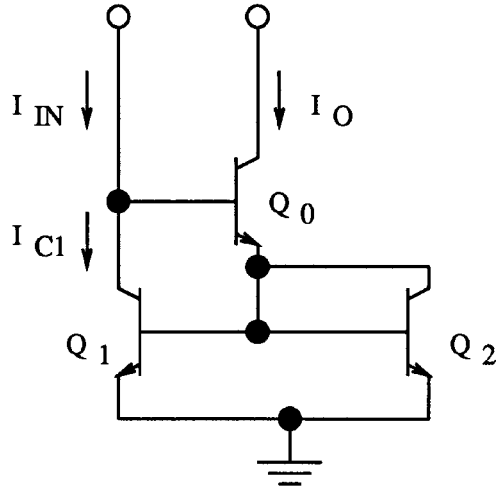

FIGURE 14.14 Wilson current mirror.

14.10 The Basic BJT Switch

In digital circuits, the BJT is used as a switch to generate one of only two possible output voltage levels, depending on the input voltage level. Each voltage level is associates with one of the binary digits, 0 or 1. Typically, the high voltage level may fall between 2.8 V and 5 V while the low voltage level may fall between 0 V and 0.8 V.

Logic circuits are based on BJT stages that are either in cutoff with both junctions reverse-biased or in a conducting mode with the emitter–base junction forward-biased. When the BJT is "on" or conducting emitter current, it can be in the active region or the saturation region. If it is in the saturation region, the collector–base region is also forward-biased.

The three possible regions of operation are summarized in Table 14.1.

TABLE 14.1 Regions of Operation

Region	Cutoff	Active	Saturation
C–B bias	Reverse	Reverse	Forward
E–B bias	Reverse	Forward	Forward

The BJT very closely approximates certain switch configurations. For example, when the switch of Fig. 14.15(a) is open, no current flows through the resistor and the output voltage is +12 V. Closing the switch causes the output voltage to drop to zero volts and a current of $12/R$ flows through the resistance. When the base voltage of the BJT of Fig. 14.15(b) is negative, the device is cut off and no collector current flows. The output voltage is +12 V, just as in the case of the open switch. If a large enough current is now driven into the base to saturate the BJT, the output voltage becomes very small, ranging from 20 mV to 500 mV, depending on the BJT used. The saturated state corresponds closely to the closed switch. During the time that the BJT switches from cutoff to saturation, the active region equivalent circuit applies. For high-speed switching of this circuit, appropriate reactive effects must be considered. For low-speed switching, these reactive effects can be neglected.

Saturation occurs in the basic switching circuit of Fig. 14.15(b) when the entire power supply voltage drops across the load resistance. No voltage, or perhaps a few tenths of volts, then appears from collector to emitter. This occurs when the base current exceeds the value

$$I_{B(sat)} = \frac{V_{CC} - V_{CE(sat)}}{\beta R_L} \tag{14.28}$$

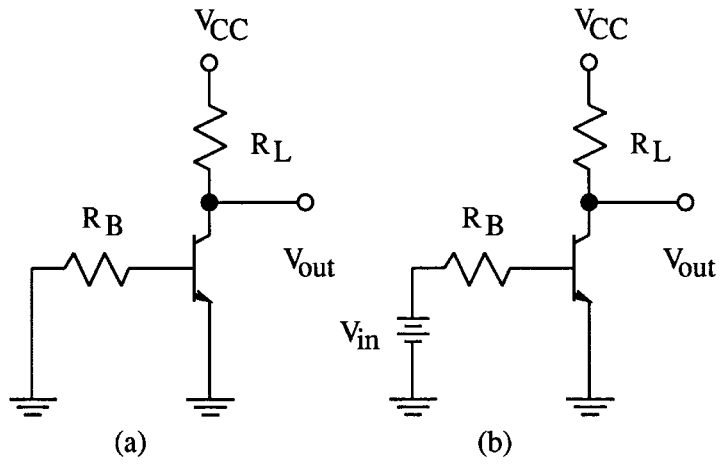

FIGURE 14.15 The BJT as a switch: (a) open switch, (b) closed switch.

When a transistor switch is driven into saturation, the collector–base junction becomes forward-biased. This situation results in the electron distribution across the base region shown in Fig. 14.16. The forward-bias of the collector–base junction leads to a non zero concentration of electrons in the base that is unnecessary to support the gradient of carriers across this region. When the input signal to the base switches to a lower level to either turn the device off or decrease the current flow, the excess charge must be removed from the base region before the current can begin to decrease.

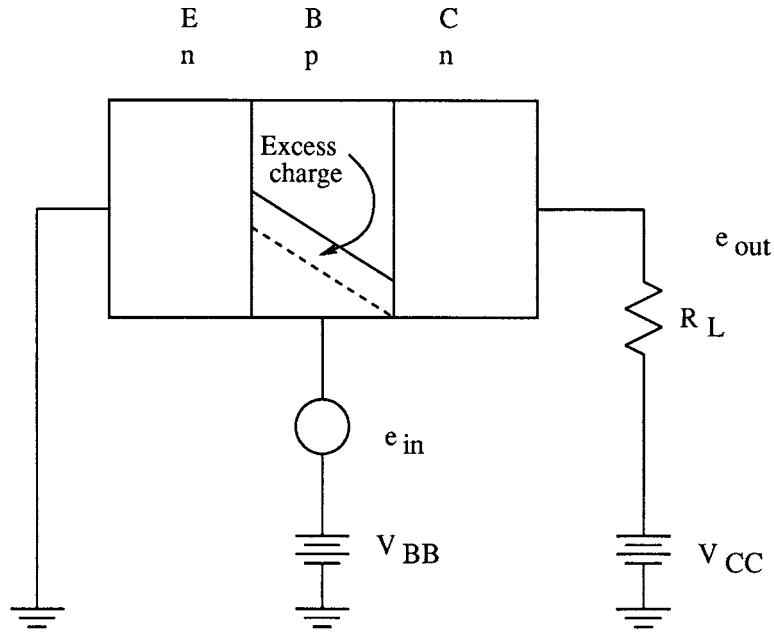

FIGURE 14.16 Electron distribution in the base region of a saturated BJT.

14.11 High-Speed BJT Switching

There are three major effects that extend switching times in a BJT:

1. The depletion-region or junction capacitances are responsible for delay time when the BJT is in the cutoff region.
2. The diffusion capacitance and the Miller-effect capacitance are responsible for the rise and fall times of the BJT as it switches through the active region.
3. The storage time constant accounts for the time taken to remove the excess charge from the base region before the BJT can switch from the saturation region to the active region.

There are other second-order effects that are generally negligible compared to the previously listed time lags.

Since the transistor is generally operating as a large-signal device, the parameters such as junction capacitance or diffusion capacitance will vary as the BJT switches. One approach to the evaluation of time constants is to calculate an average value of capacitance over the voltage swing that takes place. Not only is this method used in hand calculations, but most computer simulation programs use average values to speed calculations.

Overall Transient Response

Before discussing the individual BJT switching times, it is helpful to consider the response of a common-emitter switch to a rectangular waveform. Figure 14.17 shows a typical circuit using an npn transistor.

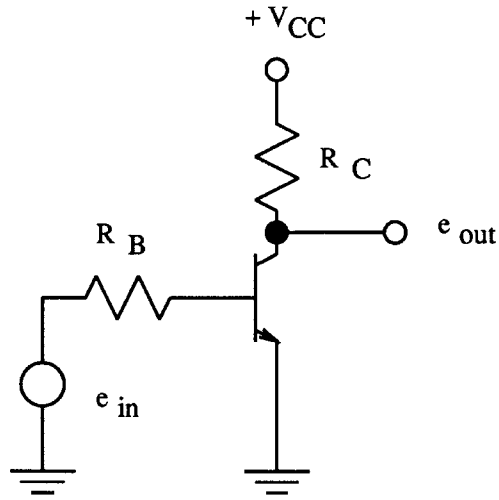

FIGURE 14.17 A simple switching circuit.

A rectangular input pulse and the corresponding output are shown in Fig. 14.18. In many switching circuits, the BJT must switch from its "off" state to saturation and later return to the "off" state. In this case, the delay time, rise time, saturation storage time, and fall time must be considered in that order to find the overall switching time.

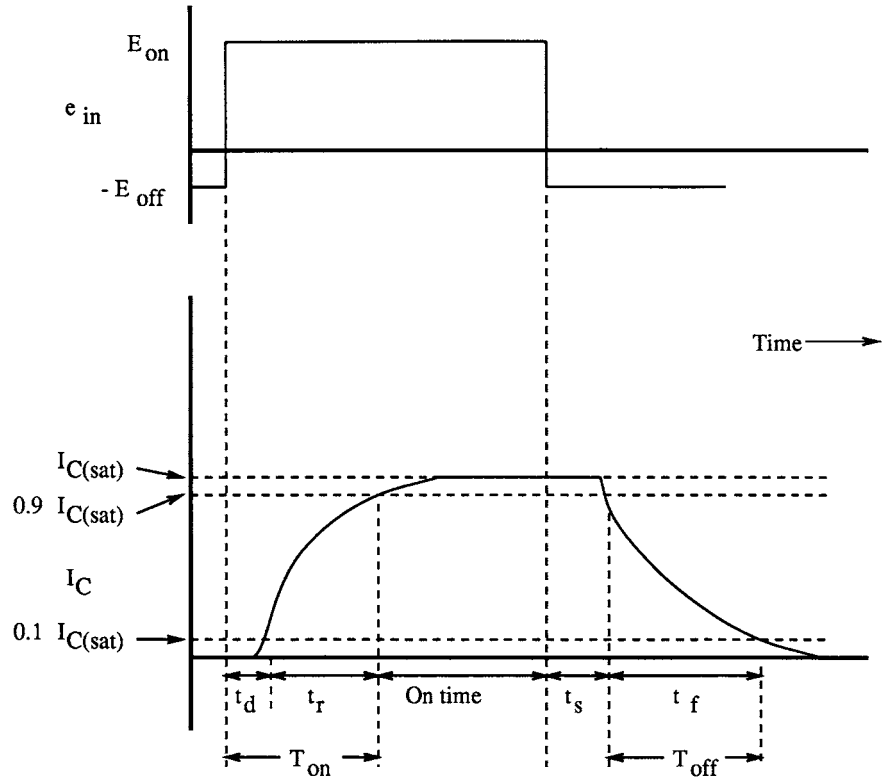

FIGURE 14.18 Input and output waveforms.

The total waveform is made up of five sections: delay time, rise time, on time, storage time, and fall time. The following list summarizes these points and serves as a guide for future reference:

t_d' = Passive delay time; time interval between application of forward base drive and start of collector-current response.
t_d = Total delay time; time interval between application of forward base drive and the point at which I_C has reached 10% of the final value.
t_r = Rise time; 10- to 90-% rise time of I_C waveform.
t_s' = Saturation storage time; time interval between removal of forward base drive and start of I_C decrease.
t_s = Total storage time; time interval between removal of forward base drive and point at which $I_C = 0.9I_{C(sat)}$.
t_f = Fall time; 90- to 10-% fall time of I_C waveform
T_{on} = Total turn-on time; time interval between application of base drive and point at which I_C has reached 90% of its final value.
T_{off} = Total turn-off time; time interval between removal of forward base drive and point at which I_C has dropped to 10% of its value during on time.

Not all applications will require evaluation of each of these switching times. For instance, if the base drive is insufficient to saturate the transistor, t_s will be zero. If the transistor never leaves the active region, the delay time will also be zero.

The factors involved in calculating the switching times are summarized in the following paragraphs.[8]

The passive delay time is found from:

$$t'_d = \tau_d \ln\left(\frac{E_{on} + E_{off}}{E_{on} - V_{BE(on)}}\right) \tag{14.29}$$

where τ_d is the product of the charging resistance and the average value of the two junction capacitances.

The active region time constant is a function of the diffusion capacitance, the collector–base junction capacitance, the transconductance, and the charging resistance. This time constant will be denoted by τ. If the transistor never enters saturation, the rise time is calculated from the well-known formula:

$$t_r = 2.2\tau \tag{14.30}$$

If the BJT is driven into saturation, the rise time is found from[8]:

$$t_r = \tau \ln\left(\frac{K - 0.1}{K - 0.9}\right) \tag{14.31}$$

where K is the overdrive factor or the ratio of forward base current drive to the value needed for saturation. The rise time for the case where K is large can be much smaller than the rise time for the nonsaturating case ($K < 1$). Unfortunately, the saturation storage time increases for large values of K.

The saturation storage time is given by:

$$t'_s = \tau_s \ln\left(\frac{I_{B1} - I_{B2}}{I_{B(sat)} - I_{B2}}\right) \tag{14.32}$$

where τ_s is the storage time constant, I_{B1} is the forward base current before switching, and I_{B2} is the current after switching and must be less than $I_{B(sat)}$. The saturation storage time can slow the overall switching time significantly. The higher speed logic gates utilize circuits that avoid the saturation region for the BJTs that make up the gate.

14.12 Simple Logic Gates

Although the resistor-transistor-logic (RTL) family has not been used since the late 1960s, it demonstrates the concept of a simple logic gate. Figure 14.19 shows a four-input RTL NOR gate.

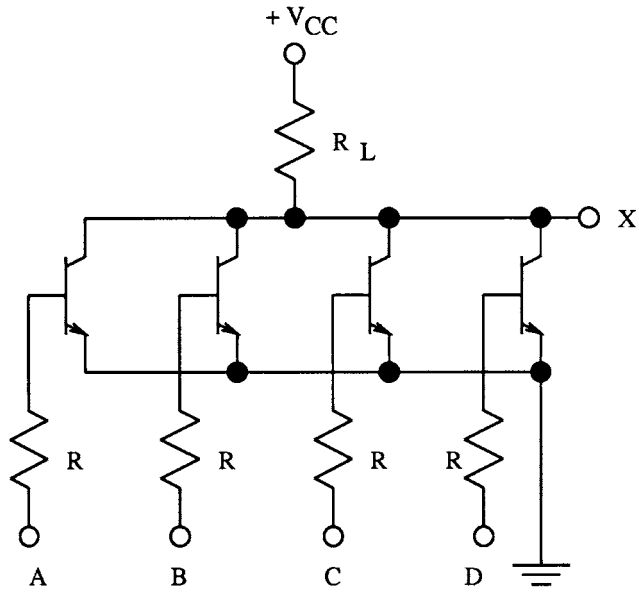

FIGURE 14.19 A four-input RTL NOR gate.

If all four inputs are at the lower voltage level (e.g., 0 V), there is no conducting path from output to ground. No voltage will drop across R_L, and the output voltage will equal V_{CC}. If any or all of the inputs moves to the higher voltage level (e.g., 4 V), any BJT with base connected to the higher voltage level will saturate, pulling the output voltage down to a few tenths of a volt. If positive logic is used, with the high voltage level corresponding to binary "1" and the low voltage level to binary "0," the gate performs the NOR function. Other logic functions can easily be constructed in the RTL family.

Over the years, the performance of logic gates has been improved by different basic configurations. RTL logic was improved by diode-transistor-logic (DTL). Then, transistor-transistor-logic (TTL) became very prominent. This family is still popular in the small-scale integration (SSI) and medium-scale integration (MSI) areas, but CMOS circuits have essentially replaced TTL in large-scale integration (LSI) and very-large-scale integration (VLSI) applications.

One popular family that is still prominent in very high-speed computer work is the emitter-coupled logic (ECL) family. While CMOS packs many more circuits into a given area than ECL, the frequency performance of ECL leads to its popularity in supercomputer applications.

14.13 Emitter-Coupled Logic

Emitter-coupled logic (ECL) was developed in the mid-1960s and remains the fastest silicon logic circuit available. Present ECL families offer propagation delays in the range of 0.2 ns.[9] The two major disadvantages of ECL are: (1) resistors which require a great deal of IC chip area, must be used in each gate, and (2) the power dissipation of an ECL gate is rather high. These two shortcomings limit the usage of ECL in VLSI systems. Instead, this family has been used for years in larger supercomputers than can afford space and power to achieve higher speeds.

The high speeds obtained with ECL are primarily based on two factors. No device in an ECL gate is ever driven into the saturation region and, thus, saturation storage time is never involved as devices switch from one state to another. The second factor is that required voltage swings are not large. Voltage excursions necessary to change an input from the low logic level to the high logic level are minimal. Although noise margins are lower than other logic families, switching times are reduced in this way.

Figure 14.20 shows an older ECL gate with two separate outputs. For positive logic, *X* is the OR output while *Y* is the NOR output.

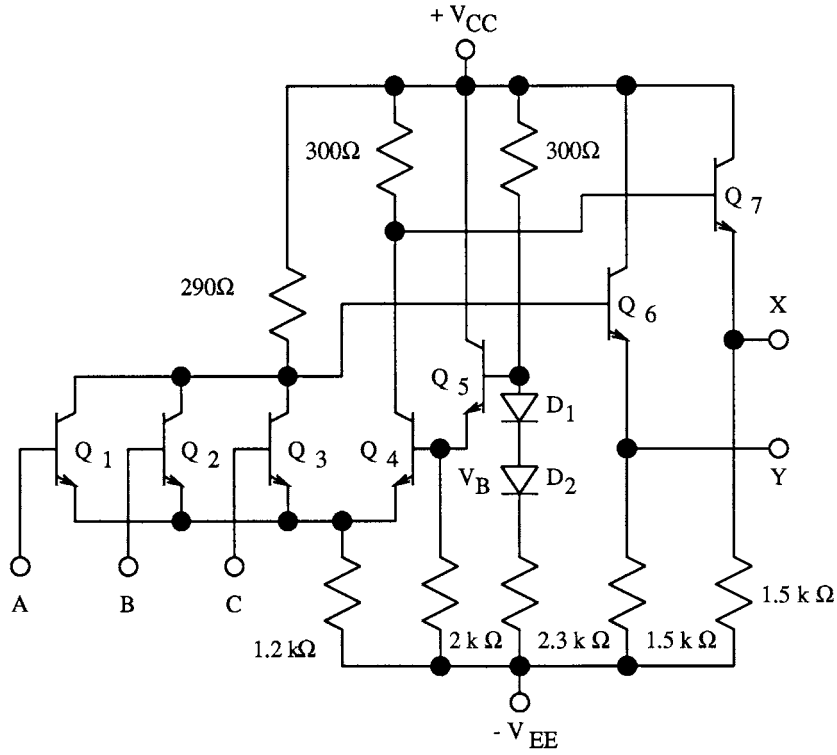

FIGURE 14.20 An ECL logic gate.

Often, the positive supply voltage is taken as 0 V and V_{EE} as –5 V due to noise considerations. The diodes and emitter follower Q_5 establish a temperature-compensated base reference for Q_4. When inputs *A*, *B*, and *C* are less than the voltage V_B, Q_4 conducts while Q_1, Q_2, and Q_3 are cut off. If any one of the inputs is switched to the 1 level, which exceeds V_B, the transistor turns on and pulls the emitter of Q_4 positive enough to cut this transistor off. Under this condition, output *Y* goes negative while *X* goes positive. The relatively large resistor common to the emitters of Q_1, Q_2, Q_3, and Q_4 prevents these transistors from saturating. In fact, with nominal logic levels of –1.9 V and –1.1 V, the current through the emitter resistance is approximately equal before and after switching takes place. Thus, only the current path changes as the circuit switches. This type of operation is sometimes called *current mode switching*. Although the output stages are emitter followers, they conduct reasonable currents for both logic level outputs and, therefore, minimize the asymmetrical output impedance problem.

In an actual ECL gate, the emitter follower load resistors are not fabricated on the chip. The newer version of the gate replaces the emitter resistance of the differential stage with a current source, and replaces the bias voltage circuit with a regulated voltage circuit.

A Closer Look at the Differential Stage

Figure 14.21 shows a simple differential stage similar to the input stage of an ECL gate.[2] Both transistors are biased by a current source, I_T, called the *tail current*. The two input signals e_1 and e_2 make up a differential input signal defined as:

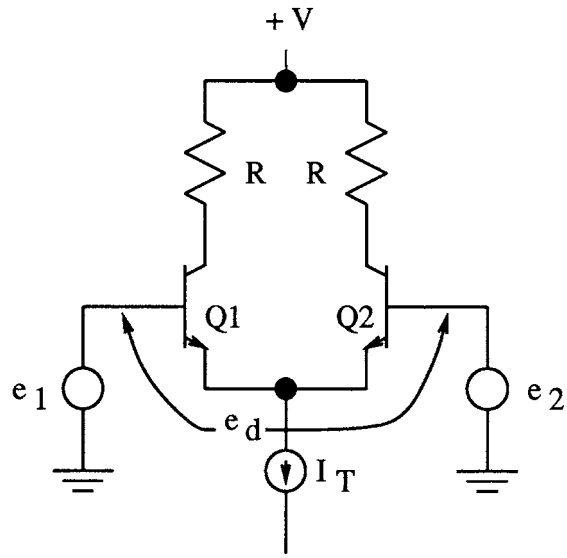

FIGURE 14.21 A simple differential stage similar to an ECL input stage.

$$e_d = e_1 - e_2 \tag{14.33}$$

This differential voltage can be expressed as the difference between the base–emitter junction voltages as:

$$e_d = V_{BE1} - V_{BE2} \tag{14.34}$$

The collector currents can be written in terms of the base–emitter voltages as:

$$I_{C1} = \alpha I_{EO} e^{V_{BE1}/V_T} \approx I_{EO} e^{V_{BE1}/V_T} \tag{14.35}$$

$$I_{C2} = \alpha I_{EO} e^{V_{BE2}/V_T} \approx I_{EO} e^{V_{BE2}/V_T} \tag{14.36}$$

where matched devices are assumed.

A differential output current can be defined as the difference of the collector currents, or

$$I_d = I_{C1} - I_{C2} \tag{14.37}$$

Since the tail current is $I_T = I_{C1} + I_{C2}$, taking the ratio of I_d to I_T gives:

$$\frac{I_d}{I_T} = \frac{I_{C1} - I_{C2}}{I_{C1} + I_{C2}} \tag{14.38}$$

Since $V_{BE1} = e_d + V_{BE2}$, we can substitute this value for V_{BE1} into Eq. 14.35 to write:

$$I_{C1} = I_{EO} e^{\left(e_d + V_{BE2}\right)/V_T} = I_{EO} e^{e_d/V_T} e^{V_{BE2}/V_T} \tag{14.39}$$

Substituting Eqs. 14.36 and 14.39 into Eq. 14.38 results in:

$$\frac{I_d}{I_T} = \frac{e^{e_d/V_T} - 1}{e^{e_d/V_T} + 1} = \tanh\frac{e_d}{2V_T} \tag{14.40}$$

or

$$I_d = I_T \tanh\frac{e_d}{2V_T} \tag{14.41}$$

This differential current is graphed in Fig. 14.22.

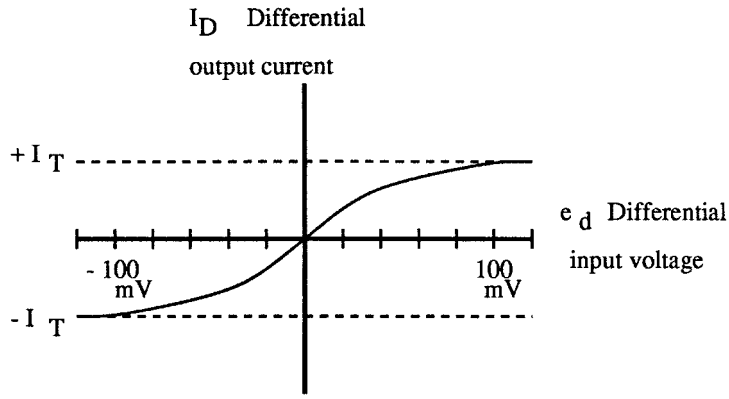

FIGURE 14.22 Differential output current as a function of differential input voltage.

When e_d is zero, the differential current is also zero, implying equal values of collector currents in the two devices. As e_d increases, so also does I_d until e_d exceeds $4V_T$, at which time I_d has reached a constant value of I_T. From the definition of differential current, this means that I_{C1} equals I_T while I_{C2} is zero. As the differential input voltage goes negative, the differential current approaches $-I_T$ as the voltage reaches $-4V_T$. In this case, $I_{C2} = I_T$ while I_{C1} goes to zero.

The implication here is that the differential stage can move from a balanced condition with $I_{C1} = I_{C2}$ to a condition of one device fully off and the other fully on with an input voltage change of around 100 mV or $4V_T$. This demonstrates that a total voltage change of about 200 mV at the input can cause an ECL gate to change states. This small voltage change contributes to smaller switching times for ECL logic.

The ability of a differential pair to convert a small change in differential base voltage to a large change in collector voltage also makes it a useful building block for analog amplifiers. In fact, a differential pair with a pnp transistor current mirror load, as illustrated in Fig. 14.23, is widely used as an input stage for integrated circuit op-amps.

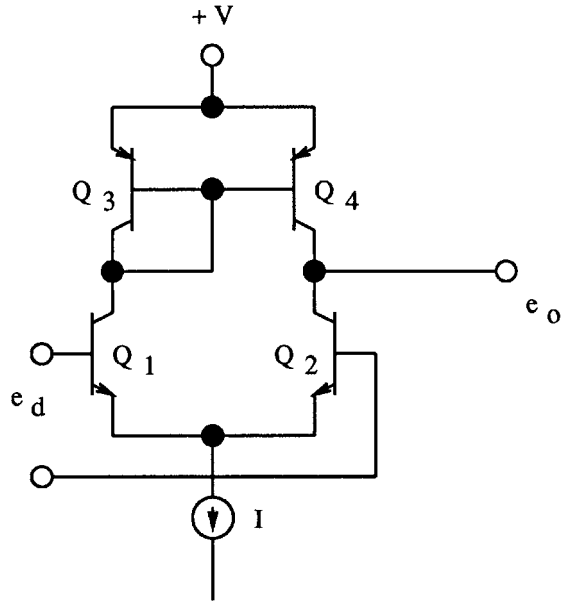

FIGURE 14.23 Differential input stage with current mirror load.

15.1 Introduction

Passive energy storage elements are widely used in radio-frequency (RF) circuits. Although their impedance behavior often can be mimicked by compact active circuitry, it remains true that passive elements offer the largest dynamic range and the lowest power consumption. Hence, the highest performance will always be obtained with passive inductors and capacitors. Unfortunately, standard integrated circuit technology has not evolved with a focus on providing good passive elements. This chapter describes the limited palette of options available, as well as means to make the most use out of what is available.

15.2 Fractal Capacitors

Of capacitors, the most commonly used are parallel-plate and MOS structures. Because of the thin gate oxides now in use, capacitors made out of MOSFETs have the highest capacitance density of any standard IC option, with a typical value of approximately 7 fF/μm^2 for a gate oxide thickness of 5 nm. A drawback, however, is that the capacitance is voltage dependent. The applied potential must be well in excess of a threshold voltage in order to remain substantially constant. The relatively low breakdown voltage (on the order of 0.5 V/nm of oxide) also imposes an unwelcome constraint on allowable signal amplitudes. An additional drawback is the effective series resistance of such structures, due to the MOS channel resistance. This resistance is particularly objectionable at radio frequencies, since the impedance of the combination may be dominated by this resistive portion.

Capacitors that are free of bias restrictions (and that have much lower series resistance) may be formed out of two (or more) layers of standard interconnect metal. Such parallel-plate capacitors are quite linear and possess high breakdown voltage, but generally offer two orders of magnitude lower capacitance density than the MOSFET structure. This inferior density is the consequence of a conscious and continuing effort by technologists to keep low the capacitance between interconnect layers. Indeed, the

vertical spacing between such layers generally does not scale from generation to generation. As a result, the disparity between MOSFET capacitance density and that of the parallel-plate structure continues to grow as technology scales.

A secondary consequence of the low density is an objectionably high capacitance between the bottom plate of the capacitor and the substrate. This bottom-plate capacitance is often a large fraction of the main capacitance. Needless to say, this level of parasitic capacitance is highly undesirable.

In many circuits, capacitors can occupy considerable area, and an area-efficient capacitor is therefore highly desirable. Recently, a high-density capacitor structure using lateral fringing and fractal geometries has been introduced.[1] It requires no additional processing steps, and so it can be built in standard digital processes. The linearity of this structure is similar to that of the conventional parallel-plate capacitor. Furthermore, the bottom-plate parasitic capacitance of the structure is small, which makes it appealing for many circuit applications. In addition, unlike conventional metal-to-metal capacitors, the density of a fractal capacitor increases with scaling.

Lateral Flux Capacitors

Figure 15.1(a) shows a lateral flux capacitor. In this capacitor, the two terminals of the device are built using a single layer of metal, unlike a vertical flux capacitor, where two different metal layers must be used. As process technologies continue to scale, lateral fringing becomes more important. The lateral spacing of the metal layers, s, shrinks with scaling, yet the thickness of the metal layers, t, and the vertical spacing of the metal layers, t_{ox}, stay relatively constant. This means that structures utilizing lateral flux enjoy a significant improvement with process scaling, unlike conventional structures that depend on vertical flux. Figure 15.1(b) shows a scaled lateral flux capacitor. It is obvious that the capacitance of the structure of Fig. 15.1(b) is larger than that of Fig. 15.1(a).

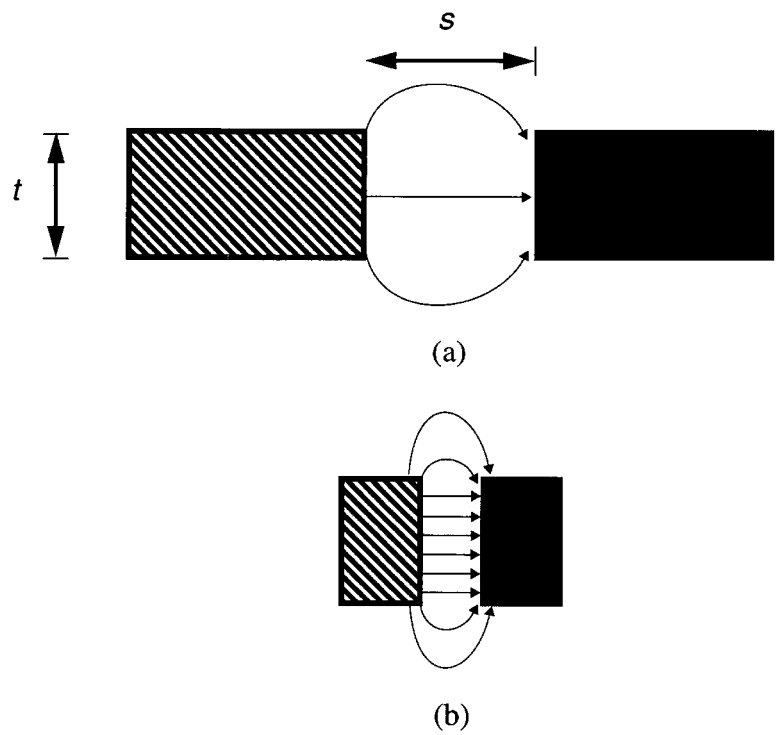

FIGURE 15.1 Effect of scaling on lateral flux capacitors: (a) before scaling and (b) after scaling.

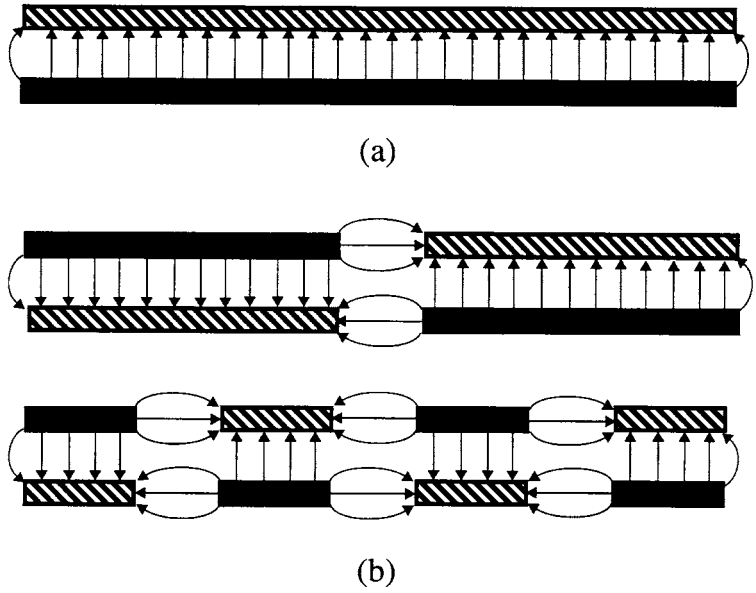

FIGURE 15.2 Vertical flux vs. lateral flux: (a) astandard parallel-plate structure, and (b) cross-connected metal layers.

Lateral flux can be used to increase the total capacitance obtained in a given area. Figure 15.2(a) is a standard parallel-plate capacitor. In Fig. 15.2(b), the plates are broken into cross-connected sections.[2] As can be seen, a higher capacitance density can be achieved by using lateral flux as well as vertical flux. To emphasize that the metal layers are cross connected, the two terminals of the capacitors in Fig. 15.2(b) are identified with two different shadings. The idea can be extended to multiple metal layers as well.

Figure 15.3 shows the ratio of metal thickness to minimum lateral spacing, *t/s*, vs. channel length for various technologies.[3–5] The trend suggests that lateral flux will have a crucial role in the design of capacitors in future technologies.

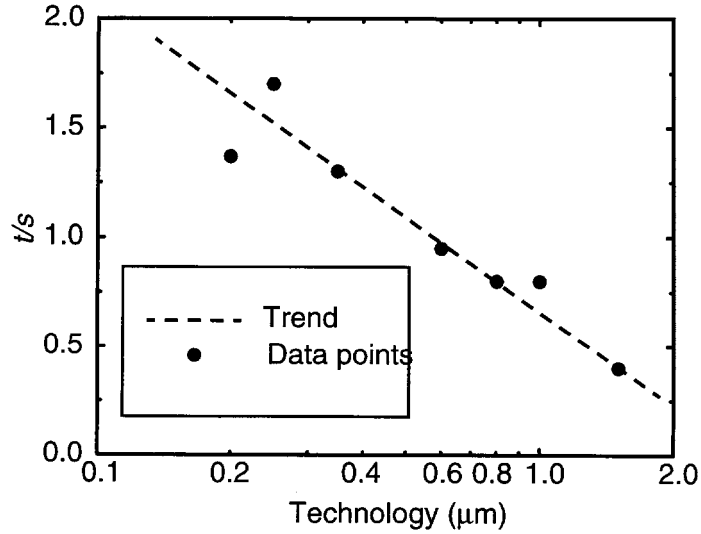

FIGURE 15.3 Ratio of metal thickness to horizontal metal spacing vs. technology (channel length).

The increase in capacitance due to fringing is proportional to the periphery of the structure; therefore, structures with large periphery per unit area are desirable. Methods for increasing this periphery are the subject of the following sections.

Fractals

A fractal is a mathematical abstract.[6] Some fractals are visualizations of mathematical formulas, while others are the result of the repeated application of an algorithm, or a *rule*, to a *seed*. Many natural phenomena can be described by fractals. Examples include the shapes of mountain ranges, clouds, coastlines, etc.

Some ideal fractals have finite area but infinite perimeter. The concept can be better understood with the help of an example. *Koch islands* are a family of fractals first introduced as a crude model for the shape of a coastline. The construction of a Koch curve begins with an *initiator*, as shown in the example of Fig. 15.4(a). A square is a simple initiator with $M = 4$ sides. The construction continues by replacing each segment of the initiator with a curve called a *generator*, an example of which is shown in Fig. 15.4(b) that has $N = 8$ segments. The size of each segment of the generator is $r = 1/4$ of the initiator. By recursively replacing each segment of the resulting curve with the generator, a fractal border is formed. The first step of this process is depicted in Fig. 15.4(c). The total area occupied remains constant throughout the succession of stages because of the particular shape of the generator. A more complicated Koch island can be seen in Fig. 15.5. The associated initiator of this fractal has four sides and its generator has 32 segments. It can be noted that the curve is self similar, that is, each section of it looks like the entire fractal. As we zoom in on Fig. 15.5, more detail becomes visible, and this is the essence of a fractal.

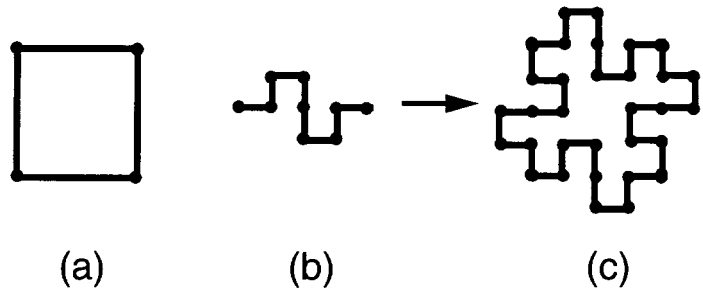

FIGURE 15.4 Construction of a Koch curve: (a) an initiator, (b) a generator, and (c) first step of the process.

Fractal dimension, *D*, is a mathematical concept that is a measure of the complexity of a fractal. The dimension of a flat curve is a number between 1 and 2, which is given by

$$D = \frac{\log(N)}{\log\left(\frac{1}{r}\right)} \tag{15.1}$$

where N is the number of segments of the generator and r is the ratio of the generator segment size to the initiator segment size. The dimension of a fractal curve is not restricted to integer values, hence the term "fractal." In particular, it exceeds 1, which is the intuitive dimension of curves. A curve that has a high degree of complexity, or *D*, fills out a two-dimensional flat surface more efficiently. The fractal in Fig. 15.4(c) has a dimension of 1.5, whereas for the border line of Fig.15.5, $D = 1.667$.

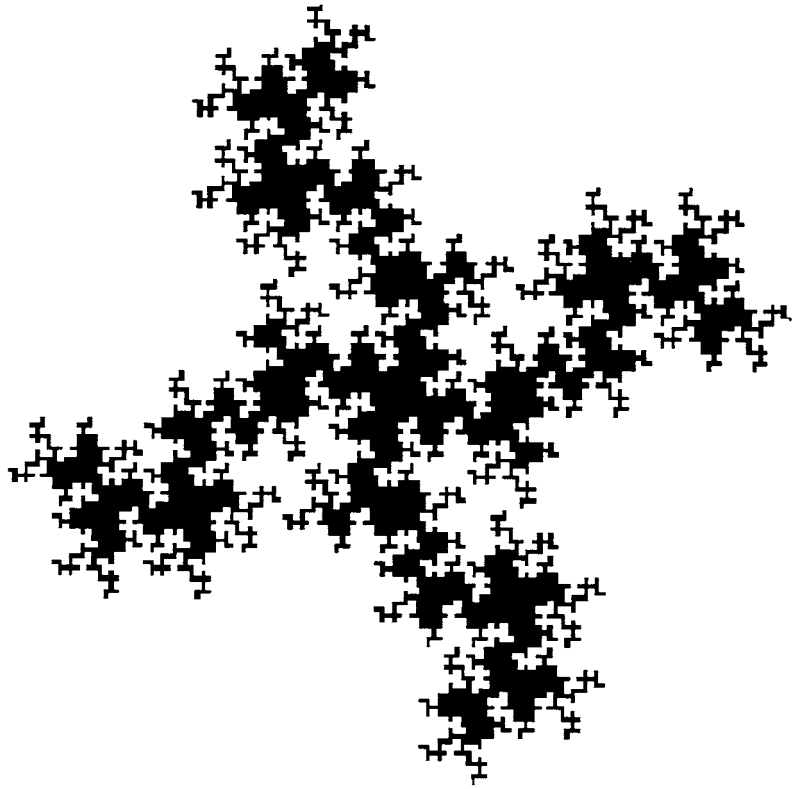

FIGURE 15.5 A Koch island with $M = 4$, $N = 32$, and $r = 1/8$.

For the general case where the initiator has M sides, the periphery of the initiator is proportional to the square root of the area:

$$P_0 = k \cdot \sqrt{A} \tag{15.2}$$

where k is a proportionality constant that depends on the geometry of the initiator. For example, for a square initiator, $k = 4$; and for an equilateral triangle, $k = 2 \cdot \sqrt[4]{27}$. After n successive applications of the generation rule, the total periphery is

$$P = k\sqrt{A} \cdot (Nr)^n \tag{15.3}$$

and the minimum feature size (the resolution) is

$$l = \frac{k\sqrt{A}}{M} \cdot r^n \tag{15.4}$$

Eliminating n from Eqs. 15.3 and 15.4 and combining the result with Eq. 15.1, we have

$$P = \frac{k^D}{M^{D-1}} \cdot \frac{(\sqrt{A})^D}{l^{D-1}} \tag{15.5}$$

Equation 15.5 demonstrates the dependence of the periphery on parameters such as the area and the resolution of the fractal border. It can be seen from Eq. 15.5 that as l tend toward zero, the periphery goes to infinity; therefore, it is possible to generate fractal structures with very large perimeters in any given area. However, the total periphery of a fractal curve is limited by the attainable resolution in practical realizations.

Fractal Capacitor Structures

The final shape of a fractal can be tailored to almost any form. The flexibility arises from the fact that a wide variety of geometries can be used as the initiator and generator. It is also possible to use different generators during each step. This is an advantage for integrated circuits where flexibility in the shape of the layout is desired.

Figure 15.6 is a three-dimensional representation of a fractal capacitor. This capacitor uses only one metal layer with a fractal border. For a better visualization of the overall picture, the terminals of this square-shaped capacitor have been identified using two different shadings. As was discussed before, multiple cross-connected metal layers may be used to improve capacitance density further.

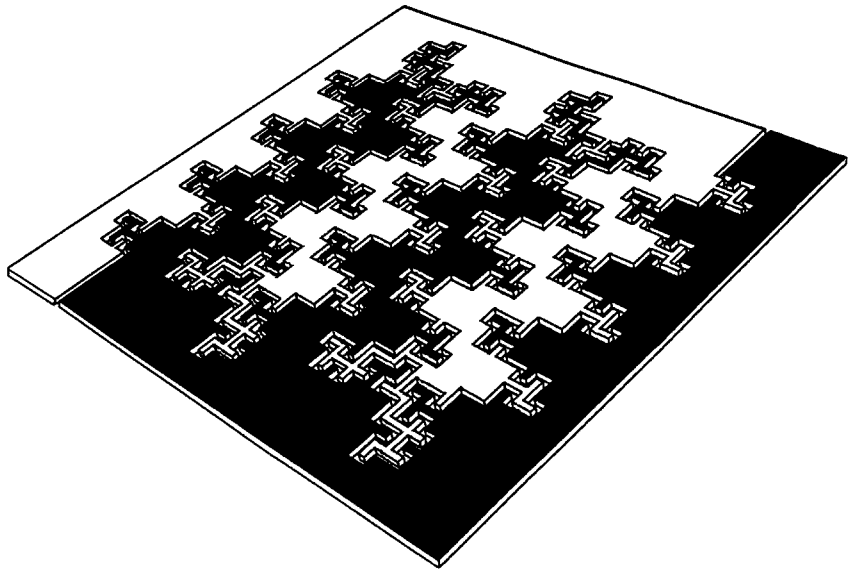

FIGURE 15.6 3-D representation of a fractal capacitor using a single metal layer.

One advantage of using lateral flux capacitors in general, and fractal capacitors in particular, is the reduction of the bottom-plate capacitance. This reduction is due to two reasons. First, the higher density of the fractal capacitor (compared to a standard parallel-plate structure) results in a smaller area. Second, some of the field lines originating from one of the bottom plates terminate on the adjacent plate, instead of the substrate, which further reduces the bottom-plate capacitance as shown in Fig. 15.7. Because of this property, some portion of the parasitic bottom-plate capacitor is converted into the more useful plate-to-plate capacitance.

The capacitance per unit area of a fractal structure depends on the dimension of the fractal. To improve the density of the layout, fractals with large dimensions should be used. The concept of fractal dimension is demonstrated in Fig. 15.8. The structure in Fig. 15.8(a) has a lower dimension compared to the one in Fig. 15.8(b), so the density (capacitance per unit area) of the latter is higher.

To demonstrate the dependence of capacitance density on dimension and lateral spacing of the metal layers, a first-order electromagnetic simulation was performed on two families of fractal

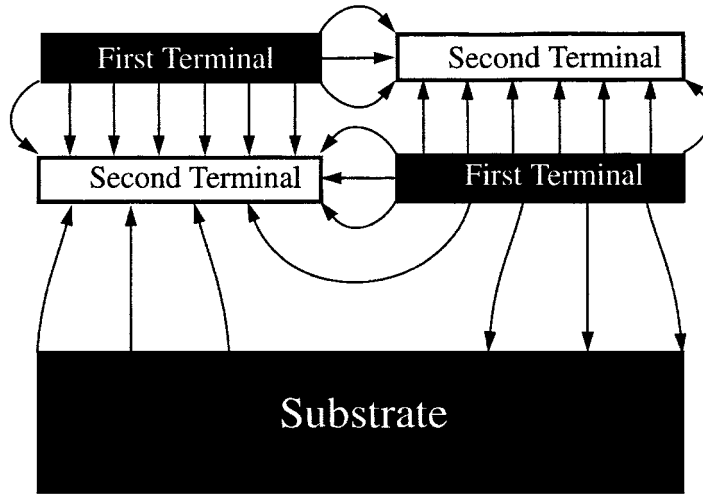

FIGURE 15.7 Reduction of the bottom-plate parasitic capacitance.

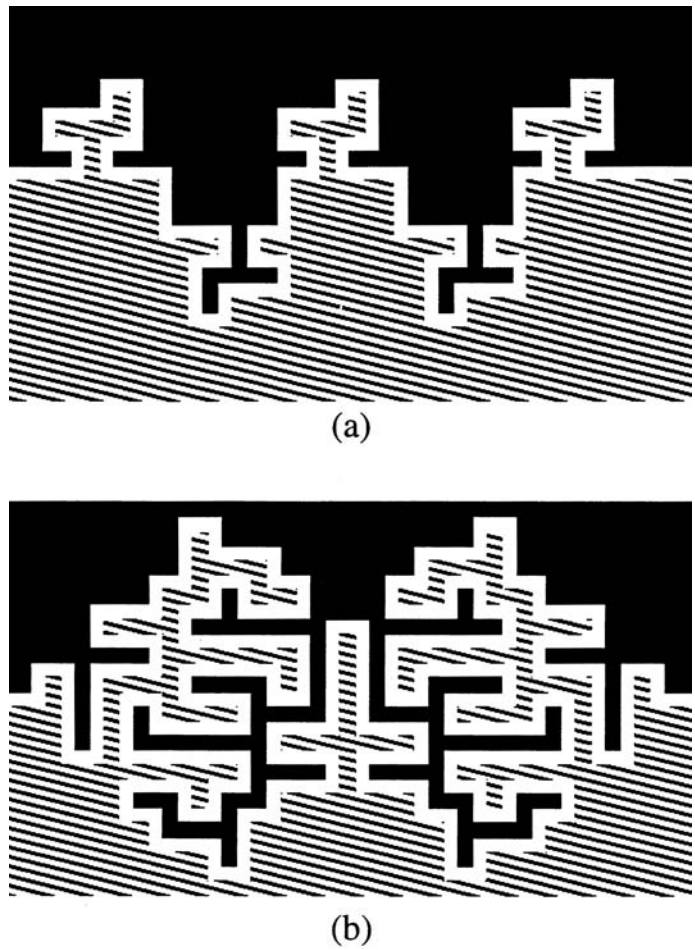

FIGURE 15.8 Fractal dimension of (a) is smaller than (b).

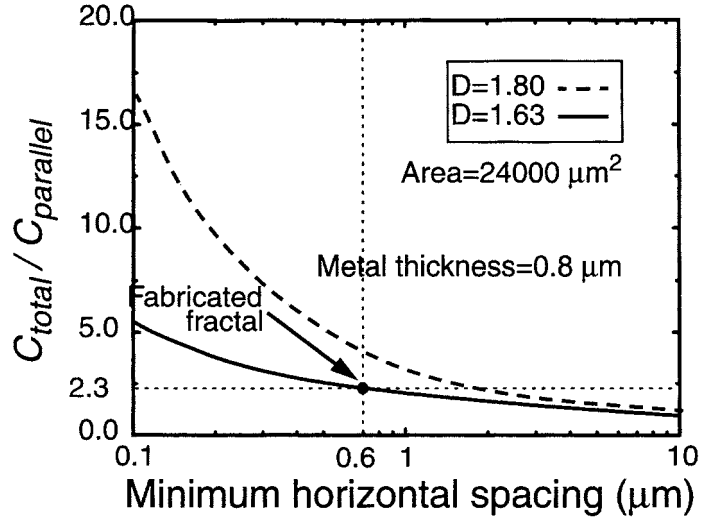

FIGURE 15.9 Boost factor vs. lateral spacing.

structures. In Fig. 15.9, the boost factor is plotted vs. horizontal spacing of the metal layers. The *boost factor* is defined as the ratio of the total capacitance of the fractal structure to the capacitance of a standard parallel-plate structure with the same area. The solid line corresponds to a family of fractals with a moderate fractal dimension of 1.63, while the dashed line represents another family of fractals with $D = 1.80$, which is a relatively large value for the dimension. In this first-order simulation, it is assumed that the vertical spacing and the thickness of the metal layers are kept constant at a 0.8-μm level. As can be seen in Fig. 15.9, the amount of boost is a strong function of the fractal dimension as well as scaling.

In addition to the capacitance density, the quality factor, *Q*, is important in RF applications. Here, the degradation in quality factor is minimal because the fractal structure automatically limits the length of the thin metal sections to a few microns, keeping the series resistance reasonably small. For applications that require low series resistance, lower dimension fractals may be used. Fractals thus add one more degree of freedom to the design of capacitors, allowing the capacitance density to be traded for a lower series resistance.

In current IC technologies, there is usually tighter control over the lateral spacing of metal layers compared to the vertical thickness of the oxide layers, from wafer to wafer and across the same wafer. Lateral flux capacitors shift the burden of matching away from oxide thickness to lithography. Therefore, by using lateral flux, matching characteristics can improve. Furthermore, the pseudo-random nature of the structure can also compensate, to some extent, the effects of non-uniformity of the etching process. To achieve accurate ratio matching, multiple copies of a unit cell should be used, as is standard practice in high-precision analog circuit design.

Another simple way of increasing capacitance density is to use an interdigitated capacitor depicted in Fig. 15.10.[2,7] One disadvantage of such a structure compared to fractals is its inherent parasitic inductance. Most of the fractal geometries randomize the direction of the current flow and thus reduce the effective series inductance; whereas for interdigitated capacitors, the current flow is in the same direction for all the parallel stubs. In addition, fractals usually have lots of rough edges that accumulate electrostatic energy more efficiently compared to interdigitated capacitors, causing a boost in capacitance (generally of the order of 15%). Furthermore, interdigitated structures are more vulnerable to non-uniformity of the etching process. However, the relative simplicity of the interdigitated capacitor does make it useful in some applications.

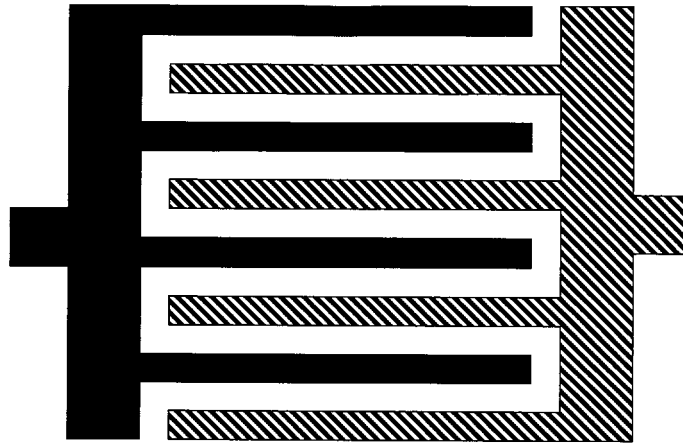

FIGURE 15.10 An interdigitated capacitor.

The woven structure shown in Fig. 15.11 may also be used to achieve high capacitance density. The vertical lines are in metal-2 and horizontal lines are in metal-1. The two terminals of the capacitor are identified using different shades. Compared to an interdigitated capacitor, a woven structure has much less inherent series inductance. The current flowing in different directions results in a higher self-resonant frequency. In addition, the series resistance contributed by vias is smaller than that of an interdigitated capacitor, because cross-connecting the metal layers can be done with greater ease. However, the capacitance density of a woven structure is smaller compared to an interdigitated capacitor with the same metal pitch, because the capacitance contributed by the vertical fields is smaller.

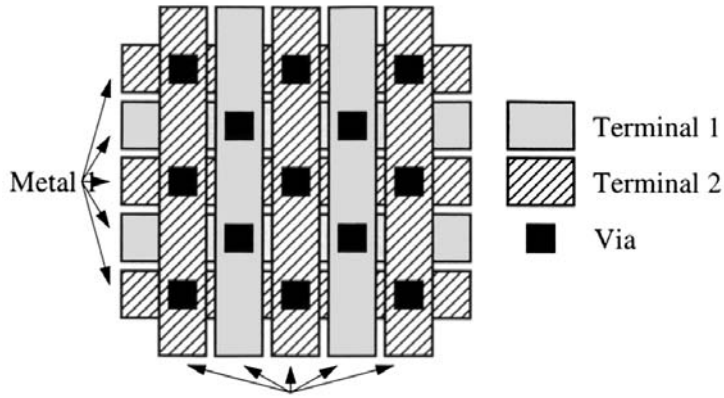

FIGURE 15.11 A woven structure.

15.3 Spiral Inductors

More than is so with capacitors, on-chip inductor options are particularly limited and unsatisfactory. Nevertheless, it is possible to build practical spiral inductors with values up to perhaps 20 nH and with Q values of approximately 10. For silicon-based RF ICs, Q degrades at high frequencies due to energy dissipation in the semiconducting substrate.[8] Additionally, noise coupling via the substrate at GHz frequencies has been reported.[9] As inductors occupy substantial chip area, they can potentially be the

source and receptor of detrimental noise coupling. Furthermore, the physical phenomena underlying the substrate effects are complicated to characterize. Therefore, decoupling the inductor from the substrate can enhance the overall performance by increasing Q, improving isolation, and simplifying modeling.

Some approaches have been proposed to address the substrate issues; however, they are accompanied by drawbacks. Some[10] have suggested the use of high-resistivity (150 to 200 Ω-cm) silicon substrates to mimic the low-loss semi-insulating GaAs substrate, but this is rarely a practical option. Another approach selectively removes the substrate by etching a pit under the inductor.[11] However, the etch adds extra processing cost and is not readily available. Moreover, it raises reliability concerns such as packaging yield and long-term mechanical stability. For low-cost integration of inductors, the solution to substrate problems should avoid increasing process complexity.

In this section, we present the *patterned ground shield* (PGS),[23] which is compatible with standard silicon technologies, and which reduces the unwanted substrate effects. The great improvement provided by the PGS reduces the disparity in quality between spiral inductors made in silicon and GaAs IC technologies.

Understanding Substrate Effects

To understand why the PGS should be effective, consider first the physical model of an ordinary inductor on silicon, with one port and the substrate grounded, as shown in Fig. 15.12.[8] An on-chip inductor is physically a three-port element including the substrate. The one-port connection shown in Fig. 15.12 avoids unnecessary complexity in the following discussion and at the same time preserves the inductor characteristics. In the model, the series branch consists of L_s, R_s, and C_s. L_s represents the spiral inductance, which can be computed using the Greenhouse method[12] or well-approximated by simple analytical formulas to be presented later. R_s is the metal series resistance whose behavior at RF is governed by the eddy current effect. This resistance accounts for the energy loss due to the skin effect in the spiral interconnect structure as well as the induced eddy current in any conductive media close to the inductor. The series feedforward capacitance, C_s, accounts for the capacitance due to the overlaps between the spiral and the center-tap underpass.[13] The effect of the inter-turn fringing capacitance is usually small because the adjacent turns are almost at equal potentials, and therefore it is neglected in this model. The overlap capacitance is more significant because of the relatively large potential difference between the spiral and the center-tap underpass. The parasitics in the shunt branch are modeled by C_{ox}, C_{Si}, and R_{Si}. C_{ox} represents the oxide capacitance between the spiral and the substrate. The silicon substrate capacitance and resistance are modeled by C_{Si} and R_{Si}, respectively.[14,15] The element R_{Si} accounts for the energy dissipation in the silicon substrate.

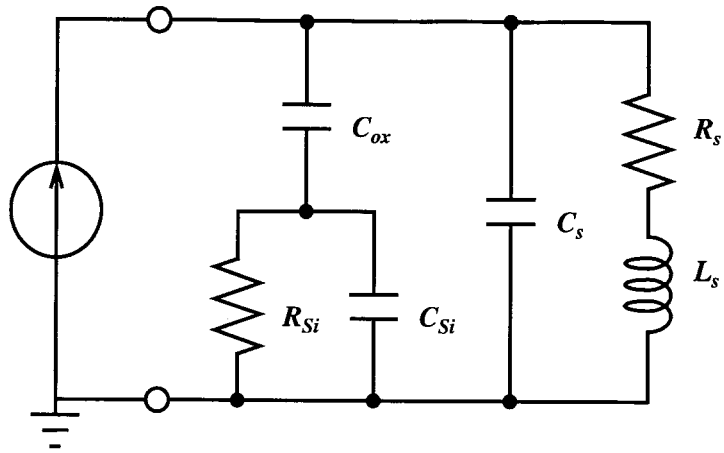

FIGURE 15.12 Lumped physical model of a spiral inductor on silicon.

Expressions for the model element values are as follows:

$$R_s = \frac{\rho l}{\delta w\left(1 - e^{-\frac{t}{\delta}}\right)} \tag{15.6}$$

$$C_s = nw^2 \cdot \frac{\varepsilon_{ox}}{t_{oxM1-M2}} \tag{15.7}$$

$$C_{ox} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot l \cdot w \tag{15.8}$$

$$C_{Si} = \frac{1}{2} \cdot l \cdot w \cdot C_{sub} \tag{15.9}$$

$$R_{Si} = \frac{2}{l \cdot w \cdot G_{sub}} \tag{15.10}$$

where ρ is the DC resistivity of the spiral; t is the overall length of the spiral windings; w is the line width; δ is the skin depth; n is the number of crossovers between the spiral and center-tap (and thus $n = N - 1$, where N is the number of turns); $t_{oxM1-M2}$ is the oxide thickness between the spiral and substrate; C_{sub} is the substrate capacitance per unit area; and G_{sub} is the substrate conductance per unit area. In general, one treats C_{sub} and G_{sub} as fitting parameters.

Exploration with the model reveals that the substrate loss stems primarily from the penetration of the electric field into the lossy silicon substrate. As the potential drop in the semiconductor (i.e., across R_{Si} in Fig. 15.12) increases with frequency, the energy dissipation in the substrate becomes more severe. It can be seen that increasing R_p to infinity reduces the substrate loss. It can be shown that R_p approaches infinity as R_{Si} goes either to zero or infinity. This observation implies that Q can be improved by making the silicon substrate *either* a perfect insulator or a perfect conductor. Using high-resistivity silicon (or etching it away) is equivalent to making the substrate an open circuit. In the absence of the freedom to do so, the next best option is to convert the substrate into a better conductor. The approach is to insert a ground plane to block the inductor electric field from entering the silicon. In effect, this ground plane becomes a pseudo-substrate with the desired characteristics.

The ground shield cannot be a solid conductor, however, because image currents would be induced in it. These image currents tend to cancel the magnetic field of the inductor proper, decreasing the inductance. To solve this problem, the ground shield is patterned with slots orthogonal to the spiral as illustrated in Fig. 15.13. The slots act as an open circuit to cut off the path of the induced loop current. The slots should be sufficiently narrow such that the vertical electric field cannot leak through the patterned ground shield into the underlying silicon substrate. With the slots etched away, the ground strips serve as the termination for the electric field. The ground strips are merged together around the four outer edges of the spiral. The separation between the merged area and the edges is not critical. However, it is crucial that the merged area not form a closed ring around the spiral since it can potentially support unwanted loop current. The shield should be strapped with the top layer metal to provide a low-impedance path to ground. The general rule is to prevent negative mutual coupling while minimizing the impedance to ground.

The shield resistance is another critical design parameter. The purpose of the patterned ground shield is to provide a good short to ground for the electric field. Since the finite shield resistance contributes to energy loss of the inductor, it must be kept small. Specifically, by keeping the shield resistance small compared to the reactance of the oxide capacitance, the voltage drop that can develop across the shield resistance is very small. As a result, the energy loss due to the shield resistance is insignificant compared to other losses. A typical on-chip spiral inductor has parasitic oxide capacitance between 0.25 and 1 pF,

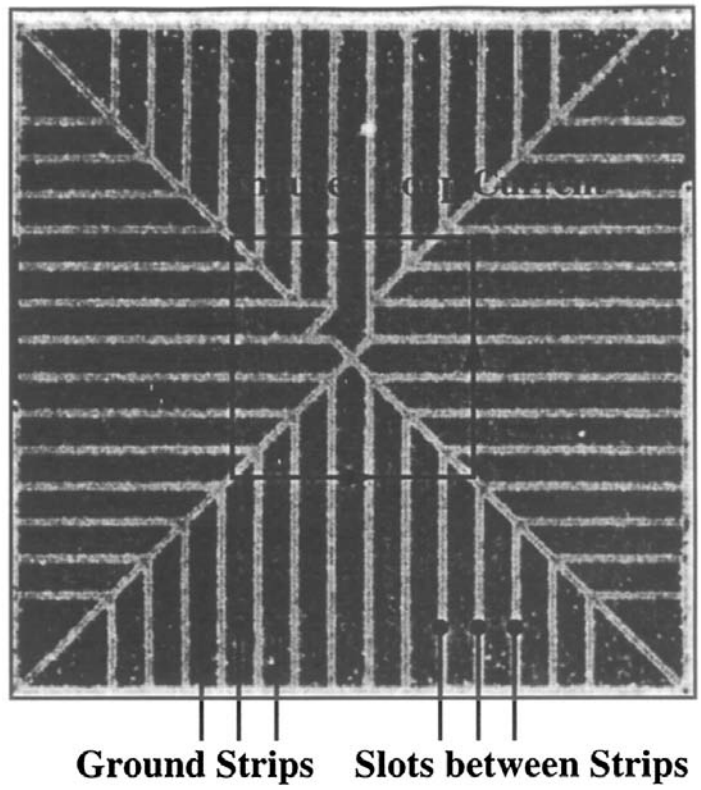

FIGURE 15.13 A close-up photo of the patterned ground shield.

depending on the size and the oxide thickness. The corresponding reactance due to the oxide capacitance at 1 to 2 GHz is of the order of 100 Ω, and hence a shield resistance of a few ohms is sufficiently small not to cause any noticeable loss.

With the PGS, one can expect typical improvements in Q ranging from 10 to 33%, in the frequency range of 1 to 2 GHz. Note that the inclusion of the ground shields increases C_p, which causes a fast roll-off in Q above the peak-Q frequency and a reduction in the self-resonant frequency. This modest improvement in inductor Q is certainly welcome, but is hardly spectacular by itself. However, a more dramatic improvement is evident when evaluating inductor-capacitor resonant circuits. Such LC tank circuits can absorb the parasitic capacitance of the ground shield. Since the energy stored in such parasitic elements is now part of the circuit, the overall circuit Q is greatly increased. Improvements of factors of approximately two are not unusual, so that tank circuits realized with PGS inductors possess roughly the same Q as those built in GaAs technologies.

As stated earlier, substrate noise coupling can be an issue of great concern owing to the relatively large size of typical inductors. Shielding by the PGS improves isolation by 25 dB or more at GHz frequencies. It should be noted that, as with any other isolation structure (such as a guard ring), the efficacy of the PGS is highly dependent on the integrity of the ground connection. One must often make a tradeoff between the desired isolation level and the chip area that is required to provide a low-impedance ground connection.

Simple, Accurate Expressions for Planar Spiral Inductances

In the previous section, a physically based model for planar spiral inductors was offered, and reference was made to the Greenhouse method as a means for computing the inductance value. This method uses

as computational atoms the self- and mutual inductances of parallel current strips. It is relatively straightforward to apply, and yields accurate results. Nevertheless, simpler analytic formulas are generally preferred for design since important insights are usually more readily obtained.

As a specific example, square spirals are popular mainly because of their ease of layout. Other polygonal spirals have also been used to improve performance by more closely approximating a circular spiral. However, a quantitative evaluation of possible improvements is cumbersome without analytical formulas for inductance.

Among alternative shapes, hexagonal and octagonal inductors are used widely. Figures 15.14 through 15.16 and show the layout for square, hexagonal, and octagonal inductors, respectively. For a given shape, an inductor is completely specified by the number of turns n, the turn width w, the turn spacing s, and any one of the following: the outer diameter d_{out}, the inner diameter d_{in}, the average diameter $d_{avg} = 0.5(d_{out} + d_{in})$, or the fill ratio, defined as $\rho = (d_{out} - d_{in})/(d_{out} + d_{in})$. The thickness of the inductor has only a very small effect on inductance and will therefore be ignored here.

We now present three approximate expressions for the inductance of square, hexagonal, and octagonal planar inductors. The first approximation is based on a modification of an expression developed by Wheeler[16]; the second is derived from electromagnetic principles by approximating the sides of the spirals as current sheets; and the third is a monomial expression derived from fitting to a large database of inductors (whose exact inductance values are obtained from a 3-D electromagnetic field solver). All three expressions are accurate, with typical errors of 2 to 3%, and very simple, and are therefore excellent candidates for use in design and optimization.

Modified Wheeler Formula

Wheeler[16] presented several formulas for planar spiral inductors, which were intended for discrete inductors. A simple modification of the original Wheeler formula allows us to obtain an expression that is valid for planar spiral integrated inductors:

$$L_{mw} = K_1 \mu_0 \frac{n^2 d_{avg}}{1 + K_2 \rho} \tag{15.11}$$

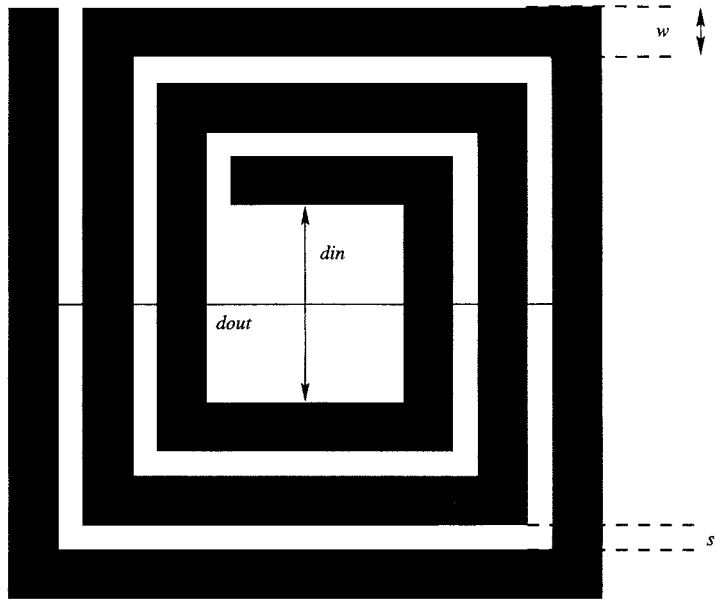

FIGURE 15.14 Square inductor.

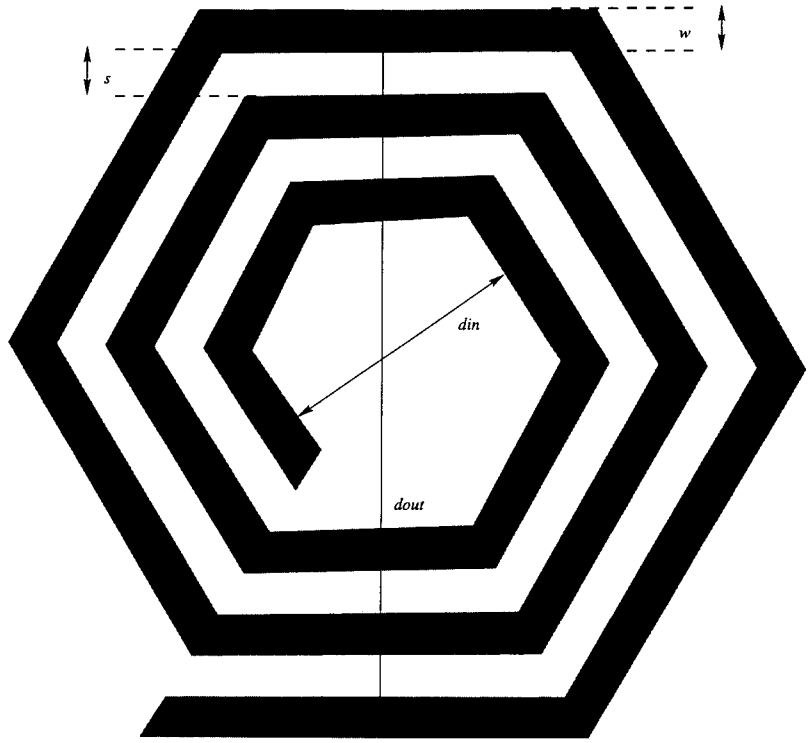

FIGURE 15.15 Hexagonal inductor.

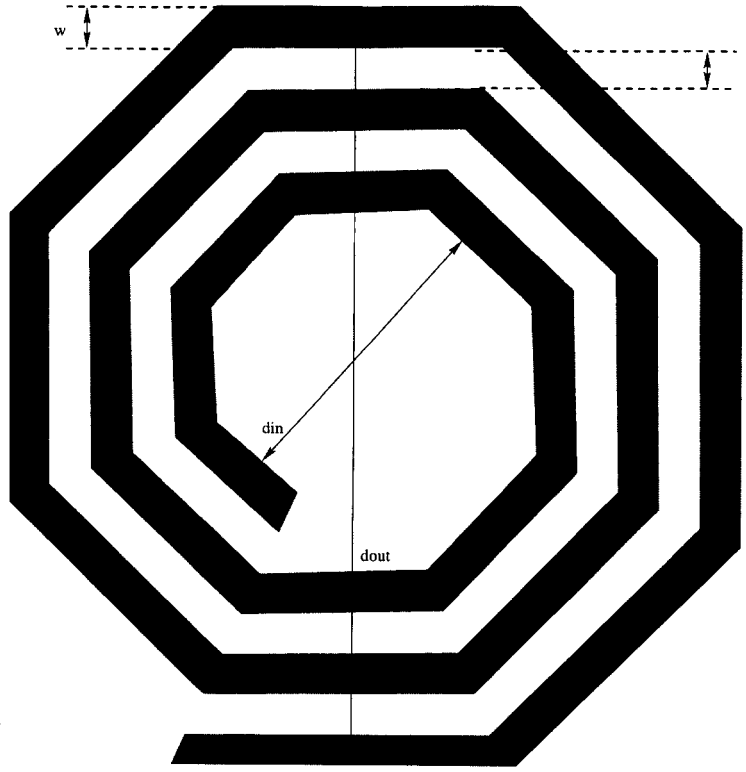

FIGURE 15.16 Octagonal inductor.

where ρ is the fill ratio defined previously. The coefficients K_1 and K_2 are layout dependent and are shown in Table 15.1

TABLE 15.1 Coefficients for Modified Wheeler Formula

Layout	K_1	K_2
Square	2.34	2.75
Hexagonal	2.33	3.82
Octagonal	2.25	3.55

The fill factor ρ represents how hollow the inductor is: for small ρ, we have a hollow inductor ($d_{out} \cong d_{in}$), and for a large ρ we have a filled inductor ($d_{out} >> d_{in}$). Two inductors with the same average diameter but different fill ratios will, of course, have different inductance values; the filled one has a smaller inductance because its inner turns are closer to the center of the spiral, and so contribute less positive mutual inductance and more negative mutual inductance. Some degree of hollowness is generally desired since the innermost turns contribute little overall inductance, but significant resistance.

Expression Based on Current Sheet Approximation

Another simple and accurate expression for the inductance of a planar spiral can be obtained by approximating the sides of the spirals by symmetrical current sheets of equivalent current densities.[17] For example, in the case of the square, we obtain four identical current sheets: the current sheets on opposite sides are parallel to one another, whereas the adjacent ones are orthogonal. Using symmetry and the fact that sheets with orthogonal current sheets have zero mutual inductance, the computation of the inductance is now reduced to evaluating the self-inductance of one sheet and the mutual inductance between opposite current sheets. These self- and mutual inductances are evaluated using the concepts of geometric mean distance (GMD) and arithmetic mean distance (AMD).[17,18] The resulting expression is:

$$L_{gmd} = \frac{\mu n^2 d_{avg}}{\pi}(c_1(\log c_2/\rho) + c_3\rho) \tag{15.12}$$

where the coefficients c_i are layout dependent and are shown in Table 15.2

TABLE 15.2 Coefficients for Current-Sheet Inductance Formula

Layout	c_1	c_2	c_3
Square	2.00	2.00	0.54
Hexagonal	1.83	1.71	0.45
Octagonal	1.87	1.68	0.60

A detailed derivation of these formulas can be found in Ref. 19. Since this formula is based on a current sheet approximation, its accuracy worsens as the ratio *s/w* becomes large. In practice, this is not a problem since practical integrated spiral inductors are built with $s < w$. The reason is that a smaller spacing improves the inter-winding magnetic coupling and reduces the area consumed by the spiral. A large spacing is only desired to reduce the inter-winding capacitance. This is rarely a concern as this capacitance is always dwarfed by the under-pass capacitance.[8]

Data-Fitted Monomial Expression

Our final expression is based on a data-fitting technique, in which a population of thousands of inductors are simulated with an electromagnetic field solver. The inductors span the entire range of values of relevance to RF circuits. A monomial expression is then fitted to the data, which ultimately yields:

$$L_{mon} = \beta d_{avg}^{\alpha 1} w^{\alpha 2} d_{avg}^{\alpha 3} n^{\alpha 4} s^{\alpha 5} \tag{15.13}$$

where the coefficients β and α_i are layout dependent, and given in Table 15.3.

TABLE 15.3 Coefficients for Monomial Inductance Formula

Layout	b	α_1	α_2	α_3	α_4	α_5
Square	1.66×10^{-3}	-1.33	-0.13	2.50	1.83	-0.022
Hexagonal	1.33×10^{-3}	-1.46	-0.16	2.67	1.80	-0.030
Octagonal	1.34×10^{-3}	-1.35	-0.15	2.56	1.77	-0.032

Of course, it is also possible to use other data-fitting techniques; for example, one which minimizes the maximum error of the fit, or one in which the coefficients must satisfy given inequalities or bounds. The monomial expression is useful since, like the other expressions, it is very accurate and very simple. Its real value, however, is that it can be used for the optimal design of inductors and circuits containing inductors, using geometric programming, which is a type of optimization method that requires monomial models.[20,21]

Figure 15.17 shows the absolute error distributions of these expressions. The plots show that typical errors are in the 1 to 2% range, and most of the errors are below 3%. These expressions for inductance, while quite simple, are thus sufficiently accurate that field solvers are rarely necessary.

These expressions can be included in a physical, scalable lumped-circuit model for spiral inductors where, in addition to providing design insight, they allow efficient optimization schemes to be employed.

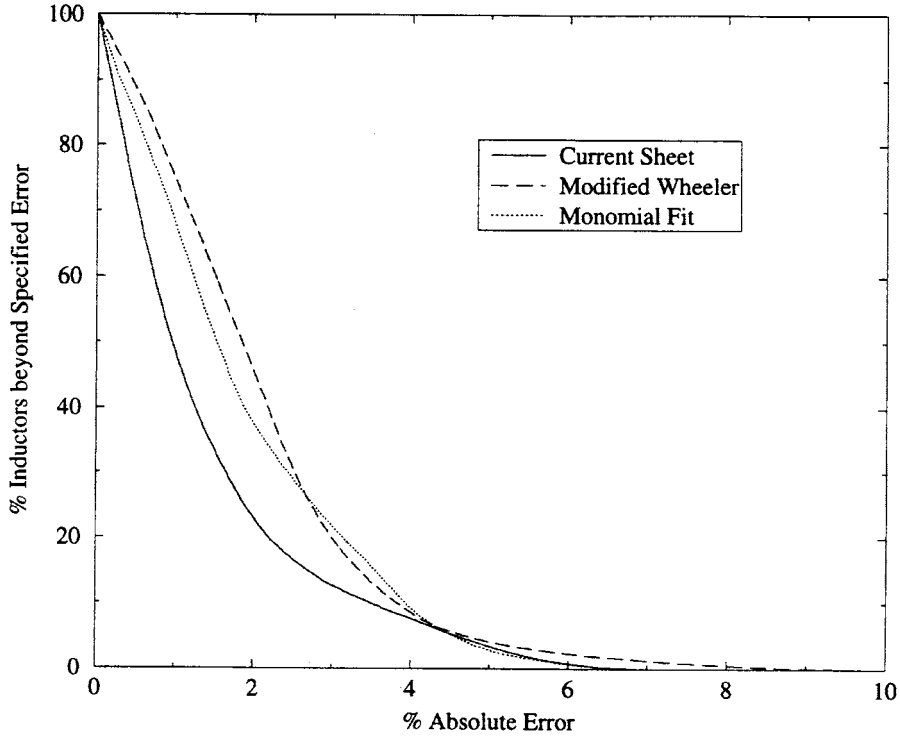

FIGURE 15.17 Error distribution for three formulas, compared to field solver simulations.

15.4 On-Chip Transformers

Transformers are important elements in RF circuits for impedance conversion, impedance matching, and bandwidth enhancement. Here, we present an analytical model for monolithic transformers that is suitable for circuit simulation and design optimization. We also provide simple expressions for calculating the mutual coupling coefficient (k).

We first discuss different on-chip transformers and their advantages and disadvantages. We then present an analytical model along with expressions for the elements in it and the mutual coupling coefficient.

Monolithic Transformer Realizations

Figures 15.18 through 15.23 illustrate common configurations of monolithic transformers. The different realizations offer varying tradeoffs among the self-inductance and series resistance of each port, the mutual coupling coefficient, the port-to-port and port-to-substrate capacitances, resonant frequencies, symmetry, and area. The models and coupling expressions allow these trade-offs to be systematically explored, thereby permitting transformers to be customized for a variety of circuit design requirements.

The characteristics desired of a transformer are application dependent. Transformers can be configured as three or four-terminal devices. They may be used for narrowband or broadband applications. For example, in single-sided to differential conversion, the transformer might be used as a four-terminal narrowband device. In this case, a high mutual coupling coefficient and high self-inductance are desired, along with low series resistance. On the other hand, for bandwidth extension applications, the transformer is used as a broadband three-terminal device. In this case, a small mutual coupling coefficient and high series resistance are acceptable, while all capacitances need to be minimized.[22]

The tapped transformer (Fig. 15.18) is best suited for three-port applications. It permits a variety of tapping ratios to be realized. This transformer relies only on lateral magnetic coupling. All windings can

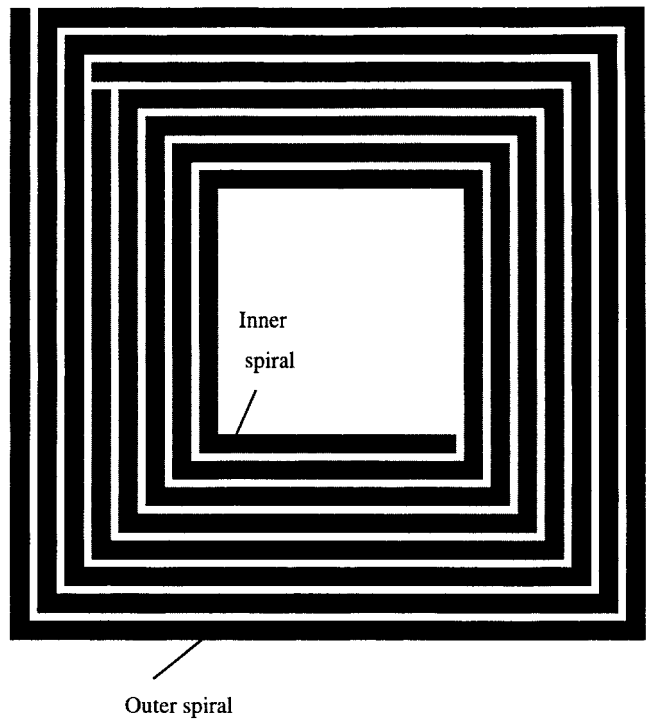

FIGURE 15.18 Tapped transformer.

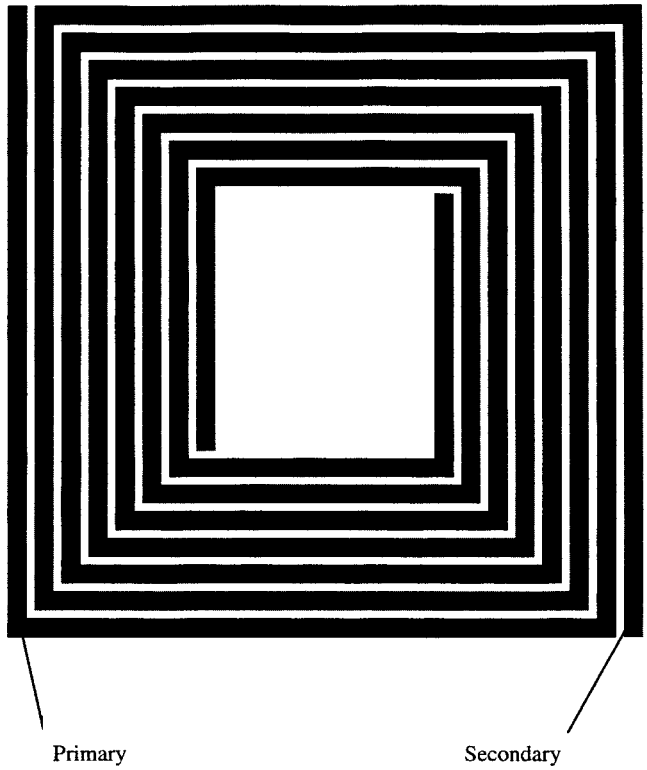

FIGURE 15.19 Interleaved transformer.

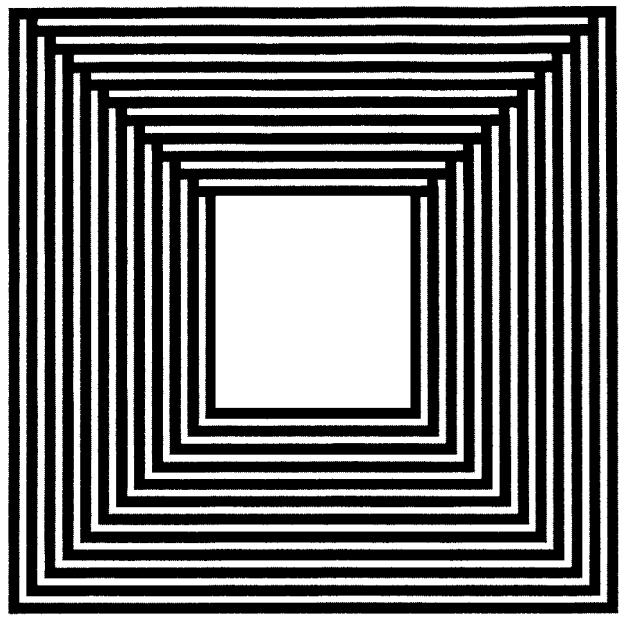

FIGURE 15.20 Stacked transformer with top spiral overlapping the bottom one.

be implemented with the top metal layer, thereby minimizing port-to-substrate capacitances. Since the two inductors occupy separate regions, the self-inductance is maximized while the port-to-port capacitance is minimized. Unfortunately, this spatial separation also leads to low mutual coupling ($k = 0.3$–0.5).

The interleaved transformer (Fig. 15.19) is best suited for four-port applications that demand symmetry. Once again, capacitances can be minimized by implementing the spirals with top level metal so that high resonant frequencies may be realized. The interleaving of the two inductances permit moderate coupling ($k = 0.7$) to be achieved at the cost of reduced self-inductance. This coupling may be increased at the cost of higher series resistance by reducing the turn width (w) and spacing (s).

The stacked transformer (Fig. 15.20) uses multiple metal layers and exploits both vertical and lateral magnetic coupling to provide the best area efficiency, the highest self-inductance, and highest coupling ($k = 0.9$). This configuration is suitable for both three- and four-terminal configurations. The main drawback is the high port-to-port capacitance, or equivalently a low self-resonant frequency. In some cases, such as narrowband impedance transformers, this capacitance may be incorporated as part of the resonant circuit. Also, in multi-level processes, the capacitance can be reduced by increasing the oxide thickness between spirals. For example, in a five-metal process, 50 to 70% reductions in port-to-port capacitance can be achieved by implementing the spirals on layers five and three instead of five and four. The increased vertical separation will reduce k by less than 5%. One can also trade off reduced coupling for reduced capacitance by displacing the centers of the stacked inductors (Figs. 15.21 and 15.22)

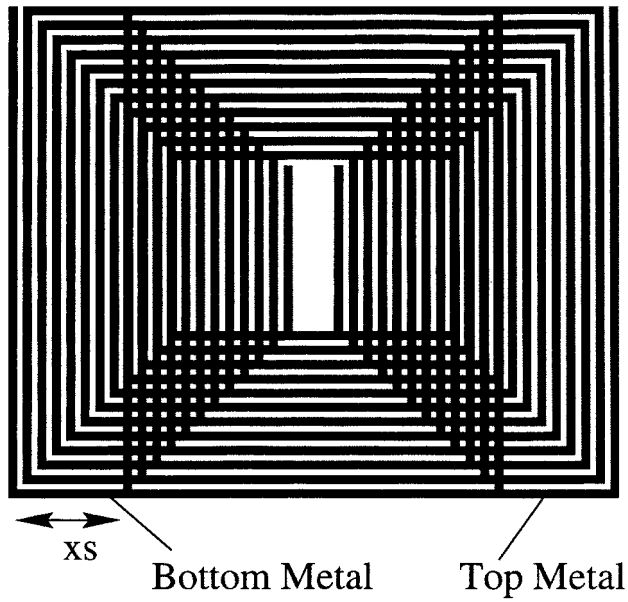

FIGURE 15.21 Stacked transformer with top and bottom spirals laterally shifted.

Analytical Transformer Models

Figures 15.23 and 15.24 present the circuit models for tapped and stacked transformers, respectively. The corresponding element values for the tapped transformer model are given by the following equations (subscript o refers to the outer spiral, i to the inner spiral, and T to the whole spiral):

$$L_T = \frac{9.375\mu_0 n_T^2 A D_T^2}{11 OD_T - 7 A D_T} \tag{15.14}$$

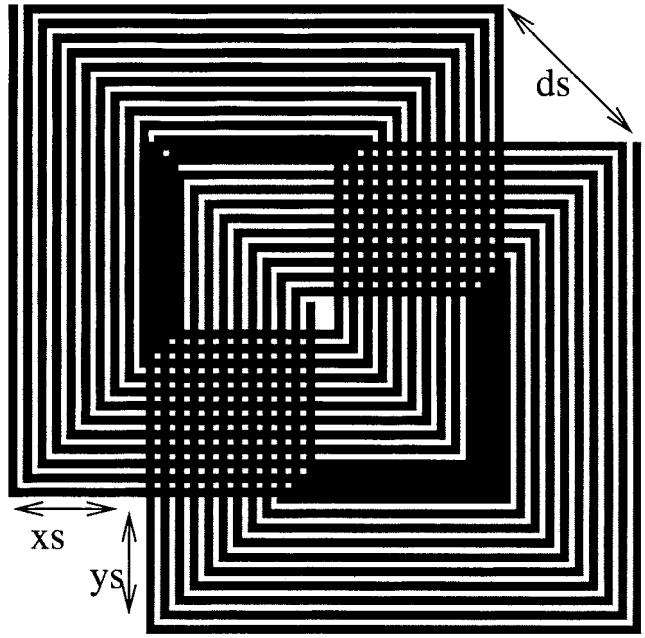

FIGURE 15.22 Stacked transformer with top and bottom spirals diagonally shifted.

$$L_o = \frac{9.375\mu_0 n_o^2 AD_o^2}{11OD_o - 7AD_o} \tag{15.15}$$

$$L_i = \frac{9.375\mu_0 n_i^2 AD_i^2}{11OD_i - 7AD_i} \tag{15.16}$$

$$M = \frac{L_T - L_o - L_i}{2\sqrt{L_o L_i}} \tag{15.17}$$

$$R_{so} = \frac{\rho l_o}{\delta w\left(1 - e^{-\frac{t}{\delta}}\right)} \tag{15.18}$$

$$R_{si} = \frac{\rho l_i}{\delta w\left(1 - e^{-\frac{t}{\delta}}\right)} \tag{15.19}$$

$$C_{ovo} = \frac{\varepsilon_{ox}}{t_{ox,\,t-b}} \cdot (n_o - 1)w^2 \tag{15.20}$$

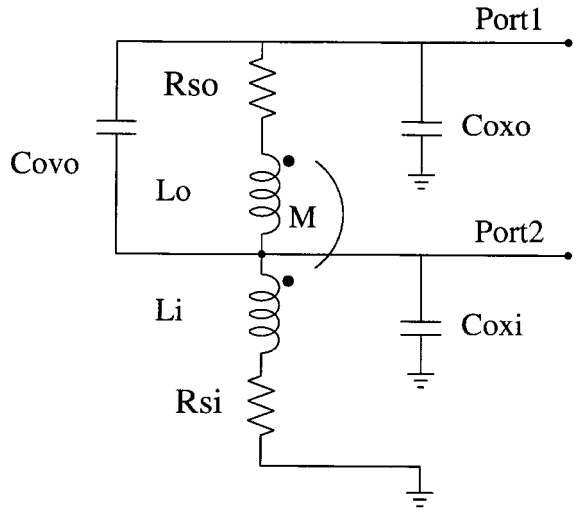

FIGURE 15.23 Tapped transformer model.

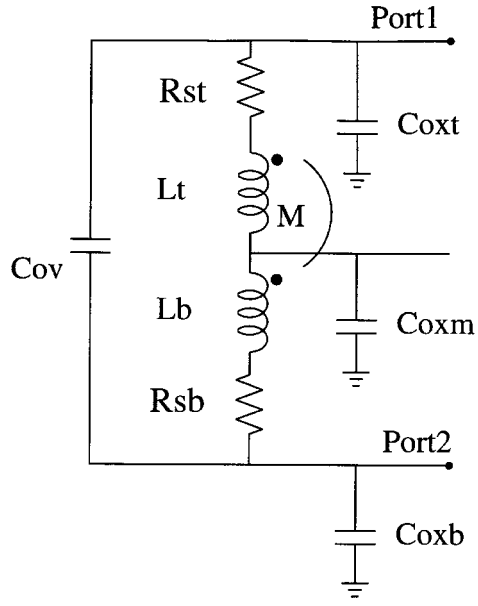

FIGURE 15.24 Stacked transformer model.

$$C_{oxo} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot l_o w \tag{15.21}$$

$$C_{oxi} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot (l_o + l_i) w \tag{15.22}$$

where ρ is the DC metal resistivity; δ is the skin depth; $t_{ox,t-b}$ is the oxide thickness from top level metal to bottom metal; n is the number of turns; *OD*, *AD*, and *ID* are the outer, average, and inner

diameters, respectively; l is the length of the spiral; w is the turn width; t is the metal thickness; and A is the area.

Expressions for the stacked transformer model are as follows (subscript t refers to the top spiral and b to the bottom spiral):

$$L_t = \frac{9.375\mu_0 n^2 AD^2}{11OD_T - 7AD_T} \tag{15.23}$$

$$L_b = L_t \tag{15.24}$$

$$k = 0.9 - \frac{d_s}{AD} \tag{15.25}$$

$$M = k\sqrt{L_t L_b} \tag{15.26}$$

$$R_{st} = \frac{\rho_t l}{\delta_t w\left(1 - e^{-\frac{t_t}{\delta_t}}\right)} \tag{15.27}$$

$$R_{sb} = \frac{\rho_b l}{\delta_b w\left(1 - e^{-\frac{t_b}{\delta_b}}\right)} \tag{15.28}$$

$$C_{ov} = \frac{\varepsilon_{ox}}{2t_{ox,\,t-b}} \cdot l \cdot w \cdot \frac{A_{ov}}{A} \tag{15.29}$$

$$C_{oxt} = \frac{\varepsilon_{ox}}{2t_{oxt}} \cdot l \cdot w \cdot \frac{A - A_{ov}}{A} \tag{15.30}$$

$$C_{oxb} = \frac{\varepsilon_{ox}}{2t_{ox}} \cdot l \cdot w \tag{15.31}$$

$$C_{oxm} = C_{oxt} + C_{oxb} \tag{15.32}$$

where t_{oxt} is the oxide thickness from top metal to the substrate; t_{oxb} is the oxide thickness from bottom metal to substrate; k is the coupling coefficient; A_{ov} is the overlap area of the two spirals; and d_s is the center-to-center spiral distance.

The expressions for the series resistances (R_{so}, R_{si}, R_{st}, and R_{sb}), the port-substrate capacitances (C_{oxo}, C_{oxi}, C_{oxt}, C_{oxb}, and C_{oxm}) and the crossover capacitances (C_{ovo}, C_{ovi}, and C_{ov}) are taken from Ref. 8. Note that the model accounts for the increase in series resistance with frequency due to skin effect. Patterned ground shields (PGS) are placed beneath the transformers to isolate them from resistive and capacitive coupling to the substrate.[23] As a result, the substrate parasitics can be neglected.

The inductance expressions in the foregoing are based on the modified Wheeler formula discussed earlier.[24] This formula does not take into account the variation in inductance due to conductor thickness and frequency. However, in practical inductor and transformer realizations, the thickness is small compared to the lateral dimensions of the coil and has only a small impact on the inductance. For typical conductor thickness variations (0.5 to 2.0 μm), the change in inductance is within a few percent for practical inductor geometries. The inductance also changes with frequency due to changes in current distribution within the conductor. However, over the useful frequency range of a spiral, this variation is negligible.[23] When compared to field solver simulations, the inductance expression exhibits a maximum error of 8% over a broad design space (outer diameter OD varying from 100 to 480 μm, L varying from 0.5 to 100 nH, w varying from 2 μm to $0.3OD$, s varying from 2 μm to w, and inner diameter ID varying from 0.2 to $0.8OD$).

For the tapped transformer, the mutual inductance is determined by first calculating the inductance of the whole spiral (L_T), the inductance of the outer spiral (L_o), the inductance of the inner spiral (L_i), and then using the expression $M = (L_T - L_o - L_i)/2$. For the stacked transformer, the spirals have identical lateral geometries and therefore identical inductances. In this case, the mutual inductance is determined by first calculating the inductance of one spiral (L_T), the coupling coefficient (k) and then using the expression $M = kL_T$. In this last case the coupling coefficient is given by $k = 0.9 - d_s/(AD)$ for $d_s < 0.7AD$, where d_s is the center-to-center spiral distance and AD is the average diameter of the spirals. As d_s increases beyond $0.7AD$, the mutual coupling coefficient becomes harder to model. Eventually, k crosses zero and reaches a minimum value of approximately –0.1 at $d_s = AD$. As d_s increases further, k asymptotically approaches zero. At $d_s = 2AD$, $k = -0.02$, indicating that the magnetic coupling between closely spaced spirals is negligible.

The self-inductances, series resistances, and mutual inductances are independent of whether a transformer is used as a three- or four-terminal device. The only elements that require recomputation are the port-to-port and port-to-substrate capacitances. This situation is analogous to that of a spiral inductor being used as a single- or dual-terminal device.

As with the inductance formulas, the transformer models obviate the need for full field solutions in all but very rare instances, allowing rapid design and optimization.

Analog Circuit Simulation

J. Gregory Rollins
Antrim Design Systems

16.1 Introduction

Analog circuit simulation usually means simulation analog circuits or very detailed simulation of digital circuits. The most widely known and used circuit simulation program is SPICE (simulation program with integrated circuit emphasis) of which it is estimated that there are over 100,000 copies in use. SPICE was first written at the University of California at Berkeley in 1975, and was based on the combined work of many reasearchers over a number of years. Research in the area of circuit simulation continues at many universities and industrial sites. Commercial versions of SPICE or related programs are available on a wide variety of computing platforms, from small personal computers to large mainframes. A list of some commercial simulator vendors can be found in the Appendix. The focus of this chapter is the simulators and the theory behind them. Examples are also given to illustrate their use.

16.2 Purpose of Simulation

Computer-aided simulation is a powerful aid during the design or analysis of VLSI circuits. Here, the main emphasis will be on analog circuits; however, the same simulation techniques may be applied to digital circuits, which are, after are, composed of analog circuits. The main limitation will be the size of these circuits because the techniques presented here provide a very detailed analysis of the circuit in question and, therefore, would be too costly in terms of computer resources to analyze a large digital system. However, some of the techniques used to analyze digital systems (like iterated timing analysis or relaxation methods) are closely related to the methods used in SPICE.

It is possible to simulate almost any type of circuit SPICE. The programs have built-in elements for resistors, capacitors, inductors, dependent and independent voltage and current sources, diodes, MOSFETs, JFETs, BJTs, transmission lines, and transformers. Commercial versions have libraries of standard

components which have all necessary parameters prefitted to typical specifications. These libraries include items such as discrete transistors, op-amps, phase-locked loops, voltage regulators, logic integrated circuits, and saturating transformer cores. Versions are also available which allow the inclusion of digital models (mixed mode simulation) or behavioral models which allow the easy modeling of mathematical equations and relations.

Computer-aided circuit simulation is now considered an essential step in the design of modern integrated circuits. Without simulation, the number of "trial runs" necessary to produce a working IC would greatly increase the cost of the IC and the critical time to market. Simulation provides other advantages, including:

- The ability to measure "inaccessible" voltages and currents which are buried inside a tiny chip or inside a single transistor.
- No loading problems are associated with placing a voltmeter or oscilloscope in the middle of the circuit, measuring difficult one-shot waveforms or probing a microscopic die.
- Mathematically ideal elements are available. Creating an ideal voltage or current source is trivial with a simulator, but impossible in the laboratory. In addition, all component values are exact and no parasitic elements exist.
- It is easy to change the values of components or the configuration of the circuit.

Unfortunately, computer-aided simulation has it own set of problems, including:

- Real circuits are distributed systems, not the "lumped element models" which are assumed by simulators. Real circuits, therefore, have resistive, capacitive, and inductive parasitic elements present in addition to the intended components. In high-speed circuits, these parasitic elements can be the dominant performance-limiting elements in the circuit, and they must be painstakingly modeled.
- Suitable predefined numerical models have not yet been developed for certain types of devices or electrical phenomena. The software user may be required, therefore, to create his or her own models out of other models which are available in the simulator. (An example is the solid-state thyristor, which may be created from an npn and pnp bipolar transistor).
- The numerical methods used may place constraints on the form of the model equations used. In addition, convergence difficulties can arise, making the simulators difficult to use.
- There are small errors associated with the solution of the equations and other errors in fitting the non-linear models to the trsnsistors which make up the circuit.

16.3 Netlists

Before simulating, a circuit must be coded into a netlist. Figure 16.1 shows the circuit for a simple differential pair. Circuit nodes are formed wherever two or more elements meet. This particular circuit has seven nodes, which are numbered zero to six. The ground or datum node is traditionally numbered as zero. The circuit elements (or branches) connect the nodes.

The netlist provides a description of the topography of a circuit and is simply a list of the branches (or elements) that make up the circuit. Typically, the elements may be entered in any order and each has a unique name, a list of nodes, and either a value or model identifier. For the differential amplifier of Fig. 16.1, the netlist is shown in Fig. 16.2.

The first line gives the title of the circuit (and is required in many simulators). The next three lines define the three voltage sources. The letter V at the beginning tells SPICE that this is a voltage source element. The list of nodes (two in this case) is next followed by the value in volts. The syntax for the resistor is similar to that of the voltage source; the starting letter R in the names of the resistors tells SPICE that these are resistors. SPICE also understands that the abbreviation "k" after a value means 1000. For the two transistors Q1 and Q2, the starting letter Q indicates a bipolar transistor. Q1 and Q2 each

FIGURE 16.2 Netlist for differential pair.

have three nodes and in SPICE, the convention for their ordering is collector, base, emitter. So, for Q1, the collector is connected to node 3, the base to node 4, and the emitter to node 2. The final entry "m2n2222" is a reference to the model for the bipolar transistor (note that both Q1 and Q2 reference the same model). The ".model" statement at the end of the listing defines this model. The model type is npn (for an npn bipolar junction transistor), and a list of "parameter = value" entries follow. These entries define the numerical values of constants in the mathematical models which are used for the bipolar transistor. (Models will be discused in more detail later on.) Most commercial circuit simulation packages come with "schematic capture" software that allows the user to draw the circuit by placing and connecting the elements with the mouse

16.4 Formulation of the Circuit Equations

In SPICE, the circuits are represented by a system of ordinary differential equations. These equations are then solved using several different numerical techniques. The equations are constructed using Kirchoff's voltage and current laws. The first system of equations pertains to the currents flowing into each node. One equation is written for each node in the circuit (except for the ground node), so the following equation is really a system of N equations for the N nodes in the circuit. The subscript *i* denotes the node index.

$$0 = F_i(V) = G_i(V) + \frac{\partial Q_i(V)}{\partial t} + W_i(t) \tag{16.1}$$

V is an N-dimensional vector that represents the voltages at the nodes. Q is another vector which represents the electrical charge (in Coulombs) at each node. The term W represents any independent current sources that may be attached to the nodes and has units of amperes. The function $G(V)$ represents the currents that flow into the nodes as a result of the voltages V. If the equations are formulated properly, a system of N equations in N unknowns results.

For example, for the circuit of Fig. 16.3 which has two nodes, we need to write two equations. At Node 1:

$$0 = (V_1 - V_2)/R_1 + \frac{d(C_1 V_1)}{dt} + I_1 \tag{16.2}$$

We can identify $G(V)$ as $(V_1 - V_2)/R$, the term $Q(V)$ is $C_1 V_1$ and $W(t)$ is simply I_1. Likewise at Node 2:

$$0 = (V_2 - V_1)/R_1 + V_2/R_2 + gmV_1 \tag{16.3}$$

In this example, G and Q are simple linear terms; however, in general, they can be non-linear functions of the voltage vector V.

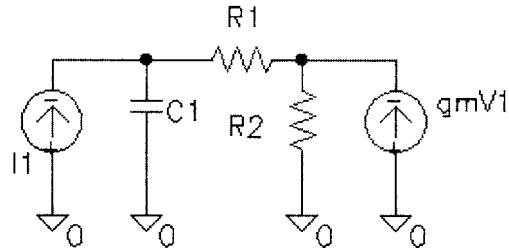

FIGURE 16.3 Example circuit for nodal analysis.

16.5 Modified Nodal Analysis

Normal nodal analysis that uses only Kirchoff's current law, cannot be used to represent ideal voltage sources or inductors. This is so because the branch current in these elements cannot be expressed as a function of the branch voltage. To resolve this problem, KVL is used to write a loop equation around each inductor or voltage source. Consider Fig. 16.4 for an example of this procedure. The unknowns to be solved for are the voltage V_1 at Node 1, V_2 the voltage at Node 2, V_3 the voltage at Node 3, the current flowing through voltage source V_1 which we shall call I_x and the current flowing in the inductor $L1$ which we shall call I_1 The system of equations is:

$$\begin{aligned} 0 &= V_1/R_1 + I_x \\ 0 &= V_2/R_2 - I_z + I_l \\ 0 &= V_3/R_3 - I_l \\ 0 &= V_1 - V_x + V_2 \\ 0 &= V_2 + \frac{d(L_1 I_1)}{dt} - V_3 \end{aligned} \tag{16.4}$$

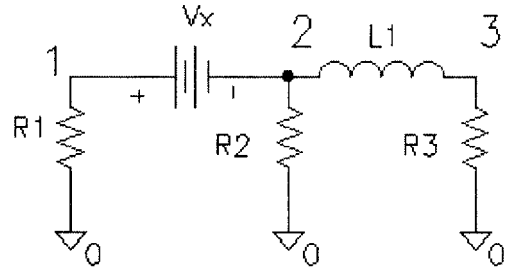

FIGURE 16.4 Circuit for modified nodal analysis.

The use of modified nodal analysis does have the disadvantage of requiring that an additional equation be included for each inductor or voltage source, but has the advantage that ideal voltage sources can be used. The total number of equations to be solved is therefore the number of nodes plus the number of voltages sources and inductors.

16.6 Active Device Models

VLSI circuits contain active devices like transistors or diodes which act as amplifiers. These devices are normally described by a complicated set of non-linear equations. We shall consider a simple model for the bipolar transistor — the Ebers-Moll model. This model is one of the first developed, and while it is too simple for practical application, it is useful for discussion.

A schematic of the Ebers-Moll model is shown in Fig. 16.5. The model contains three non-linear voltage-dependent current sources I_c, I_{bf}, and I_{br} and two non-linear capacitances C_{be} and C_{bc}. The current flowing in the three current sources are given by the following equations:

$$I_c = I_s(\exp(V_{be}/V_t)) - \exp(V_{ce}/V_t) \tag{16.5}$$

$$I_{bf} = \frac{I_s}{B_f}(\exp(V_{be}/V_t) - 1) \tag{16.6}$$

$$I_{br} = \frac{I_s}{B_r}(\exp(V_{bc}/V_t) - 1) \tag{16.7}$$

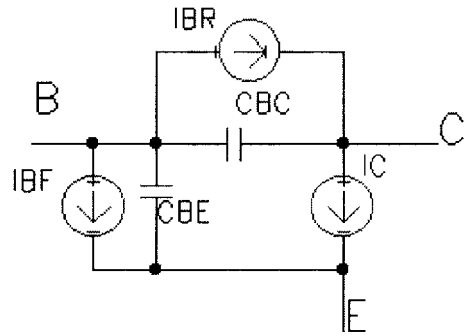

FIGURE 16.5 The Ebers-Moll model for the bipolar transistor.

The voltages V_{be} and V_{bc} are the voltages between base and emitter and the base and collector, respectively. I_s, B_f and B_r are three user-defined parameters which govern the DC operation of the BJT. V_t is the "thermal voltage" or kT/q, which has the numerical value of approximately 0.26 volts at room temperature. Observe that in the normal forward active mode, where $V_{be} > 0$ and $V_{ce} < 0$, I_{br} and the second term in I_c vanish and the current gain of the BJT, which is defined as I_c/I_b becomes numerically equal to B_f. Likewise, in the reverse mode where $V_{ce} > 0$ and $V_{be} < 0$, the reverse gain (I_e/I_b) is equal to B_r.

The two capacitances in Fig. 16.5 contribute charge to the emitter, base, and collector, and this charge is given by the following equations:

$$Q_{be} = \tau_f I_s(\exp V_{be}/V_t - 1) + C_{je}\int_0^{V_{be}} (1 - V/V_{je})^{-m_e} \tag{16.8}$$

$$Q_{bc} = \tau_r I_s(\exp V_{bc}/V_t - 1) + C_{jc}\int_0^{V_{bc}} (1 - V/V_{jc})^{-m_c} \tag{16.9}$$

Q_{be} contributes positive charge to the base and negative charge to the emitter. Q_{bc} contributes positive charge to the base and negative charge to the collector. The first term in each charge expression is due to charge injected into the base from the emitter for Q_{be} and from the collector into the base for Q_{bc}. Observe that the exponential terms in the charge terms are identical to the term in I_c. This is so because the injected charge is proportional to the current flowing into the transistor. The terms τ_f and τ_r are the forward and reverse transit times, respectively, and correspond to the amount of time it takes the electrons (or holes) to cross the base. The second term in the charge expression (the term with the integral) corresponds to the charge in the depletion region of the base–emitter junction for Q_{be} and in the base–collector junction for Q_{bc}. Recall that the depletion width in a pn junction is a function of the applied voltage. The terms V_{je} and V_{jc} are the "built-in" potentials with units of volts for the base–emitter and base–collector junctions. The terms m_c and m_e are the grading coefficients for the two junctions and are related to how rapidly the material changes from n-type to p-type across the junction.

This "simple" model has eleven constants I_s, B_f, B_r, C_{je}, C_{jc}, M_e, M_c, V_{je}, V_{jc}, T_f, and T_r which must be specified by the user. Typically, these constants would be extracted from measured I-V and C-V data taken from real transistors using a fitting or optimization procedure (typically a non-linear least-squares fitting method is needed). The Ebers-Moll model has a number of shortcomings which are addressed in newer models like Gummel-Poon, Mextram, and VBIC. The Gummel-Poon model has over 40 parameters that must be adjusted to get a good fit to data in all regions of operation.

Models for MOS devices are even more complicated than the bipolar models. Modeling the MOSFET is more difficult than the bipolar transistor because it is often necessary to use a different equation for each of the four regions of operation (off, subthreshold, linear, saturation) and the drain current and capacitance are functions of three voltages (V_{ds}, V_{bs}, and V_{gs}) rather than just two (V_{be} and V_{ce}) as in the case of the BJT. If a Newton-Raphson solver is to be used, the I-V characteristics and capacitances must be continuous and it is best if their first derivatives are continuous as well. Furthermore, MOS models contain the width (W) and length (L) of the MOSFET channel as parameters; and for the best utility the model should remain accurate for many values of W and L. This property is referred to as "scalability."

Over the years, literally hundreds of different MOS models have been developed. However, for modern VLSI devices, only three or four are commonly used today. These are the SPICE Level-3 MOS model, the HSPICE Level-28 model (which is a proprietary model developed by Meta Software), the public domain BSIM3 model develeped at UC Berkeley, and MOS9 developed at Phillips. These models are supported by many of the "silicon foundries," that is, parameters for the models are provided to chip designers by the foundries. BSIM3 has been observed to provide a good fit to measured data and its I-V curves to be smooth and continuous (thereby resulting in good simulator convergence). The

main drawback of BSIM3 is that it has over 100 parameters which are related in intricate ways, making extraction of the parameter set a difficult process.

A process known as "binning" is used to provide greater accuracy. When binning is used, a different set of model parameters is used for each range of the channel length and width (L and W). An example of this is shown in Fig. 16.6. For a given type of MOSFET, 12 complete sets of model parameters are extracted and each is valid for a given range. For example, in Fig. 16.6, the set represented by the number "11" would only be valid for channel lengths between 0.8 and 2.0 microns and for channel widths between 0.5 and 0.8 microns. Thus, for a typical BSIM3 model with about 60 parameters, $12 \times 60 = 720$ parameters would need to be extracted in all and this just for one type of device.

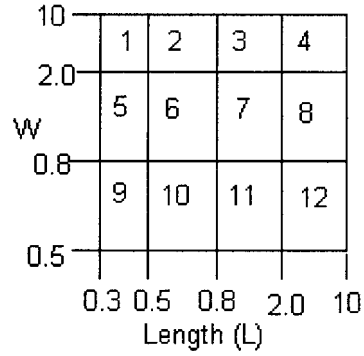

FIGURE 16.6 Binning of MOS parameters.

Many commercial simulators contain other types of models besides the traditional R, L, C, MOS, and BJT devices. Some simulators contain "behavioral" models which are useful for systems design or integration tasks; examples of these are integrators, multipliers, summation, and LaPlace operator blocks. Some simulators are provided with libraries of prefitted models for commercially available operational amplifiers, logic chips, and discrete devices. Some programs allow "mixed-mode" simulation, which is a combination of logic simulation (which normally allows only a few discrete voltage states) and analog circuit simulation.

16.7 Types of Analysis

For analog circuits, there are three commonly used methods of analysis, these being DC, AC, and transient analysis. DC analysis is used to examine the steady-state operation of a circuit; that is, what the circuit voltages and currents would be if all inputs were held constant for an infinite time. AC analysis (or sinusoidal steady state) examines circuit performance in the frequency domain using phasor analysis. Transient analysis is performed in the time domain and is the most powerful and computationally intensive of the three. For special applications, other methods of analysis are available such as the Harminic-Balance method, which is useful for detailed analysis of non-linear effects in circuits excited by purely perodic signals (like mixers and RF amplifiers).

DC (Steady-State) Analysis

DC analysis calculates the steady-state response of a circuit (with all inductors shorted and capacitors removed). DC analysis is used to determine the operating point (Q-point) of a circuit, power consumption, regulation and output voltage of power supplies, transfer functions, noise margin and fanout in logic gates, and many other types of analysis. In addition, a DC solution must be calculated to find the starting point for AC and transient analysis.

To calculate the DC solution, we need to solve Kirchoff's equations formulated earlier. Unfortunately, since the circuit elements will be non-linear in most cases, a system of transcendental equations will normally result and it is impossible to solve this system analytically. The method which has met with the most success is Newton's method or one of its derivatives.

Newton's Method

Newton's method is actually quite simple. We need is to solve the system of equations $F(X) = 0$ for X, where both F and X are vectors of dimension N. (F is the system of equations from modified nodal analysis, and X is the vector of voltages and current that we are solving for.) Newton's method states that given an initial guess for X^i, we can obtain a better guess X^{i+1} from the equation:

$$X^{i+1} = X^i - [J(X^i)]^{-1} F(X^i) \tag{16.10}$$

Note that all terms on the right side of the equation are functions only of the vector X^i. The term $J(X)$ is a N × N square matrix of partial derivatives of F, called the Jacobian. Each term in J is given by:

$$J_{i,j} = \frac{\partial F_i(X)}{\partial X_j} \tag{16.11}$$

We assemble the Jacobian matrix for the circuit at the same time that we assemble the circuit equations. Analytic derivatives are used in most simulators.

The –1 in Eq. 16.10 indicates that we need to invert the Jacobian matrix before multiplying by the vector F. Of course, we do not need to actually invert J to solve the problem; we only need to solve the linear problem $F = YJ$ for the vector Y and then calculate $X^{i+1} = X^i - Y$. A direct method such as the LU decomposition is usually employed to solve the linear system.

For the small circuit of Fig. 16.3, analyzed in steady state (without the capacitor), the Jacobian entries are:

$$\begin{aligned} J_{1,1} &= 1/R_1 & J_{1,2} &= -1/R_1 \\ J_{2,1} &= 1/R_1 + gm & J_{2,2} &= 1/R_1 + 1/R_2 \end{aligned} \tag{16.12}$$

For a passive circuit (i.e., a circuit without gain), the Jacobian will be symmetric and for any row, the diagonal entry will be greater than the sum of all the other entries.

Newton's method converges quadratically, provided that the initial guess X^i is sufficiently close to the true solution. Quadratically implies that if the distance between X^i and the true solution is d, then the distance between X^{i+1} and the true solution will be d^2. Of course, we are assuming that d is small to start with. Still, programs like SPICE may require 50 or more iterations to achieve convergence. The reason for this is that, often times, the initial guess is poor and quadratic convergence is not obtained until the last few iterations. There are additional complications like the fact that the model equations can become invalid for certain voltages. For example, the BJT model will "explode" if a junction is forward-biased by more than 1 V or so since : $\exp(1/Vt) = 5e16$. Special limiting or damping methods must be used to keep the voltages and currents to within reasonable limits.

Example Simulation

Most circuit simulators allow the user to ramp one or more voltage sources and plot the voltage at any node or the current in certain branches. Returning to the differential pair of Fig.16.1, we can perform a DC analysis by simply adding a .DC statement (see Fig. 16.7). A plot of the differential output voltage (between the two collectors) and the voltage at the two emitters is shown in Fig. 16.8. Observe that the output voltage is zero when the differential pair is "balanced" with 2.0 V on both inputs. The output saturates at both high and low values for V_1, illustrating the non-linear nature of the analysis. This

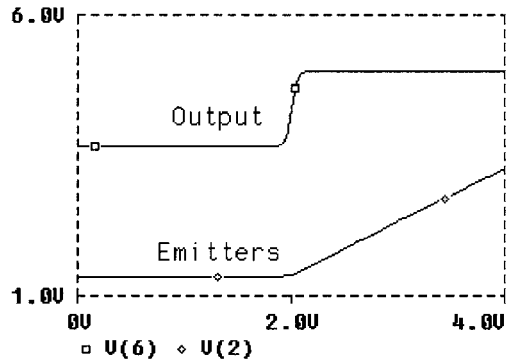

FIGURE 16.8 Output from DC analysis.

simulation was run using the PSPICE package from MicroSim Corporation. The simulation run is a few seconds on a 486 type PC.

AC Analysis

AC analysis is performed in the frequency domain under the assumption that all signals are represented as a DC component V_{dc} plus a small sinusoidal component V_{ac}.

$$V = V_{dc} + V_{ac}\exp(j\omega t) \tag{16.13}$$

Here, $j = \sqrt{-1}$, ω is the radial frequency ($2\pi f$), and V_{ac} is a complex number. Expanding (1) about the DC bias point V_{dc} (also referred to as the Q point), we obtain:

$$F(V) = F(V_{dc}) + W_{dc} + W_{ac} + \frac{\partial G(V_{dc})}{\partial V_{dc}} V_{ac} + \frac{\partial}{\partial t}\left(\frac{\partial Q(V_{dc})}{\partial V_{dc}}\right) V_{ac} + \alpha V_{ac}^2 \Lambda \tag{16.14}$$

The series has an infinite number of terms; however, we assume that if V_{ac} is sufficiently small, all terms above first order can be neglected. The first two terms on the right-hand side are the DC solution and, when taken together, yield zero. The third term W_{ac} is the vector of independent AC current sources which drive the circuit. The partial derivative in the fourth term is the Jacobian element, and the derivative of Q in parentheses is the capacitance at the node. When we substitute the exponential into Eq. 16.14, each term will have an exponential term that can be canceled. The result of all these simplifications is the familiar result:

$$0 = W_{ac} + JV_{ac} + j\omega CV_{ac} \tag{16.15}$$

This equation contains only linear terms which are equal to the partial derivatives of the original problem evaluated at the Q point. Therefore, before we can solve the AC problem, we must calculate the DC bias point. Rearranging terms slightly, we obtain:

$$V_{ac} = -(J + j\omega C)^{-1} W_{ac} \tag{16.16}$$

The solution at a given frequency can be obtained from a single matrix inversion. The matrix, however, is complex but normally the complex terms share a sparsity pattern similar to the real terms. It is normally possible (in FORTRAN and C++) to create a suitable linear solver by taking the linear solver which is used to calculate the DC solution and substituting "complex" variables for "real" variables. Since there is no non-linear iteration, there are no convergence problems and AC analysis is straightforward and fool-proof.

The same type of analysis can be applied to the equations for modified nodal analysis. The unknowns will of course be currents and the driving sources voltage sources.

$$I_{ac} = -(J + j\omega L)^{-1} E_{ac} \tag{16.17}$$

The only things that must be remembered with AC analysis are:

1. The AC solution is sensitive to the Q point, so if an amplifier is biased near its saturated DC output level, the AC gain will be smaller than if the amplifier were biased near the center of its range.
2. This is a linear analysis and therefore "clipping" and slew rate effects are not modeled. For example, if a 1-V AC signal is applied to the input of a small signal amplifier with a gain of 100 and a power supply voltage of 5 V, AC analysis will predict an output voltage of 100 V. This is of course impossible since the output voltage cannot exceed the power supply voltage of 5 V. If you want to include these effects, use transient analysis.

AC Analysis Example

In the following example, we will analyze the differential pair using AC analysis to determine its frequency response. To perform this analysis in SPICE, we need only specify which sources are the AC driving sources (by adding the magnitude of the AC signal at the end) and specify the frequency range on the .AC statement (see Fig. 16.9). SPICE lets the user specify the range as linear or "decade," indicating that we desire a logarithmic frequency scale. The first number is the number of frequency points per decade. The second number is the starting frequency, and the third number is the ending frequency.

FIGURE 16.9 Input file for AC analysis.

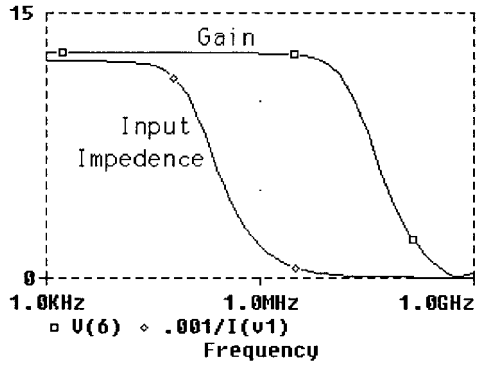

FIGURE 16.10 Gain and input impedance calculated by AC analysis.

Figure 16.10 shows the results of the analysis. The gain begins to roll off at about 30 MHz due to the parasitic capacitances within the transistor models. The input impedance (which is plotted in kΩ) begins to roll off at a much lower frequency. The reduction in input impedance is due to the increasing current that flows in the base-emitter capacitance as the current increases. SPICE does not have a method of calculating input impedance, so we have calculated it as $Z = V_{in}/I(V_{in})$, where $V_{in} = 1.0$, using the post-processing capability of PSPICE. This analysis took about 2 seconds on a 486 type PC.

Noise Analysis

Noise is a problem primarily in circuits that are designed for the amplification of small signals like the RF and IF amplifiers of a receiver. Noise is the result of random fluctuations in the currents which flow in the circuit and is generated in every circuit element. In circuit simulation, noise analysis, is an extension of AC analysis. During noise analysis, it is assumed that every circuit element contributes some small noise component either as a voltage V_n in series with the element or as a current I_n across the element. Since the noise sources are small in comparison to the DC signal levels, AC small signal analysis is an applicable analysis method.

Different models have been developed for the noise sources. In a resistor, thermal noise is the most important component. Thermal noise is due to the random motion of the electrons:

$$I_n^2 = \frac{4kT\Delta f}{R} \tag{16.18}$$

where T is the temperature, k is Boltzman's constant, and Δf is the bandwidth of the circuit. In a semiconductor diode, shot noise is important. Shot noise is related to the probability that an electron will surmount the semiconductor barrier energy and be transported across the junction:

$$I_n^2 = 2qI_d\Delta f \tag{17.19}$$

There are other types of noise that occur in diodes and transistors; examples are flicker and popcorn noise. Noise sources, in general, are frequency dependent.

Noise signals will be amplified or attenuated as they pass through different circuits. Normally, noise is referenced to some output point called the "summing node." This would normally be the output of the amplifier where we would actually measure the noise. We can call the gain between the summing node and the current flowing in an element j in the circuit $A_j(f)$. Here, f is the analysis frequency since the gain will normally be frequency dependent.

Noise signals are random and uncorrelated to each other so their magnitudes must be root-mean-squared summed rather than simply summed. Summing all noise sources in a circuit yields:

$$I_n(f) = \sqrt{\sum_j A_j^2(f) I_j^2(f)} \tag{16.20}$$

It is also common to reference noise back to the amplifier input and this is easily calculated by dividing the above expression by the amplifier gain. Specifying noise analysis in SPICE is simple. All the user needs to do is add a statement specifying the summing node and the input source. Spice then calculates the noise at each as a function of frequency

```
.noise v([6]) V1
```
(16.21)

See Fig. 16.11 for example output. Many circuit simulators will also list the noise contributions of each element as part of the output. This is particularly helpful in locating the source of noise problems.

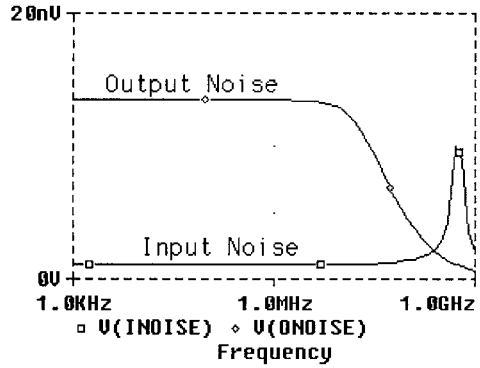

FIGURE 16.11 Noise referenced to output and input.

Transient Analysis

Transient analysis is the most powerful analysis capability because the transient response of a circuit is so difficult to calculate analytically. Transient analysis can be used for many types of analysis, such as switching speed, distortion, and checking the operation of circuits like logic gates, oscillators, phase-locked loops, or switching power supplies. Transient analysis is also the most CPU intensive and can require 100 or 1000 times the CPU time of DC or AC analysis.

Numerical Method

In transient analysis, time is discretized into intervals called *time steps*. Typically, the time steps are of unequal length, with the smallest steps being taken during intervals where the circuit voltages and currents are changing most rapidly. The following procedure is used to discretize the time-dependent terms in Eq. 16.1.

Time derivatives are replaced by difference operators, the simplest of which is the forward difference operator:

$$\frac{dQ(t_k)}{dt} = \frac{Q(t_{k+1}) - Q(t_k)}{h} \tag{16.22}$$

where h is the time step given by $h = t_{k+1} - t_k$. We can easily solve for the charge $Q(t_{k+1})$ at the next time point:

$$Q(t_{k+1}) = Q(t_k) - h(G_i(V(t_k)) + W_i(t_k)) \tag{16.23}$$

using only values from past time points. This means that it would be possible to solve the system simply by plugging in the updated values for V each time. This can be done without any matrix assembly or inversion and is very nice. (Note for simple linear capacitors, $V = Q/C$ at each node, so it is easy to get V back from Q.) However, this approach is undesirable for circuit simulation for two reasons. (1) The charge Q, which is a "state variable" of the system, is not a convenient choice since some nodes may not have capacitors (or inductors) attached, in which case they will not have Q values. (2) It turns out that forward (or explicit) time discretization methods like this one are unstable for "stiff" systems, and most circuit problems result in "stiff systems." The term "stiff system" refers to a system that has greatly varying time constants.

To overcome the stiffness problem, we must use implicit time discretization methods which, in essence, means that the G and W terms in the above equations must be evaluated at t_{k+1}. Since G is non-linear, we will need to use Newton's method once again.

The most popular implicit method is the trapezoidal method. The trapezoidal method has the advantage of only requiring information from one past time point and, furthermore, has the smallest error of any method requiring one past time point. The trapezoidal method states that if I is the current in a capacitor, then:

$$I(t_{k+1}) = \frac{dQ}{dt} = 2\frac{Q(V(t_{k+1})) - Q(V(t_k))}{h} - I(t_k) \tag{16.24}$$

Therefore, we need only substitute the above equation into Eq. (16.1) to solve the transient problem. Observe that we are solving for the voltages $V(t_{k+1})$, and all terms involving t_k are constant and will not be included in the Jacobian matrix. An equivalent electrical model for the capacitor is shown in Fig. 16.12. Therefore, the solution of the transient problem is in effect a series of DC solutions where the values of some of the elements depend on voltages from the previous time points.

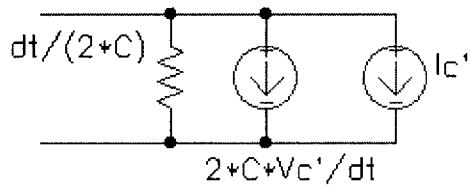

FIGURE 16.12 Electrical model for a capacitor; the two current sources are independent sources. The prime (') indicates values from a preceding time point.

All modern circuit simulators feature automatic time step control. This feature selects small time steps during intervals where changes are occurring rapidly and large time steps in intervals where there is little change. The most commonly used method of time step selection is based on the local truncation error (LTE) for each time step. For the trapezoidal rule, the LTE is given by:

$$\varepsilon = \frac{h^3}{12}\frac{d^3x}{dt^3}(\xi) \tag{16.25}$$

and represents the maximum error introduced by the trapezoidal method at each time step. If the error (ε) is larger than some preset value, the step size is reduced. If the error is smaller, then the step size is increased. In addition, most simulators select time points so that they coincide with the edges of pulse-type waveforms.

Transient Analysis Examples

As a simple example, we return to the differential pair and apply a sine wave differentially to the input. The amplitude (2 V p-p) is selected to drive the amplifier into saturation. In addition, we make the frequency (50 MHz) high enough to see phase shift effects. The output signal is therefore clipped due to the non-linearities and shifted in phase due to the capacitive elements in the transistor models (see Fig. 16.13). The first cycle shows extra distortion since it takes time for the "zero-state" response to die out. This simulation, using PSPICE, runs in about one second on a 486 type computer.

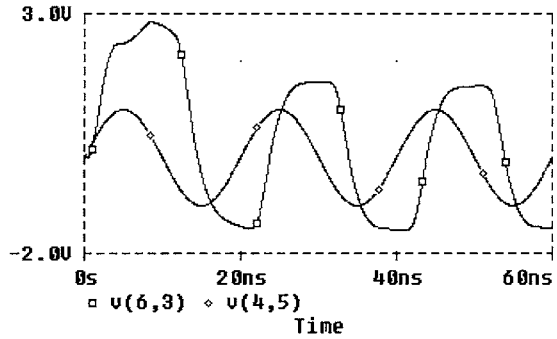

FIGURE 16.13 Transient response V(6,3) of differential amplifier to sinusoidal input at V(4,5).

16.8 Verilog-A

Verilog-A is a new language designed for simulation of analog circuits at various levels. Mathematical equations can be entered directly as well as normal SPICE-type circuit elements.

Groups of equations and elements can be combined into reusable "modules" that are similar to subcircuits. Special functions are also provided for converting analog signals into digital equivalents, and vice versa. Systems-type elements such as LaPlace operators, integrators, and differentators are also provided. This makes it possible to perform new types of modeling which were not possible in simulators like SPICE:

- Equations can be used to construct new models for electrical devices (for example, the Ebers-Moll model described earlier could be easily implemented).
- Behavioral models for complex circuits like op-amps, comparitors, phase detectors, etc. can be constructed. These models can capture the key behavior of a circuit and yet be simulated in a small fraction of the time it takes to simulate at the circuit level.
- Special interface elements make it possible to connect an analog block to a digital simulator, making mixed-mode simulation possible.Verilog-A is related to and compatible with the popular Verilog-D modeling language for digital circuits.

As an example, consider a phase-locked loop circuit which is designed as an 50X frequency multiplier. A block diagram for the PLL is shown in Fig. 16.14 and the Verilog-A input listing is shown in Figs. 16.15 and 16.16.

Simulation of this system at the circuit level is very time consuming due to the extreme difference in frequencies. The phase detector operates at a low frequency of 1.0 MHz, while the VCO operates at close to 50 MHz. However, we need to simulate enough complete cycles at the phase detector output to verify that the circuit correctly locks onto the reference signal.

The circuit is broken up into five blocks or modules: The "top module," VCO, divider, phase detector, and loop filter. The VCO has a simple linear dependence of frequency on the VCO input voltage and produces a sinusoidal output voltage. The VCO frequency is calculated by the simple expression freq = center + gain * ($V_{in} - V_{min}$). Center and gain are parameters which can be passed in when the VCO is

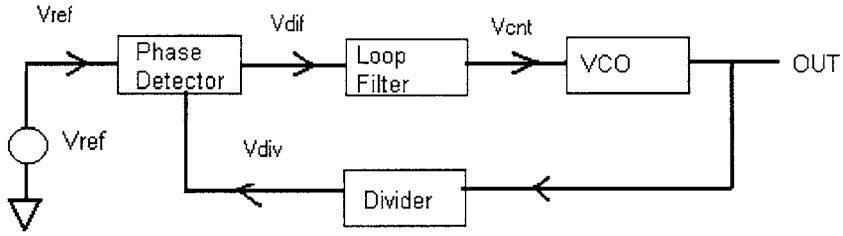

FIGURE 16.14 Block diagram of phase-locked loop.

created within the top module by the special syntax "`#(.gain(2e7), .center(3e7)`" in the top module. If the parameters are not specified when the module is created, then the default values specified within the module are used instead. The special V() operator is used to obtain the voltage at a node (in this case `V(in)` and `V(Vdd)`). The sinusoidal output is created using the SIN and IDT operators. SIN calculates the sin of its argument. I_{dt} calculates the integral of its argument with respect to time. The amplitude of the output is taken from the V_{dd} input, thus making it easy to integrate the VCO block with others. Given that V_{dd} = 5 volts, gain = 2e7 Hz/V center = 3e7 Hz, and in = 1.8, the final expression for the VCO output is:

$$V_{out} = 2.5 + 2.5\sin\left(3e7 + 2e7\int 2\pi(V_{in} - 1.8)dt\right) \tag{16.26}$$

FIGURE 16.16 Part two of Verilog-A PLL listing.

The phase detector functions as a charge pump which drives current into or out of the loop filter, depending on the phase difference between its two inputs. The `@cross(V1,dir)` function becomes true whenever signal V_1 crosses zero in the direction specified by `dir`. This either increments or decrements the variable STATE. The "transition" function is used to convert the STATE signal, which is essentially digital and changes abruptly, into a smoothly changing analog signal which can be applied to the rest of the circuit. The "<+" (or contribution) operator adds the current specified by the equation on the right to the node on the left. Therefore, the phase detector block forces current into the output node whenever the VCO signal leads the reference signal and forcing current out of the output node whenever the reference leads the vco signal. The phase detector also has an output resistance which is specified by parameter ROUT.

The loop filter is a simple SPICE subcircuit composed of two resistors and one capacitor. Of course, this subcircuit could contain other types of elements as well and can even contain other Verilog-A modules. The divider block simply counts zero crossings and, when the count reaches the preset divisor, the output of the divider is toggeled from 0 to 1, or vice versa. The transition function is used to ensure that a smooth, continuous analog output is generated by the divider.

This PLL was simulated using AMS from Antrim Design Systems. The results of the simulations are shown in Fig. 16.17. The top of Fig. 16.17 shows the output from the loop filter (V_{cnt}). After a few cycles, the PLL has locked onto the reference signal. The DC value of the loop filter output is approximately 2.8 V. Referring back to the VCO model, this gives an output frequency of 2e7*(2.8 – 1.8) + 3e7 = 50 MHz,

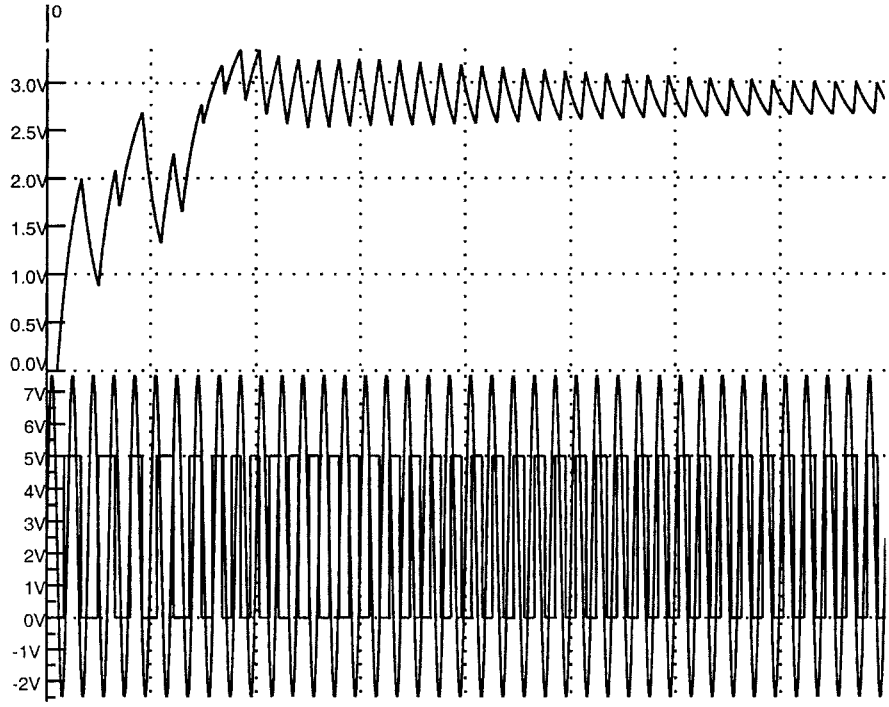

FIGURE 16.17 Loop filter output (top) V_{ref} and divider output (bottom) from PLL simulation.

which is as expected. The lower portion of Fig. 16.17 shows the divider output (V_{div}) and the reference signal (V_{ref}). It can be seen that the two signals are locked in phase. Figure 16.18 shows the VCO output and the divider output. As expected, the VCO frequency is 50 times the divider frequency.

The behavioral models used in this example are extremely simple ones. Typically, more complex models must be used to accurately simulate the operation of an actual PLL. A better model might include effects such as the non-linear dependence of the VCO frequency on the input voltage, the effects on signals introduced through power supply lines, delays in the divider and phase detector, and finite signal rise and fall times. These models can be built up from measurements, or transistor-level simulation of the underlying blocks (a process known as *characterization*). Of course, during the simulation, any of the behavioral blocks could be replaced by detailed transistor level models or complex Verilog-D digital models.

Another Verilog-A example is shown in Fig. 16.19. Here, the Ebers-Moll model developed earlier is implemented as a module. This module can then be used in a circuit in much the same way as the normal built-in models. Verilog-A takes care of calculating all the derivatives needed to form the Jacobian matrix. The "parameter" entries can be used in the same way as the parameters on a SPICE.MODEL statement. Observe the special "ddt" operator. This operator is used to take the time derivative of its argument. In this case, the time derivative of the charge (a current) is calculated and summed in with the other DC components. The "$limexp" operation is a special limited exponential operator designed to give better convergence when modeling pn junctions. Of course, this module could be expanded and additional features could be added.

16.9 Fast Simulation Methods

As circuits get larger, simulation times become larger. In addition, as integrated circuit feature sizes shrink, second-order effects become more important and many circuit designers would like to be able to simulate

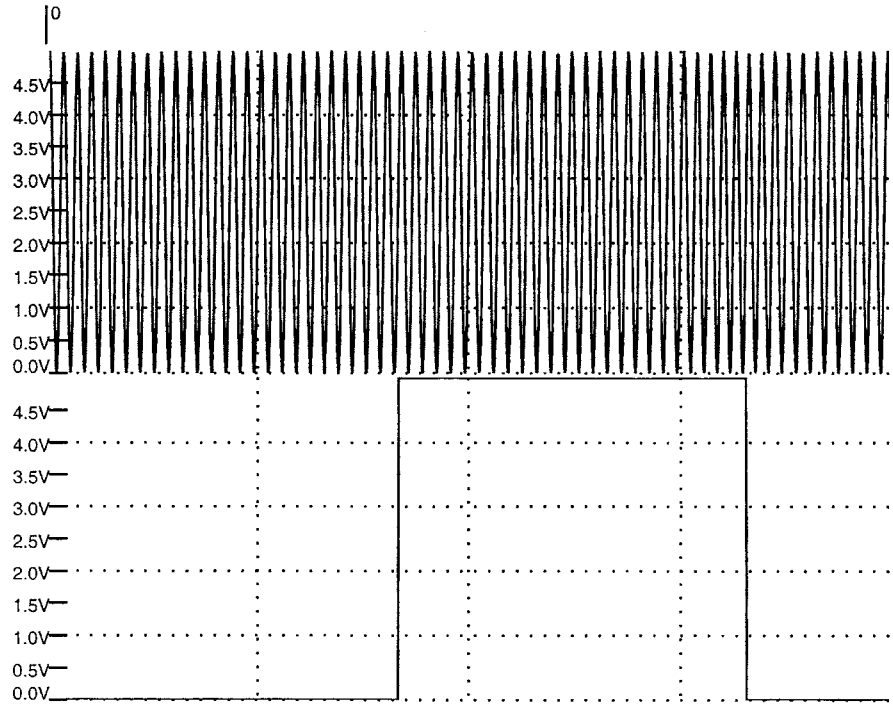

FIGURE 16.18 VCO output and divder output from PLL simulation.

large digital systems at the transistor level (requiring 10,000 to 100,000 nodes). Numerical studies in early versions of SPICE showed that the linear solution time could be reduced to 26% for relatively small circuits with careful coding. The remainder is used during the assembly of the matrix, primarily for model evaluation. The same studies found that the CPU time for the matrix solution was proportional to $n^{1.24}$, where n is the number of nodes. The matrix assembly time on the other hand should increase linearly with node count. Circuits have since grown much bigger, but the models (particularly for MOS devices) have also become more complicated.

Matrix assembly time can be reduced by a number of methods. One method is to simplify the models; however, accuracy will be lost as well. A better way is to precompute the charge and current characteristics for the complicated models and store them into tables. During simulation, the actual current and charges can be found from table lookup and interpolation, which can be done quickly and efficiently. However, there are some problems:

1. To assure convergence of Newton's method, both the charge and current functions and their derivatives must be continuous. This rules out most simple interpolation schemes and means that something like a cubic spline must be used.
2. The tables can become large. A MOS device has four terminals, which means that all tables will be functions of three independent variables. In addition, the MOSFET requires four separate tables (Id, Qg, Qd, Qb). If we are lucky, we can account for simple parameteric variations (like channel width) by a simple multiplying factor. However, if there are more complex dependencies as is the case with channel length, oxide thickness, temperature, or device type, we will need one complete set of tables for each device.

If the voltages applied to an element do not change from the past iteration to the present iteration, then there is no need to recompute the element currents, charges, and their derivatives. This method is referred to as taking advantage of latency and can result in large CPU time savings in logic circuits, particularly if coupled with a method which only refractors part of the Jacobian matrix. The tricky part

endmodule
```

FIGURE 16.19 Verilog-A implimentation of the Ebers-Moll model.

is knowing when the changes in voltage can be ignored. Consider, for example, the input to a high-gain op-amp, here ignoring a microvolt change at the input could result in a large error at the output. Use of sophisticated latency-determining methods could also cut into the savings.

Another set of methods are the waveform relaxation techniques which increase efficiency by temporarily ignoring couplings between nodes. The simplest version of the method is as follows. Consider a circuit with n nodes which requires m time points for its solution. The circuit can be represented by the vector equation:

$$F_i(V(t)) + \frac{dQ_i(V(t))}{dt} = 0 \tag{16.27}$$

Using trapezoidal time integration gives a new function:

$$W_i(V(k)) = F_i(V(k)) + F_i(V(k-1)) + 2[Q_i(V(k)) - Q_i(V(k-1))]/dt = 0 \tag{16.28}$$

We need to find the $V(k)$ which makes W zero for all k time points at all i nodes. The normal method solves for all n nodes simultaneously at each time point before advancing k. Waveform relaxation solves for all m time points at a single node (calculates the waveform at that node) before advancing to the next node. An outer loop is used to assure that all the individual nodal waveforms are consistent with each other.

Waveform relaxation is extremely efficient as long as the number of outer loops is small. The number of iterations will be small if the equations are solved in the correct order; that is, starting on nodes which are signal sources and following the direction of signal propagation through the circuit. This way, the

waveform at node $i + 1$ will depend strongly on the waveform at node i, but the waveform at node i will depend weakly on the signal at node $i + 1$. The method is particularly effective if signal propagation is unidirectional, as is sometimes the case in logic circuits. During practical implementation, the total simulation interval is divided into several subintervals and the subintervals are solved sequentially. This reduces the total number of time points which must be stored. Variants of the method solve small numbers of tightly coupled nodes as a group; such a group might include all the nodes in a TTL gate or in a small feedback loop. Large feedback loops can be handled by making the simulation time for each subinterval less than the time required for a signal to propagate around the loop.

The efficiency of this method can be further improved using different time steps at different nodes, yielding a multi-rate method. This way, during a given interval, small time steps are used at active nodes while large steps are used at inactive nodes (taking advantage of latency).

16.10 Commercially Available Simulators

The simulations in this chapter were performed with the evaluation version of PSPICE from Microsim and AMS from Antrim design systems. The following vendors market circuit simulation software. The different programs have strengths in different areas and most vendors allow you to try their software in-house for an "evaluation period" before you buy.

17.1 Introduction

With the rapid developments in VLSI technology, design, and CAD techniques, at both the chip and package level, the central processor cycle times are reaching the vicinity of 1 ns and communication switches are being designed to transmit data that have bit rates faster than 1 Gb/s. The ever-increasing quest for high-speed applications is placing higher demands on interconnect performance and highlights the previously negligible effects of interconnects (Fig. 17.1), such as ringing, signal delay, distortion, reflections, and crosstalk.[1–33] In addition, the trend in the VLSI industry toward miniature designs, low power consumption, and increased integration of analog circuits with digital blocks has further complicated the issue of signal integrity analysis. Fig. 17.2 describes the effect of scaling of chip on the global interconnect delay. As seen, the global interconnect delay grows as a cubic power of the scaling factor.[1] It is predicted that interconnects will be responsible for nearly 70 to 80% of the signal delay in high-speed systems.

Thousands of engineers, intent on the best design possible, use SPICE[7] on a daily basis for analog simulation and general-purpose circuit analysis. However, the high-speed interconnect problems are not always handled appropriately by the present levels of SPICE. If not considered during the design stage, these interconnect effects can cause logic glitches that render a fabricated digital circuit inoperable, or they can distort an analog signal such that it fails to meet specifications. Since extra iterations in the

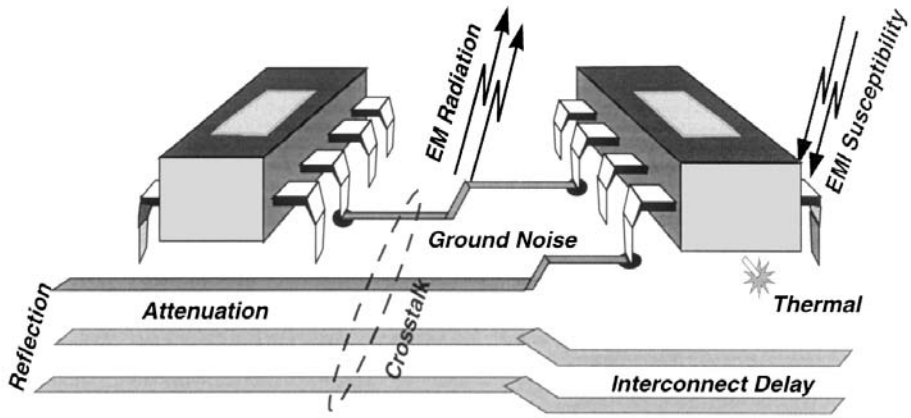

FIGURE 17.1 High-speed interconnect effects.

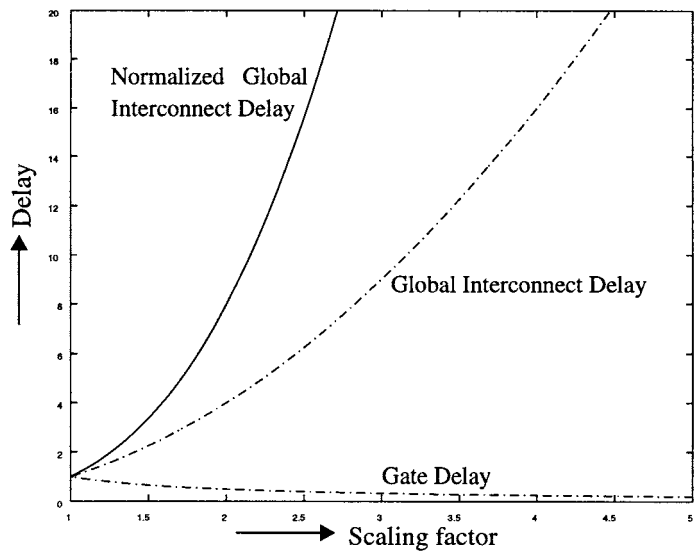

FIGURE 17.2 Impact of scaling on signal delay in high-speed systems.

design cycle are costly, accurate prediction of these effects is a necessity in high-speed designs. Hence, it becomes extremely important for designers to simulate the entire design along with interconnect subcircuits as efficiently as possible while retaining the accuracy of simulation.[12,26–65]

What Is High Speed?

Speaking on a broader perspective, a "high-speed interconnect" is the one in which the time taken by the propagating signal to travel between its end points cannot be neglected. An obvious factor that influences this definition is the physical extent of the interconnect — the longer the interconnect, the more time the signal takes to travel between its end points. Smoothness of signal propagation suffers once the line becomes long enough for the signal's rise/fall times to roughly match its propagation time through the line. Then, the interconnect electrically isolates the driver from the receivers, which no longer

function directly as loads to the driver. Instead, within the time of the signal's transition between its high and low voltage levels, the impedance of the interconnect becomes the load for the driver and also the input impedance to the receivers.[1–6] This leads to various transmission line effects, such as reflections, overshoot, undershoot, and crosstalk, and modeling of these needs the blending of EM and circuit theory.

Alternatively, the term "high-speed" can be defined in terms of the frequency content of the signal. At low frequencies, an ordinary wire (i.e., an interconnect) will effectively short two connected circuits. However, this is not the case at higher frequencies. The same wire, which is so effective at lower frequencies for connection purposes, has too much inductive/capacitive effect to function as a short at higher frequencies. Faster clock speeds and sharper slew rates tend to add more and more high-frequency contents.

An important criterion used for classifying interconnects is the *electrical length* of an interconnect. An interconnect is considered to be "electrically short," if at the highest operating frequency of interest, the interconnect length is physically shorter than one-tenth of the wavelength (i.e., length of the interconnect/$\lambda < 0.1$, $\lambda = v/f$). Otherwise the interconnect is referred as electrically long.[1,8] In most digital applications, the desired highest operating frequency (which corresponds to the minimum wavelength) of interest is governed by the rise/fall time of the propagating signal. For example, the energy spectrum of a trapezoidal pulse is spread over an infinite frequency range; however, most of the signal energy is concentrated near the low-frequency region and decreases rapidly with increase in frequency (this is illustrated in Fig.17.3 for two different instances of rise times: 1 ns and 0.1 ns). Hence, ignoring the high-frequency components of the spectrum above a maximum frequency, f_{max}, will not seriously alter the overall signal shape. Consequently, for all practical purposes, the width of the spectrum can be assumed to be finite. In other words, the signal energy of interest is assumed to be contained in the major lobe of the spectrum, and f_{max} can be defined as coresponding to 3-dB bandwidth point[2,3,25]

$$f_{max} = \frac{0.35}{t_r} \tag{17.1}$$

where t_r is the rise/fall time of the signal. This implies that, for example, for a rise time of 0.1 ns, the maximum frequency of interest is approximately 3 GHz or the minimum wave-length of interest is 10 cm. In some cases, the limit can be more conservatively set as[25]

$$f_{max} = \frac{1}{t_r} \tag{17.2}$$

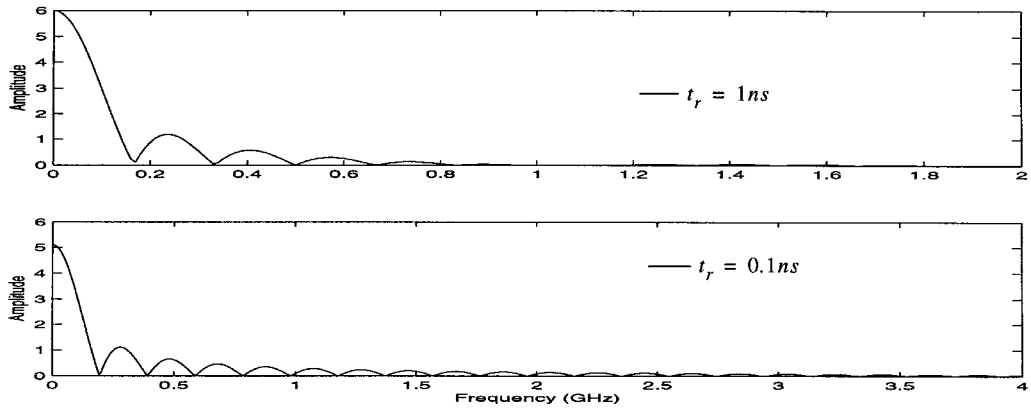

FIGURE 17.3 Frequency spectrum of trapezoidal pulse t_{pw} = 5 ns.

In summary, the primary factors with regard to high-speed signal distortion effects that should be considered are interconnect length, cross-sectional dimensions, signal slew rate, and clock speed. Other factors that also should be considered are logic levels, dielectric material, and conductor resistance. Electrically short interconnects can be represented by lumped models, whereas electrically long interconnects need distributed or full-wave models.

17.2 Interconnect Models

High-speed system designers are driven by the motivation to have signals with higher clock and slew rates while at the same time to innovate on reducing the wiring cross-section as well as packing the lines together. Reducing the wiring dimensions results in appreciably resistive lines. In addition, all these interconnections may have non-uniform cross-sections caused by discontinuities such as connectors, vias, wire bonds, flip-chip solder balls, redistribution leads, and orthogonal lines. Interconnections can be from various levels of design hierarchy (Fig. 17.4) such as on-chip, packaging structures, multi-chip modules, printed circuit boards, and backplanes. On a broader perspective, interconnection technology can be classified into five categories, as shown in Table 17.1,[6] namely, on-chip wiring, thin-film wiring, ceramic carriers, thin-film wiring, printed circuit boards, and shielded cables. For the categories shown in Table 17.1, the wavelength is of the order of 1 to 10 cm. The propagated signal rise times are in the range 100 to 1000 ps. Hence, the line lengths are either comparable or much longer than the signal wavelengths. Depending on the operating frequency, signal rise times, and the nature of the structure, the interconnects can be modeled as lumped (RC or RLC), distributed (frequency-independent/dependent RLCG parameters, lossy, coupled), full-wave models, or measured linear subnetworks.

Lumped Models

In the past, interconnect models have been generally restricted to RC tree models. RC trees are RC circuits with capacitors from all nodes to ground, no floating capacitors, no resistors to ground. The signal delay

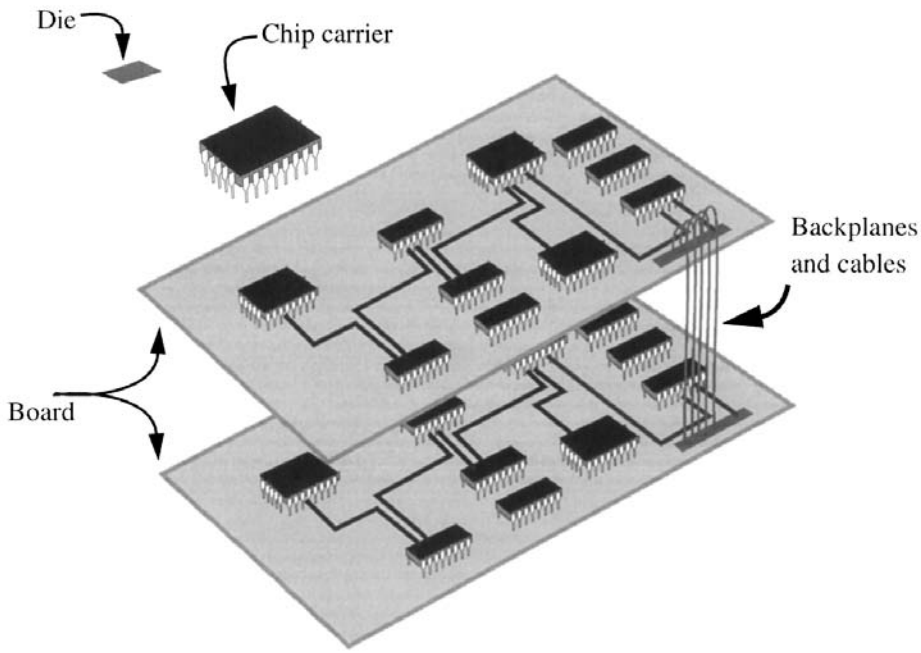

FIGURE 17.4 Interconnect hierarchy.

TABLE 17.1 Interconnect Technologies

Interconnection Type	Line Width (μm)	Line Thickness (μm)	Line Resistance (ohm/cm)	Maximum Length (cm)
On-chip	0.5–2	0.7–2	100–1000	0.3–1.5
Thin-film	10–25	5–8	1.25–4	20–45
Ceramic	75–100	16–25	0.4–0.7	20–50
Printed circuit board	60–100	30–50	0.06–0.08	40–70
Shielded cables	100–450	35–450	0.0013–0.033	150–500

through RC trees were often estimated using a form of the *Elmore delay*,[8,34] which provided a dominant time constant approximation for monotonic step responses.

Elmore Delay

There are many definitions of delay, given the actual transient response. Elmore delay is defined as the time at which the output transient rises to 50% of its final value. Elmore's expression approximates the mid-point of the *monotonic step response* waveform by the mean of the impulse response as

$$T_D = \int_0^\infty t\dot{v}dt \tag{17.3}$$

Since $v(t)$ is monotonic, its first derivative (the impulse response) will have the form of a probability density function. The mean of the distribution of the first derivative is a good approximation for the 50% point of the transient portion of $v(t)$. For an RC tree, Elmore's expression can be applied since step responses for these circuits are always monotonic.

However, with increasing signal speeds, and in diverse technologies such as bipolar, BiCMOS, or MCMs, RC tree models are no longer adequate. In bipolar circuits, lumped-element interconnect models may require the use of inductors or grounded resistors, which are not compatible with RC trees. Even for MOS circuits operating at higher frequencies, the effects of coupling capacitances may need to be included in the delay estimate.

RLC circuits with non-equilibrium initial conditions may have responses that are non-monotonic. This typically results in visible signal ringing in the waveform. A single time constant approximation with Elmore delay is not generally sufficient for such circuits. Usually, lumped interconnect circuits extracted from layouts contain large number of nodes, which make the simulation highly CPU intensive. Figure 17.5 shows a general lumped model where *r*, *l*, *c*, and *g* correspond to the resistance, inductance, capacitance, and conductance of the interconnect, respectively.

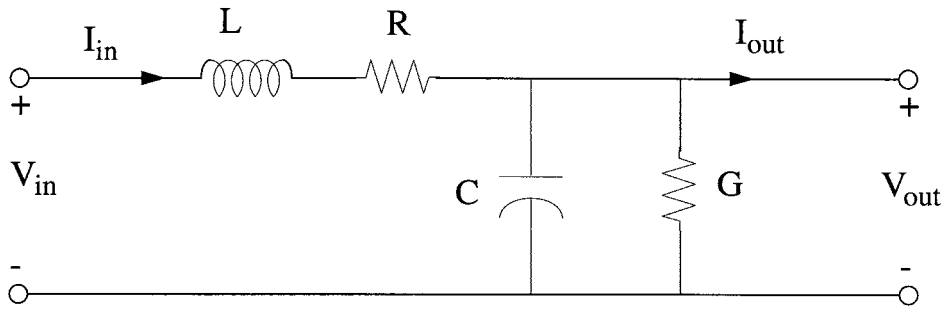

FIGURE 17.5 Lumped-component model.

Distributed Transmission Line Models

At relatively higher signal speeds, the electrical length of interconnects becomes a significant fraction of the operating wavelength, giving rise to signal-distorting effects that do not exist at lower frequencies. Consequently, the conventional lumped impedance interconnect models become inadequate, and transmission line models based on quasi-TEM assumptions are needed. The *TEM* (*Transverse Electromagnetic Mode*) approximation represents the ideal case, where both E and H fields are perpendicular to the direction of propagation and it is valid under the condition that the line cross-section is much smaller than the wavelength. However, in practical wiring configurations, the structure has all the inhomogeneities mentioned previously. Such effects give rise to E or H fields in the direction of propagation. If the line cross-section or the extent of these non-uniformities remain a small fraction of the wavelength in the frequency range of interest, the solution to Maxwell's equations are given by the so-called quasi-TEM modes and are characterized by distributed R, L, C, G per unit length parameters (Fig. 17.6).

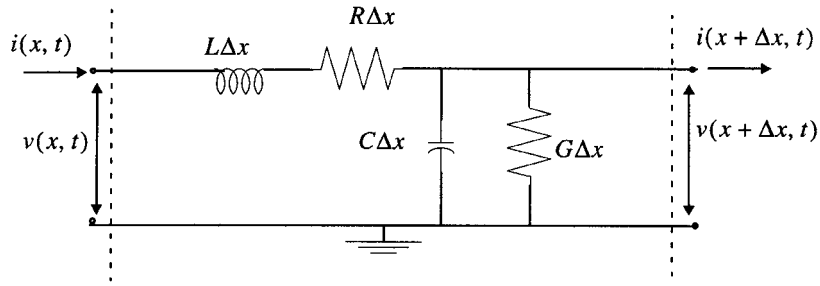

FIGURE 17.6 One seqment of distributed transmission line model.

The basic quasi-TEM model is the simple "delay" line or lossless line ($R = G = 0$). In this case, a signal traveling along a line has the same amplitude at all points, but is shifted in time with a propagation delay per unit length (τ) given by

$$\tau = \sqrt{LC} = \sqrt{\varepsilon\mu} \tag{17.4}$$

where ε and μ are the dielectric permitivity and permeability of the medium, respectively. The characteristic impedance for the lossless case is given by

$$Z = \sqrt{L/C} \tag{17.5}$$

More complicated models include per-unit-length loss (either in the direction of traveling wave or due to dielectric substrate loss) or coupling between adjacent transmission lines, where the coupling may be resistive, inductive, capacitive, or a combination of these.[8] In such cases, the propagation constants (γ) and the characteristic impedances (Z) are given by

$$\gamma = \sqrt{(R + jwL)(G + jwC)} \tag{17.6}$$

$$Z = \sqrt{\frac{R + jwL}{G + jwC}} \tag{17.7}$$

Distributed Models with Frequency-Dependent Parameters

As the operating frequency increases, the per unit length parameters of the transmission line can vary. This is mainly due to varying current distribution in the conductor and ground plane caused

by the induced electric field. This phenomenon can be categorized as follows: skin, edge, and proximity effects.[8,20,56]

Edge and Proximity Effects

The *edge* and *proximity effects* influence the interconnect parameters in the low to medium frequency region. The edge effect causes the current to concentrate near the sharp edges of the conductor, thus raising the resistance. It affects both the signal and ground conductors, but is more pronounced on signal conductors. The proximity effect causes the current to concentrate in the sections of ground plane that are close to the signal conductor. This modifies the magnetic field between the two conductors, which in turn reduces the inductance per unit length. It also raises the resistance per unit length as more current is crowded in the ground plane under the conductor. The proximity effect appears at medium frequencies. While both effects need to be accounted for, the proximity effect seems to have more significance, especially in its effect on the inductance.

Skin Effect

The *skin effect* causes the current to concentrate in a thin layer at the conductor surface. It is pronounced mostly at high frequencies on both the signal and ground conductors. The current distribution falls off exponentially as we approach the interior of the conductor. The average depth of current penetration is a function of frequency and is known as *skin depth*, which is given by

$$\delta = \left(\frac{2\rho}{w\mu}\right)^{1/2} \tag{17.8}$$

where w is frequency (rad/s), ρ is the volume resistivity, and μ is the magnetic permeability. This results in the resistance being proportional to the square root of the frequency at very high operating frequencies. The magnetic fields inside the conductors are also reduced due to skin effect. This reduces the internal inductance and therefore the total inductance. At even higher frequencies, as the internal inductance approaches zero, the edge, and proximity effects being fully pronounced, the inductance becomes essentially constant.

Typical Behavior of *R* and *L*

The frequency plots of R and L of the microstrip in Fig. 17.7 are shown in Fig. 17.8 and Fig. 17.9. These plots present a typical behavior of R and L in general. L starts off as essentially constant until the edge and proximity effects get into effect. The edge effect causes the resistance to increase, and the current crowding under signal conductor (due to the proximity effect) causes the inductance to decrease and resistance to increase. As we go higher in frequency, the edge and proximity effects become fully pronounced and will cause little additional change in R and L, but the skin effect becomes significant. Initially, the inductance is reduced due to skin effect because of the reduction of magnetic fields inside the conductors; but as the contribution of those magnetic fields to the overall inductance becomes insignificant, L becomes essentially constant at very high frequency. The resistance, on the other hand, becomes a direct function of the skin depth and therefore varies with the square root of the frequency.

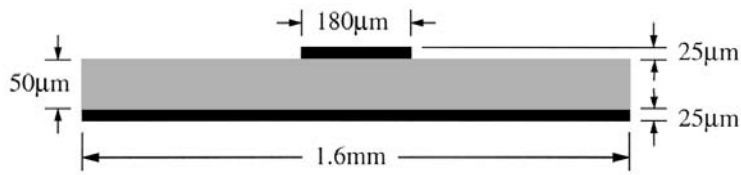

FIGURE 17.7 An interconnect over a ground plane.

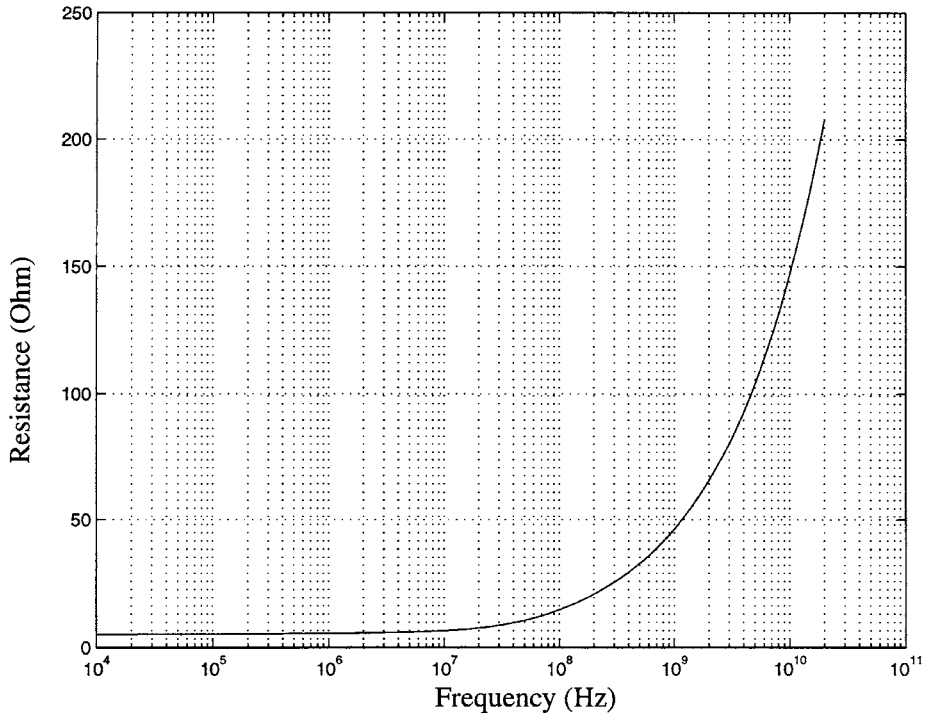

FIGURE 17.8 Frequency-dependent resistance.

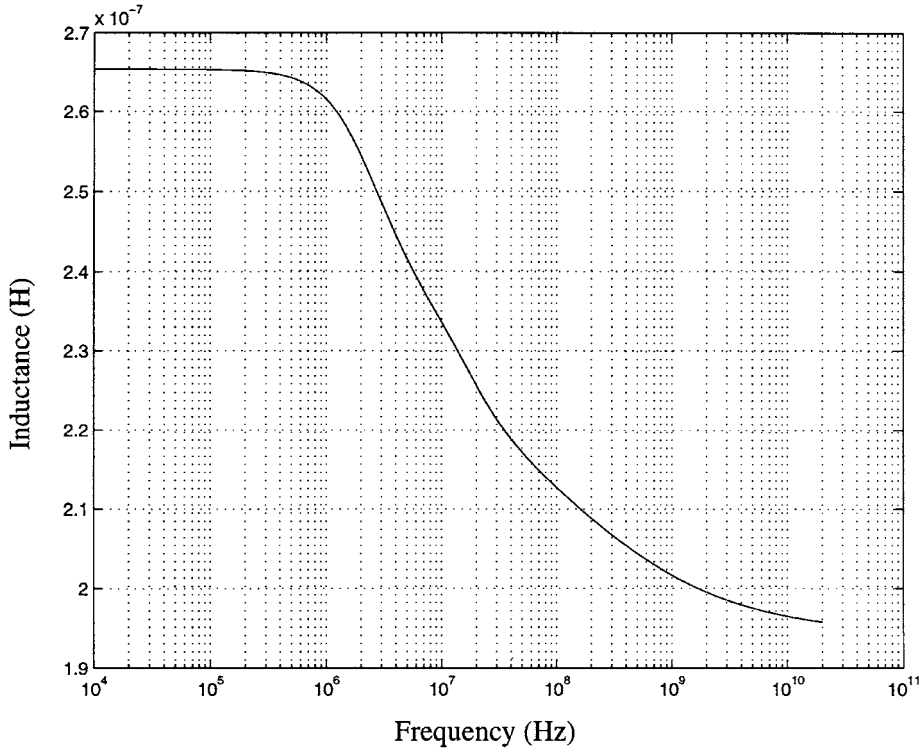

FIGURE 17.9 Frequency-dependent inductance.

Full-Wave Models

At further subnanosecond rise times, the line cross-section or the non-uniformities become a significant fraction of the wavelength and, under these conditions, the field components in the direction of propagation can no longer be neglected (Fig. 17.10). Consequently, even the distributed models based on quasi-TEM approximations become inaccurate in describing the interconnect performance.[12–19] In such situations, full-wave models, which take into account all possible field components and satisfies all boundary conditions, are required to give an accurate estimation of high-frequency effects.

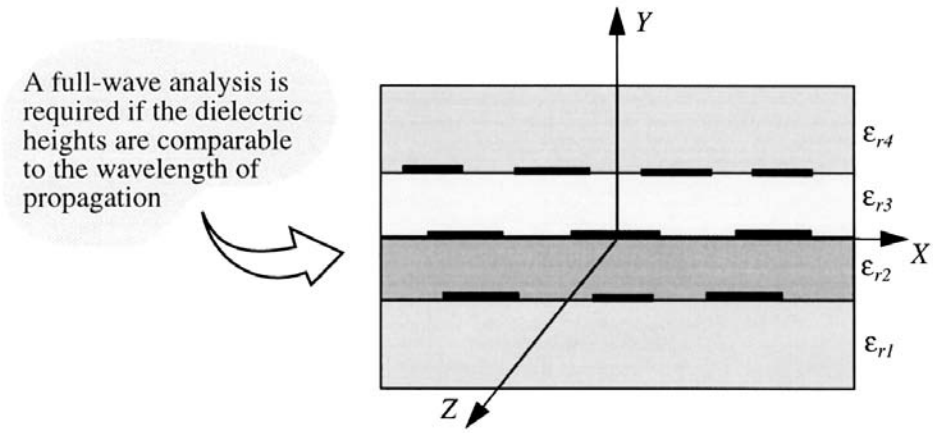

FIGURE 17.10 Cross-sectional view of a multiconductor dispersive system.

The information that is obtained through a full-wave analysis is in terms of field parameters such as propagation constant, characteristic impedance, etc. A typical behavior of the modal propagation constant and characteristic impedances obtained using the full-wave spectral domain method for the structure shown in Fig. 17.11 is given in Fig. 17.12. The deviation suffered by the quasi-TEM models with respect to full-wave results is illustrated through a simple test circuit shown in Fig. 17.13. As seen from Fig. 17.14 for the structure under consideration, quasi-TEM results deviated from full-wave results as early as 400 MHz. The differences in the modeling schemes with respect to the transient responses are illustrated in Fig. 17.15 and Fig. 17.16. *In general, an increase in the dielectric thickness causes quasi-TEM models to become inaccurate at relatively lower frequencies.* This implies that a full-wave analysis becomes necessary as we move up in the integration hierarchy, from the chip to PCB/system level. It is found that depending on the interconnect structure, when the cross-sectional dimensions approach 1/40 to 1/10 of the effective

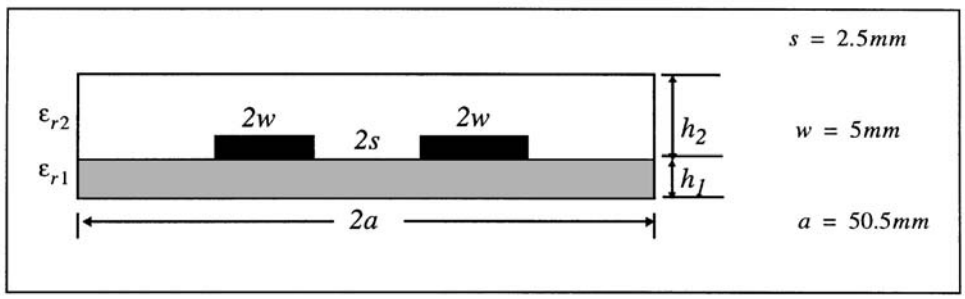

FIGURE 17.11 A coupled interconnect structure.

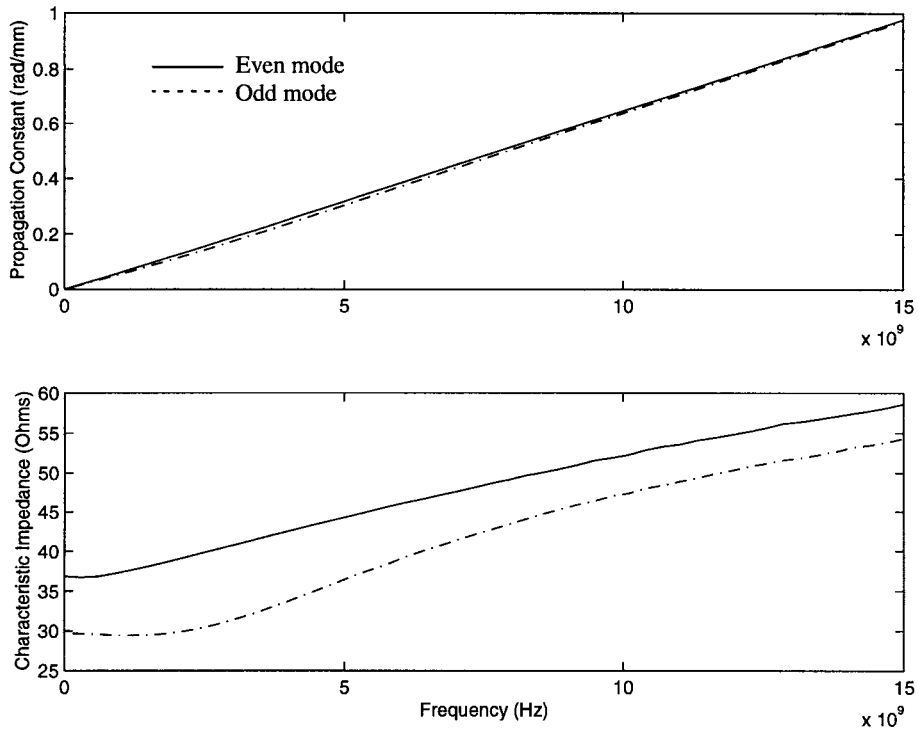

FIGURE 17.12 Modal propagation constans and charactersitic impedances.

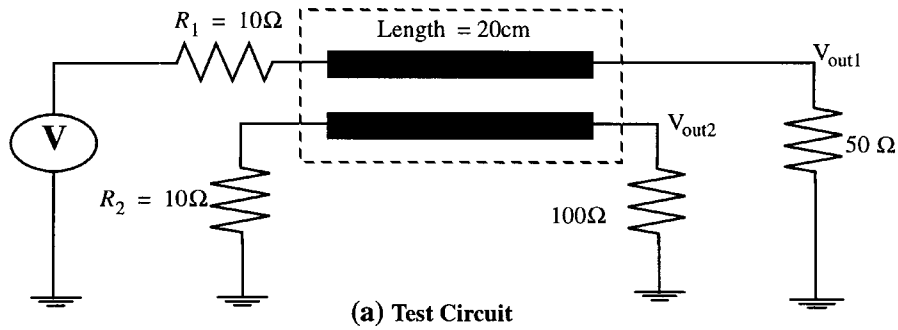

FIGURE 17.13 Test circuit for simulation of interconnect structure in Fig. 18.13.

wavelength, quasi-TEM approximation deviates considerably from full-wave results. (The effective wavelength of a wave propagating in a dielectric medium at a certain frequency is given by

$$\lambda_e = \frac{velocity\ of\ the\ wave}{frequency} = \frac{1/(\sqrt{\mu_r E_{effective}})}{f} \tag{17.9}$$

Also, a reduction in the separation width between adjacent conductors makes the full-wave analysis more essential, especially for crosstalk evaluation. The same is true with an increase in the dielectric constant values.

However, circuit simulation of full-wave models is highly involved. A circuit simulator requires the information in terms of currents, voltages, and circuit impedances. This demands a generalized method to combine modal results into circuit simulators in terms of a full-wave stencil. Another important issue involved here is the cost of a full-wave analysis associated with each interconnect subnetwork at each

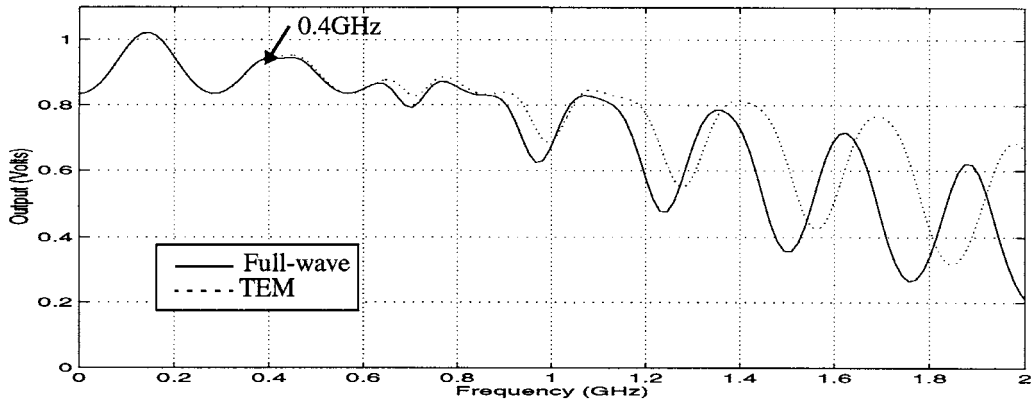

FIGURE 17.14 Comparison of full-wave and quasi-TEM frequency responses.

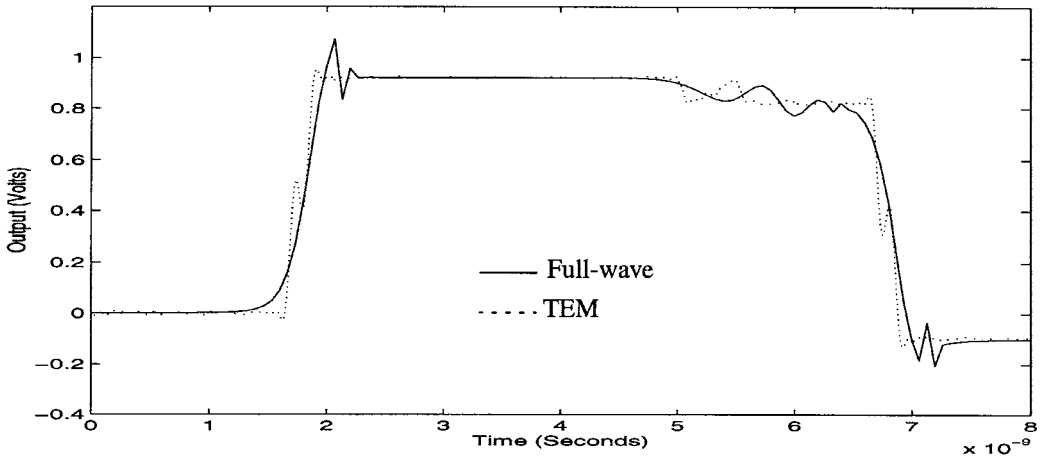

FIGURE 17.15 Comparison of full-wave and quasi-TEM transient responses at node V_{out1}.

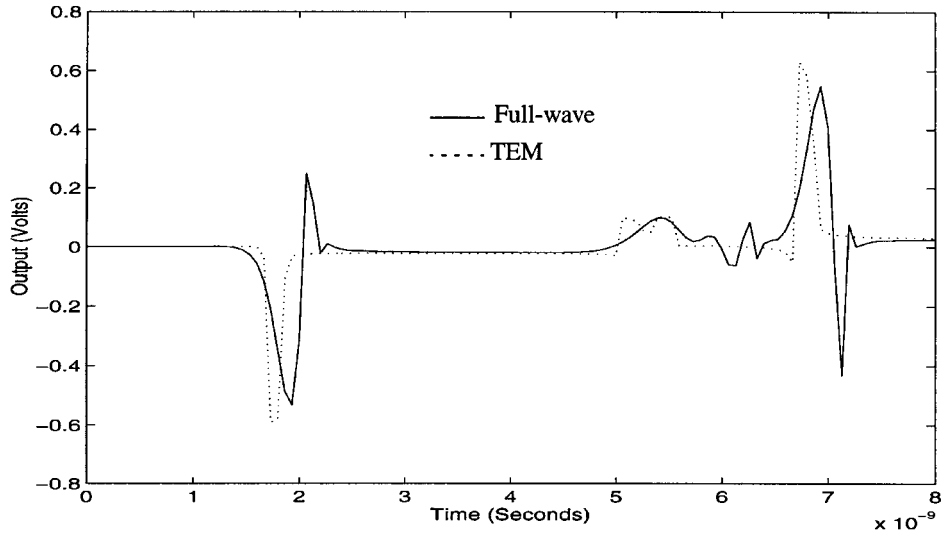

FIGURE 17.16 Comparison of full-wave and quasi-TEM crosstalk responses (node V_{out2}).

frequency point of analysis. For typical high-speed interconnect circuits which need thousands of frequency point solutions to get accurate responses, it would become prohibitively CPU-expensive to simulate because of the combined cost involved (i.e., evaluation of a full-wave model to obtain modal parameters and computation of circuit response at each point).

Measured Subnetworks

In practice, it may not be possible to obtain accurate analytical models for interconnects because of the geometric inhomogeneity and associated discontinuities. To handle such situations, modeling techniques based on measured data have been proposed in the literature.[22,24,59–65] In general, the behavior of high-speed interconnects can easily be represented by measured frequency-dependent scattering parameters or time-domain terminal measurements. Time-domain data could be obtained by time-domain reflectometry (TDR) measurements[59] or electromagnetic techniques.[23,24] One important factor to note here is that the subnetwork can be characterized by large sets of time-domain data, making the system overdetermined. This kind of measurement data in large number of sets is essential in a practical environment as the measurements are usually contaminated by noise, and the use of only a single set of measurements may lead to inaccurate results. Including all available sets of measurements in the simulation helps to reduce the impact of noise on network responses. However, handling such overdetermined situations in circuit simulation is a tedious and a computationally expensive process.[22]

EMI Subnetworks

Electrically long interconnects function as spurious antennas to pick up emissions from other nearby electronic systems. This makes susceptibility to emissions a major concern to current system designers of high-frequency products. Hence, the availability of interconnect simulation tools, including the effect of incident fields, is becoming an important design requirement. In addition, analysis of radiations from interconnects is also becoming increasingly important in high-furnace designs.[9,57,58]

17.3 Distributed Transmission Line Equations

Transmission line characteristics are in general described by Telegrapher's equations. Consider the multiconductor transmission line (MTL) system shown in Fig. 17.17. Telegrapher's equations for such a structure are derived by discretizing the lines into infinitesimal sections of length Δx and assuming uniform per-unit length parameters of resistance (R), inductance (L), conductance (G), and capacitance (C). Each section then includes a resistance $R\Delta x$, inductance $L\Delta x$, conductance $G\Delta x$, and capacitance $C\Delta x$ (Fig. 17.6). Using Kirchoff's current and voltage laws, one can write

$$v(x + \Delta x, t) = v(x, t) - R\Delta x i(x, t) - L\Delta x \frac{\partial}{\partial t} i(x, t) \tag{17.10}$$

or

$$\frac{v(x + \Delta x, t) - v(x, t)}{\Delta x} = -Ri(x, t) - L\frac{\partial}{\partial t} i(x, t) \tag{17.11}$$

Taking the limit $\Delta x \to 0$, one gets

$$\frac{\partial}{\partial x} v(x, t) = -Ri(x, t) - L\frac{\partial}{\partial t} i(x, t) \tag{17.12}$$

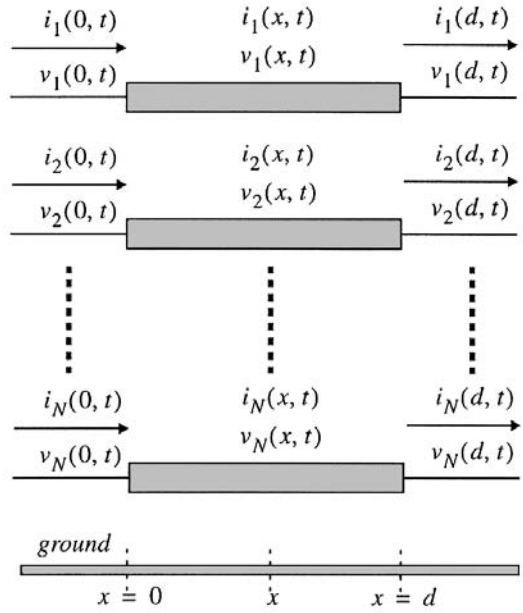

FIGURE 17.17 Multiconductor transmission line system.

Similarly for $i(x, t)$, one can write

$$\frac{\partial}{\partial x} i(x, t) = -Gv(x, t) - C\frac{\partial}{\partial t} v(x, t) \tag{17.13}$$

The equations for a single line also hold good for multiple coupled lines, with a modification that per-unit-length parameters now become matrices (R, L, G, and C) and voltage–current variables become vectors represented by V and I, respectively. Noting this and taking Laplace transform of Eqs. 17.12 and 17.13, one can write

$$\frac{\partial}{\partial x} \boldsymbol{V}(x, s) = -(\boldsymbol{R} + s\boldsymbol{L})\boldsymbol{I}(x, s) \tag{17.14}$$

$$\frac{\partial}{\partial x} \boldsymbol{I}(x, s) = -(\boldsymbol{G} + s\boldsymbol{C})\boldsymbol{V}(x, s) \tag{17.15}$$

Equations 17.14 and 17.15 can be written as

$$\frac{\partial}{\partial x} \boldsymbol{V}(x, s) = -\boldsymbol{Z}_P \boldsymbol{I}(x, s) \tag{17.16}$$

$$\frac{\partial}{\partial x} \boldsymbol{I}(x, s) = -\boldsymbol{Y}_P \boldsymbol{V}(x, s) \tag{17.17}$$

where $\boldsymbol{Z}_P$ and $\boldsymbol{Y}_P$ represent the impedance and admittance matrices, given by

$$\boldsymbol{Z}_P = \boldsymbol{R} + s\boldsymbol{L}; \qquad \boldsymbol{Y}_P = \boldsymbol{G} + s\boldsymbol{C} \tag{17.18}$$

Eigenvalue-Based Transmission Line Stencil

The two differential equations given in Eqs. 17.16 and 17.17 can be combined into a set of wave equations as

$$\frac{\partial}{\partial x^2}\boldsymbol{V}(x, s) = \boldsymbol{Z}_P\boldsymbol{Y}_P\boldsymbol{V}_P(x, s) \tag{17.19}$$

$$\frac{\partial}{\partial x^2}\boldsymbol{I}(x, s) = \boldsymbol{Y}_P\boldsymbol{Z}_P\boldsymbol{I}_P(x, s) \tag{17.20}$$

which will have a solution of the form

$$\boldsymbol{V}_m(x, s) = \boldsymbol{V}_m(0, s)e^{\pm\gamma_m(s)x} \tag{17.21}$$

$$\boldsymbol{I}_m(x, s) = \boldsymbol{I}_m(0, s)e^{\pm\gamma_m(s)x} \tag{17.22}$$

where $\gamma_m(s)$ is the complex propagation constant. Substituting the solution forms of Eqs. 17.21 and 17.22 into wave equation 17.19 yields

$$det\{\gamma_m^2\boldsymbol{U} - \boldsymbol{Z}_P\boldsymbol{Y}_P\}\,\boldsymbol{V}_m(0) = 0 \tag{17.23}$$

where $\boldsymbol{U}$ is an identity matrix. $\boldsymbol{V}_m(0)$ will have nontrivial solutions if γ_m^2 satisfies the eigenvalue problem given by

$$det\{\gamma_m^2\boldsymbol{U} - \boldsymbol{Z}_P\boldsymbol{Y}_P\} = 0 \tag{17.24}$$

For inhomogeneous dielectrics, there exist in general m distinct eigenvalues where $m = 1, 2, \ldots, N$. Each eigenvalue has its corresponding eigenvector S_m. Let Γ be a diagonal matrix whose elements are the complex propagation constants $\{\gamma_1, \gamma_2, \ldots, \gamma_N\}$. Let S_v be a matrix with eigenvectors S_m placed in respective columns. The transmission line stencil can now be derived after little manipulations as

$$\boldsymbol{P}\boldsymbol{V}(s) + \boldsymbol{Q}\boldsymbol{I}(s) = 0 \tag{17.25}$$

where

$$\boldsymbol{P} = \begin{bmatrix} \boldsymbol{S}_V\boldsymbol{E}_1\boldsymbol{S}_v^{-1} & -\boldsymbol{U} \\ \boldsymbol{S}_i\boldsymbol{E}_2\boldsymbol{S}_v^{-1} & \boldsymbol{0} \end{bmatrix}; \qquad \boldsymbol{Q} = \begin{bmatrix} \boldsymbol{S}_v\boldsymbol{E}_1\boldsymbol{S}_v^{-1} & \boldsymbol{0} \\ \boldsymbol{S}_i\boldsymbol{E}_2\boldsymbol{S}_i^{-1} & -\boldsymbol{U} \end{bmatrix} \tag{17.26}$$

$$\boldsymbol{E}_1 = diag\left\{\frac{e^{(-\gamma_m d)} + e^{(\gamma_m d)}}{2}\right\}; \qquad \boldsymbol{E}_2 = diag\left\{\frac{e^{(-\gamma_m d)} - e^{(\gamma_m d)}}{2}\right\} \tag{17.27}$$

where d is length of the line and $m = 1, 2, \ldots, N$. S_i is computed as $\boldsymbol{S}_i = \boldsymbol{Z}_P^{-1}\boldsymbol{S}_v\boldsymbol{\Gamma}$. V and I represent the Laplace-domain terminal voltage and current vectors of multiconductor transmission line, given by

$$\boldsymbol{V}(s) = \begin{bmatrix} \boldsymbol{V}(0) \\ \boldsymbol{V}(d) \end{bmatrix}; \qquad \boldsymbol{I}(s) = \begin{bmatrix} \boldsymbol{I}(0) \\ \boldsymbol{I}(d) \end{bmatrix} \tag{17.28}$$

The MTL stencil described by Eq. 17.25 is widely used in moment matching techniques (MMTs) for transmission line analysis.[38] Another form of MTL stencil is also quite popular and it has the matrix exponential form,[44] which is explained below.

Matrix Exponential Stencil

Equations 17.14 and 17.15 can be written in the hybrid form as

$$\frac{\partial}{\partial x}\begin{bmatrix} \boldsymbol{V}(x, s) \\ \boldsymbol{I}(x, s) \end{bmatrix} = (\boldsymbol{D} + s\boldsymbol{E})\begin{bmatrix} \boldsymbol{V}(x, s) \\ \boldsymbol{I}(x, s) \end{bmatrix} \tag{17.30}$$

where

$$\boldsymbol{D} = \begin{bmatrix} \boldsymbol{0} & -\boldsymbol{R} \\ -\boldsymbol{G} & \boldsymbol{0} \end{bmatrix}; \qquad \boldsymbol{E} = \begin{bmatrix} \boldsymbol{0} & -\boldsymbol{L} \\ -\boldsymbol{C} & \boldsymbol{0} \end{bmatrix} \tag{17.30}$$

Hybrid transmission line stencil in the exponential form can be written as

$$\begin{bmatrix} \boldsymbol{V}(d, s) \\ \boldsymbol{I}(d, s) \end{bmatrix} = e^{(\boldsymbol{D} + s\boldsymbol{E})d}\begin{bmatrix} \boldsymbol{V}(0, s) \\ \boldsymbol{I}(0, s) \end{bmatrix} \tag{17.31}$$

Parameters $\boldsymbol{P}$ and $\boldsymbol{Q}$ of the transmission line in Eq. 17.26 can also be computed making use of Eq. 17.31 as follows: Define $\boldsymbol{T}(s)$ as

$$\boldsymbol{T}(s) = \begin{bmatrix} \boldsymbol{T}_{11} & \boldsymbol{T}_{12} \\ \boldsymbol{T}_{21} & \boldsymbol{T}_{22} \end{bmatrix} = e^{(\boldsymbol{D} + s\boldsymbol{E})d} \tag{17.32}$$

Using Eq. 17.32 and rewriting Eq. 17.31 in the form of Eq. 17.26, we get

$$\boldsymbol{P} = \begin{bmatrix} -\boldsymbol{T}_{11} & \boldsymbol{U} \\ -\boldsymbol{T}_{21} & 0 \end{bmatrix} \qquad \boldsymbol{Q} = \begin{bmatrix} -\boldsymbol{T}_{12} & 0 \\ -\boldsymbol{T}_{22} & \boldsymbol{U} \end{bmatrix} \tag{17.33}$$

Distributed vs. Lumped: Number of Lumped Segments Required

It is often of practical interest to switch between distributed models and lumped representations. In this case, it is necessary to know approximately how many lumped segments are required to approximate a distributed model. For the purpose of illustration, consider LC segments, which can be viewed as low-pass filters. For a reasonable approximation, this filter must pass at least some multiples of the highest frequency content f_{max} of the propagating signal (say, ten times, $f_0 \geq 10f_{max}$). In order to relate these,[2,3] we make use of the 3-dB passband of the LC filter given by

$$f_0 = \frac{1}{\pi\sqrt{LdCd}} = \frac{1}{\pi\tau d} \tag{17.34}$$

where d is the length of the line. From Eq. 17.1, we have $f_{max} = 0.35/t_r$ and using Eq. 17.34, we can express the relation $f_0 \geq 10f_{max}$ in terms of the delay of the line and the rise time as

$$\frac{1}{\pi\tau d} \geq 10 \times 0.35 / t_r \tag{17.35}$$

or

$$t_r \geq 3.5(\pi\tau d) \approx 10\tau d \tag{17.36}$$

In other words, delay allowed per segment is $0.1t_r$. Hence, the total number of segments (N) required is given by

$$N = \frac{10\tau d}{t_r} \tag{17.37}$$

In the case of RLC segments, in addition to satisfying Eq. 17.36, the series resistance of each segment must also be accounted for. The series resistance *Rd* representing the ohmic drop should not lead to impedance mismatch, which can result in excessive reflection within the segment.[2,3]

Example

Consider a digital signal with rise time of 0.2 ns propagating on a lossless wire of length 10 cm, with a per unit delay of 70.7 ns. This can be represented by a distributed model with per unit length parameters of L = 5 nH/cm and C = 1 pF/cm. If the same circuit were to be represented by lumped segments, one needs $N = ((10 \times 70.7e^{-12} \times 10)/(0.2e^{-9})) = 35$ sections. It is to be noted that using more sections does not clean up ripples completely, but helps reduce the first overshoot (Gibb's phenomenon). Ripples are reduced when some loss is taken into account.

17.4 Interconnect Simulation Issues

As pointed out earlier, simulation of interconnects is associated with two major bottlenecks: mixed frequency/time problem and the CPU expense.

Mixed Frequency/Time Problem

The major difficulty in simulating these high-frequency models lies in the fact that distributed/full-wave elements, while formulated in terms of partial differential equations, are best described in the frequency domain. Non-linear terminations, on the other hand, can only be given in the time domain. These simultaneous formulations cannot be handled by a traditional ordinary differential equation solver such as SPICE.[8,38]

CPU Expense

In general, interconnect networks consist of hundreds or thousands of components, such as resistors, capacitors, inductors, transmission lines, and other levels of interconnect models. At the terminations, there generally exist some nonlinear elements such as drivers and receivers. If only lumped RLC models are considered, ordinary differential equation solvers such as SPICE may be used for simulation purposes. However, the CPU cost may be large, owing to the fact that SPICE is mainly a non-linear simulator and it does not handle large RLC networks efficiently.

Background on Circuit Simulation

Prior to introducing interconnect simulation algorithms, it would be useful to have a glimpse at the basic circuit simulation techniques. Conventional circuit simulators are based on the simultaneous solution of linear equations which are obtained by applying Kirchoff's current law (KCL) to each node in the network. Either for frequency- or time-domain analysis, the first step is to set up the *modified nodal analysis matrix (MNA)*.[68] For example, consider the small circuit in Fig. 17.18. Its MNA equations are

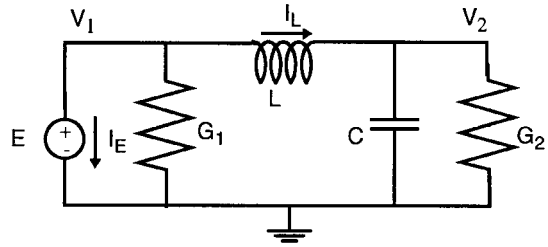

FIGURE 17.18 Example circuit for MNA formulation.

$$\left(\begin{bmatrix} G_1 & 0 & 1 & 1 \\ 0 & G_2 & -1 & 0 \\ 1 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix} + s \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & C & 0 & 0 \\ 0 & 0 & -L & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \right) \begin{bmatrix} V_1 \\ V_2 \\ I_L \\ I_E \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ E \end{bmatrix} \tag{17.38}$$

The above equation, representing a simple two-node circuit, has the same form as any other MNA matrix representing a large linear lumped network. Hence, MNA equations in general for lumped linear networks can be written as

$$(\boldsymbol{G} + s\boldsymbol{W})\boldsymbol{X}(s) - \boldsymbol{b} = \boldsymbol{0} \tag{17.39}$$

or, in the time domain, it can be written as

$$\boldsymbol{G}\boldsymbol{x}(t) + \boldsymbol{W}\dot{\boldsymbol{x}}(t) - \boldsymbol{b}(t) = \boldsymbol{0} \tag{17.40}$$

Discussion of CPU Cost in Conventional Simulation Techniques

Frequency-domain simulation is conventionally done by solving Eq. 17.39 at each frequency point through LU decomposition and forward-backward substitution. For time-domain simulation, linear multi-step techniques[69] are used. The most common of these integration formulas is the trapezoidal rule, which gives the following difference formula

$$\boldsymbol{x}(t + \Delta t) = \boldsymbol{x}(t) + \Delta t \left(\frac{\dot{\boldsymbol{x}}(t) + \dot{\boldsymbol{x}}(t + \Delta t)}{2} \right) \tag{17.41}$$

$$\left(\boldsymbol{G} + \frac{2}{\Delta t}\boldsymbol{W} \right) \boldsymbol{x}(t + \Delta t) = \left(\frac{2}{\Delta t}\boldsymbol{W} - \boldsymbol{G} \right) \boldsymbol{x}(t) + (\boldsymbol{b}(t) + \boldsymbol{b}(t + \Delta t)) \tag{17.42}$$

Note that the trapezoidal rule is an integration formula of order of 2, which is the highest possible order that could ensure absolute stability.[69] Due to such relatively low order, simulators are forced to use small step sizes to ensure the accuracy during transient simulation. Transient response computation requires the LU decomposition of Eq. 17.42 at every time step. It gets further complicated in the presence of nonlinear elements, in which case the Eq. 17.40 gets modified as

$$\boldsymbol{G}\boldsymbol{x}(t) + \boldsymbol{W}\dot{\boldsymbol{x}}(t) + \phi(\boldsymbol{x}(t)) - \boldsymbol{b}(t) = \boldsymbol{0} \tag{17.43}$$

where $\phi(\boldsymbol{x}(t))$ is a non-linear function of $\boldsymbol{x}$. The difference equation based on the trapezoidal rule therefore becomes

$$\left(\boldsymbol{G} + \frac{2}{\Delta t}\boldsymbol{W}\right)\boldsymbol{x}(t + \Delta t) + \phi(\boldsymbol{x}(t + \Delta t)) = \left(\frac{2}{\Delta t}\boldsymbol{W} - \boldsymbol{G}\right)\boldsymbol{x}(t) + (\boldsymbol{b}(t) + \boldsymbol{b}(t + \Delta t)) - \phi(\boldsymbol{x}(t)) \quad (17.44)$$

In the case of nonlinear elements, Newton iterations are used to solve Eq. 17.44, which requires two to three LU decompositions at each time step. This causes (note that W and G matrices for interconnect networks are usually very large) the CPU cost of a time-domain analysis to be very expensive. This led to the development of model-reduction algorithms, which effects a reduction in the order of the linear subnetwork before performing a non-linear analysis so as to yield fast simulation results.

Circuit Equations in the Presence of Distributed Elements

Now consider the general case in which the network ϕ also contains arbitrary linear subnetworks along with lumped components. The arbitrary linear subnetworks may contain lossy coupled transmission lines and also measured subnetworks. Let there be N_t lossy coupled transmission line sets, with n_a coupled conductors in the linear subnetwork a. Without loss of generality, the modified nodal admittance (MNA)[68,69] matrix for the network ϕ with an impulse input excitation can be formulated as

$$\boldsymbol{C}\frac{\partial}{\partial t}\boldsymbol{v}(t) + \boldsymbol{G}\boldsymbol{v}(t) + \sum_{a=1} \boldsymbol{D}_a \boldsymbol{i}_a(t) - \boldsymbol{b}\delta(t) = 0, \qquad t \in [0, T] \quad (17.45)$$

where:

- $\boldsymbol{D}_a = [d_{i,j}] \in \{0, 1\}$, where $i \in \{1, 2, \ldots, N_\phi\}$, $j \in \{1, 2, \ldots, 2n_a\}$ with a maximum of one non-zero in each row or column, is a selector matrix that maps $\boldsymbol{i}_a(t) \in \Re^{2n_a}$, the vector of terminal currents entering the transmission line subnetwork a, into the node space $\Re^N\phi$ of network ϕ.
- N_ϕ is the total number of variables in the MNA formulation.

Using the transmission line stencil given by Eq. 17.25 and taking the Laplace transform of Eq. 17.45 assuming zero initial conditions, one obtains

$$\begin{bmatrix} \boldsymbol{G} + s\boldsymbol{C} & \boldsymbol{D}_1 & \ldots & \boldsymbol{D}_{N_t} \\ \boldsymbol{P}_1\boldsymbol{D}_1^t & \boldsymbol{Q}_1 & \boldsymbol{0} & \boldsymbol{0} \\ \ldots & \boldsymbol{0} & \ldots & \boldsymbol{0} \\ \boldsymbol{P}_{N_t}\boldsymbol{D}_{N_t}^t & \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{Q}_{N_t} \end{bmatrix} \begin{bmatrix} \boldsymbol{V}(s) \\ \boldsymbol{I}_1(s) \\ \ldots \\ \boldsymbol{I}_{N_t}(s) \end{bmatrix} = \begin{bmatrix} \boldsymbol{b} \\ \boldsymbol{0} \\ \ldots \\ \boldsymbol{0} \end{bmatrix} \quad (17.46)$$

or

$$\boldsymbol{Y}(s)\boldsymbol{X}(s) = \boldsymbol{E} \quad (17.47)$$

$$\boldsymbol{X}(s) = [\boldsymbol{V}^t(s)\boldsymbol{I}_1^t(s), \boldsymbol{I}_2^t(s), \ldots, \boldsymbol{I}_{N_t}^t(s)]^t \quad (17.48)$$

$$\boldsymbol{E} = [\boldsymbol{b}^t\boldsymbol{0}^t \ldots \boldsymbol{0}^t] \quad (17.49)$$

Example

To illustrate the above formulation, consider the network shown in Fig. 17.19, which is a modified version of the previous example with introduction of a coupled transmission line. The network can be described by Eq. 17.46 as

$$\boldsymbol{G} + s\boldsymbol{C} = \begin{bmatrix} sC_1 + G_1 & 0 & 0 & 0 & 0 & 0 \\ 0 & G_2 & 0 & 0 & 0 & 0 \\ 0 & 0 & G_3 & 0 & -G_3 & 0 \\ 0 & 0 & 0 & sC_2 & 0 & 0 \\ 0 & 0 & -G_3 & 0 & G_3 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}; \qquad \boldsymbol{D}_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{17.50}$$

$$\boldsymbol{V}(s) = [V_1 \; V_2 \; V_3 \; V_4 \; V_5 \; I_e]^t \tag{17.51}$$

$$\boldsymbol{I}_1(s) = [I_a \; I_b \; I_c \; I_d]^t \tag{17.52}$$

$$\boldsymbol{b} = [0 \; 0 \; 0 \; 0 \; 0 e]^t \tag{17.53}$$

Conventional simulation methods obtain the frequency response of a circuit by solving Eq. 17.46 using LU decomposition and forward-backward substitution at various frequency points (usually thousands of points are required to get an accurate response over a desired frequency range). However, moment-matching techniques such as AWE extract the poles and residues of Eq. 17.46 using one LU decomposition only. The transfer function of the network and its frequent response can then be deduced from poles and residues. In addition to speeding up the simulation, MMTs provide a convenient way to handle mixed frequency/time simulation problem through macromodeling.

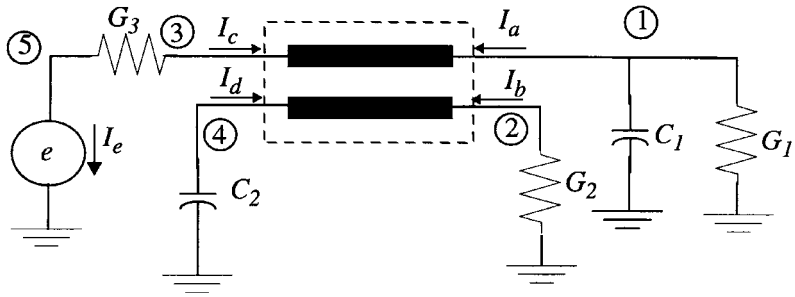

FIGURE 17.19 An example circuit containing transmission line components.

17.5 Interconnect Simulation Techniques

The main objective behind the interconnect simulation algorithms is to address the mixed frequency/time problem as well as ability to handle large linear circuits without too much CPU expense. There have been several algorithms proposed for this purpose, and they are discussed below.

Method of Characteristics

The method of characteristics transforms partial differential equations of a transmission line into ordinary differential equations.[28,29] Extensions to this method to allow it to handle lossy transmission

lines can also be found in the literature; for example, the iterative waveform relaxation techniques (IWR).[28,29] The method of characteristics is still used as one of the most practical techniques for simulation of lossless lines.

An analytical solution for Eqs. 17.21 and 17.22 was derived in Ref. 28 for two conductor lines which provides the Y parameters of the two-port transmission line network

$$\boldsymbol{I} = \boldsymbol{YV}; \qquad \begin{bmatrix} I_1 \\ I_2 \end{bmatrix} = \frac{1}{Z_0(1-e^{-2\gamma l})} \begin{bmatrix} 1+e^{-2\gamma l} & -2e^{-\gamma l} \\ -2e^{-\gamma l} & 1+e^{-2\gamma l} \end{bmatrix} \begin{bmatrix} V_1 \\ V_2 \end{bmatrix} \tag{17.54}$$

where γ is the propagation constant, and Z_0 is the characteristic impedance. V_1 and I_1 are the terminal voltage and current at the near end of the line, V_2 and I_2 are the terminal voltage and current at the far end of the line. The Y parameters of the transmission line are complex functions of s, and in most cases cannot be directly transformed into an ordinary differential equation in the time domain. The method of characteristics succeeded in doing such a transformation, but only for lossless transmission lines. Although this method was originally developed in the time domain using what was referred to as characteristic curves (hence, the name), a short alternative derivation in the frequency domain will be presented here. The frequency-domain approach gives more insight as to the limitations of this technique and possible solutions to those limitations.

By rearranging the terms in Eq. 17.54, we can write

$$\begin{aligned} V_1 &= Z_0 I_1 + W_{c1} \\ V_2 &= Z_0 I_2 + W_{c2} \end{aligned} \tag{17.55}$$

where W_{c1} and W_{c2} are defined as

$$\begin{aligned} W_{c1} &= e^{-\gamma l}[2V_2 - e^{-\gamma l}(Z_0 I_1 + V_1)] \\ W_{c2} &= e^{-\gamma l}[2V_1 - e^{-\gamma l}(Z_0 I_2 + V_2)] \end{aligned} \tag{17.56}$$

Using Eqs. 17.55 and 17.56, a recursive relation for W_{c1} and W_{c2} can be obtained as

$$\begin{aligned} W_{c1} &= e^{-\gamma l}[2V_2 - W_{c2}] \\ W_{c2} &= e^{-\gamma l}[2V_1 - W_{c1}] \end{aligned} \tag{17.57}$$

A lumped model of the transmission line can then be deduced from Eqs. 17.55 and 17.56, as shown in Fig. 17.20. If the lines were lossless (in which case the propagation constant is purely imaginary; $\gamma = j\beta$), the frequency-domain expression (Eq. 17.57) can be analytically converted into time domain using inverse Laplace transform as

$$\begin{aligned} w_{c1}(t+\tau) &= 2v_2(t) - w_{c2}(t) \\ w_{c2}(t+\tau) &= 2v_1(t) - w_{c1}(t) \end{aligned} \tag{17.58}$$

where $e^{-j\beta}$ is replaced by a time shift (or delay). Each transmission line can therefore be modeled by two impedances and two voltage-controlled voltage sources with time delay. While this transmission line model is in the time domain and can be easily linked to time-domain circuit simulation, the time shift affects the stability of the integration formula and causes the step size to significantly decrease, therefore increasing the CPU time. For lossy lines, the propagation constant is not purely imaginary and can therefore not be replaced by a pure delay. In that case, analytical expressions for w_{c1} and w_{c2} cannot be

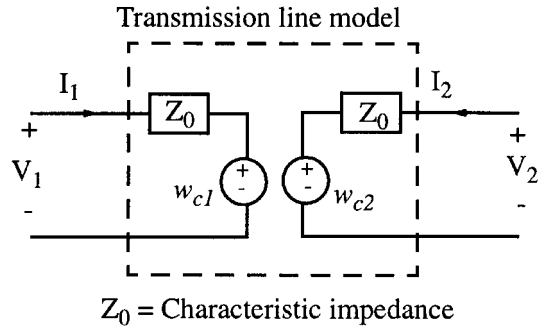

FIGURE 17.20 Macromodel using method of characteristics.

found in the time domain, although some numerical techniques were proposed (e.g., the iterative waveform relaxation techniques (IWR)).[28]

Recently, there have been several publications based on approximating the frequency characteristics of transmission-line equations using rational polynomials.[27] Analytical techniques to directly convert partial differential equations into time-domain macromodels based on Padé rational approximations of exponential matrices have also been reported.[26]

Moment-Matching Techniques

Interconnect networks generally tend to have large number of poles, spread over a wide frequency range. Although the majority of these poles would normally have very little effect on simulation results, they make the simulation CPU extensive by forcing the simulator to take smaller step sizes.

Dominant Poles

Dominant poles are those that are close to the imaginary axis and significantly influence the time as well as the frequency characteristics of the system. The moment-matching techniques (MMTs)[34–67] capitalize on the fact that, irrespective of the presence of large number of poles in a system, only the dominant poles are sufficient to accurately characterize a given system. This effect is demonstrated in Fig. 17.21, where it is clear that pole P_2 will have little effect on the final transient result.

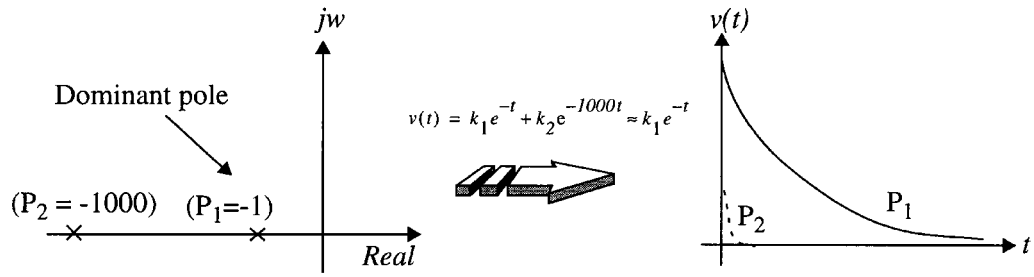

FIGURE 17.21 Summary of the steps involved in the MMT algorithm.

A brief mathematical description of the underlying concepts of moment-matching techniques is given below. Consider a single input/single output system and let $H(s)$ be the transfer function. $H(s)$ can be represented in a rational form as

$$H(s) = \frac{P(s)}{Q(s)} \tag{17.59}$$

where $P(s)$ and $Q(s)$ are polynomials in s. Equivalently, Eq. 17.59 can be written as

$$H(s) = c + \sum_{i=0}^{N_p} \frac{k_i}{s - p_i} \tag{17.60}$$

where P_i and k_i are the ith pole-residue pair, N_p is the total number of system poles, and c is the direct coupling constant. Next, the time-domain impulse response can be computed in a closed form using inverse Laplace transform as

$$h(t) = c\delta t + \sum_{i=0}^{N_p} k_i e^{p_i t} \tag{17.61}$$

In the case of large networks, N_p, the total number of poles can be of the order of thousands. Generating all the N_p poles will be highly CPU intensive even for a small network; and for large networks, it is completely impractical. MMTs address the above issue by deriving a reduced-order approximation $\hat{H}(s)$ in terms of dominant poles, instead of trying to compute all the poles of a system. Assuming that only L dominant poles were extracted which give a reasonably good approximation to the original system, Eq. 17.59 and the corresponding approximate frequency and time responses can be written as

$$H(s) \approx \hat{H}(s) = \frac{\hat{P}(s)}{\hat{Q}(s)} = \hat{c} + \sum_{i=0}^{L} \frac{\hat{k}_i}{s - \hat{p}_i} \tag{17.62}$$

$$h(t) \approx \hat{h}(t) = \hat{c}\delta t + \sum_{i=0}^{L} \hat{k}_i e^{\hat{p}_i t} \tag{17.63}$$

MMTs are based on the Padé approximation, and the steps involved in generating a reduced-order model using Padé approximation are outlined below.

Padé Approximations

Consider a system-transfer function $H(s)$ which is approximated by a rational function $\hat{H}(s)$ as

$$H(s) \approx \hat{H}(s) = \frac{a_0 + a_1 s + a_2 s^L + \ldots + a_L s^L}{1 + b_1 s + \ldots + b_M s^M} = \frac{P_L(s)}{Q_M(s)} \tag{17.64}$$

where $a_0, \ldots, a_L, b_1, \ldots, b_M$ are the unknowns (total of $L + M$ variables). Next, expanding $H(s)$ using Taylor series coefficients M_i (moments), we have

$$H(s) \approx \hat{H}(s) = m_0 + m_1 s + m_2 s^2 + \ldots + m_n s^n = \sum_{i=0}^{n} s^i m_i \tag{17.65}$$

The series in Eq. 17.65 is then matched to the lower-order rational polynomial given by Eq. 17.64; hence, the name moment-matching techniques (MMTs), also known as Padé approximation). There are $L + M$ unknowns and hence we need to match only the first $L + M$ moments as

$$\frac{a_0 + a_1 s + a_2 s^L + \ldots + a_L s^L}{1 + b_1 s + \ldots + b_M s^M} = m_0 + m_1 s + m_2 s^2 + \ldots + m_{(L+M)} s^{L+M} \tag{17.66}$$

Cross-multiplying and equating the powers of s starting from s^{L+1} to s^{L+M} on both sides of Eq. 17.66, we can evaluate the denominator polynomial coefficients as

$$\begin{bmatrix} m_{L-M+1} & m_{L-M+2} & \ldots & m_L \\ m_{L-M+2} & \ldots & \ldots & m_{L+1} \\ \ldots & \ldots & \ldots & \ldots \\ m_L & m_{L+1} & \ldots & m_{L+M-1} \end{bmatrix} \begin{bmatrix} b_M \\ b_{M-2} \\ \ldots \\ b_1 \end{bmatrix} = - \begin{bmatrix} m_{L+1} \\ m_{L+2} \\ \ldots \\ m_{L+M} \end{bmatrix} \tag{17.67}$$

The numerator coefficients can then be found by equating the remaining powers of s, starting from s^0 to s^L as

$$\begin{aligned} a_0 &= m_0 \\ a_1 &= m_1 + b_1 m_0 \\ &\ldots \\ a_L &= m_L + \sum_{i=1}^{min(L,M)} b_i m_{L-i} \end{aligned} \tag{17.68}$$

Equations 17.67 and 17.68 yield an approximate transfer function in terms of rational polynomials. Alternatively, an equivalent pole-residue model can be found as follows. Poles p_i are obtained by applying a root-solving algorithm on denominator polynomial $\hat{Q}(s)$. In order to obtain k_i, expand the approximate transfer function given by Eq. 17.62 using Maclaurin series as

$$\hat{H}(s) = \hat{c} - \sum_{n=0}^{\infty} s^n \left(\sum_{i=0}^{\tilde{} } \frac{\hat{k}_i}{\hat{p}_i^{n+1}} \right) \tag{17.69}$$

Comparing $\hat{H}(s)$ from Eqs. 17.65 and 17.69, we note that

$$\begin{aligned} m_0 &= \hat{c} - \sum_{i=0}^{L} \frac{\hat{k}_i}{\hat{p}_i} \\ &\ldots \quad (0 < i < 2L) \\ m_i &= -\sum_{i=0}^{L} \frac{\hat{k}_i}{\hat{p}_i^{i+1}} \end{aligned} \tag{17.70}$$

Residues can be evaluated by writing the equations in Eq. 17.70 in a matrix form as

$$\begin{bmatrix} \hat{p}_1^{-1} & \hat{p}_2^{-1} & & \hat{p}_L^{-1} & -1 \\ \hat{p}_1^{-2} & \hat{p}_2^{-2} & & \hat{p}_L^{-2} & 0 \\ & & \ldots & & \\ & & \ldots & & \\ \hat{p}_1^{-L-1} & \hat{p}_2^{-L-1} & & \hat{p}_L^{-L-1} & 0 \end{bmatrix} \begin{bmatrix} \hat{k}_1 \\ \hat{k}_2 \\ \ldots \\ \hat{k}_L \\ \hat{c} \end{bmatrix} = - \begin{bmatrix} M_0 \\ M_1 \\ \ldots \\ M_{L-1} \\ M_L \end{bmatrix} \tag{17.71}$$

In the above equations, $\hat{c}$ represents the direct coupling between input and output. There are more exact ways to compute $\hat{c}$ which are not detailed here; interested readers can refer to Ref. 35.

Computation of Moments

Having outlined the concept of MMTs, to proceed further, we need to evaluate the moments of the system. Consider the circuit equation represented by Eq. 17.46 and expand the response vector $\boldsymbol{X}(s)$ using Taylor series as

$$\boldsymbol{X}(s) = \boldsymbol{M_0} + \boldsymbol{M_1}s + \boldsymbol{M_2}s^2 + \ldots + \boldsymbol{M_n}s^n = \sum_{i=0}^{n} s^i \boldsymbol{M_i} \tag{17.72}$$

where $\boldsymbol{M_i}$ represents the ith moment-vector. For the purpose of illustration, consider the simple case of network with only lumped models. In this case, the network can be represented in the form Eq. 17.39 as

$$[\boldsymbol{G} + s\boldsymbol{C}][\boldsymbol{X}(s)] = [\boldsymbol{E}] \tag{17.73}$$

or

$$[\boldsymbol{G} + s\boldsymbol{C}][\boldsymbol{M_0} + \boldsymbol{M_1}s + \boldsymbol{M_2}s^2 + \ldots] = [\boldsymbol{E}] \tag{17.74}$$

Equating powers of s on both sides of Eq. 17.74, we obtain the following relationships

$$\begin{aligned} \boldsymbol{G}\boldsymbol{M_0} &= \boldsymbol{E} \\ \boldsymbol{G}\boldsymbol{M_i} &= -\boldsymbol{C}\boldsymbol{M_{i-1}} \qquad i > 0 \end{aligned} \tag{17.75}$$

The above equations give a closed form relationship for the computation of moments. The moments of a particular output node of interest (which are represented by m_i in Eqs. 17.65 to 17.71), are picked from moment-vectors $\boldsymbol{M_i}$. As seen, Eq. 17.75 requires only one LU decomposition and few forward-backward substitutions during the recursive computation of higher-order moments. Since the major cost involved in circuit simulation is due to LU decomposition, MMTs yield very high speed advantage (100 to 1000 times) compared to conventional simulators.

Generalized Computation of Moments

In the case of networks containing transmission lines and measured subnetworks, moment computation is not straightforward. A generalized relation for recursive computation of higher-order moments at an expansion point $s = \alpha$ can be derived[44] using Eq. 17.46 as:

$$\begin{aligned} [\Psi(\alpha)]\boldsymbol{M}_0 &= E \\ [\Psi(\alpha)]\boldsymbol{M}_n &= -\sum_{r=1}^{n} \frac{(\Psi^{(r)}\big|_{s=\alpha})\boldsymbol{M}_{n-r}}{r!} \end{aligned} \tag{17.76}$$

where the superscript r denotes the rth derivative at $s = \alpha$. It can be seen that the coefficient on the left-hand side does not change during higher-order moment computation and, hence, only one LU decomposition would suffice. It is also noted that the lumped networks are a special case of Eq. 18.76 (where $\Psi^{(r)} = 0$ for $r \geq 2$, in which case Eq. 17.76 reduces to the form given by Eq. 17.75).

Having obtained a recursive relationship Eq. 17.76 for higher-order moments, in order to proceed further, we need the derivatives of (Ψ). The derivatives $\boldsymbol{A_d}^{(r)}$ and $\boldsymbol{B_d}^{(r)}$ corresponding to transmission lines can be computed using the matrix exponential-based method.[34,38] Efficient techniques for computation of moments of transmission lines with frequency-dependent parameters,[56] full-wave,[12] and measured subnetworks[63,65] can also be found in the literature.

Computation of Time-Domain Macromodel

Once a pole-residue model describing the interconnect network is obtained, a time-domain realization in the form of state-space equations can be obtained as[39–41,75,76]:

$$\begin{aligned} \frac{d}{dt}[\boldsymbol{z}_\pi(t)] - [\boldsymbol{A}_\pi][\boldsymbol{z}_\pi(t)] - [\boldsymbol{B}_\pi][\boldsymbol{i}_\pi(t)] &= \mathbf{0} \\ [\boldsymbol{v}_\pi(t)] - [\boldsymbol{C}_\pi][\boldsymbol{z}_\pi(t)] + [\boldsymbol{D}_\pi][\boldsymbol{i}_\pi(t)] &= \mathbf{0} \end{aligned} \tag{17.77}$$

where i_π and v_π are the vectors of terminal currents and voltages of the linear subnetwork π. Using standard non-linear solvers or any of the general-purpose circuit simulators, the unified set of differential equations represented by Eq. 17.77 can be solved to yield unified transient solutions for the entire non-linear circuit consisting of high-frequency interconnect subnetworks. For those simulators (such as HSPICE) that do not directly accept the differential equations as input, the macromodel represented by Eq. 17.77 can be converted to an equivalent subcircuit, and is described in the next section. Figure 17.22 summarizes the computational steps involved in the MMT algorithm.

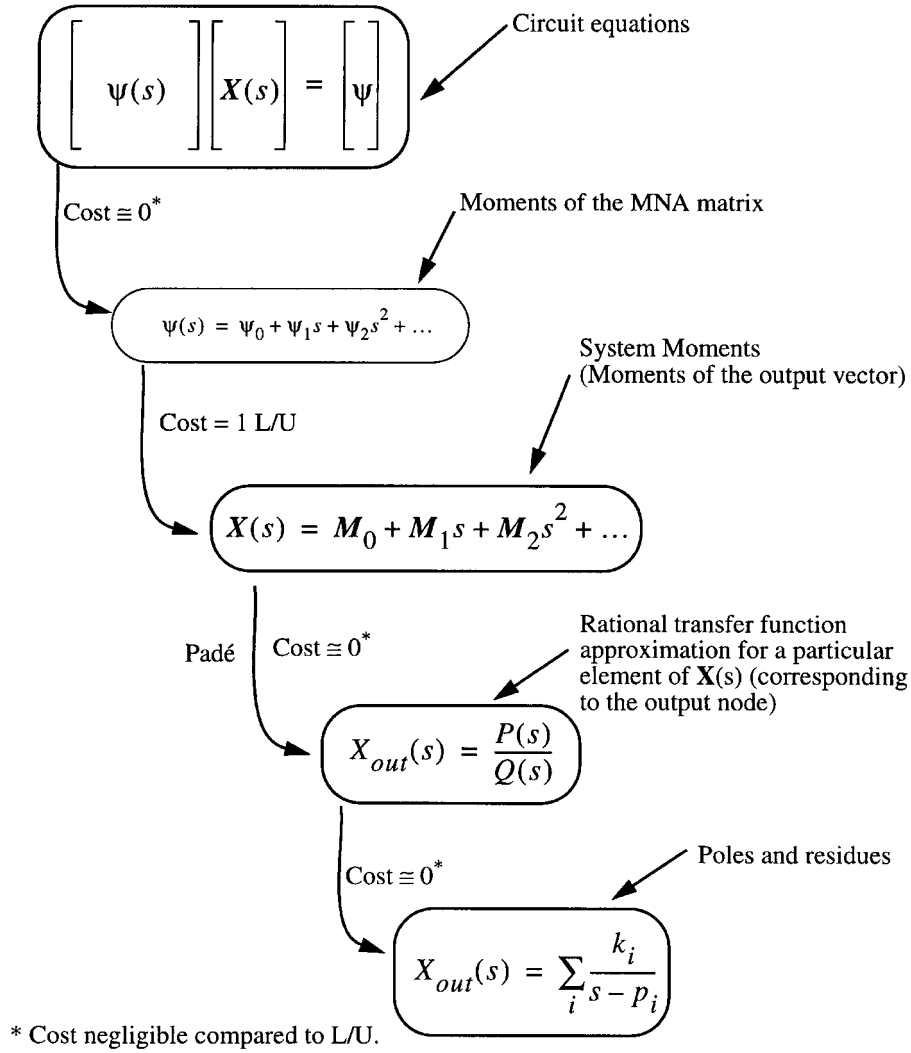

FIGURE 17.22 Summary of the steps involved in the MMT algorithm.

Limitations of Single-Expansion MMT Algorithms

Obtaining a lower-order approximation of the network transfer function using a single Padé expansion is commonly referred as *asymptotic waveform evaluation (AWE)* in the literature. However, due to the inherent limitations of Padé approximants, MMTs based on single expansion often give inaccurate results. The following is a list of those properties that have the most impact on MMTs.

- The matrix in Eq. 17.67 (which is known as Toeplitz matrix) is ill-conditioned if its size is large. This implies that we can only expect to detect six to eight accurate poles from a single expansion.
- Padé often produces unstable poles on the right-hand side of the complex plane.
- Padé accuracy deteriorates as we move away from the expansion point.
- Padé provides no estimates for error bounds.

Generally, AWE gives accurate results for RC networks, but often fails for non-RC networks. This is due to the fact that the poles of an RC network are all on the real axis and therefore an expansion at the origin could clearly determine which ones are dominant and which ones are not. However, in the case of general RLC networks, it is possible to have some of the dominant poles outside the radius of convergence of the Padé expansion. In systems containing distributed elements, the number of dominant poles will be significantly higher, and it is very difficult to capture all with a single Padé expansion.

In addition, there is no guarantee that the reduced-model obtained as above is passive. Passivity implies that a network cannot generate more energy than it absorbs, and no passive termination of the network will cause the system to go unstable.[70–73] The loss of passivity can be a serious problem because transient simulations of reduced networks may encounter artificial oscillations.

Recent Advances in Moment-Matching Techniques

In order to address the above difficulties, recent research in the circuit simulation area has focused on arriving at compact, accurate, as well as passive macromodels for high-speed interconnects. The problem of accuracy is addressed using multi-point expansion techniques such as *complex frequency hopping (CFH)*.[44–46] Also, in order to enhance the accuracy range of an approximation at a given expansion and to reduce the number of hops, several techniques based on Krylov-space formulations are developed.[47–55] Also, efficient schemes based on congruent transformation for preservation of passivity during the reduction of interconnect networks is available in the literature.[47–55] For further readings, interested readers can look at the recent proceedings of ICCAD, DAC, or IEEE transactions on computer-aided design of ICs (T-CAD), circuits and systems (T-CAS), and microwave theory and techniques (T-MTT).

Acknowledgments

The authors wish to thank and acknowledge the help and contributions provided by Roni Khazaka of Carlton University while preparing the section about frequency-dependent parameters.

Power Simulation and Estimation in VLSI Circuits

Massoud Pedram
University of Southern California

18.1 Introduction

In the past, the major concerns of the designer were area, speed, and cost. Power consideration was typically of secondary importance. In recent years, however, this has begun to change and, increasingly, power is being given comparable weight to other design considerations. Several factors have contributed to this trend. Perhaps the primary driving factor has been the remarkable success and growth of the class of personal computing devices (portable desktops, audio- and video-based multimedia products) and wireless communications systems (personal digital assistants and personal communicators), which demand high-speed computation and complex functionality with low power consumption. There also exists a strong pressure for producers of high-end products to reduce their power consumption to reduce the packaging and cooling costs and improve product reliability.

When the target is a low-power application, the search for the optimal solution must include, at each level of abstraction, a "design improvement loop." In such a loop, a power analyzer/estimator ranks the various design, synthesis, and optimization options and thus helps in selecting the one that is potentially more effective from the power standpoint. Obviously, collecting the feedback on the impact of the different choices on a level-by-level basis, instead of just at the very end of the flow (i.e., at the gate level), enables a shorter development time. On the other hand, this paradigm requires the availability of power simulators and estimators, as well as synthesis and optimization tools, that provide accurate and reliable results at various levels of abstraction.

It was pointed out that the availability of level-by-level power analysis and estimation tools that are able to provide fast and accurate results is key for increasing the effectiveness of automatic design frameworks organized. We start this chapter, with a concise description of techniques for software-level estimation (Section 18.2). We then move to the behavioral level (Section 18.3), where we discuss existing power estimation approaches that rely on information-theoretic, complexity-based, and synthesis-based models. Finally, we focus our attention on designs described at the RT-level (Section 18.4). This is the area where most of the research activity on power modeling and estimation has been concentrated in recent years; we cover two of the most investigated classes of methods: namely, regression-based models and sampling-based models. Finally, we move to the gate-level power estimation (Section 18.5), where we discuss existing dynamic power estimation approaches that rely on statistical sampling and probabilistic compaction, as well as probability-based signal propagation schemes.

This chapter may be supplemented with other surveys on the topic, including Refs. 1 through 4.

18.2 Software-Level Power Estimation

The first task in the estimation of power consumption of a digital system is to identify the typical application programs that will be executed on the system. A non-trivial application program consumes millions of machine cycles, making it nearly impossible to perform power estimation using the complete program at, say, the RT-level. Most of the reported results are based on *power macro-modeling*, an estimation approach which is extensively used for behavioral and RT-level estimation (see Sections 18.3 and 18.4).

In Ref. 5, the power cost of a CPU module is characterized by estimating the average capacitance that would switch when the given CPU module is activated. In Ref. 6, the switching activities on (address, instruction, and data) buses are used to estimate the power consumption of the microprocessor. In Ref. 7, based on actual current measurements of some processors, Tiwari et al. present the following instruction-level power model:

$$Energy_p = \sum_i (BC_i N_i) + \sum_{i,j} (SC_{i,j} N_{i,j}) + \sum_k OC_k \qquad (18.1)$$

where $Energy_p$ is the total energy dissipation of the program which is divided into three parts. The first part is the summation of the base energy cost of each instruction (BC_i is the base energy cost and N_i is the number of times instruction i is executed). The second part accounts for the circuit state ($SC_{i,j}$ is the energy cost when instruction i is followed by j during the program execution). Finally, the third part accounts for energy contribution OC_k of other instruction effects such as stalls and cache misses during the program execution.

In Ref. 8, Hsieh et al. present a new approach, called *profile-driven program synthesis*, to perform RT-level power estimation for high-performance CPUs. Instead of using a macro-modeling equation to model the energy dissipation of a microprocessor in such a way that the resulting instruction trace behaves (in terms of performance and power dissipation) much the same as the original trace. The new instruction trace is however much shorter than the original one, and can hence be simulated on an RT-level description of the target microprocessor to provide the lower dissipation results quickly.

Specifically, this approach consists of the following steps:

1. Perform architectural simulation of the target microprocessor under the instruction trace of typical application programs.
2. Extract a *characteristic profile*, including parameters such as the instruction mix, instruction/data cache miss rates, branch prediction miss rate, pipeline stalls, etc., for the microprocessor.
3. Use mixed-integer linear programming and heuristic rules to gradually transform a generic program template into a fully functional program.
4. Perform RT-level simulation of the target microprocessor under the instruction trace of the new synthesized program.

Notice that the performance of the architectural simulator in gate-vectors/second is roughly 3 to 4 orders of magnitude higher than that of an RT-level simulator.

This approach has been applied to the Intel Pentium processor (which is a super-scalar pipelined CPU with 8-KB 2-way set-associative data, instruction and data caches, branch prediction, and dual instruction pipeline) demonstrating 3 to 5 orders of magnitude reduction in the RT-level simulation time with negligible estimation error.

18.3 Behavioral-Level Power Estimation

Conversely from some of the RT-level methods that will be discussed in Section 18.4, estimation techniques at the behavioral level cannot rely on information about the gate-level structure of the design components, and hence, must resort to abstract notions of physical capacitance and switching activity to predict power dissipation in the design.

Information-Theoretic Models

Information theoretic approaches for high-level power estimation[9,10] depend on information-theoretic measures of activity (e.g., entropy) to obtain quick power estimates.

Entropy characterizes the randomness or uncertainty of a sequence of applied vectors and thus it is intuitively related to switching activity; that is, if the signal switching is high, it is likely that the bit sequence is random, resulting in high entropy. Suppose the sequence contains t distinct vectors and let p_i denote the occurrence probability of any vector v in the sequence. Obviously, $\sum_{i=1}^{t} p_i = 1$. The entropy of the sequence is given by:

$$h = -\sum_{i=1}^{t} p_i \log p_i \tag{18.2}$$

where log x denotes the base 2 logarithm of x. The entropy achieves its maximum value of log t when $p_i = 1/t$. For an n-bit vector, $t \leq 2^n$. This makes the computation of the exact entropy very expensive. Assuming that the individual bits in the vector are independent, then we can write:

$$h = -\sum_{i=1}^{n} (q_i \log q_i + (1 - q_i)\log(1 - q_i)) \tag{18.3}$$

where q_i denotes the signal probability of bit i in the vector sequence. Note that this equation is only an upperbound on the exact entropy, since the bits may be dependent. This upperbound expression is, however, the one that is used for power estimation purposes. Furthermore, in Ref. 9, it has been shown that, under the temporal independence assumption, the average switching activity of a bit is upper-bounded by one half of its entropy. The power dissipation in the circuit can be approximated as:

$$Power = 0.5 V^2 f C_{tot} E_{avg} \tag{18.4}$$

where C_{tot} is the total capacitance of the logic module (including gate and interconnect capacitances) and E_{avg} is the average activity of each line in the circuit which is, in turn, approximated by one half of its average entropy, h_{avg}. The average line entropy is computed by abstracting information obtained from a gate-level implementation. In Ref. 10, it is assumed that the word-level entropy per logic level reduces quadratically from circuit inputs to circuit outputs, whereas in Ref. 9, it is assumed that the bit-level entropy from one logic level to next decreases in an exponential manner. Based on these assumptions, two different computational models are obtained.

In Ref. 9, Marculescu et al. derive a closed-form expression for the average line entropy for the case of a linear gate distribution; that is, when the number of nodes scales linearly between the number of circuit inputs, n, and circuit outputs, m. The expression for h_{avg} is given by:

$$h_{avg} = \frac{2nh_{in}}{(n+m)\ln\frac{h_{in}}{h_{out}}}\left(1 - \frac{m}{n}\frac{h_{out}}{h_{in}} - \frac{\left(1-\frac{m}{n}\right)\left(1-\frac{h_{out}}{h_{in}}\right)}{\ln\frac{h_{in}}{h_{out}}}\right) \tag{18.5}$$

where h_{in} and h_{out} denote the average bit-level entropies of circuit inputs and outputs, respectively. h_{in} is extracted from the given input sequence, whereas h_{out} is calculated from a quick functional simulation of the circuit under the given input sequence or by empirical entropy propagation techniques for precharacterized library modules. In Ref. 10, Nemani and Najm propose the following expression for h_{avg}:

$$h_{avg} = \frac{2}{3(n+m)}(H_{in} + H_{out}) \tag{18.6}$$

where H_{in} and H_{out} denote the average sectional (word-level) entropies of circuit inputs and outputs, respectively. The sectional entropy measures H_{in} and H_{out} may be obtained by monitoring the input and output signal values during a high-level simulation of the circuit. In practice, however, they are approximated as the summation of individual bit-level entropies, h_{in} and h_{out}.

If the circuit structure is given, the total module capacitance is calculated by traversing the circuit netlist and summing up the gate loadings. Wire capacitances are estimated using statistical wire load models. Otherwise, C_{tot} is estimated by quick mapping (e.g., mapping to 3-input universal gates) or by information theoretic models that relate the gate complexity of a design to the difference of its input and output entropies. One such model proposed by Cheng and Agrawal,[11] for example, estimates C_{tot} as:

$$C_{tot} = \frac{m}{n}2^n h_{out} \tag{18.7}$$

This estimate tends to be too pessimistic when n is large; hence, Ferrandi et al.[12] present a new total capacitance estimate based on the number N of nodes (i.e., 2-to-1 multiplexers) in the *Ordered Binary Decision Diagrams* (OBDD)[13] representation of the logic circuit as follows:

$$C_{tot} = \alpha\frac{m}{n}Nh_{out} + \beta \tag{18.8}$$

The coefficients of the model are obtained empirically by doing linear regression analysis on the total capacitance values for a large number of synthesized circuits.

Entropic models for the controller circuitry are proposed by Tyagi,[14] where three entropic lower bounds on the average Hamming distance (bit changes) with state set S and with T states are provided. The tightest lower bound derived in this chapter for a sparse finite state machine (FSM) (i.e., $t \le 2.23T^{1.72}/\sqrt{\log T}$, where t is the total number of transitions with non-zero steady-state probability) is the following:

$$\sum_{s_i, s_j \in S} p_{i,j}H(s_i, s_j) \ge h(p_{i,j}) - 1.52\log T - 2.16 + 0.5\log(\log T) \tag{18.9}$$

where $p_{i,j}$ is the steady-state transition probability from s_i to s_j, $H(s_i, s_j)$ is the Hamming distance between the two states, and $h(p_{i,j})$ is the entropy of the probability distribution $p_{i,j}$. Notice that the lower bound is valid regardless of the state encoding used.

In Ref. 15, using a Markov chain model for the behavior of the states of the FSM, the authors derive theoretical lower and upper bounds for the average Hamming distance on the state lines which are valid irrespective of the state encoding used in the final implementation. Experimental results obtained for the mcnc'91 benchmark suite show that these bounds are tighter than the bounds reported in Ref. 14.

Complexity-Based Models

These models relate the circuit power dissipation to some notion of *circuit complexity*. Example parameters that influence the circuit complexity include the number and the type of arithmetic and/or Boolean operations in the behavioral description, the number of states and/or transitions in a controller description, and the number of cubes (literals) in a minimum sum-of-products (factored-form) expression of a Boolean function.

Most of the proposed complexity-based models rely on the assumption that the complexity of a circuit can be estimated by the number of "equivalent gates." This information may be generated on-the-fly using analytical predictor functions, or retrieved from a pre-characterized high-level design library. An example of this technique is the *chip estimation system*,[16] which uses the following expression for the average power dissipation of a logic module:

$$Power = fN(Energy_{gate} + 0.5V^2 C_{load})E_{gate} \tag{18.10}$$

where f is the clock frequency, N is the gate equivalent count for the component, $Energy_{gate}$ is the average internal consumption for an equivalent gate (in includes parasitic capacitance contributions as well as short-circuit currents) per logic transition, C_{load} is the average capacitive load for an equivalent gate (it includes fanout load capacitances and interconnect capacitances), and E_{gate} is the average output activity for an equivalent gate per cycle. C_{load} is estimated statistically, based on the average fanout count in the circuit and custom woire load models. E_{gate} is dependent on the functionality of the module. The data is precalculated and stored in the library and is independent of the implementation style (static vs. dynamic logic, clocking strategy), and the circuit context in which the module is instantiated. This is an example of an implementation-independent and data-independent power estimation model.

In Ref. 17, Nemani and Najm present a high-level estimation model for predicting the area of an optimized single-output Boolean function. The model is based on the assumption that the area complexity of a Boolean function f is related to the distribution of the sizes of the on-set and off-set of the function. For example, using the "linear measure," the area complexity of the on-set of f is written as:

$$C_1(f) = \sum_{i=1}^{N} c_i p_i \tag{18.11}$$

where the set of integers $\{c_1, c_2, \ldots, c_N\}$ consists of the distinct sizes of the essential prime implicants of the on-set and weight p_i is the probability of the set of all minterms in the on-set of f which are covered by essential primes of size c_i, but not by essential primes of any larger size. The area complexity of the off-set of f $C_0(f)$ is similarly calculated. Hence, the complexity of function f is estimated as:

$$C(f) = \frac{C_1(f) + C_0(f)}{2} \tag{18.12}$$

The authors next derive a family of regression curves (which happen to have exponential form) relating the actual area $A(f)$ of random logic functions optimized by the SIS logic optimization program (in terms of the number of gates) to the area complexity measure $C(f)$ for different output probabilities of function f. These regression equations are subsequently used for total capacitance estimation and hence high-level power estimation. The work is extended in Ref. 18 to area estimation of multiple-output Boolean functions.

A similar technique would rely on predicting the quality of results produced by electronic design automation (EDA) flows and tools. The predictor function is obtained by performing regression analysis on a large number of circuits synthesized by the tools and relating circuit-specific parameters and/or design constraints to post-synthesis power dissipation results. For example, one may be able to produce the power estimate for an unoptimized Boolean network by extracting certain structural properties of the underlying directed acyclic graph, average complexity of each node, and user-specified constraints and plugging these values into the predictor function.

Complexity-based power prediction models for controller circuitry have been proposed by Landman and Rabaey.[19] These techniques provide quick estimation of the power dissipation in a control circuit based on the knowledge of its target implementation style (i.e., pre-charged pseudo-NMOS or dynamic PLA), the number of inputs, outputs, states, etc. The estimates will have a higher degree of accuracy by introducing empirical parameters that are determined by curve-fitting and least-squared fit error analysis on real data. For example, the power model for an FSM implemented in standard cells is given by:

$$Power = 0.5 V^2 f (N_I C_I E_I + N_O C_O E_O) N_M \tag{18.13}$$

where N_I and N_O denote the number of external input plus state lines for the FSM, C_I and C_O are regression coefficients which are empirically derived from low-level simulation of previously designed standard cell controllers, E_I and E_O denote the switching activities on the external input plus state lines and external output plus state lines, and finally N_M denotes the number of minterms in an optimized cover of the FSM. Dependence on N_M indicates that this model requires a partial (perhaps symbolic) implementation of the FSM.

Synthesis-Based Models

One approach for behavioral-level power prediction is to assume some RT-level template and produce estimates based on that assumption. This approach requires the development of a *quick synthesis* capability that makes some behavioral choices (mimicking a full synthesis program). Important behavioral choices include type of I/O, memory organization, pipelining issues, synchronization scheme, bus architecture, and controller design. This is a difficult problem, especially in the presence of tight timing constraints. Fortunately, designers or the environment often provide hints on what choices should be made. After the RT-level structure is obtained, the power is estimated using any of the RT-level techniques that will be described in Section 18.4.

Relevant data statistics such as the number of operations of a given type, bus and memory accesses, and I/O operations, are captured by *static profiling* based on stochastic analysis of the behavioral description and data streams,[20,21] or *dynamic profiling* based on direct simulation of the behavior under a typical input stream.[22,23] Instruction-level or behavioral simulators are easily adapted to produce this information.

18.4 RT-Level Power Estimation

Most RT-level power estimation techniques use regression-based, switched capacitance models for circuit modules. Such techniques, which are commonly known as *power macro-modeling*, are reviewed next.

Regression-Based Models

A typical RT-level power estimation flow consists of the following steps:

1. Characterize every component in the high-level design library by simulating it under pseudo-random data and fitting a multi-variable regression curve (i.e., the power macro-model equation) to the power dissipation results using a least mean square error fit.[24]

2. Extract the variable values for the macro-model equation from either static analysis of the circuit structure and functionality, or by performing a behavioral simulation of the circuit. In the latter case, a power co-simulator linked with a standard RT-level simulator can be used to collect input data statistics for various RT-level modules in the design.
3. Evaluate the power macro-model equations for high-level design components which are found in the library by plugging the parameter values into the corresponding macro-model equations.
4. Estimate the power dissipation for random logic or interface circuitry by simulating the gate-level description of these components, or by performing probabilistic power estimation. The low-level simulation can be significantly sped up by the application of statistical sampling techniques or automata-based compaction techniques.

The macro-model for the components may be parameterized in terms of the input bit width, the internal organization/architecture of the component, and the supply voltage level. Notice that there are cases where the construction of the macro-model of step (1) can be done analytically using the information about the structure of the gate-level description of the modules, without resorting to simulation as proposed by Benini et al.[25] On the other hand, if the low-level netlist of the library components is not known (which may be the case for soft macros), step (1) can be replaced by data collection from past designs of the component followed by appropriate process technology scaling.[26] In addition, the macro-model equation in step (2) may be replaced by a table lookup with necessary interpolation equations.

In the following paragraphs, we review various power macro-model equations which exhibit different levels of accuracy vs. computation/information usage tradeoff.

The simplest power macro-model, known as the *power factor approximation* technique,[27] is a *constant type model* that uses an experimentally determined weighting factor to model the average power consumed by a given module per input change. For example, the power dissipation of an $n \times n$ bit integer multiplier can be written as:

$$Power = 0.5 V^2 n^2 C f_{activ} \tag{18.14}$$

where V is the supply voltage level, C is the capacitive regression coefficient, and f_{activ} is the activation frequency of the module (this should not be confused with the average, bit-level switching activity of multiplier inputs).

The weakness of this technique is that it does not account for the data dependency of the power dissipation. For example, if one of the inputs to the multiplier is always 1, we would expect the power dissipation to be less than when both inputs are changing randomly. In contrast, the *stochastic power analysis* technique proposed by Landman and Rabaey[28] is based on an activity-sensitive macro-model, called the *dual bit type model*, which maintains that switching activities of high-order bits depend on the temporal correlation of data, whereas lower-order bits behave randomly. The module is thus completely characterized by its capacitance models in the sign and white noise bit regions. The macro-model equation form is then given by:

$$Power = 0.5 V^2 f \left(n_u C_u E_u + n_s \sum_{xy = ++}^{--} C_{xy} E_{xy} \right) \tag{18.15}$$

where C_u and E_u represent the capacitance coefficient and the mean activity of the unsigned bits of the input sequence, while C_{xy} and E_{xy} denote the capacitance coefficient and the transition probability for the sign change xy in the input stream. n_u and n_s represent the number of unsigned and sign bits in the input patterns, respectively. Note that E_u, E_{xy}, and the boundary between sign and noise bits are determined based on the applied signal statistics collected from simulation runs. Expanding this direction, one can use a *bitwise data model* as follows:

$$Power = 0.5V^2 f \sum_{i=1}^{n} C_i E_i \tag{18.16}$$

where n is the number of inputs for the module in question, C_i is the (regression) capacitance for input pin i, and E_i is the switching activity for the ith pin of the module. This equation can produce more accurate results by including, for example, spatio-temporal correlation coefficients among the circuit inputs. This will, however, significantly increase the number of variables in the macro-model equation, and thus the equation evaluation overhead.

Accuracy may be improved (especially for components with deep logic nesting, such as multipliers) by power macro-modeling with respect to both the average input and output activities (the *input-output data model*); that is:

$$Power = 0.5V^2 f(C_I E_I + C_O E_O) \tag{18.17}$$

where C_I and C_O represent the capacitance coefficients for the mean activities of the input and output bits, respectively. The dual bit type model or the bitwise data model may be combined with the input-output data model to create a more accurate, but more expensive, macro-model form. Recently, in Ref. 29, the authors presented a 3-D table, power macro-modeling technique which captures the dependence of power dissipation in a combinational logic circuit on the average input signal probability, the average switching activity of the input lines, and the average (zero-delay) switching activity of the output lines. The latter parameter is obtained from a fast functional simulation of the circuit. The paper also presents an automatic macro-model construction procedure based on random sampling principles. Note that the equation form and variables used for every module are the same (although the regression coefficients are different).

A parametric power model is described by Liu and Svensson,[30] where the power dissipation of the various components of a typical processor architecture, including on-chip memory, busses, local and global interconnect lines, H-tree clock net, off-chip drivers, random logic, and data path, are expressed as a function of a set of parameters related to the implementation style and internal architecture of these components. For example, consider a typical on-chip memory (a storage array of 6-transistor memory cells) which consists of four parts: the memory cells, the row decoder, the column selection, the read/write circuits. The power model for a cell array of 2^{n-k} rows and 2^k columns in turn consists of expressions for: (1) the power consumed by 2^k memory cells on a row during one pre-charge or one evaluation; (2) the power consumed by the row decoder; (3) the power needed for driving the selected row; (4) the power consumed by the column select part; and (5) the power dissipated in the sense amplifier and the readout inverter. For instance, the memory cell power (expression 1 in above) is given by:

$$Power_{memcell} = 0.5VV_{swing}2^k(C_{int} + 2^{n-k}C_{tr}) \tag{18.18}$$

where V_{swing} is the voltage swing on the bit/$\overline{bit}$ line (which may be different for read versus write), C_{int} gives the wiring-related row capacitance per memory cell, and $2^{n-k}C_{tr}$ gives the total drain capacitances on the bit/$\overline{bit}$ line. Notice that during the read time, every memory cell on the selected row drives exactly bit or $\overline{bit}$.

A salient feature of the above macro-model techniques that that they only provide information about average power consumption over a relatively large number of clock cycles. The above techniques, which are suitable for estimating the average-power dissipation, are referred to as *cumulative* power macro-models. In some applications, however, estimation of average power only is not sufficient. Examples are circuit reliability analysis (maximum current limits, heat dissipation and temperature gradient calculation, latch-up conditions), noise analysis (resistive voltage drop and inductive bounce on power and ground lines), and design optimization (power/ground net topology design, number and placement of decoupling capacitors, buffer insertion, etc.). In these cases, *cycle-accurate* (*pattern-accurate*) power estimates are required.

Mehta et al.[31] propose a clustering approach for pattern-accurate power estimation. This approach relies on the assumption that closely related input transitions have similar power dissipation. Hence, each input pattern is first mapped into a cluster, and then a table lookup is performed to obtain the corresponding power estimates from pre-calculated and stored power characterization data for the cluster. The weakness of this approach is that, for efficiency reasons, the number of clusters has to be relatively small, which would introduce errors into the estimation result. In addition, the assumption that closely related patterns (e.g., patterns with short Hamming distance) result in similar power distribution may be quite inaccurate, especially when the *mode-changing bits* are involved; that is, when a bit change may cause a dramatic change in the module behavior.

Addressing these problems, Wu et al.[32] describe an automatic procedure for cycle-accurate macro-model generation based on statistical sampling for the *training set* design and regression analysis combined with appropriate statistical tests (i.e., the F^* test) for macro-model variable selection and coefficient calculation. The test identifies the most (least) power-critical variable to add to (delete from) the set of selected variables. The statistical framework enables prediction of the power value and the confidence level for the predicted power value. This work is extended by Qiu et al.[33] to capture "important" first-order temporal correlations of up to order three at the circuit inputs. Note that here the equation form and variables used for each module are unique to that module type. Experimental results show that power macro-models with a relatively small number of input variables (i.e., 8) predict the module power with a typical error of 5 to 10% for the average power and 10 to 20% for the cycle power.

The above-mentioned high-level power macro-modeling techniques are mostly applicable to the combinational modules (such as adders, multipliers) in the circuit. This is because the power consumption in a combinational circuit module can be fully determined from the statistical characteristics of the vector sequence applied to its primary inputs. As mentioned above, in some cases, it is beneficial to use variables related to the vectors which appear on the primary outputs to further improve the accuracy of the power macro-model for combinational modules. For sequential circuit modules, using only variables related to the external inputs and outputs is not enough to model the power consumption accurately. this is because power consumption in sequential circuits strongly depends on the state transitions, which are not visible from outside. To generate an accurate power model for the sequential module, one thus needs to include some variables related to the internal state of the module.

For complex intellectual property (IP) cores, generating a power macro-model is even more challenging because of the following:

- The IP core may have internal state variables; it is therefore very difficult to generate an accurate power model for the IP core if we have access to information about its primary inputs and primary outputs only. Therefore, it is desirable to construct a power macro-model for the IP core that includes variables related to not only its primary inputs/outputs, but also to its internal state variables.
- At the system level, IP cores are usually specified behaviorally through input/output behavioral modeling. Power modeling however requires information about the internal states of the IP core. Therefore, it is necessary to modify the IP core specification at the system level so that the power model and power evaluation tool can retrieve the information they need for power estimation and optimization.
- There may be thousands of internal state variables in the IP core. Using all of these variables will result in a power model which is too large to store in the system library and too expensive to evaluate. Furthermore, requiring information about all internal states greatly increases the complexity of IP core specification and puts undue burden on the IP vendor to reveal details about the IP core, which can otherwise be hidden from the IP user.

To solve these problems, one needs to develop an IP power model constructor which will automatically generate power macro-models for IP cores using the minimum number of internal state variables. This may be achieved using a statistical relevance testing procedure such that only the "important" variables

are retained in the power model. In this way, a power macro-model with small number of variables, yet sufficient accuracy, can be constructed.

Sampling-Based Models

RT-level power evaluation can be implemented in the form of a *power co-simulator* for standard RT-level simulators. The co-simulator responsible for collecting input statistics from the output of the behavioral simulator and producing the power value at the end. If the co-simulator is invoked by the RT-level simulator every simulation cycle to collect activity information in the circuit, it is called *census macro-modeling*.

Evaluating the macro-model equation at each cycle during the simulation is actually a census survey. The overhead of data collection and macro-model evaluation can be high. To reduce the runtime overhead, Hsieh et al.[34] use *simple random sampling* to select a sample and calculate the macro-model equation for the vector pairs in the sample only. The sample size is determined before simulation. The *sampler macro-modeling* randomly selects *n* cycles and marks those cycles. When the behavioral simulator reaches the marked cycle, the macro-modeling invokes the behavioral simulator for the current input vectors and previous input vectors for each module. The input statistics are only collected in these marked cycles. Instead of selecting only one sample of large size, we can select several samples of at least 30 units (to ensure normality of sample distribution) before the simulation. Then, the average value of sample means is the estimate of population mean. In this manner, the overhead of collecting input statistics at every cycle which is required by census macro-modeling is substantially reduced. Experimental results show that sampler macro-modeling results in an average efficiency improvement of 50X over the census macro-modeling with an average error of 1%.

The macro-model equation is developed using a training set of input vectors. The training set satisfies certain assumptions such as being pseudo-random data, speech data, etc. Hence, the macro-model may become biased, meaning that it produces very good results for the class of data which behave similarly to the training set; otherwise, it produces poor results. One way to reduce the gap between the power macro-model equation and the gate-level power estimation is to use a *regression estimator* as follows.[34] It can be shown that the plot of the gate-level power value versus a well-designed macro-model equation estimate for many functional units reveals an approximately linear relationship. Hence, the macro-model equation can be used as a predictor for the gate-level power value. In other words, the sample variance of the ratio of gate-level power to macro-model equation power tends to be much smaller than that of the gate-level power by itself. It is thus more efficient to estimate the mean value of this ratio and then use a linear regression equation to calculate the mean value of the circuit-level power. The *adaptive macro-modeling* thus invokes a gate-level simulator on a small number of cycles to improve the macro-model equation estimation accuracy. In this manner, the "bias" of the static macro-models is reduced or even eliminated. Experimental results show that the census macro-modeling incurs large error (an average of 30% for the benchmark circuits) compared to gate-level simulation. The adaptive macro-modeling however exhibits an average error of only 5%, which demonstrates the superiority of the adaptive macro-modeling technique.

18.5 Gate-Level Power Estimation

In CMOS circuits, power is mostly consumed during logic switching. This simplifies the power estimation problem to that of calculating the toggle count of each circuit node under a gate-level delay model. Several gate-level power estimation techniques have been proposed in the past. These techniques, which offer orders of magnitude speed-up compared to the conventional simulation-based techniques at the circuit level, can be classified into two classes: *dynamic* and *static*. Dynamic techniques explicitly simulate the circuit under a "typical" input vector sequence (or input stream). The potential problem with these approaches is that the estimation results strongly depend on the input vector sequence, a phenomenon often described as *pattern dependence*. The static technique do not explicitly simulate under any input

vector sequence. Instead, they rely on statistical information (such as the mean activity and correlations) about the input stream. The pattern dependence problem in these techniques is less severe as these techniques either implicitly consider all input vector sequences or perform a "smoothing" operation on the input streams to reduce dependence on any given sequence.

Statistical Sampling

Existing techniques for power estimation at the gate and circuit levels can be divided into two classes: *static* and *dynamic*. Static techniques rely on probabilistic information about the input stream (such as the mean activity of the input signals and their correlations) to estimate the internal switching activity of the circuit. While these are very efficient, their main limitation is that they cannot accurately capture factors such as slew rates, glitch generation and propagation, and DC fighting. Dynamic techniques explicitly simulate the circuit under a "typical" input stream. They can be applied at both the circuit and gate levels. Their main shortcoming is, however, that they are very slow. Moreover, their results are highly dependent on the simulated sequence. To alleviate this dependence, and thereby produce a trustworthy power estimate, the required number of simulated vectors is usually high, which further exacerbates the runtime problem. An example of direct simulation techniques is given in Ref. 35.

To address this problem, a *Monte Carlo simulation* technique was proposed.[36] This technique uses an input model based on a Markov process to generate the input stream for simulation. The simulation is performed in an iterative fashion. In each iteration, a vector sequence of fixed length (called sample) is simulated. The simulation results are monitored to calculate the mean value and variance of the samples. The iteration terminates when some stopping criterion is met (see Fig. 18.1).

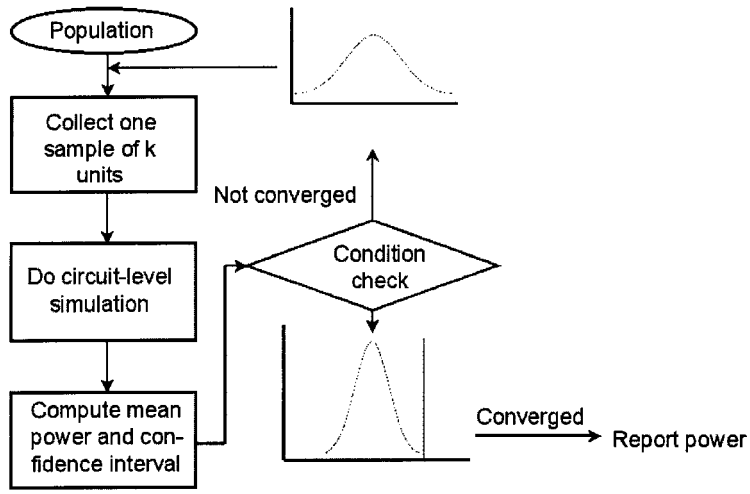

FIGURE 18.1 Monte Carlo simulation loop.

This approach suffers from three major shortcomings. First, when the vectors are regenerated for simulation, the spatial correlations among various inputs cannot be adequately captured, which may lead to inaccuracy in the power estimates. Second, the required number of samples, which directly impacts the simulation runtime, is approximately proportional to the ratio between the sample variance and the square of the sample mean value. For certain input sequences, this ratio becomes large, thus significantly increasing the simulation runtime. Finally, there is a general concern about the normality assumption of the sample distribution. Since the stopping criterion is based on such an assumption, if the sample distribution deviates significantly from the normal distribution (which may happen if the number of units per sample is small or the population distribution is ill-behaved), then the simulation may terminate

prematurely. Ill-behaved population distributions that may cause premature termination include bi-modal, multi-modal, and distributions with long or asymmetric tails.

The first concern can be addressed by developing a sampling procedure which randomly draws the units in the sample from the input population (instead of building an approximate Markov model of the population and then generating samples which conform to this approximate model). Such techniques are known as *simple random sampling*.[37] They may or may not be combined with the Monte Carlo simulation loop.

The second (and to some extent, the third) concern can be addressed by developing more efficient sampling procedures. One such procedure, called *stratified random sampling*, is introduced in Ref. 37. They key idea is to partition the population into disjoint subpopulations (called *strata*) in such a way that the power consumption characteristics within each stratum becomes more homogeneous. The samples are then taken randomly from each stratum. The units in each sample are allocated proportional to the sizes of the strata. This generally results in a significant reduction in the sampling variance (see Figs. 18.2 and 18.3).

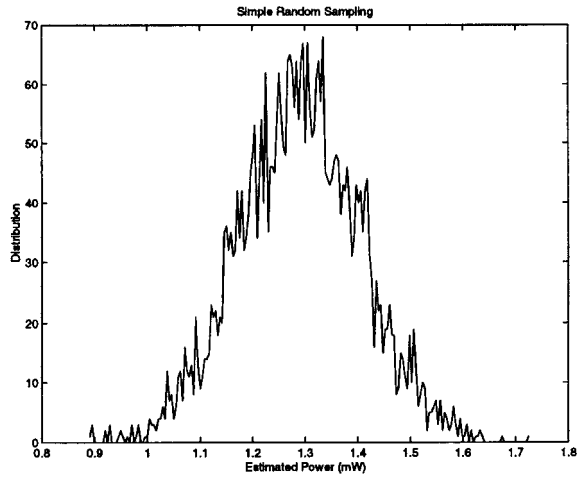

FIGURE 18.2 Sample distribution for simple random sampling.

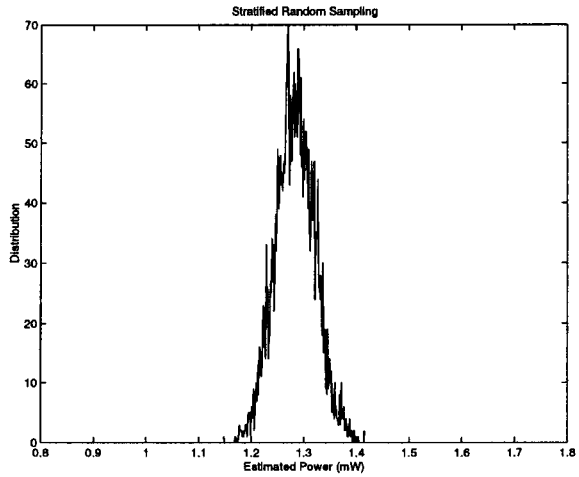

FIGURE 18.3 Sample distribution for stratified random sampling.

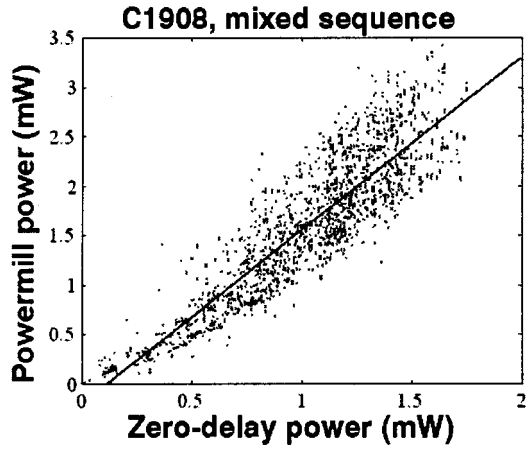

FIGURE 18.4 Scatter plot of circuit-level power vs. zero-delay power.

The stratification itself is based on a low-cost predictor (e.g., zero-delay power estimation) which needs to be evaluated for every unit in the population. The zero-delay power estimates need not produce high accuracy on a unit-by-unit basis; indeed, they should only show high statistical correlation with circuit-level power estimates (see, for example, the scatter plot for the ISCAS-85 benchmark C1809 shown in Fig. 18.4). When the population size is large, one can use a two-stage stratified sampling procedure to reduce the overhead of predictor calculation and stratification. The proposed two-stage stratified sampling technique can be easily extended to multi-stage sampling.

Compared to Ref. 36, the technique in Ref. 37 offers the following advantages: (1) it performs sampling directly on the population and thus the estimation results are unbiased; (2) experimental results on a large set of the ISCAS'85 benchmarks under non-random input sequences show a 10X improvement in the sampling efficiency; and (3) difficult population distributions can be handled more effectively.

Another efficient sampling procedure, called *linear regression estimation*, is introduced in Ref. 34. The key observation is that the sample variance of the ratio of circuit-level power to zero-delay power tends to be much smaller than that of the circuit-level power by itself. This can be easily seen by examining the scatter plots of circuit-level power versus zero-delay power for a large number of circuits under a variety of input populations.

It is thus more efficient to estimate the mean value of this ratio and then use a regression equation to calculate the mean value of the circuit-level power. Experimental results again show a 10X improvement in the sampling efficiency compared to simple random sampling.

So far, we have only considered examples of parametric sampling techniques (i.e., those whose stopping criterion is derived by assuming normality of the sample distribution). A non-parametric sampling technique (i.e., those whose stopping criterion is derived without any *a priori* assumption about the sample distribution) is presented in Ref. 38. In general, non-parametric techniques do not suffer from the premature termination problem; however, they tend to be too conservative and lead to over-sampling to achieve the specified error and confidence levels. The technique in Ref. 38, which uses the properties of "order statistics," tries to reach a good tradeoff between the estimation accuracy and the computational efficiency. More research is needed to assess the efficiency and robustness of non-parametric versus parametric sampling techniques.

For synchronous sequential circuits (e.g., finite state machines driven by a common clock), if we know the state transition graph of the FSM, we can solve the Chapman-Kolmogorov equations for the stationary state probabilities. Next, based on these probabilities, we can randomly generate a present-state vector which, along with a randomly generated external input vector, determines the next-state vector. With a

second random external input vector (generated according to the statistics of the external input sequence), a unit of the power sample can be constructed. The subsequent units are generated by randomly setting the state line vectors, followed by random generation of two external input vectors and power measurement. Unfortunately, the number of Chapman-Kolmogorov equations is exponential in the number of flip-flops, and hence this approach is not possible for large FSMs.

Existing statistical technique for the estimation of the mean power is synchronous sequential circuits (e.g., finite state machines driven by a common clock) are classified into two groups: hierarchical and flat. The hierarchical technique performs behavioral or RT-level simulation of the target circuit for all units (i.e., external input patterns) in the user-specified population, and collects the state line values corresponding to each unit. Next, it treats the FSM as a combinational circuit (i.e., it cuts the sequential feedback lines) which receives an extended input sequence and which needs to be simulated at the circuit level for accurate power estimation; the new sequence is the concatenation of the external input line and the state line values. The FSM power estimation problem is thereby transformed into a sampling problem for the resulting combinational circuit (assuming that all the flip-flops are edge-triggered). The shortcomings of this technique are that it requires RT-level simulation of the target FSM for all units of the population and that the resulting state line values must be stored for sampling in the next phase. The first problem is not critical since the RT level simulation is orders of magnitude faster than the circuit-level simulation and hence we can afford simulating the whole vector sequence at the RT level. The second problem may be of concern if the length of the input sequence is large and the computer memory is limited.

The hierarchical technique takes a somewhat more complicated form when the input population is infinite; in this case, the signal and transition probabilities of the state lines must be modeled by a Markov process which is, in turn, derived from a Markov model representation of the external input sequence. This problem has been tackled in Ref. 39, where the following two-phase procedure is proposed: (1) use sequence generation based on the given Markov model of each bit of the external input sequence and do Monte Carlo simulation to compute the signal probabilities and transition probabilities of each state line (and hence construct the corresponding Markov model for each state line); (2) cut the feedback lines in the FSM and do Monte Carlo simulation on the combinational part of the FSM using the bit-level Markov models of the external input and state lines. A major disadvantage of this technique is that in the second step, while estimating power in the combinational circuit, spatial correlations between the signal lines are ignored. This introduces large errors in the power estimates.

The flat technique[36,40] consists of two phases: warm-up period and random sampling. The purpose of the warm-up period is to perform a number of input vector simulations to achieve steady-state probability conditions on the state lines. Only then can power sampling be performed. This is because, for meaningful power sampling, the state vectors fed into the circuit have to be generated according to their stationary state probability distribution in the FSM. The problems of how to choose an initial state for each sample and how long the warm-up length should be are discussed in Ref. 40. A randomness test to dynamically decide the proper warm-up length is proposed in Ref. 41. The test is applied to the sequence of power values observed during the warm-up period (a binning technique is used to transform the sequence of power values into a binary sequence so that the test can be applied). A major concern with this technique is that the randomness test should actually be applied to the sequence of state line patterns, rather than to the sequence of power values. The former task appears to be difficult.

In practice, the warm-up period requires a large number of simulated vectors (depending on the FSM behavior and characteristics of the external input sequence). This makes the efficiency of power estimation for sequential circuits much lower than that for combinational circuits.

In addition to estimating the mean value of the power dissipation in a circuit, theory of order statistics and stratified sampling techniques have been used to estimate the maximum power dissipation[42] and the cumulative distribution function for the power dissipation.[43] This information is very useful to chip designers who are interested in reliability analysis and AC/DC noise analysis.

Probabilistic Compaction

Another approach for reducing the power simulation time is to compact the given long stream of bit vectors using probabilistic automata.[44,45] The idea in Ref. 45 is to build a *stochastic state machine* (SSM) which captures the relevant statistical properties of a given long bit stream, and then excite this machine by a small number of random inputs so that the output sequence of the machine is statistically equivalent to the initial one. The relevant statistical properties denote, for example, the signal and transition probabilities, and first-order spatio-temporal correlations among bits and across consecutive time frames. The procedure then consists of decomposing the SSM into a set of deterministic state machines, and realizing it through SSM synthesis with some auxiliary inputs. The compacted sequence is generated by uniformly random excitement of such inputs. As an example, consider the input sequence shown in Fig. 18.5; the corresponding SSM model is shown in Fig. 18.6, and the compacted sequence is shown in Fig. 18.7. Note that the average bit activities for the initial compacted sequences are 23/16 and 8/5, respectively.

FIGURE 18.7 Compacted sequence.

The number of states in the probabilistic automaton is proportional to the number of distinct patterns in the initial vector sequence. Since this number may be large (i.e., worst-case exponential in the number of bits in each vector), one has to manage the complexity by either: (1) partitioning the n bits into b groups with a maximum size of k bits per group and then building a probabilistic

automaton for each group of bits independently; or (2) partitioning the long vector sequence into consecutive blocks of vectors such that the number of distinct vectors in each block does not exceed some user-defined parameter, say *K*. The shortcoming of the first approach is that one may generate a bit pattern (vector) that was not present in the initial sequence (since correlations across different groups of bits are ignored). This is, in turn, a problem in certain applications with forbidden input patterns (codes not used, illegal instructions, bad memory addressed, etc.). Thus, the second approach is often more desirable.

An improved algorithm for vector compaction is presented in Ref. 46. The foundation of this approach is also probabilistic in nature: it relies on adaptive (dynamic) modeling of binary input streams as first-order Markov sources of information and is applicable to both combinational and sequential circuits. The adaptive modeling technique itself (best known as *dynamic Markov chain modeling*) was recently introduced in the literature on data compression[47] as a candidate to solve various data compression problems. This original formulation is extended in Ref. 46 to manage not only correlations among adjacent bits that belong to the same input vector, but also correlations between successive patterns. The model captures completely spatial correlations and first-order temporal correlations and, conceptually, it has no inherent limitation to be further extended to capture temporal dependencies of higher orders.

A hierarchical technique for compacting large sequences of input vectors is presented in Ref. 48. The distinctive feature of this approach is that it introduces hierarchical Markov chain modeling as a flexible framework for capturing not only complex spatio-temporal correlations, but also dynamic changes in the sequence characteristics such as different input modes. The hierarchical Markov model is used to structure the input space into a hierarchy of macro- and micro-states: at the first level in the hierarchy, there is a Markov chain of macro-states describing the input modes, whereas at the second level there is a Markov chain of micro-states describing the internal behavior of each input mode. The primary motivation in doing this structuring is to enable a better modeling of the different stochastic levels that are present in sequences that arise in practice.

Another important property of such models is to individualize different operating modes of a circuit or system via higher levels in the hierarchical Markov model, thus providing a high adaptability of different system operating modes (e.g., active, standby, sleep, etc.). The structure of the model itself is general and, with further extensions, can allow an arbitrary number of activations of its sub-models. Once we have constructed the hierarchy for the input sequence, starting with a macro-state, a compaction procedure with a specified compaction ratio is applied to compact the set of micro-states within that macro-state. When done with processing the current macro-state, the control returns to the higher level in the hierarchy and, based ont he conditional probabilities that characterize the Markov chain at this level, a new macro-state is entered and the process repeats.

This sequence compaction approach has been extended in Ref. 49 to handle FSMs. More precisely, it is shown that: (1) under the stationarity and ergodicity assumptions, complete capture of the characteristics of the external input sequence feeding into a target FSM is sufficient to correctly characterize the joint (external inputs plus internal states) transition probabilities; (2) if the external input sequence has order k, then a lag-k Markov chain model of this sequence will suffice to exactly model the joint transition probabilities in the target FSM; (3) if the input sequence has order 2 or higher, then modeling it as a lag-1 Markov chain cannot exactly preserve even the first-order joint transition probabilities in the target FSM. They key problem is thus to determine the order of the Markov source which models the external input sequence. In Ref. 50, based on the notion of block (metric) entropy, a technique for identify the order of a *composite* source of information (i.e., a source which emits sequences that can be piecewise modeled by Markov chains of different orders) is introduced.

Results of these approaches show 1 to 4 orders of magnitude compaction (depending on the initial length and characteristics of the input sequence) with negligible error (i.e., $\leq$5% in most cases) using PowerMill as the simulator. As a peculiar property, note that none of these approaches needs the actual circuit to compact the input sequences.

Probabilistic Simulation

Power dissipation in CMOS circuits comes from three sources: (1) the leakage current, (2) the short-circuit which is due to the DC path between the supply rails during output transitions, and (3) the charging and discharging of capacitive loads during logic changes. In a well-designed circuit, the contribution of first two sources is relatively small. Therefore, power dissipation at the gate level can be accurately approximated by only considering the charging and discharging of capacitive loads as given by:

$$Power_{gate} = \frac{1}{2T_c} V_{dd}^2 \sum_n C_n sw_n \tag{18.19}$$

where T_c is the clock period, V_{dd} is the supply voltage, the summation is performed over all gates (nodes) in the circuit, C_n is the load capacitance of node n and sw_n is the average switching activity of node n, (that is, the expected number of signal changes) per clock cycle.

In the above equation, sw_n is related to the timing relationship (or delay) among the input signals of each gate. Indeed, the output signal of a node may change more than once due to unequal signal arriving times at its inputs. The power consumed by these extra signal changes is generally referred to as the *glitch power*. If the contribution of the glitch power is relatively small, one can approximate sw_n using the zero-delay model (e.g., assuming that all logic changes propagate through the circuit instantaneously, and hence each node changes logic value at most once). The ratio of the power estimations obtained under real-delay and the zero-delay models reflects the significance of glitch power. A typical value for this ratio is 1.20. For some types of circuits, such as parity chains, adders, or multipliers, this ratio could be well above 2.0. For these types of circuits, the delay model becomes very important, that is, the delay characterization of each gate must be very accurate. Moreover, CMOS gates have an inertial delay. Only glitches with adequate strength (that is, glitch width) can overcome the gate inertia and propagate through the gate to its output. Accurate modeling of these effects requires significantly longer execution time.

A direct simulative approach to power estimation would enumerate all pairs of input vectors and compute the number of logic changes per vector pair. The "average" switching activity is then the sum over all possible vector pairs of the product of the occurrence probability and the number of the logic changes for each vector pair. This procedure will obviously be exponential in complexity. In the following, we review some important definitions that will help manage this complexity:

1. *Signal probability*: The signal probability $P_s(n)$ of a node n is defined as the average fraction of clock cycle in which the steady-state value of n is logic one under the zero-delay model.
2. *Transition probability*: The transition $P_t^{it}(n)$ of a node is defined as the average fraction of clock cycles in which the steady-state value of n undergoes a change from logic value i to logic value j under the zero-delay model. Note that $P_t^{01}(n) = P_t^{10}(n)$ and $P_t^{01}(n) + P_t^{11}(n) = P_s(n)$.
3. *Temporal independence*: Under the temporal independence assumption, the signal value of an input node n at clock cycle i is independent of its signal value at clock cycle $i - 1$.
4. *Spatial independence*: Under the spatial independence assumption, the logic value of an input node n is independent of the logic value of any other input node m.
5. *Spatiotemporal correlation*: The spatial and temporal correlation of the input signals are collectively referred as *spatiotemporal correlation*.
6. *Full signal swing*. All logic transitions are from zero to one and vice versa (i.e., no intermediate voltages are present).

The concepts of signal and transition probabilities are very useful for power estimation under the zero-delay model. Under the real-delay model, the signal and transition probabilities are mainly used to describe the input vector statistics.

Under the zero-delay model, $P_t^{01}(n) + P_t^{10}(n)$ can replace the term sw_n in the power calculation to give the power consumption for each node. With the temporal independence assumption, $P_t^{01}(n)$ can be written as:

$$P_t^{01}(n) = (1 - P_s(n))P_s(n) \tag{18.20}$$

Therefore, the simulation can be performed using one vector to obtain the signal probabilities instead of using two vectors to explicitly calculate the transition probabilities.

The early works for computing the signal probabilities in a combinational network adopt the spatial independence assumption to keep the problem manageable. In Fig. 18.8, we use signal probability calculation based on OBDDs to illustrate how the spatial independence assumption improves the efficiency. Fig. 18.8(a) shows the example circuit and Fig. 18.8(b) shows the global function of node g represented by an OBDD. With the spatial independence assumption, the signal probability $P_s(g)$ can be calculated by recursively co-factoring the global function of g, that is:

$$g = cg_c + \bar{c}g_{\bar{c}} \tag{18.21}$$

$$P_s(g) = P_s(c)P(g_c) + (1 - P_s(c))P(g_{\bar{c}}) \tag{18.22}$$

In Fig. 18.8(b), the left and right branches of the root node compute g_c and $g_{\bar{c}}$, respectively. By recursively applying these equations with respect to all OBDD variables, $P_s(g)$ can be computed efficiently by traversing each OBDD node exactly once using a dynamic programming approach. Without the spatial independence assumption, the second equation becomes invalid. In the worst case, one may need to explicitly enumerate all the disjoint cubes (paths in the OBDD representation) in function g to compute $P_s(g)$.

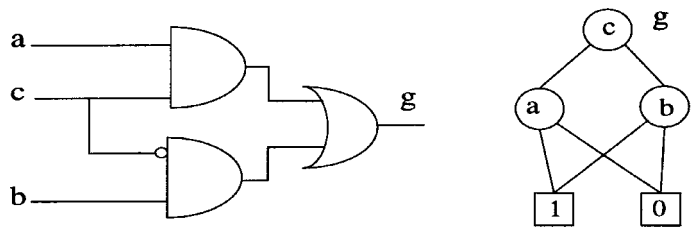

FIGURE 18.8 An OBDD example.

When we compute the signal probabilities using OBDD, the OBDDs can be either *global* or *local*. The former refers to OBDDs which are constructed in terms of the variables associated with circuit inputs, while the latter refers to OBDDs which are constructed in terms of the variables associated with some set of intermediate nodes in the fanin cone of the node in question.

We should point out that the temporal and spatial independence assumptions are only made to improve the efficiency at the cost of reducing the accuracy. These assumptions do not hold for most real-life input vectors. Therefore, the ability to do power estimation while accounting for real-life temporal and spatial correlations becomes an important criterion when comparing various estimation techniques.

The second class of switching activity estimation techniques, called *static techniques*, does not explicitly simulate under the given input vector sequence. This class can be further divided into the following groups: *exact* and *approximate*.

Exact Probabilistic Analysis

These exact techniques provide the exact switching activity estimates under the assumed delay models and specified input statistics. This is achieved by *implicitly exhaustive enumeration* of all input vectors. Unfortunately, the worst-case complexity of these approaches is exponential. Moreover, the data structures employed to perform the implicit enumeration are also exponential in the circuit input size. As a result, the feasibility of these techniques is restricted to small-size circuits.

Exact Techniques under the Zero Delay Model

In Ref. 51, each of the circuit inputs is associated with a variable name that represents the input signal probability. Given the algebraic expressions, in term of these variables, of all fanin nodes of an internal circuit node g, an algebraic expression for g can be derived based on the node function of g. The signal probability of each circuit node g is then calculated from the derived algebraic expression. A much more effective approach based on OBDDs in proposed in Ref. 52. This latter technique was illustrated with the example in Fig. 18.8. Both of these approaches assume temporal and spatial independence of circuit input signals.

Another OBDD-based approach that considers the temporal correlation of the input signals is proposed in Ref. 53. The technique uses OBDD variables of twice the number of circuit inputs. That is, for each circuit input c, two OBDD variables, c_1 and c_2, are used to represent the signal values of c at time $-\infty$ and 0 in a two-vector simulation. The computation of transition probability of each circuit node g is carried out as follows. Let g^{01} represent the Boolean function for g to produce a 0 to 1 signal change under the zero-delay model. We can write:

$$g^{01} = \bar{c}_1\bar{c}_2 g_{\bar{c}_1\bar{c}_2} + \bar{c}_1 c_2 g_{\bar{c}_1 c_2} + c_1\bar{c}_2 g_{c_1\bar{c}_2} + c_1 c_2 g_{c_1 c_2} \tag{18.23}$$

$$P_t^{01}(g) = P_t^{00}(c)P\left(g_{\bar{c}_1\bar{c}_2}\right) + P_t^{01}(c)P\left(g_{\bar{c}_1 c_2}\right) + P_t^{10}(c)P\left(g_{c_1\bar{c}_2}\right) + P_t^{11}(c)P(g_{c_1 c_2}) \tag{18.24}$$

The ordering of the OBDD variables is arranged so that c_1 and c_2 for each circuit input c are next to each other. This ordering provides an effective method to find the co-factors directly from the OBDD nodes. A more efficient method of calculating the transition probabilities without variable duplication is presented in Ref. 54.

Exact Techniques under the Real-Delay Model

An approach based on *symbolic simulation* is proposed in Ref. 55. In the symbolic simulation, the state of an internal circuit node g is described by a set of symbolic functions defined over time $(-\infty, \infty)$ in the temporal order; for example, $g_{t_0}, g_{t_1}, \cdots, g_{t_n}$ where $t_0 = -\infty$ and g_{t_i} specifies the input vectors that will produce logic one over time $[g_{t_i}, g_{t_{i+1}}]([g_{t_i}, \infty])$ if $i < n$ $(i = n)$. The state of each circuit input c is described by two single-variable symbolic functions, c_1 and c_2, defined at time $-\infty$ and 0, respectively. The computation of all symbolic functions for each gate can be performed during a topological order. This procedure is similar to event-driven simulation. That is, for each symbolic function defined at time t at any fanin of gate g, a new symbolic function at the output of g at time $t + d$ (d is the delay of the gate) is constructed based on the Boolean function of g and the states of all other fanins of g at time t. The sw_n is calculated by summing the signal probabilities of the exclusive or functions of symbolic functions that are defined at two consecutive time instances; for example,

$$sw_g = \sum_{i=0}^{n-1} P_s(g_{t_i} \oplus g_{t_{i+1}}) \tag{18.25}$$

The major disadvantage of this method is that it is computationally intractable, as the number of symbolic functions for each gate could be large. Moreover, the symbolic functions could become very complicated when one attempts to model the glitch propagation mechanism accurately and potential filter out glitches that have short width.

So far, no exact technique have been proposed for considering the spatial correlation of input signals under either the zero or the real-delay model. The difficulty lies in the fact that the spatial correlations can in general exist among every m-tuple of inputs where m ranges from 2 to the number of circuit inputs n. In the worst case, there is an exponential number of spatial correlation parameters that need to be considered compared to the $4n$ for the temporal correlation case.

Approximate Techniques

These techniques are developed as approximation techniques for the implicit enumeration approaches. They are referred as *approximate probabilistic techniques,* mainly because the probabilistic quantities such as signal and transition probabilities are explicitly (vs. implicitly in exact techniques) propagated in the networks.

Probabilistic Techniques under the Zero-Delay Model

An efficient algorithm to estimate the signal probability of each internal node using pair-wise correlation coefficients among circuit nodes is proposed in Ref. 56. This technique allows the spatial correlations between pairs of circuit input signals to be considered. A more general approach that accounts for spatiotemporal correlations is proposed in Ref. 54. The mathematical foundation of this extension is a four-state, time-homogeneous Markov chain where each state represents some assignment of binary values to two lines x and y, and each edge describes the conditional probability for going from one state to the next. The computational requirement of this extension can however be high since it is linear in the product of the number of nodes and number of paths in the OBDD representation of the Boolean function in question. A practical method using local OBDD constructions and dynamic level founding is described by the authors.

This work has been extended to handle highly correlated input streams using the notions of conditional independence and isotropy of signals.[57] Based on these notions, it is shown that the relative error in calculating the signal probability of a logic gate using pairwise correlation coefficients can be bounded from above.

Probabilistic Techniques under the Real-Delay Model

In Ref. 58 (*CREST*), the concept of *probability waveforms* is proposed to estimate the mean and variance of the current drawn by each circuit node. Although *CREST* was originally developed for switch-level simulation, the concept of probability waveforms can be easily extended to the gate level as well. A probability waveform, consists of an initial signal probability and a sequence of transition events occurring at different time instances. Associates with each transition event is the probability of the signal change. In a probability waveform, one can calculate the signal probability at any time instance t from the initial signal probability and probabilities of each transition event which occurred before t. The propagation mechanism for probability waveforms is event-driven in nature. For each transition event arrived at time t at the input of a gate g, a transition event is scheduled at the gate output at time $t + d$ (d is the delay of the gate); probability of the event is calculated based on the probability of the input events and the signal probabilities of other fanins at time t.

In Ref. 59 (*DENSIM*), the notion of *transition density* — which is the average number of transitions per second — is proposed. It can replace SW_n/T_c in power calculation equation to compute the power dissipation for each node. An efficient algorithm based on the Boolean difference operation is proposed to propagate the transition densities from circuit inputs throughout the circuit with the transition density of each node calculated based on the following formula:

$$D(y) = \sum_{i=1}^{n} P\left(\frac{\partial y}{\partial x_i}\right) D(x_i) \tag{18.26}$$

where y is the output of a node, x_i's are the inputs of y, $D(y)$ is the transition density of node y, and $(\partial y)/(\partial x_i)$ is the Boolean difference of y respect to x_i. $P((\partial y)/(\partial x_i))$ is calculated using OBDDs. The accuracy of the transition density equation can be improved by considering higher-order Boolean difference.[60]

Under the real-delay model, the correlation between gate fanins is the major source of inaccuracy for the probabilistic techniques. Moreover, because the signals may change more than once, it is very difficult to accurately model these correlations. In Ref. 61, based on an assumption on the probability distribution function of the glitch width, a conceptual low-pass filter module is proposed that improves the accuracy of *DENSIM*.

In Ref. 62 (*TPS*), the concept of probability waveforms is extended to partially account for the signal correlation among different gate fanins. The signal correlation is approximated by the steady-state correlations under the zero-delay model. To efficiently implement the techniques, the probability waveform of a node is divided into four *tagged waveforms* based on initial and final steady state. For a two-input node g, there are 16 joint tagged waveforms at the gate inputs. After the probability waveforms for all 16 joint tagged waveforms are calculated, they are combined into four tagged waveforms according to a forcing set table[62] derived from the node function of g. The OBDDs are used to calculate the probabilities of each tagged waveform and the signal correlations. This approach requires significantly less memory and runs much faster than symbolic simulation, yet achieves high accuracy (e.g., the average error in aggregate power consumption is about 10%). One interesting characteristic of this approach is that it will give an exact power estimate for the zero-delay model if the zero-delay model is assumed. Moreover, the technique can be combined with Refs. 54 and 57 to consider the spatiotemporal correlations of circuit input signals.

Both *DENSIM* and *TPS* use OBDDs to improve their efficiency; their computational work can be divided into two phases. The first phase constructs the required OBDDs and computes the signal probabilities or correlations using OBDDs; the second phase computes either the transition density or the tagged waveforms during a post-order traversal from circuit inputs to circuit outputs.

Probabilistic Techniques for Finite State Machines

The above-mentioned probabilistic methods for power estimation focus on combinational logic circuits. Accurate average switching activity estimation for FSMs is considerably more difficult that that for combinational circuits for two reasons:

- The probability of the circuit being in each of its possible states has to be calculated.
- The present-state line inputs of the FSM are strongly correlated (i.e., they are temporally correlated due to the machine behavior as represented in its State Transition Graph description and they are spatially correlated because of the given state encoding).

A first attempt at estimating switching activity in the FSMs was presented in Ref. 55. The idea is to "unroll" the next-state logic once (thus capturing the temporal correlations of present-state lines) and then perform symbolic simulation on the resulting circuit (which is hence treated as a combinational circuit). This method does not however capture the spatial correlations among present-state lines and makes the simplistic assumption that the state probabilities are uniform.

The above work was improved on in Ref. 63 as follows. For each state s_i, $1 \le i \le K$ in the STG, we associate a variable $prob(s_i)$ corresponding to the steady-state probability of the machine being in state s_i at $t = \infty$. For each edge e in the STG, we have *e.Current* signifying the state that the edge fans out from, *e.Next* signifying the state that the edge fans out to, and *e.Input* signifying the input combination corresponding to the edge. Given static probabilities for the primary inputs to the machine, we can compute $prob(Input)$, the probability of the combination *Input* occurring.[1] We can compute $prob(e.Input)$ using:

[1] Static probabilities can be computed from specified transition probabilities.

$$prob(e.Input) = prob(e.Current) \times prob(Input) \tag{18.27}$$

For each state s_i, we can write an equation:

$$prob(s_i) = \sum_{\forall e \text{ such that } e.Next = s_i} prob(e.Input) \tag{18.28}$$

Given K states, we obtain K equations, out of which any one equation can be derived from the remaining $K - 1$ equations. We have a final equation:

$$\sum_{i=1}^{K} prob(s_i) = 1 \tag{18.29}$$

This linear set of K equations can be solved to obtain the different $prob(s_i)$s. This system of equations is known as the Chapman-Kolmogorov equations for a discrete-time discrete-transition Markov process. Indeed, if the process satisfies the conditions that it has a finite number of states, its essential states form a single chain, and it contains no periodic states, then the above system of equations will have a unique solution.

The Chapman-Kolmogorov method requires the solution of a linear system of equations of size 2N, where N is the number of flip-flops in the machine. In general, this method cannot handle circuits with large numbers of flip-flops because it requires explicit consideration of each state in the circuit. One the positive side, state probabilities for some very large FSMs have been calculated using a fully implicit technique described in Ref. 64.

The authors of Ref. 63 also describe a method for approximate switching activity estimation of sequential circuits. The basic computation step is the solution of a non-linear system of equations as follows:

$$\begin{aligned} prob(ns_1) &= prob(f_1(i_1, i_2, \ldots, i_M, ps_1, ps_2, \ldots, ps_N)) \\ prob(ns_2) &= prob(f_2(i_1, i_2, \ldots, i_M, ps_1, ps_2, \ldots, ps_N)) \\ &\ldots \\ prob(ns_N) &= prob(f_N(i_1, i_2, \ldots, i_M, ps_1, ps_2, \ldots, ps_N)) \end{aligned} \tag{18.30}$$

where $prob(ns_i)$ corresponds to the probability that ns_i is a 1, and $prob(f_i(i_1, i_2, \ldots, i_M, ps_1, ps_2, \ldots, ps_N))$ corresponds to the probability that $f_i(i_1, i_2, \ldots, i_M, ps_1, ps_2, \ldots, ps_N)$ is a 1, which is of course dependent on the $prob(ps_j)$ and the $prob(i_k)$.

We are interested in the steady-state probabilities of the present and next-state lines implying that:

$$prob(ps_i) = prob(ns_i) = p_i \qquad 1 \le i \le N \tag{18.31}$$

A similar relationship was used in the Chapman-Kolmogorov equations.

The set of equations given the values of $prob(i_k)$ becomes:

$$\begin{aligned} y_1 &= p_1 - g_1(p_1, p_2, \ldots, p_N) = 0 \\ y_2 &= p_2 - g_2(p_1, p_2, \ldots, p_N) = 0 \\ &\ldots \\ y_N &= p_N - g_N(p_1, p_2, \ldots, p_N) = 0 \end{aligned} \tag{18.32}$$

where the g_i's are non-linear functions of the p_i's. We will denote the above equations as $Y(P) = 0$ or as $P = G(P)$. In general, the Boolean function f_i can be written as list of minterns over the i_k and ps_j, and the corresponding g_i function can be easily derived.

The fixed point (or zero) of this system of equations $P = G(P)$ (or $Y(P) = 0$) can be found using the Picard-Peano (or Newton-Raphson) iteration.[65] The uniqueness or the existence of the solution is not guaranteed for an arbitrary system of non-linear equations. However, since in our application we have a correspondence between the non-linear system of equations and the State Transition Graph of the sequential circuit, there will exist at least one solution to the non-linear system. Further, convergence is guaranteed under mild assumptions for our application.

Increasing the number of variables or the number of equations in the above system results in increased accuracy.[148] For a wide variety of examples, it is shown that the approximation scheme is within 1–3, but is orders of magnitude faster for large circuits. Previous sequential switching activity estimation methods exhibit significantly greater inaccuracies.

18.6 Transistor-Level Power Estimation

Transistor-level simulators provide the highest accuracy for circuit power estimation. They are capable of handling various device models, different circuit design styles, single- and multi-phase clocking methodologies, tristate drives, etc. However, they suffer from memory and execution time constraints and are not suitable for large, cell-based designs. Circuit techniques for power measurement (capacitive and short-circuit power components) using the "power meters" is described in Refs. 66 and 67. A fast and accurate circuit-level simulator based on the stepwise equivalent conductance and piecewise linear waveform approximation has been described in Ref. 68.

PowerMill[69] is a transistor-level power simulator and analyzer which applies an event-driven timing simulation algorithm (based on simplified table-driven device models, circuit partitioning and single-step nonlinear iteration) to increase the speed by two to three orders of magnitude over SPICE, while maintaining an accuracy of within 10power information (instantaneous, average, and RMS current values) as well as the total power consumption (due to capacitance currents, transient short circuit currents, and leakage currents).

18.7 Conclusion

The increased degree of automation of industrial design frameworks has produced a substantial change in the way digital ICs are developed. The design of modern systems usually starts from specifications given at a very high level of abstraction. This is because existing EDA tools are able to automatically produce low-level design implementations directly from descriptions of this type.

It is widely recognized that power consumption has become a critical issue in the development of digital systems; then, electronic designers need tools that allow them to explicitly control the power budget during the phases of the design process. This is because the power savings obtainable through automatic optimization are usually more significant than those achievable by means of technological choices (e.g., process and supply-voltage scaling).

This chapter has provided review of existing methodologies and tools for power modeling, simulation, and estimation, techniques of VLSI circuits at different design abstraction levels. A wealth of research results and a few pioneering commercial tools have appeared in the last few years. This chapter has, however, described representative contributions to this important field and has been non-exhaustive. We expect this field to remain quite active in the foreseeable future. New trends and techniques will emerge, some approaches described in this review will consolidate, while others will become obsolete; this is in view of technological and strategic changes in the world of microelectronics.

Analog Interfaces

19.1 Introduction

This chapter discusses the design, operation, and layout of CMOS analog amplifiers and subcircuits (current mirrors, biasing circuits, etc.). To make this discussion meaningful and clear, we need to define some important variables related to the DC operation of MOSFETs (Fig. 19.1). Figure 19.1(a) shows the simplified schematic representations of n- and p-channel MOSFETs. We say simplified because, when these symbols are used, it is *assumed* that the fourth terminal of the MOSFET (i.e., the body connection) is connected to either the lowest potential on the chip (V_{SS} or ground for the NMOS) or the highest potential (V_{DD} for the PMOS). Figure 19.1(b) shows the more general schematic representation of n- and p-channel MOSFETs. We are assuming that, although the drain and source of the MOSFETs are interchangeable, drain current flows from the top of the device to the bottom. Because of the assumed direction of current flow, the drain terminal of the n-channel is on the top of the symbol, while the drain terminal of the p-channel is on the bottom of the schematic symbol. The following are short descriptions of some important characteristics of MOSFETs that will be useful in the following discussion.

The Threshold Voltage

Loosely defined, the threshold voltage, V_{THN} or V_{THP}, is the minimum gate-to-source voltage (V_{GS} for the n-channel or V_{SG} for the p-channel) that causes a current to flow when a voltage is applied between the drain and source of the MOSFET. As shown in Fig. 19.1(c) the threshold voltage is estimated by plotting the square root of the drain current against the gate-source voltage of the MOSFET and looking at the intersection of the line tangent with this plot with the x-axis (V_{GS} for the n-channel). As seen in the figure, a current does flow below the threshold voltage of the device. This current is termed, for obvious reasons, the *subthreshold current*. The subthreshold current is characterized by

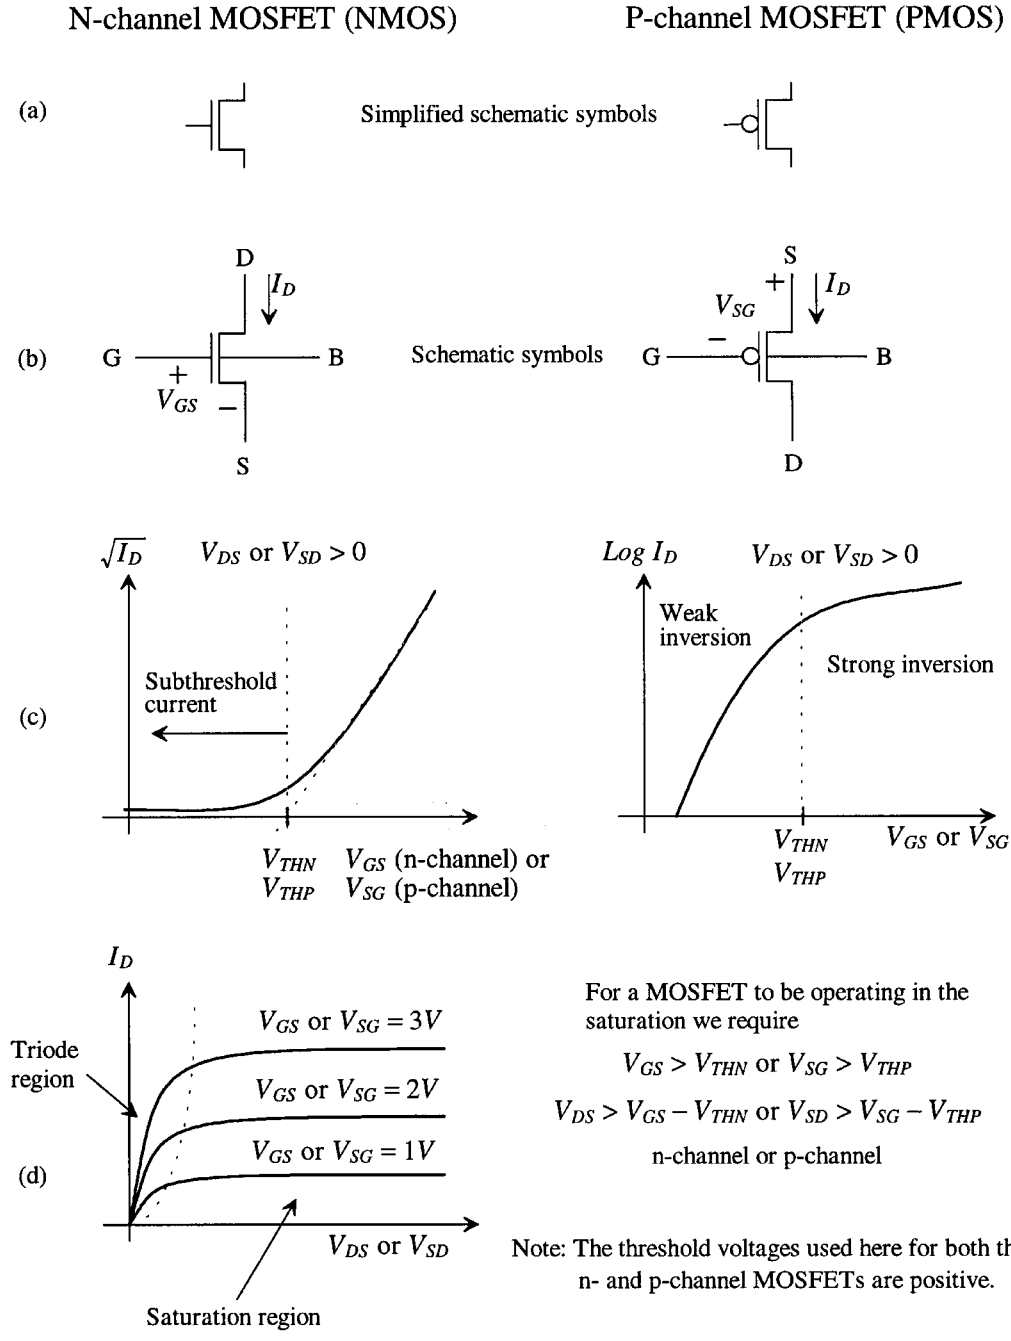

FIGURE 19.1 MOSFET device characteristics.

plotting the Log of the drain current against the gate-source voltage. The slope of the curve in the subthreshold region (sometimes also called the *weak inversion region*) is used to specify how the drain current changes with V_{GS}. A typical value for the reciprocal of the slope of this curve is 100 mV/dec. An equation relating the drain current of an n-channel MOSFET operating in the subthreshold region to V_{GS} is (assuming $V_{DS} > 100$ mV):

$$I_D = I_{D0} \cdot \frac{W}{L} \cdot \exp\left[\frac{q(V_{GS} - V_{THN})}{kT \cdot N}\right] \tag{19.1}$$

where W and L are the width and length of the MOSFET, I_{D0} is a measured constant, k is Boltzmann's constant (1.38×10^{-23} J/K), T is temperature in Kelvin, q is the electronic charge (1.609×10^{-23} C), and N is the slope parameter. Note that the slope of the Log I_D vs. V_{GS} curve in the subthreshold region is

$$\frac{\Delta \log I_D}{V_{GS}} = \frac{q \cdot \log e}{N \cdot kT} \tag{19.2}$$

The Body Effect

The threshold voltage of a MOSFET is dependent on the potential between the source of the MOSFET and its body. Consider Fig. 19.2, showing the situation when the body of an n-channel MOSFET is connected to ground and the source of the MOSFET is held V_{SB} above ground. As V_{SB} is increased (i.e., the potential on the source of the MOSFET increases relative to ground), the minimum V_{GS} needed to cause appreciable current to flow increases (V_{THN} increases as V_{SB} increases). We can relate V_{THN} to V_{SB} using the body-effect coefficient, γ, by

$$V_{THN} = V_{THN0} + \gamma\sqrt{|2\phi_F| + V_{SB}} - \sqrt{|2\phi_F|} \tag{19.3}$$

where V_{THN0} is the zero-bias threshold voltage when $V_{SB} = 0$ and ϕ_F is the surface electrostatic potential[1] with a typical value of 300 mV. An important thing to notice here is that the threshold voltage tends to change less with increasing source-to-substrate (body) potential (increasing V_{SB}).

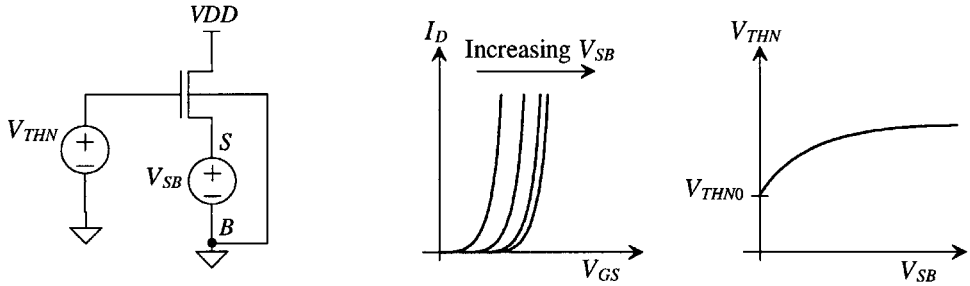

FIGURE 19.2 Illustration of the threshold voltage dependence on body-effect.

The Drain Current

In the following discussion, we will assume that the gate-source voltage of a MOSFET is greater than the threshold voltage so that a reasonably sized drain current can flow ($V_{GS} > V_{THN}$ or $V_{SG} > V_{THP}$). If this is the case, the MOSFET operates in either the triode region or the saturation region [Fig. 19.1(d)]. The drain current of a *long L* n-channel MOSFET operating in the *triode region*, is given by

$$I_D = \beta\left[(V_{GS} - V_{THN})V_{DS} - \frac{V_{DS}^2}{2}\right] \tag{19.4}$$

assuming long L with $V_{DS} \le V_{GS} - V_{THN}$. Note that the MOSFET behaves like a voltage-controlled resistor when operating in the deep triode region with a channel resistance (the resistance is measured between the drain and source of the MOSFET) approximated by

$$R_{CH} = \frac{1}{\beta(V_{GS} - V_{THN}) - \beta V_{DS}} \text{ or } \frac{1}{\beta(V_{GS} - V_{THN})} \text{ if } V_{DS} \ll V_{GS} - V_{THN} \qquad (19.5)$$

When doing analog design, it is often useful to implement a resistor whose value is dependent on a controlling voltage (a voltage-controlled resistor). When the NMOS device is operating in the saturation region, the drain current is given by

$$I_D = \beta(V_{GS} - V_{THN})^2[1 + \lambda(V_{DS} - V_{DS,\,sat})] \qquad (19.6)$$

assuming long L with $V_{DS} \geq V_{GS} - V_{THN}$, where $V_{DS,sat} = V_{GS}\ V_{THN}$.

The *transconductance parameter*, β, is given by

$$\beta = KP \cdot \frac{W}{L} = \mu_{n,\,p} C_{ox} \cdot \frac{W}{L} \qquad (19.7)$$

where $\mu_{n,p}$ is the mobility of either the electron or hole and C_{ox} is the oxide capacitance per unit area [ε_{ox}/t_{ox}, the dieletric constant of the gate oxide (35.4 aF/μm) divided by the gate oxide thickness]. Typical values for KP_n, KP_p, and C_{ox} for a 0.5-μm process are 150 μA/V^2, 50 μA/V^2, and 4 fF/μm^2, respectively. Also, an important thing to note in these equations for an n-channel MOSFET, is that V_{GS}, V_{DS}, and V_{THN} can be directly replaced with V_{SG}, V_{SD}, and V_{THP}, respectively, to obtain the operating equations for the p-channel MOSFET (keeping in mind that all quantities under normal conditions for operation are positive.) Also note that the saturation slope parameter λ (also known as the channel length/mobility modulation parameter) determines how changes in the drain-to-source voltage affect the MOSFET drain current and thus the MOSFET output resistance.

Short-Channel MOSFETs

As the channel length of a MOSFET is reduced, the electron and hole mobilities, μ_n and μ_p, start to get smaller. The mobility is simply a ratio of the electron or hole velocity to the applied electric field. Reducing the channel length increases the applied electric field while at the same time causing the velocity of the electron or hole to saturate (this velocity is labeled v_{sat}). This effect is called *mobility reduction* or *hot-carrier effects* (because the mobility also decreases with increasing temperature). The result, for a MOSFET with a short channel length L, is a reduction in drain current and a labeling of *short-channel MOSFET*. A short-channel MOSFET's current is, in general, linearly dependent on the MOSFET V_{GS} or

$$I_D = W \cdot v_{sat} \cdot C_{ox}(V_{GS} - V_{THN} - V_{DS,\,sat}) \qquad (19.8)$$

To avoid short-channel effects (and, as we shall see, increase the output resistance of the MOSFET when doing analog design), the channel length of the MOSFET is made, generally, 2 to 5 times larger than the minimum allowable L. For a 0.5-μm CMOS process, this means we make the channel length of the MOSFETs 1.0 to 2.5 μm.

MOSFET Output Resistance

An important parameter of a MOSFET in analog applications is its output resistance. Consider the portion of a MOSFET's I-V characteristics shown in Fig. 19.3(a). When the MOSFET is operating in the saturation region, the slope of I_D, because of changes in the drain current with changes in the drain-source voltage, is relatively small. If this change were zero, the drain current would be a fixed value independent of the voltage between the drain and source of the MOSFET (in other words, the MOSFET would act like an ideal current source.) Even with the small change in current with V_{DS}, we can think of the MOSFET as a current source. To model the changes in current with V_{DS}, we can simply place a resistor across the drain and source of the MOSFET [Fig. 19.3(b)]. The value of this resistor is

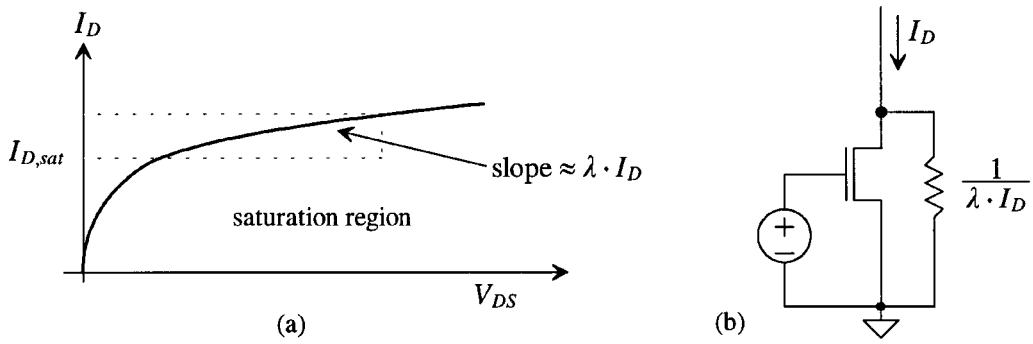

FIGURE 19.3 Output resistance of a MOSFET.

$$r_o \approx \frac{1}{\lambda I_D} \tag{19.9}$$

where λ is in the range of 0.1 to 0.01 V^{-1}.

At this point, several practical comments should be made: (1) in general, to increase λ, the channel length is made 2 to 5 times the minimum allowable channel L (this was also necessary to reduce the short-channel effects discussed above); (2) the value of λ is normally determined empirically; trying to determine λ from an equation is, in general, not too useful; (3) the output resistance of a MOSFET is a function of the MOSFET's drain current. The exact value of this current is not important when estimating the output resistance. Whether $I_{D,sat}$ (the drain current at $V_{D,sat}$) or the actual operating point current, I_D, is used is not practically important when determining r_o.

MOSFET Transconductance

It is useful to determine how a change in the gate-source voltage changes the drain current of a MOSFET operating in the saturation region. We can relate the change in drain current, i_d, to the change in gate-source voltage, v_{gs}, using the MOSFET transconductance, g_m, or

$$g_m = \frac{\Delta i_D}{\Delta v_{GS}} \Rightarrow i_d = g_m v_{gs} \tag{19.10}$$

Neglecting the output resistance of a MOSFET, we can write the sum of the DC and AC (or changing) components of the drain current and gate-source voltage using

$$i_D = i_d(\text{AC}) + I_D(\text{DC}) = \frac{\beta}{2}\left(V_{GS}(\text{DC}) + v_{gs}(\text{AC}) - V_{THN}\right)^2 \tag{19.11}$$

If we hold the DC values constant and assume they are large compared to the AC components, then by simply taking the derivative of i_D with respect to v_{gs}, we can determine g_m. Doing this results in

$$g_m = \beta(V_{GS} - V_{THN}) = \sqrt{2\beta I_D} \tag{19.12}$$

Following this same procedure for the MOSFET operating in the subthreshold region results in

$$g_m = \frac{I_D \cdot q}{kT} \tag{19.13}$$

Notice how the change in transconductance is linear with drain current when the device is operating in the subthreshold region. The larger incremental increase in g_m is due to the exponential relationship between I_D and V_{GS} when the device is operating in the weak inversion region (as compared to the square law relationship when the device is operating in the strong inversion region).

MOSFET Open-Circuit Voltage Gain

At this point, we can ask, "What's the largest possible voltage gain I can get from a MOSFET under ideal biasing conditions?" Consider the schematic diagram shown in Fig. 19.4(a) without biasing circuitry shown and with the effects of finite MOSFET output resistance modeled by an external resistor. The open-circuit voltage gain can be written as

$$|A| = \frac{v_{out}}{v_{gs}} = g_m r_o = \frac{\sqrt{2\beta I_D}}{\lambda I_D} = \frac{\sqrt{2\beta}}{\lambda\sqrt{I_D}} \text{ (for normal operation)} \tag{19.14}$$

which increases as the DC drain biasing current is reduced (and the MOSFET intrinsic speed decreases) until the MOSFET enters the subthreshold region. Once in the subthreshold region, the voltage gain flattens out and becomes

$$A_v = g_m r_o = \frac{I_D \cdot q}{kT} \cdot \frac{1}{\lambda I_D} = \frac{q}{\lambda \cdot kT} \text{ (in the subthreshold region)} \tag{19.15}$$

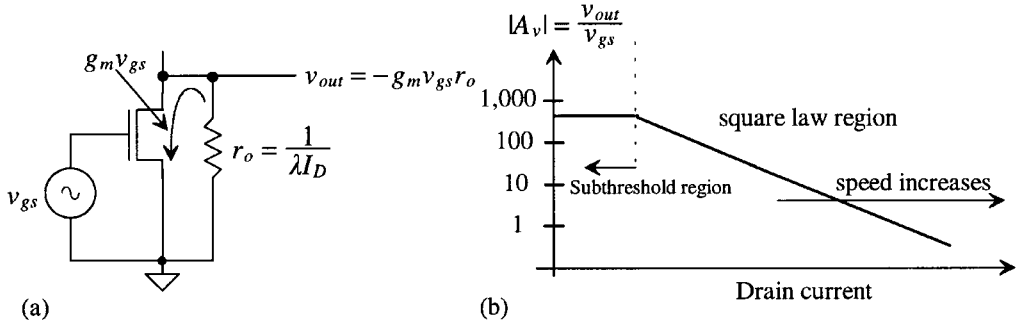

FIGURE 19.4 Open-circuit voltage gain (DC biasing not shown).

Layout of the MOSFET

Figure 19.5 shows the layout of both n-channel and p-channel devices. In this layout, we are assuming that a p-type substrate is used for the body of the NMOS (the body connection for the n-channel MOSFET is made through the p^+ diffusion on the left in the layout). An n-well is used for the body of the PMOS devices (the connection to the n-well is made through the n^+ diffusion on the right in the layout). An important thing to notice from this layout is that the intersection of polysilicon (poly for short) and n^+ (in the p-substrate) or p^+ (in the n-well) forms a MOSFET. The length and width of the MOSFET, as seen in Fig. 19.5, is determined by the size of this overlap. Also note that the four metal connections to the terminals of each MOSFET, in this layout, are floating; that is, not connected to anything but the MOSFETs themselves. It is important to understand, since the p-substrate is common to all MOSFETs on the chip, that this would require the body of the n-channel MOSFET (again the p^+ diffusion on the left in the layout) be connected to *VSS* (ground for most digital applications).

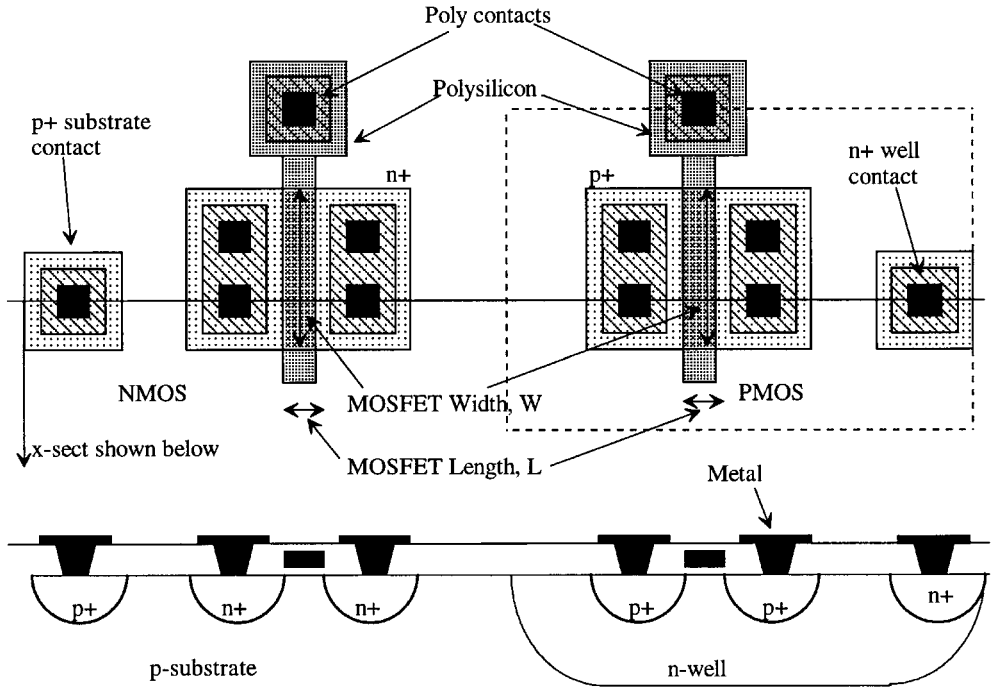

FIGURE 19.5 Layout and cross-sectional views of NMOS and PMOS devices.

19.2 Biasing Circuits

A fundamental component of any CMOS amplifier is a biasing circuit. This section presents important design topologies and considerations used in the design of CMOS biasing circuits. We begin this section with a discussion of current mirrors.

The Current Mirror

The basic CMOS current mirror is shown in Fig. 19.6. For the moment, we will not concern ourselves with the implementation of I_{REF}. By tying M1's gate to its drain, we set V_{GS} at a value given by

$$V_{GS} = V_{THN} + \sqrt{\frac{2I_{REF}}{\beta_1}} \tag{19.16}$$

For most design applications, the term under the square root is set to a few hundred millivolts or less. Because M2's gate-source voltage, and thus its drain current (I_{OUT}), is set by I_{REF}, we say that M2 mirrors the current in M1. If M2's β is different than M1's, we can relate the currents by

$$\frac{I_{OUT}}{I_{REF}} = \frac{2\beta_2(V_{GS} - V_{THN})^2}{2\beta_1(V_{GS} - V_{THN})^2} = \frac{\beta_2}{\beta_1} = \frac{W_2}{W_1} \text{ if } L_1 = L_2 \tag{19.17}$$

Notice that we have neglected the finite output resistance of the MOSFETs in this equation. If we include the effects of finite output resistance, and assume M1 and M2 are sized the same, we see from Fig. 19.6 that the only time I_{REF} and I_{OUT} are equal is when $V_{GS} = V_{OUT} = V_{DS2}$.

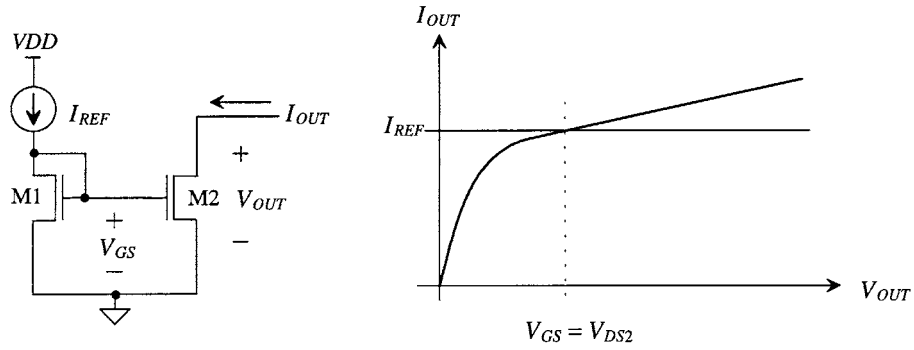

FIGURE 19.6 Basic CMOS current mirror.

Design Example

Design a 100-μA current sink and a 200-μA current source assuming that you are designing with a 0.5-μm CMOS process with KP_n = 150 μA/V², KP_p = 50 μA/V², V_{THN} = 0.8 V, and V_{THP} = 0.9 V. Assume λ was empirically determined (or determined from simulations) to be 0.05 V^{-1} with L = 2.0 μm. Assume that an I_{REF} of 50 μA is available for the design. Determine the output resistance of the current source/sink and the minimum voltage across the current source/sink.

The schematic of the design is shown in Fig. 19.7. If we design so that that term $\sqrt{(2I_{REF})/\beta_1}$ is 300 mV, the width of M1, W_1, is 15 μm (KP_n = 150 μA/V², L = 2 μm). The MOSFET, M1, has a gate-source voltage 300 mV in *excess* of the threshold voltage, or, in other words, the MOSFET V_{GS} is 1.1 V. For M2 and M3 to sink 100 μA (twice the current in M1), we simply increase their widths to 30 μm for the same V_{GS} bias supplied by M1. Note the minimum voltage required across M3, V_{DS3}, in order to keep M3 out of the triode region (V_{DS3} $V_{GS} - V_{THN}$), is simply the *excess gate voltage*, $\sqrt{(2I_{REF})/\beta_1}$, or, for this example, 300 mV. (Note: simply put, 300 mV is the minimum voltage on the drain of M3 required to keep it in the saturation region.) Increasing the widths of the MOSFETs lowers the minimum voltage required across the MOSFETs (lowers the excess gate voltage) so they remain in saturation at the price of increased layout area. Also, differences in MOSFET threshold voltage become more significant, affecting the matching between devices. Note that the output resistance of M3 is simply.

The purpose of M2 should be obvious at this point; it provides a 100-μA bias for the p-channel current mirror M4/M5. Again, if we set M4's excess gate voltage to 300 mV (so that the V_{SG} of the p-channel MOSFET is 1.2 V), the width of M4 can be calculated (assuming that L is 2 μm and KP_p = 50 μA/V²) to be 45 μm (or a factor of 3 times the n-channel width due to the differences in the transconductance

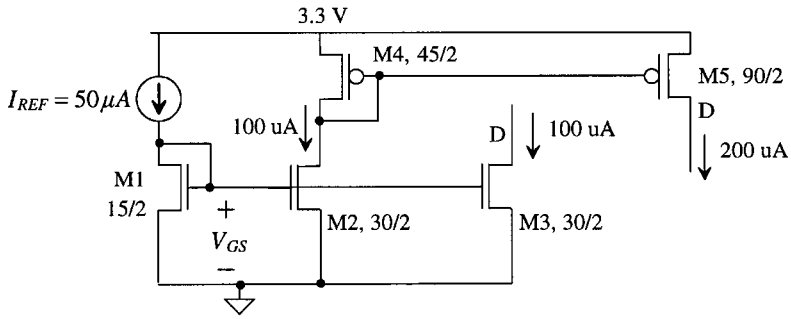

FIGURE 19.7 Design example.

parameters of the MOSFETs). Since the design required a current source of 200 μA, we increase the width of the p-channel, M5, to 90 μm (so that it mirrors twice the current that flows in M4). The output resistance of the current source, M5, is 100 kΩ, while the maximum voltage on the drain of M5 is 3 V (in order to keep M5 in saturation.)

Layout of Current Mirrors

In order to get the best matching between devices, we need to lay the MOSFETs out so that differences in the mirrored MOSFETs' widths and lengths are minimized. Figure 19.8 shows the layout of the M1 (15/2) and M2 (30/2) MOSFETs of Fig. 19.7. Notice how, instead of laying M2 out in a fashion similar to M1 (i.e., a single poly over active strip), we split M2 into two separate MOSFETs that have the same shape as M1.

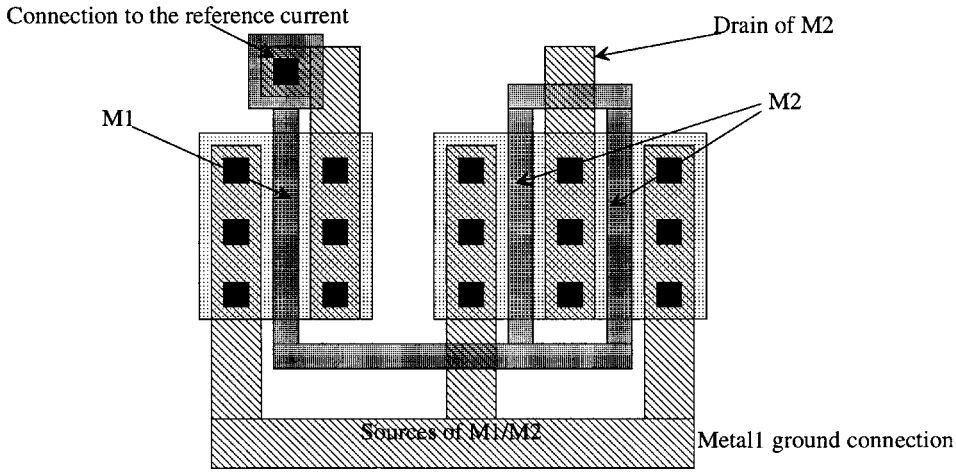

FIGURE 19.8 Layout of MOSFET mirror M1/M2 in Fig. 19.7.

The matching between current mirrors can also be improved using a *common-centroid* layout (Fig. 19.9). Parameters such as the threshold voltage and *KP* in practice can have a somewhat linear change with position on the wafer. This may be the result of varying temperature on the top of the wafer during processing, or fluctuations in implant dose with position. If we lay MOSFETs M2 and M1 out as shown

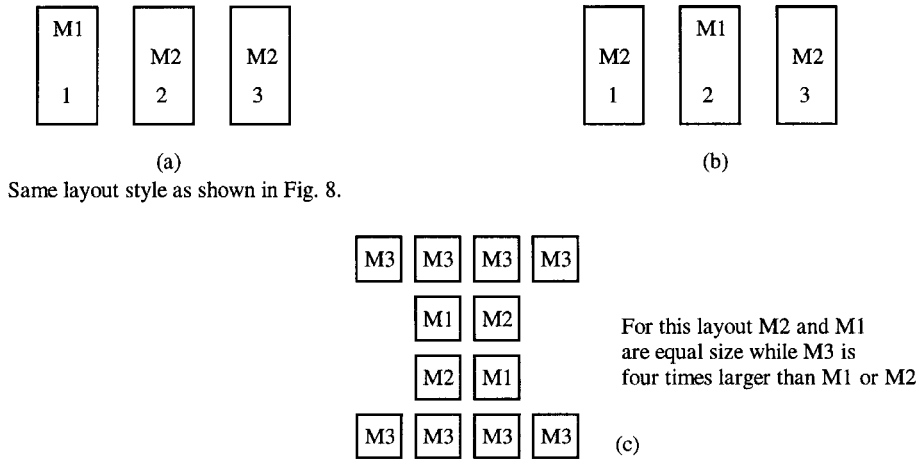

FIGURE 19.9 Common-centroid layout used to improve matching.

in Fig. 19.9(a) (which is the same way they were laid out in Fig. 19.8), M1 has a "weight" of 1 while M2 has a weight of 5. These numbers may correspond to the threshold voltages of three individual MOSFETs with numerical values 0.81, 0.82, and 0.83 V. By using the layout shown in Fig. 19.9(b), M1's or M2's average weight is 2. In other words, using the threshold voltages as an example, M1's threshold voltage is 0.82 V while the average of M2's threshold voltage is also 0.82 V. Similar discussions can be made if the transconductance parameters vary with position. Figure 19.9(c) shows how three devices can be matched using a common-centroid layout (M2 and M1 are the same size while M3 is 4 times their size.) A good exercise at this point is to modify the layout of Fig. 19.9(c) so that M2 is twice the size of M1 and one half the size of M3.

The Cascode Current Mirror

We saw that in order to improve the matching between the two currents in the basic current mirror of Fig. 19.6, we needed to force the drain-source voltage of M2 to be the same as the drain-source voltage of M1 (which is also V_{GS} in Fig. 19.6). This can be accomplished using the cascode connection of MOSFETs shown in Fig. 19.10. The term "cascode" comes from the days of vacuum tube design where a cascade of a common-cathode amplifier driving a common-grid amplifier was used to increase the speed and gain of an overall amplifier design.

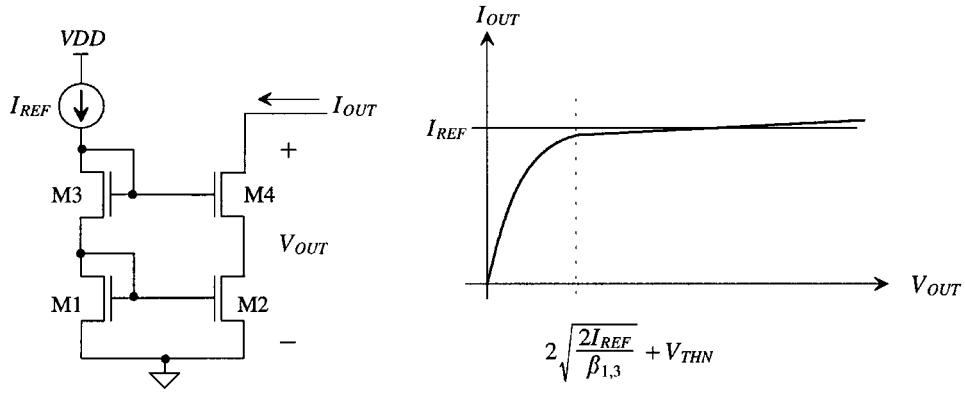

FIGURE 19.10 Basic cascode CMOS current mirror.

Using the cascode configuration results in higher output resistance and thus better matching. For the following discussion, we will assume that M1 and M3 are the same size, as are M2 and M4. Again, remember that M1 and M2 form a current mirror and operate in the same way as previously discussed. The addition of M3 and M4 helps force the drain-source voltages of M1/M2 to the same value. The minimum V_{OUT} allowable, in order to keep M4 out of the triode region, across the current mirror increases to

$$V_{OUT,\,min} = 2\sqrt{\frac{2I_{REF}}{\beta_{1,3}}} + V_{THN} \tag{19.18}$$

which is basically an increase of V_{GS} over the basic current mirror of Fig. 19.6.

The output resistance of the cascode configuration can be derived with the circuit model of Fig. 19.11. Here, we assume that the gates of M4 and M2 are at fixed DC potentials (which are set by I_{REF} flowing through M1/M3). Since the source of M2 is held at ground, we know that the AC component of v_{gs2} is 0. Therefore, we can replace M2 with a small-signal resistance $r_o = (1/\lambda I_{OUT})$. To determine the output resistance of the cascode current mirror, we apply an AC test voltage, v_{test}, and measure the AC test current

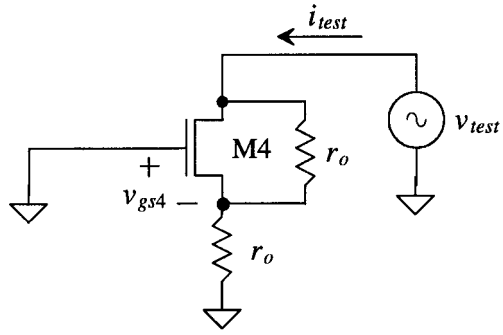

FIGURE 19.11 Determining the small-signal output resistance of the cascode current mirror.

that flows into the drain of M4. Ideally, only the DC component will flow through v_{test}. We can write the AC gate-source voltage of M4 as $v_{gs4} = -i_{test} \cdot r_o$. The drain current of M4 is then $g_{m4}v_{gs4} = -i_{test} \cdot g_{m4}r_o$ while the current through the small-signal output resistance of M4, r_o, is $(v_{test} - (-i_{test}r_o))/r_o$. Combining these equations yields the cascode output resistance of

$$R_{out,\,cascode} = \frac{v_{test}}{i_{test}} = r_o(1 + g_m r_o) + r_o \approx g_m r_o^2 \tag{19.19}$$

The cascode current source output resistance is $g_m r_o$ (the open-circuit voltage gain of a MOSFET) times larger than r_o (the simple current mirror output resistance.) The main drawback of the cascode configuration is the increase in the minimum required voltage across the current sink in order for all MOSFETs to remain in the saturation region of operation.

Low-Voltage Cascode Current Mirror

If we look at the cascode current mirror of Fig. 19.10, we see that the drain of M2 is held at the same potential as the drain of M1, that is, VGS or $\sqrt{(2I_{REF})/\beta} + V_{THN}$. We know that the voltage on the drain of M2 can be as low as $\sqrt{(2I_{REF})/\beta}$ before it starts to enter the triode region. Knowing this, consider the *wide-swing current mirror* shown in Fig. 19.12. Here, "wide-swing" means the minimum voltage across the current mirror is $2\sqrt{(2I_{REF})/\beta}$, the sum of the excess gate voltages of M2 and M4. To understand the operation of this circuit, assume that M1 through M4 have the same W/L ratio (their βs are all equal). We know that the V_{GS} of M1 and M2 is $\sqrt{(2I_{REF})/\beta} + V_{THN}$. It is desirable to keep M2's drain

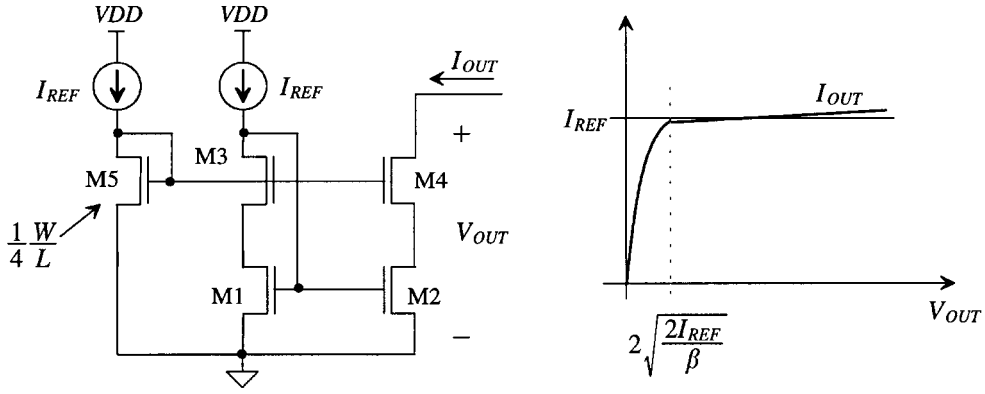

FIGURE 19.12 Wide-swing CMOS cascode current mirror.

at $\sqrt{(2I_{REF})/\beta}$ for wide-swing operation. This means, since M3/M4 are the same size as M1/M2, the gate voltage of M3/M4 must be $V_{GS} + \sqrt{(2I_{REF})/\beta}$ or $2\sqrt{(2I_{REF})/\beta} + V_{THN}$. By sizing M5's channel width so that it is one fourth of the size of the other transistor widths and forcing I_{REF} through the diode connected M5, we can generate this voltage. We should point out that the size (its W/L ratio) of M5 can be further decreased, say to 1/5, in order to keep M1/M2 from entering the triode region (and the output resistance from decreasing). The cost is an increase in the minimum allowable voltage across M2/M4, that is, V_{OUT}.

Simple Current Mirror Biasing Circuits

Figure 19.13 shows two simple circuits useful for generating the reference current, I_{REF}, used in the current mirrors discussed in the previous section. The circuit shown in Fig. 13(a) uses a simple resistor with a gate-drain connected MOSFET to generate a reference current. Note how, by adding MOSFETs mirroring the current in M1 or M2, we can generate any multiple of I_{REF} needed. The reference current, of Fig. 19.13(a), can be determined by solving

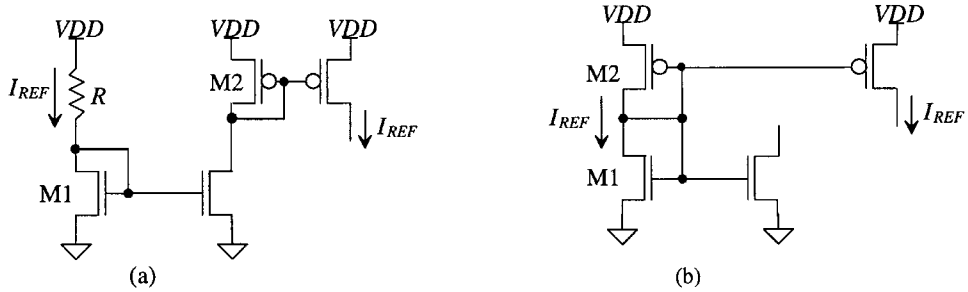

FIGURE 19.13 Simple biasing circuits.

$$I_{REF} = \frac{VDD - V_{GS}}{R} = \frac{\beta}{2}(V_{GS} - V_{THN})^2 \tag{19.20}$$

Figure 19.13(b) shows a MOSFET-only bias circuit. Since the same current flows in M1 and M2, we can mirror off of either MOSFET to generate our bias currents. The current flowing in M1/M2 is designed using

$$I_{REF} = \frac{\beta_1}{2}(V_{GS} - V_{THN})^2 = \frac{\beta_2}{2}(VDD - V_{GS} - V_{THN})^2 \tag{19.21}$$

Notice in both equations above that the reference current is a function of the power supply voltage. Fluctuations, as a result of power supply noise, in *VDD* directly affect the bias currents. In the next section, we will present a method for generating currents that reduces the currents' sensitivity to changes in *VDD*.

Temperature Dependence of Resistors and MOSFETS

Figure 19.14 shows how a resistor changes with temperature, assuming a linear dependence. The temperature coefficient is used to relate the value of a resistor at room temperature, or some known temperature T_0, to the value at a different temperature. This relationship can be written as

$$R(T) = R(T_0) \cdot [1 + TCR(T - T_0)] \tag{19.22}$$

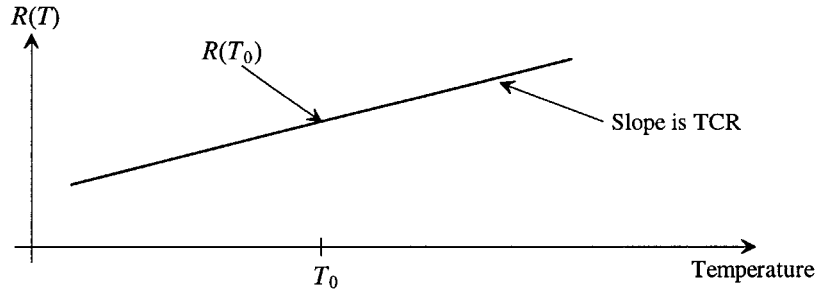

FIGURE 19.14 Variation of a resistor with temperature.

where *TCR* is the temperature coefficient of the resistor *ppm*/°C (parts per million, a multiplier of 10^{-6}, per degree C). Typical values for TCRs for n-well, n^+, p^+, and poly resistors are 2000, 500, 750, and 100 ppm/°C, respectively.

Figure 19.15 shows how the drain current of a MOSFET changes with temperature. At low gate-source voltages, the drain current increases with increasing temperature. This is a result of the threshold voltage decreasing with increasing temperature which dominates the I-V characteristics of the MOSFET. The temperature coefficient of the threshold voltage (NMOS or PMOS), TCV_{TH}, is generally around –3000 ppm/°C. We can relate the threshold voltage to temperature using

$$V_{TH}(T) = V_{TH}(T_0)[1 + TCV_{TH}(T - T_0)] \tag{19.23}$$

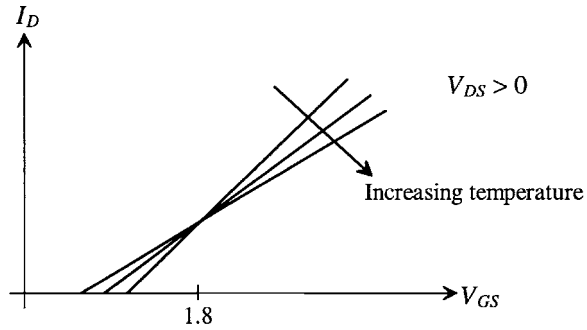

FIGURE 19.15 Temperature characteristics of a MOSFET.

At larger gate-source voltages, the drain current decreases with increasing temperature as a result of the electron or hole mobility decreasing with increasing temperature. In other words, at low gate-source voltages, the temperature changing the threshold voltage dominates the I-V characteristics of the MOSFET; while at larger gate-source voltages, the mobility changing with temperature dominates. Note that at around 1.8 V, for a typical CMOS process, the drain current does not change with temperature. The mobility can be related to temperature by

$$\mu(T) = \mu(T_0)\left(\frac{T}{T_0}\right)^{-1.5} \tag{19.24}$$

The Self-Biased Beta Multiplier Current Reference

Figure 19.16 shows the self-biased beta multiplier current reference. This circuit employs positive feedback, with a gain less than one, to reduce the sensitivity of the reference current to power supply changes.

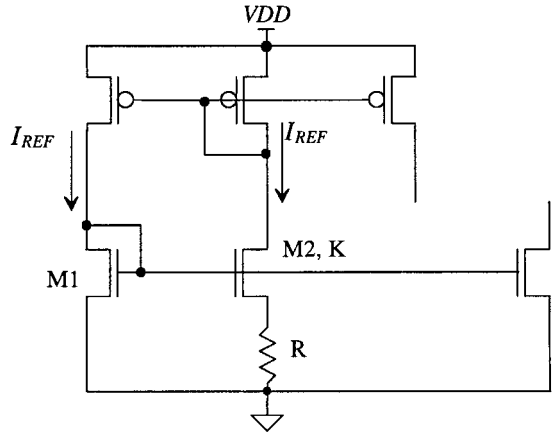

FIGURE 19.16 Beta multiplier current reference.

MOSFET M2 is made K times wider than MOSFET M1 (in other words, $\beta_2 = K\beta_1$; hence, the name beta multiplier). We know from this figure that $V_{GS1} = V_{GS2} + I_{REF}R$, where $V_{GS1} = \sqrt{(2I_{REF})/\beta_1} + V_{THN}$ and $V_{GS2} = \sqrt{(2I_{REF})/K\beta_1} + V_{THN}$; therefore, we can write the current in the circuit as

$$I_{REF} = \frac{2}{R^2\beta_1}\left[1 - \sqrt{\frac{1}{K}}\right]^2 \tag{19.25}$$

which shows no first-order dependence on the power supply voltage.

Start-up Circuit

One of the drawbacks of using the reference circuit of Fig. 19.16 is that it has two stable operating points [Fig. 19.17(a)]. The desirable operating point, point A, occurs when the current flowing in the circuit is I_{REF}. The undesirable operating point occurs when zero current flows in the circuit, point B. Because of the possibility of zero current flowing in the reference, a start-up circuit should always be used when using the beta multiplier. The purpose of the start-up circuit is to ensure that point B is avoided. When designed properly, the start-up circuit [Fig. 19.17(b)] does not affect the beta multiplier operation when I_{REF} is non-zero (M3 is off when operating at point A).

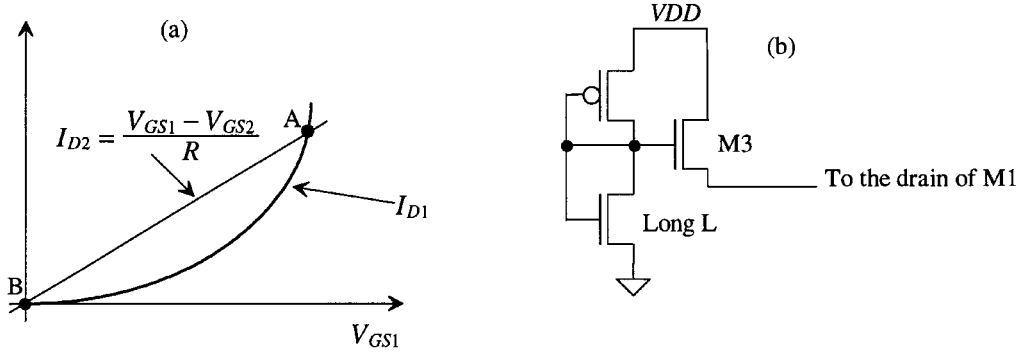

FIGURE 19.17 Start-up circuit for the beta multiplier circuit shown in Fig. 19.16.

A Comment About Stability

Since the beta multiplier employs positive feedback, it is possible that the circuit can become unstable and oscillate. However, with the inclusion of the resistor in series with the source of M2, the gain around the loop, from the gate of M2 to the drain/gate of M1, with the loop broken between the gates of M1 and M2, is less than one, keeping the reference stable. Adding a large capacitance across *R*, however, can increase the loop gain to the point of instability. This situation could easily occur if *R* is bonded out to externally set the current.

19.3 Amplifiers

Now that we have introduced biasing circuits and MOS device characteristics, we will immediately dive into the design of operational amplifiers. Since space is very limited, we will employ a top-down approach in which a series of increasingly complex circuits are dissected stage by stage and individual blocks analyzed.

Operational amplifiers typically are composed of either two or three stages consisting of a differential amplifier, a gain stage and an output stage as seen in Fig. 19.18. In some applications, the gain stage and the output stage are one and the same if the load is purely capacitive. However, if the output is to drive a resistive load or a large resistive load, then a high current gain buffer amplifier is used at the output. Each stage plays an important role in the performance of the amplifier.

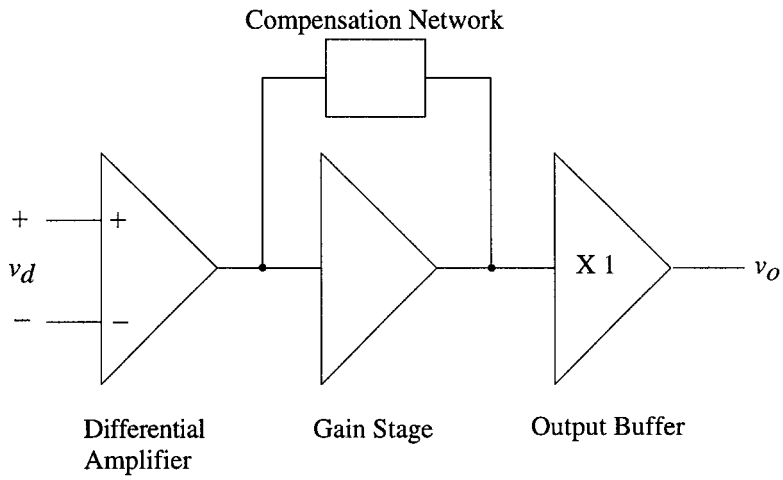

FIGURE 19.18 Block diagram for a generic op-amp.

The differential amplifier offers a variety of advantages and is always used as the input to the overall amplifier. Since it provides common-mode rejection, it eliminates noise common on both inputs, while at the same time amplifying any differences between the inputs. The limit for which this common mode rejection occurs is called *common-mode range* and signifies the upper and lower common mode signal values for which the devices in the diff-amp are saturated. The differential amplifier also provides gain. The gain stage is typically a common-source or cascode type amplifier. So that the amplifier is stable, a compensation network is used to intentionally lower the gain at higher frequencies. The output stage provides high current driving capability for either driving large capacitive or resistive loads. The output stage typically will have a low output impedance and high signal swing characteristics. In some cases, it may be advantageous to add bipolar devices to improve the performance of the circuitry. These will be presented as the block level circuits are analyzed.

The Simple Unbuffered Op-Amp

Examine the simple operational amplifier shown in Fig. 19.19. Here, the amplifier can be segregated into a biasing block, a differential input stage, an output stage, and a compensation capacitor.

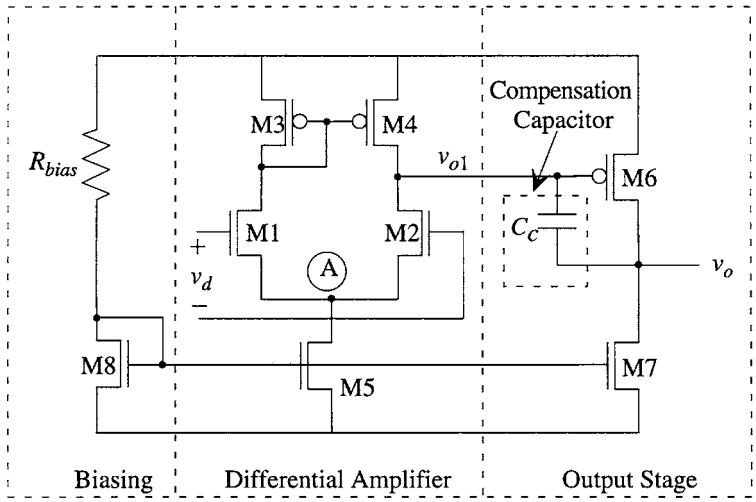

FIGURE 19.19 Basic two-stage op-amp.

The biasing circuit is a simple current mirror driver, consisting of the resistor R_{bias} and the transistor M8. The current through M8 is mirrored through both M5 and M7. Thus, the current through the entire circuit is set by the value of R_{bias} and the relative W/Ls of M8, M5, and M7. The actual values of this current will be discussed a little bit later on. When designing with R_{bias}, one must be careful not to ignore the effect of temperature on R_{bias}, and thus the values of the currents through the circuit. We will see later on how the bias current greatly affects the performance of the amplifier. For the commercial temperature range of 0°C to 125°C, the current through M8 should be simulated with R_{bias} at values of ±30 % of its nominal value. Other, more sophisticated voltage references (as discussed earlier) can be used in place of the resistor reference, and will be presented as we progress.

The Differential Amplifier

The differential amplifier is composed of M1, M2, M3, M4, and M5, with M1 matching M2 and M3 matching M4. The transistor M5 can be replaced by a current source in the ideal case to enhance one's understanding of the circuit's functionality. The node labeled as node A can be thought of as a virtual ground, since the current through M5 is constant and thus the voltage at node A is also constant.

Now assume that the gate of M2 is tied to ground as seen in Fig. 19.20. Any small signal on the gate of M1 will result in a small signal current i_{d1}, which will flow from drain to source of M1 and will also be mirrored from M3 to M4. Note that since M5 can be thought of as an ideal current source, it can be replaced with its ideal impedance of an open circuit. Therefore, i_{d1} will also flow from source to drain of M2. Remember that the small signal current is different from the DC current flowing through M2. The small signal current can be thought of as the current generated from the instantaneous (AC + DC) voltage at the output. If the instantaneous voltage at the output node swings up, then the small signal current through M2 will flow from drain to source. However, if the instantaneous voltage swings down, the change in voltage will be considered negative and thus the small signal current will assume an identical polarity, thus flowing from source to drain of M2. The small signal voltage produced at the output node will then be $2i_{d1}$ times the output impedance of the amplifier. In this case, R_{out} is simply $r_{o2}||r_{o4}$. The value of the small signal current, i_{d1}, is simply

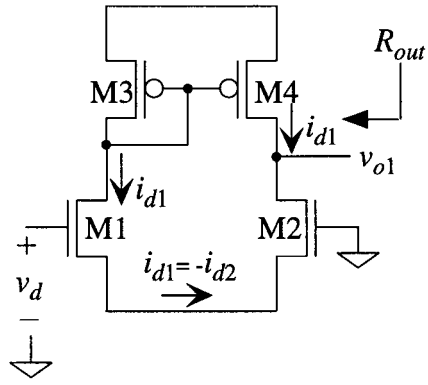

FIGURE 19.20 Pseudo-AC circuit showing small signal currents.

$$i_{d1} = g_{m1} v_{gs1} \tag{19.26}$$

and the differential voltage, $v_d = v_{gs1} + v_{sg2}$. Therefore, since $v_{gs1} = v_{gs2}$, then,

$$\frac{i_{d1}}{v_d} = \frac{g_{m1}}{2} \tag{19.27}$$

the small signal output voltage is simply

$$v_{o1} = 2 \cdot i_{d1} \cdot r_{o2} \| r_{o4} \tag{19.28}$$

and the small signal voltage gain can then be easily derived as

$$\frac{v_{o1}}{v_d} = g_{m1,2}(r_{o2} \| r_{o4}) \tag{19.29}$$

Now let us examine this equation more carefully. Substituting the expressions for g_m and r_o, the previous equation becomes

$$\frac{v_{o1}}{v_d} \approx \sqrt{2\beta_{1,2} I_{D1,2}} \cdot \frac{1}{2\lambda I_{D1,2}} = K' \cdot \sqrt{\frac{W_{1,2}}{L_{1,2} I_{D1,2}}} \cdot \frac{1}{\lambda} \tag{19.30}$$

where K' is a constant, which is uncontrollable by the designer. When designing analog circuits, it is just as important to understand the effects of the controllable variables on the specification as it is to know the absolute value of the gain using hand calculations. This is because the hand analysis and computer simulations will vary a great deal because of the complex modeling used in today's CAD tools. Examining Eq. (19.30), and knowing that the effect of λ on the gain diminishes as L increases such that $1/\lambda$ is directly proportional to channel length. Then, a proportionality can be established between $W/L_{1,2}$ and the drain current versus the small signal gain such that

$$\frac{v_{o1}}{v_d} \propto \sqrt{\frac{W_{1,2} \cdot L_{1,2}}{I_{D1,2}}} \tag{19.31}$$

Notice that the constant was not included since the value is not dependent on anything the designer can adjust. The importance of this equation tells us that the gain is proportional to the square root of the

product of W and L and inversely proportional to the square root of the drain current through M1 and M2, which is also 1/2 I_{D6}. So to increase the gain, one must increase W or L or decrease the value I_{D6}, which is dependent on the value of R_{bias}.

The Gain Stage

Now examine the output stage consisting of M6 and M7. Here, the driving transistor, M6, is a simple inverting amplifier with a current source load as seen in equivalent circuit shown in Fig. 19.21. The value of the small signal current is defined by the AC signal v_{o1}, which is equal to v_{sg6}. Therefore,

$$\frac{i_{d6}}{v_{o1}} = -g_{m6} \tag{19.32}$$

and the gain of the stage is simply

$$\frac{d6}{v_{o1}} \cdot \frac{v_o}{i_{d6}} = \frac{v_o}{v_{o1}} = -g^{m6} \cdot r_{o6} \| r_{o7} \tag{19.33}$$

Again, we can write the gain in terms of the designer's variables, so that the gain of the amplifier can be expressed as a proportion of

$$\frac{v_o}{v_{o1}} \propto \sqrt{\frac{W_6 \cdot L_{6,7}}{I_{D6,7}}} \tag{19.34}$$

Therefore, overall, the gain of the entire amplifier is

$$\frac{v_o}{v_d} = g_{m1,2}(r_{o2} \| r_{o4}) \cdot -g^{m6}(r_{o6} \| r_{o7}) \tag{19.35}$$

or as the proportionalities

$$\frac{v_o}{v_d} \propto \sqrt{\frac{W_{1,2} \cdot L_{1,2}}{I_{D1,2}}} \cdot \sqrt{\frac{W_6 \cdot L_{6,7}}{I_{D6,7}}} \tag{19.36}$$

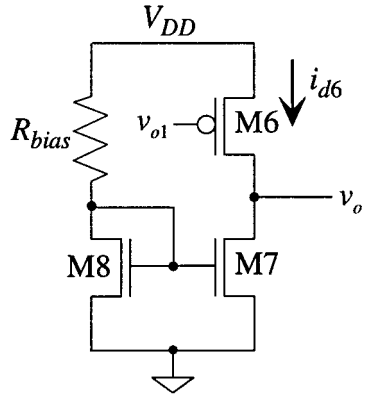

FIGURE 19.21 Output stage circuit.

So, the key variables for adjusting gain are the drain currents (the smaller the better) and the W and L ratios of M1, M2, and M6 (the larger the better). Of course, there are lower and upper limits to the drain currents and the W/Ls, respectively, that we will examine as we analyze other specifications that will ultimately determine the bounds of adjustability.

Frequency Response

Now examine the amplifier circuit shown in Fig. 19.22. In this particular circuit, the compensation capacitor, C_C, is removed and will be re-added shortly. The capacitors C_1 and C_2 represent the total lumped capacitance from each ground. Since the output nodes associated with each output is a high impedance, these nodes will be the dominant frequency-dependent nodes in the circuit. Since each node in a circuit contributes a high-frequency pole, the frequency response will be dominated by the high-impedance nodes.

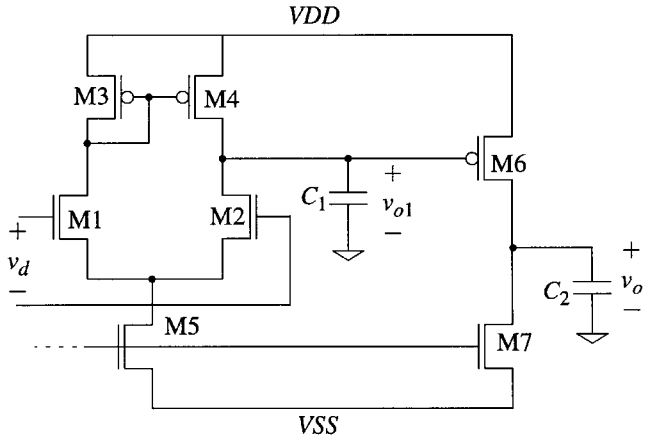

FIGURE 19.22 Two-stage op-amp with lumped parasitic capacitors.

An additional capacitor could have been included at the gate of M4 to ground. However, the equivalent impedance from the gate of M4 to ground is approximately equal to the impedance of a gate-drain connected device or $1/g_{m3}$ as seen in Fig. 19.23 (a)–(c). If a controlled source has the controlling voltage directly across its terminals [Fig. 19.23(b)], then the effective resistance is simply the controlling voltage

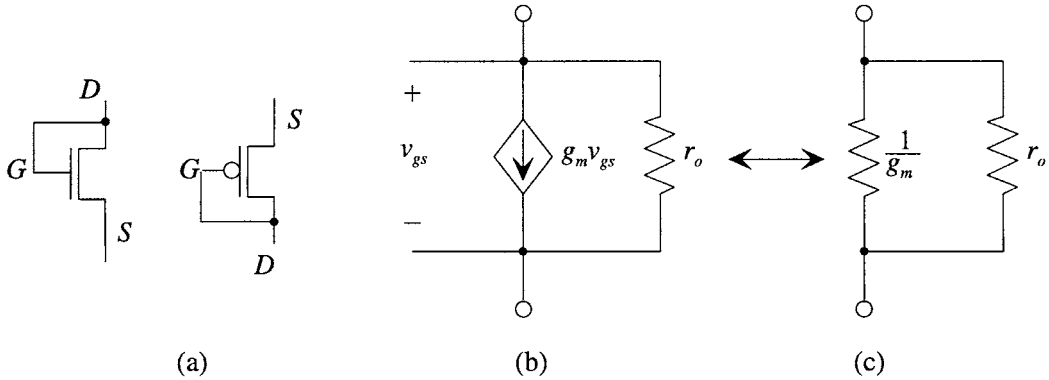

FIGURE 19.23 Equivalent resistance for a gate-drain connected MOSFET device.

(in this case, v_{gs}) divided by the controlled current ($g_m v_{gs}$), which is $1/g_m || r_o$ or approximately $1/g_m$ if r_o is much greater than $1/g_m$ [Fig. 19.23(c)]. Therefore, the impedance seen from the gate of M4 to ground is low, and the pole associated with the node will be at a much higher frequency than the high-impedance nodes. The same holds true with the node associated with the drain of M5. That node is considered an AC ground, so it has no effect on the frequency response of the small signal circuit. The only remaining node is the node which defines the current mirrors (the gate of M8). Since this node is not in the small signal path, and is a DC bias voltage, it can be also be considered to be an AC ground.

One can approximate the frequency response of the amplifier by examining both the effective impedance and parasitic capacitance at the output of each stage. The parasitic capacitances can be seen in the small signal model of a MOSFET in Fig. 19.24. The capacitors C_{gb}, C_{sb}, and C_{db} represent the bulk depletion capacitors of the transistors, while C_{gd} and C_{gs} represent the overlap capacitances from gate to drain and gate to source, respectively. Referring to Fig. 19.25, which shows the parasitic capacitors explicitly, C_1 can now be written as

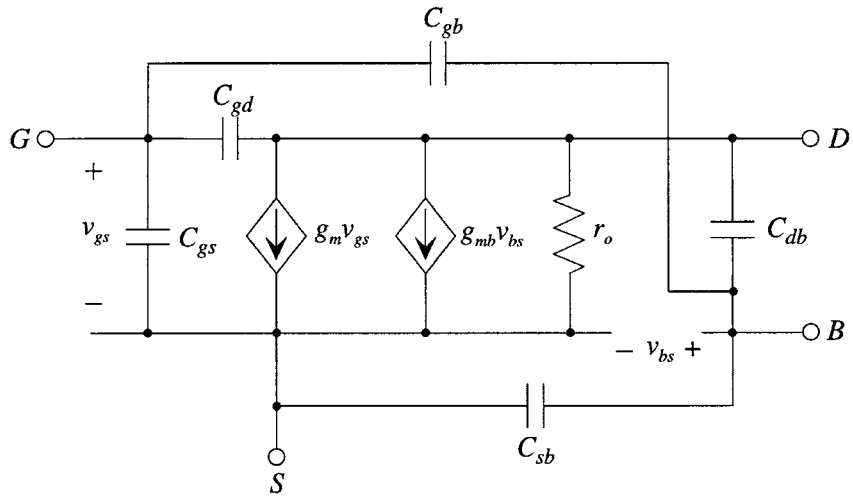

FIGURE 19.24 High-frequency, small signal model with parasitic capacitors.

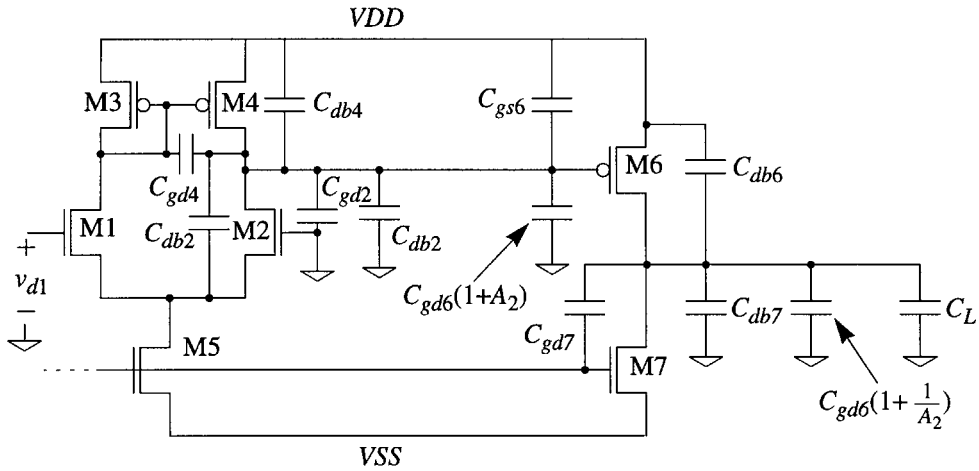

FIGURE 19.25 Two-stage op-amp with parasitics shown explicitly.

$$C_1 = C_{db4} + C_{gd4} + C_{db2} + C_{gd2} + C_{gs6} + C_{gd6}(1 + A_2) \tag{19.37}$$

Note that C_{gd4} is included as capacitor to ground since the low impedance caused by the gate-drain device of M3 can be considered equivalent to an AC ground. The capacitor C_{db2} is also connected to AC ground at the source-coupled node consisting of M1 and M2.

Miller's theorem was used to determine the effect of the bridging capacitor C_{db6}, connected from the gate to the drain of M6. Miller's theorem approximates the effects of the gate-drain capacitor by replacing the bridging capacitor with an equivalent input capacitor of value $C_{db6}\cdot(1 - A_2)$ and an equivalent output capacitor with a value of $C_{db6}\cdot(1 - 1/A_2)$. The term A_2 is the gain across the original bridging capacitor and is $-g_{m6}\cdot r_{o6}||r_{o7}$. The reader should consult Ref. 2 for a proof of Miller's theorem.

The capacitor C_2 can also be determined by examining Fig. 19.25,

$$C_2 = C_{db6} + C_{db7} + C_{gd7} + C_{gd6}\cdot\left(1 + \frac{1}{A_2}\right) + C_L \tag{19.38}$$

Now assume that C_1 is greater than C_2. This means that the pole associated with the diff-amp output will be lower in frequency than the pole associated with the output of the output stage. Thus, a good model for the op-amp can be seen in Fig. 19.26. The transfer function, ignoring C_C, will then become

$$\frac{v_o(s)}{v_{d1}(s)} = -g_{m1}(r_{o2}||r_{o4})\cdot g_{m6}(r_{o6}||r_{o7})\cdot\frac{1}{\left(j\frac{f}{f_{p1}} + 1\right)\left(\frac{f}{f_{p2}} + 1\right)} \tag{19.39}$$

where

$$f_{p1} = \frac{1}{2\pi R_{out1}C_1}, f_{p2} = \frac{1}{2\pi R_{out}C_2} \tag{19.40}$$

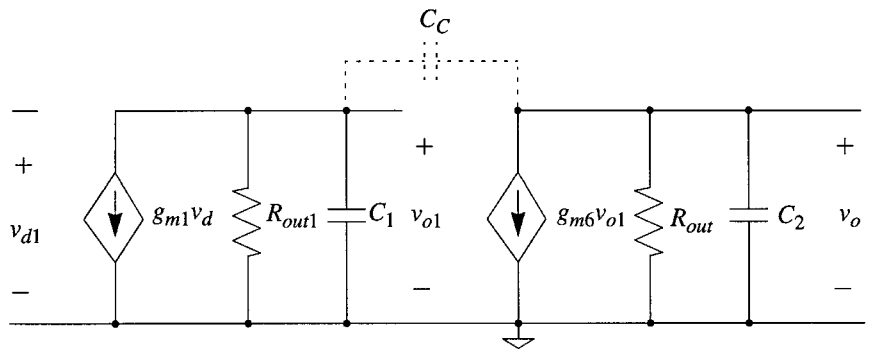

FIGURE 19.26 Model used to determine the frequency response of the two-stage op-amp.

The plot of the transfer function can be seen in Fig. 19.27. Note that in examining the frequency response, that the phase margin is virtually zero. Remember that phase margin is the difference between phase at the frequency at which the magnitude plot reaches 0 dB (also known as the gain-bandwidth product) and the phase at the frequency at which the phase has shifted –180°. It is recommended for stability reasons, that the phase margin of any amplifier be at least 45° (60° is recommended). A phase

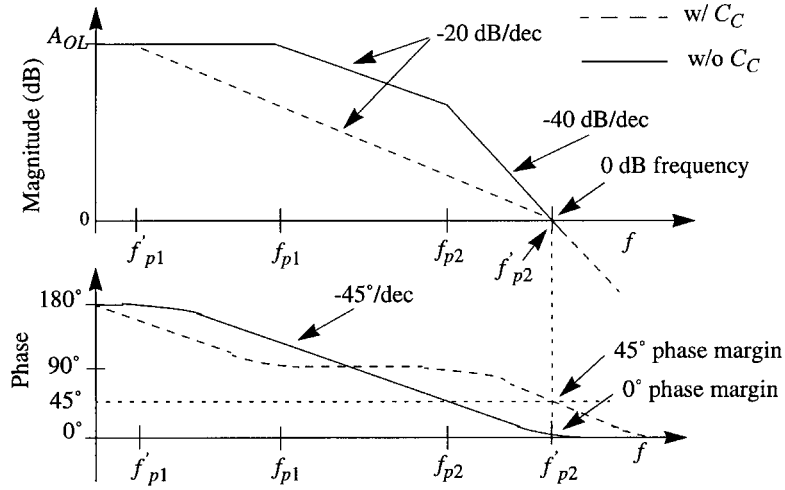

FIGURE 19.27 Magnitude and phase of the two-stage op-amp with and without compensation.

margin below 45° will result in long settling times and increased propagation delays. The system can also be thought of as a simple second-order linear controls system with the phase margin directly affecting the transient response of the system.

Compensation

Now we will include C_C in the circuit. If C_C is much greater than C_{gd6}, then the C_C will dominate the value of C_1 [especially since it is multiplied by $(1 - A_2)$] and will cause the pole, f_{p1}, to roll-off much earlier than without C_C to a new location, f_{p1}. One could solve, using circuit analysis, the circuit shown in Fig. 19.26 with C_C included to also prove that the second pole, f_{p2}, moves further out[3] to a higher frequency, f_{p2}. Ideally, the addition of C_C will cause an equivalent single pole roll-off of the overall frequency response. The second pole should not begin to affect the frequency response until after the magnitude response is below 0 dB. The new values of the poles are

$$f'_{p1} \approx \frac{1}{2\pi(g_{m6}R_{out})C_C R_{out1}}, f'_{p2} \approx \frac{g_{m6}C_C}{2\pi \cdot (C_2C_1 + C_2C_C + C_CC_1)} \approx \frac{g_{m6}}{2\pi \cdot C_2} \qquad (19.41)$$

If the previously discussed analysis was performed, one would also see that by using Miller's theorem, we are neglecting a right-hand plane (RHP) zero that could have negative consequences on our phase margin, since the phase of an RHP zero is similar to the phase of a left-hand plane (LHP) zero. An RHP zero behaves similarly to an LHP zero when examining the magnitude response; however, the phase response will cause the phase plot to shift –180° more quickly. The RHP zero is at a value of

$$f_{z1} = \frac{g_{m6}}{C_C} \qquad (19.42)$$

To avoid effects of the RHP zero, one must try to move the zero out well beyond the point at which the magnitude plot reaches 0 dB (suggested rule of thumb: factor of 10 greater). The comparison of the frequency response of the two-stage op-amp with and without C_C can be seen in Fig. 19.27.

One remedy to the zero problem is to add a resistor, R_z, in series with compensation capacitor as seen in Fig. 19.28. The expression of the zero after adding the resistor becomes

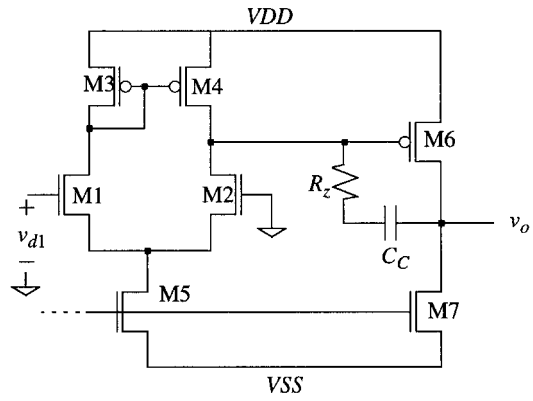

FIGURE 19.28 Compensation including a nulling resistor.

$$f_{z1} = \frac{1}{C_C\left(\frac{1}{g_{m6}} - R_Z\right)} \tag{19.43}$$

and the zero can be pushed into the LHP where it adds phase shift and increases phase margin if $R_z > 1/g_{m6}$. Fig. 19.29[4] shows the root locus plot for the zero as R_z is introduced. With $R_z = 0$, the zero location is on the RHP real axis. As R_z increases in value, the zero gets pushed to infinity at the point at which $R_z = 1/g_{m6}$. Once $R_z > 1/g_{m6}$, the zero appears in the LHP where its phase shift adds to the overall phase response, thus improving phase margin. This type of compensation is commonly referred to as *lead compensation,* and is commonly used as a simple method for improving the phase margin. One should be careful about using R_z, since the absolute values of the resistors are not well predicted. The value of the resistor should be simulated over its maximum and minimum values to ensure that no matter if the zero is pushed into the LHP or the RHP, that the value of the zero is always 10 times greater than the gain-bandwidth product.

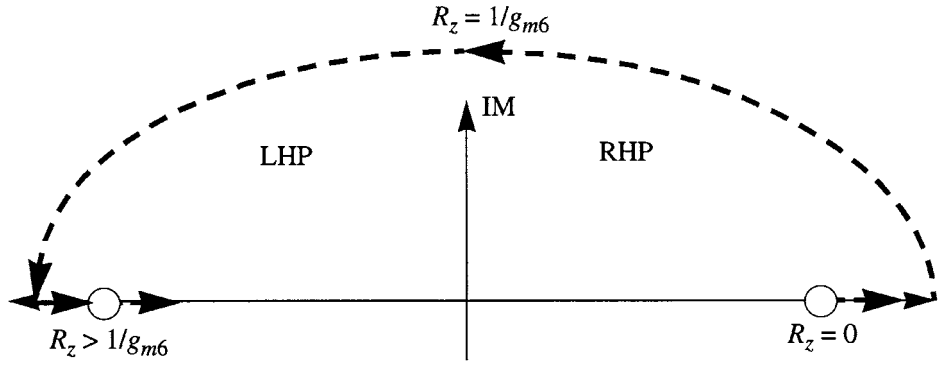

FIGURE 19.29 Root locus plot of how the zero shifts from the RHP to the LHP as R_z increases in value.

Other AC Specifications

Referring back to the equations for gain and the first pole location, we can now see adjustable parameters for affecting frequency response by plugging in the proportionalities for their corresponding factors. Since the value of the resistors are directly proportional to the length of L (the longer the L, the higher the resistance, since longer channel lengths diminish the effects of channel length modulation, λ).

The *gain-bandwidth product* for the compensated op-amp is the open-loop gain multiplied by the bandwidth of the amplifier (as set by f_{p1}). Therefore, the gain-bandwidth product is

$$GBW = (g_{m1} \cdot r_{o2} || r_{o4})(g_{m6} \cdot r_{o6} || r_{o7}) \left(\frac{1}{2\pi (g_{m6} R_{out}) C_C R_{out1}} \right) = \frac{g_{m1}}{2\pi C_C} \tag{19.44}$$

Or we can write the expression as

$$GBW \propto \frac{\sqrt{\frac{W}{L}_{1,2} I_{D1,2}}}{C_C} \tag{19.45}$$

which shows that the most efficient way to increase *GBW* is to decrease C_C. One could increase the $W/L_{1,2}$ ratio, but its increase is only by the square root of $W/L_{1,2}$. Increasing $I_{D1,2}$ will also yield an increase (also to the square root) in *GBW*, but one must remember that it simultaneously decreases the open-loop gain. The value of C_C must be large enough to affect the initial roll-off frequency as a larger C_C improves phase margin. One could easily determine the value of C_C by first knowing the gain-bandwidth specification, then iteratively choosing values for $W/L_{1,2}$ and $I_{D1,2}$ and then solving for C_C.

One other word of warning: the designer must not neglect the effects of loading on the circuit. Practically speaking, the load capacitor usually dominates the value of the capacitor, C_2 in Fig. 19.22. The value of the load capacitor directly affects the phase shift through the amplifier by changing the pole location associated with the output node. The second pole has a value of approximately $g_{m6}/2\pi C_L$ as was seen earlier. Since the second pole needs to be greater than the gain-bandwidth product, the following relationship can be deduced:

$$\frac{g_{m6}}{C_L} > \frac{g_{m1,2}}{C_C} \tag{19.46}$$

or

$$C_C > \frac{g_{m1,2}}{g_{m6}} \cdot C_L \tag{19.47}$$

Thus, one can see the effect of C_L on phase margin in that the minimum size of the compensation capacitor is directly dependent on the size of the load capacitor. For a phase margin of 60°, it can be shown[3] that the second pole must be 2.2 times greater than the *GBW*.

The *common-mode rejection ratio* (CMRR) measures how well the amplifier can reject signals common to both inputs and is written by

$$\text{CMRR} = 20\log\left|\frac{A_d}{A_{cm}}\right| = 20\log\left|\frac{v_o / v_d}{v_o / v_{cm}}\right| \tag{19.48}$$

where V_{cm} is a common mode input signal, which in this case is composed of an AC and a DC component (the higher the value of CMRR, the better the rejection). The circuit for calculating common mode gain can be seen in Fig. 19.30. The gain through the output stage will be the same for both the differential gain, A_d, and the common-mode gain, A_{cm}. The last stage will cancel itself out in the expression for CMRR; thus, the differential amplifier will determine how well the entire amplifier rejects common mode signals. This rejection is one of the most advantageous reasons for using a diff-amp as an input stage. If the inputs are subjected to the same noise source, the diff-amp has the ability to reject the noise signal and only amplify the difference in the inputs. For the diff-amp used in this example, the common-mode gain is

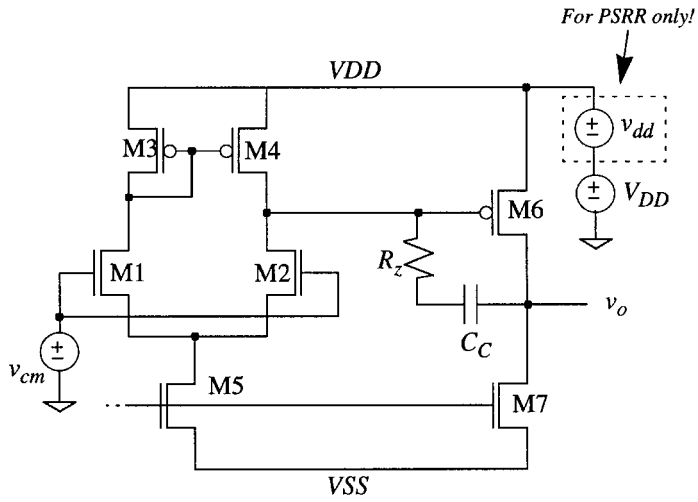

FIGURE 19.30 Circuit used to determine CMRR and PSRR.

$$\frac{v_{o1}}{v_{cm}} = -\frac{1}{2g_{m4}r_{o5}} \tag{19.49}$$

This equation bears some explanation. Since the inputs are tied together, the source-coupled node can no longer be considered an AC ground. Therefore, the resistance of the tail current device, M5, must be considered in the analysis. The AC currents flowing through both M1 and M2 are equal and $v_{gs3} = v_{gs4}$. The output impedance of the diff-amp will drop considerably when using a common-mode signal due to the feedback loop consisting of M1, M3, M4, and M2. As a result, the common-mode signal appearing on the drains of M3 and M4 will be identical.

One can determine this gain by using half-circuit analysis (Fig. 19.31). This is equivalent to a common source amplifier with a large source resistance of value $2r_{o5}$. When using half-circuit analysis, the current source resistance doubles because the current through the driving device M1 is one half of the original tail current. Therefore, the gain of this circuit can be approximately determined as the negative ratio between the resistance attached to the drain of M1 divided by the resistance attached to the source of M1, or

$$\frac{v_{o1}}{v_{cm}} = -\frac{1/g_{m3,4}}{2r_{o5}} \tag{19.50}$$

Adding the expression for the differential gain of the diff-amp, v_{o1}/v_d, we can write the expression for the CMRR as

$$\text{CMRR} = 20\log(2g_{m1,2}g_{m3,4}(r_{o2}||r_{o4})r_{o5}) \tag{19.51}$$

or as a proportion,

$$\text{CMRR} \propto 20\log\left(\sqrt{\frac{W_{1,2}\cdot L_{1,2}}{I_{D1,2}}}\cdot\sqrt{\frac{(W/L)_{3,4}}{2I_{D5}}}\cdot L_5\right) \tag{19.52}$$

So, it can be seen that the most efficient manner in which to increase the CMRR of this amplifier is to increase the channel length of M5 (the tail current device). This, too, has a large signal implication that we will discuss later in this section.

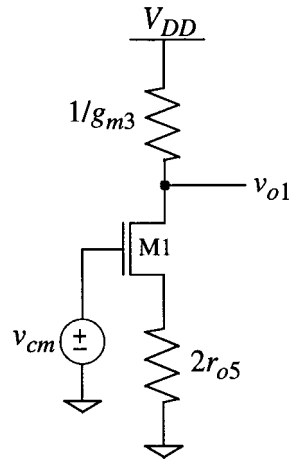

FIGURE 19.31 Half-circuit used to determine the common-mode gain.

The *power supply rejection ratio* (PSRR) measures how well the amplifier can reject changes in the power supply. This is also a critical specification because it would be desirable to reject noise on the power supply outright. PSRR from the positive supply is defined as:

$$\text{PSRR}^{v_{dd}} = \frac{v_o / v_d}{v_o / v_{dd}} \tag{19.53}$$

where the gain v_o/v_{dd} is the small signal gain from v_{dd} (refer back to Fig. 19.30) to the output of the amplifier with the input signal, v_d, equal to zero. PSRR can also be measured from V_{SS} by inserting a small signal source in series with ground. One should be careful, however, when simulating this specification to make sure that the inputs are properly biased so as to ensure that they are in saturation before simulating. It is best to use a fully differential (differential input and differential output) to most effectively reject power supply noise (to be discussed later).

Large Signal Considerations

Other considerations that must be discussed are the large signal tradeoffs. One cannot ignore the effects of adjusting the small signal specifications on the large signal characteristics. The large signal characteristics that are important include the common-mode range, slew rate, and output signal swing.

Slew rate is defined as the maximum rate of change of the output voltage due to a change in the input voltage. For this particular amplifier, the maximum output voltage is ultimately limited by how fast the tail current device (M5) can charge and discharge the compensation capacitor. The slew rate can then be approximated as

$$SR = \frac{dVo}{dt} \approx \frac{I_{D5}}{C_C} \tag{19.54}$$

Typically, the diff-amp is the major limitation when considering slew rate. However, the tradeoff issues again come into play. If I_{D5} is increased too much, the gain of the diff-amp may decrease below a satisfactory amount. If C_C is made too small, then the phase margin may decrease below an acceptable amount.

The *common-mode range* is defined as the range between the maximum and minimum common-mode voltages for which the amplifier behaves linearly. Referring to Fig. 19.32, suppose that the common-mode voltage is DC value and that the differential signal as is also shown. If the common-mode voltage is swept

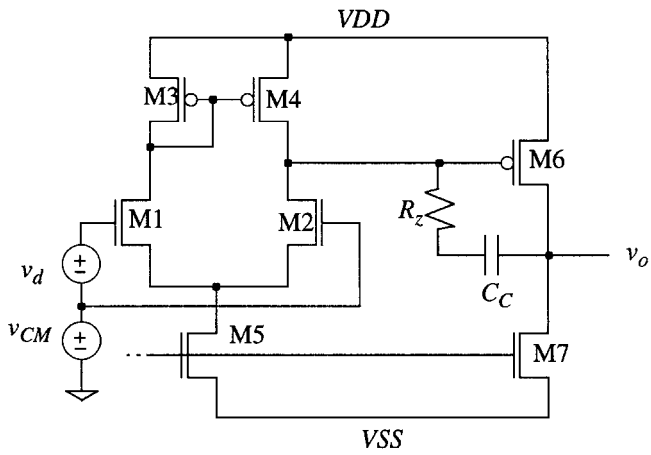

FIGURE 19.32 Determining the CMR for the two-stage op-amp.

from ground to V_{DD}, there will be a range for which the amplifier will behave normally and where the gain of the amplifier is relatively constant. Above or below that range, the gain drops considerably because the common-mode voltage forces one or more devices into the triode region.

The maximum common-mode voltage is limited by both M1 and M2 going into triode. This point can be defined by a borderline equation in which $V_{DS1,2} = V_{GS1,2} - V_{THN}$ or, in this case, $V_{D1,2} = V_{G1,2} - V_{THN}$. Substituting $V_{DD} - V_{SG3}$ for $V_{D1,2}$, and solving for $V_{G1,2}$, which now represents the maximum common-mode voltage, the expression becomes

$$V_{G1,\,2(max)} = V_{DD} - \left[\sqrt{\frac{I_{D5}}{\beta_3}} + V_{THP}\right] + V_{THN} \tag{19.55}$$

where the value of V_{SG3} is written in terms of its drain current using the saturation equation. If the threshold voltages are assumed to be approximately the same value, then the equation can be written as

$$V_{G1,\,2(max)} = V_{DD} - \sqrt{\frac{I_{D5}}{\beta_3}} = V_{DD} - \sqrt{\frac{L_3 \cdot I_{D5}}{W_3 \cdot K_3}} \tag{19.56}$$

The minimum voltage is limited by M5 being driven into nonsaturation by the common-mode voltage source. The borderline equation ($V_{D5} = V_{G5} - V_{THN}$) for this transistor can then be used with $V_{D5} = V_{G1,2} - V_{GS1,2}$ and writing both V_{G5} and $V_{GS1,2}$ in terms of its drain current yields

$$V_{G1,\,2(min)} = V_{SS} + \sqrt{\frac{2I_{D5}}{\beta_5}} + \sqrt{\frac{I_{D5}}{\beta_{1,2}}} = V_{SS} + \sqrt{\frac{2L_5 \cdot I_{D5}}{W_5 \cdot K_5}} + \sqrt{\frac{L_{1,2} \cdot I_{D5}}{W_{1,2} \cdot K_{1,2}}} \tag{19.57}$$

Now notice the influencing factors for improving the common-mode range ($V_{G1,2(max)}$ is increased and $V_{G1,2(min)}$ is decreased). Assume that V_{DD} and V_{SS} are defined by the circuit application and are not adjustable. To make $V_{G1,2(max)}$ as large as possible, I_{D5} and L_3 should be made as small as possible while W_3 is made as large as possible. And to make $V_{G1,2(min)}$ as small as possible, L_5, I_{D5}, and $L_{1,2}$ should be made as small as possible while increasing W_5 and $W_{1,2}$ as large as possible. Making the drain current as small as possible is in direct conflict with the slew rate. Decreasing L_5 will also degrade the common-mode rejection ratio, and increasing W_3 will affect the pole location of the output node associated with the diff-amp, thus altering the phase margin. All these tradeoffs must be considered as the designer chooses a circuit topology and begins the process of iterating to a final design.

The output swing of the amplifier is defined as the maximum and minimum values that can appear on the output of the amplifier. In analog applications, we are concerned with producing the largest swing possible while keeping the output driver, M6, in saturation. This can be determined by inspecting the output stage. If the output voltage exceeds the gate voltage of M6 by more than a threshold voltage, then M6 will go into triode. Thus, since the gate voltage of M6 is defined as $V_{DD} - V_{SG3,4}$, the maximum output voltage will be determined by the size of M3 and M4. The larger the channel width of M3 and M4, the smaller the value of $V_{SG3,4}$ and the higher the output can swing. However, again the tradeoff of making M3 and M4 too large is the reduction in bandwidth due to the increased parasitic capacitance associated with the output of the diff-amp.

The minimum value of the output swing is limited by the gate voltage of M7, which is defined by biasing circuitry. Again using the borderline equation, the drain of M7 may not go below the gate of M7 by more than a V_{THN}. Thus, to improve the swing, the value of V_{GS7} must be made small, which implies that the value of V_{GS8} and V_{GS5} also be made small, resulting in large values of M5, M8, and M7. This is not a very wise option because increasing M5 causes all the PMOS devices to increase by the same factor, resulting in large devices for the entire circuit. By carefully designing the bias device M8, one can design V_{GS8} to be around 0.3 V above VTHN. Thus, the output can swing to within 0.3 V of V_{SS}.

Tradeoff Example

When designing amplifiers, the tradeoff issues that occur are many. For example, there are many effects that occur just by increasing the drain current through the diff-amp: the open-loop gain goes down (by the square root of I_D) while the bandwidth increases (by I_D) due to the fact that the resistors r_{o2} and r_{o4} decrease by $1/I_D$. The overall effect is an increase (by the square root of I_D) in GBW, as predicted earlier. A table summarizing the various tradeoffs that occur from attempting to increase the DC gain can be seen in Table 19.1. It is assumed that if a designer only takes the one action listed that the following secondary effects will occur. In fact, the designer should understand the secondary effects enough to where a counteraction is taken to offset the secondary effects.

TABLE 19.1 Tradeoff Issues for Increasing the Gain of the Two-Stage Op-Amp

Desire	Action(s)	Secondary effects
Increase DC gain	Increase W/L1,2	Decreases phase margin
		Increases GBW
		Increases CMRR
		Decreases CMR
	Decrease ID5	Decreases SR
		Increases CMR
		Increases CMRR
		Increases phase margin
	Increase W/L6	Increases phase margin
		Increases output swing
	decrease ID6	Decreases output current drive
		Decreases phase margin

The key for the entire circuit design is the size of M5; the remaining transistors can be written as factors of W_5. The minimum amount of current flowing through M5 is determined by the slew rate. Since M3 and M4 carry half the current of M5, then the widths of M3 and M4 can be determined by assuming that $V_{SG3} = V_{SG4} = V_{GS5}$

$$\frac{2I_{D3,4}}{I_{D5}} \approx \frac{2K_P \cdot (W/L)_{3,4} \cdot (V_{SG3,4} - |V_{THP}|)^2}{K_n \cdot (W/L)_5 \cdot (V_{GS5} - V_{THN})^2} \approx \frac{2K_P \cdot (W/L)_{3,4}}{K_n \cdot (W/L)_5} \tag{19.58}$$

and since $L_3 = L_5$, and $K_n = 3K_p$, then that leads to the conclusion that $W_{3,4} = 1.5 \cdot W_5$. If the nulling resistor is used in the compensation network, the values for M6 and M7 are determined by the amount of load capacitance attached to the output. If a large capacitance is present, the widths of M6 and M7 will need to be large so as to provide enough sinking and sourcing current to and from the load capacitor. Suppose it was decided that the amount of current needed for M6 and M7 was twice that of M5. Then, W_7 would be twice as large as W_5, and W_6 would be six times larger than W_5 to account for the differing K values. Alternatively, if everything is saturated, then $I_{D3} = I_{D4}$, and the drain voltage at the output of the diff-amp is identical to the drain voltage of M3. This implies that under saturation conditions, the gate of M6 is at the same potential as the gate of M4; thus, again it must be emphasized that we are talking about quiescent conditions here, and the current through M6 will be defined by the ratio of M6 to M4. Therefore, since M6 is carrying four times as much current as M3, then $W_6 = 4W_{3,4}$, which is six times the value of W_5. Thus, every device except M1 and M2 is written in terms of M5.

The sizes of M1 and M2 are the most critical of the amplifier. If $W_{1,2}$ are made too large, then C_C will be big due to its relationship with C_L and the ratio of g_{m1} and g_{m6} [Eq. (19.48)]. However, if $W_{1,2}$ is made too small, the gain may not meet the requirements needed.

One word about high-impedance nodes. If two current sources are in a series as shown in Fig. 19.33(a), then the value of the voltage between them is difficult to predict. In the ideal case, both current sources have infinite impedances, so any slight mismatch between I_1 and I_2 will result in large swings in v_A. The same holds true for Fig. 19.33(b). Since the two devices form a high impedance at the output, and each device can be considered a current source, any mismatches in the currents defined by $\beta_2(V_{SG2} - V_{THP})^2$ and $\beta_1(V_{GS1} - V_{THN})^2$ will result in large voltage offsets at the output, with the device with the larger defined current being driven into triode. Thus, the smaller of the two defined currents will be the one flowing through both devices. Another way to visualize this condition is to place a large resistor representing the output impedance from v_o to ground. Any difference between the two transistor currents will flow into or out of the resistor, creating a large voltage offset. Feedback is typically used around the op-amp to stabilize the DC output value.

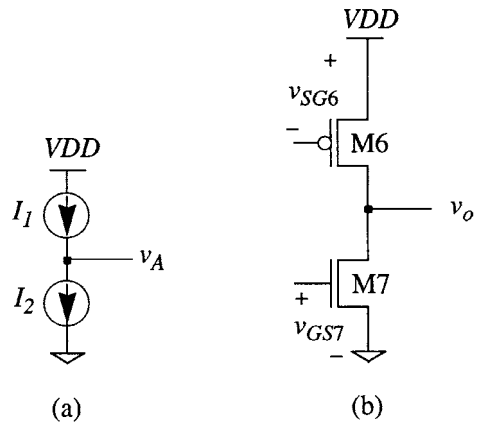

FIGURE 19.33 Illustration of a high-impedance node.

A Word about Circuit Simulation

Circuit simulators have become powerful design tools for analysis of complicated analog circuits. However, the designer must be very careful about the role of the simulator in the design. When simulating high-gain amplifier circuits, it is important to understand the trends and inner working of the circuit before simulations begin. One should always *interpret* rather than blindly trust the simulation results (the latter is a guaranteed recipe for disaster!). For example, the previously mentioned high-impedance nodes should always be given careful consideration when simulating the circuit.

Because these nodes are highly dependent on λ, predicting the actual DC value of the nodes either through simulation or hand analysis is a near impossibility. Before any AC analysis is performed, check the values of the DC points in the circuit to ensure that every device is in saturation. Failure to do so will result in very wrong answers.

Other Output Stages

With the preceding design, the output stage was a high-impedance driver, capable of handling only capacitive loads. If a resistive load is present, an additional stage should be added that has a low output impedance and high current drive capability. An example of the output stage can be seen in Fig. 19.34. Here, the output impedance is simply $1/g_{m9}||1/g_{m10}$. Since we do not wish to have a large output impedance, the values for L_9 and L_{10} should be made as small as possible. The transistors M11 and M12 are used to help bias the output devices such that M9 and M10 are just barely on under quiescent conditions. This kind of amplifier is known as a class AB output stage and has limitations in CMOS due to the body effect.

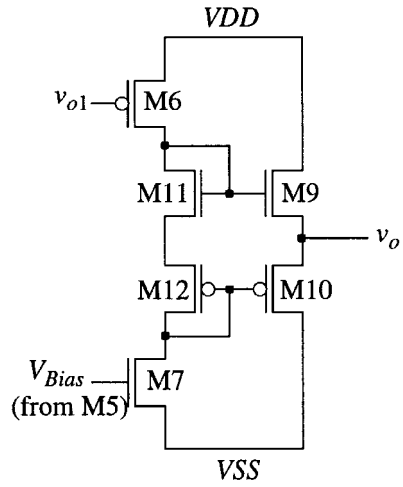

FIGURE 19.34 A low-impedance output stage.

In some cases, it is advantageous to use a bipolar output driver as seen in Fig. 19.35. Since most BiCMOS processes provide only one flavor of BJT (an npn), the transistor Q1 can be used for extra current drive. This results in a dual-sloped transfer curve characteristic as the output stage goes from sourcing to sinking. It should be noted that one could use this output stage with the complementary version of the two-stage amplifier previously discussed.

Another BiCMOS output stage can be seen in Fig. 19.36.[5] This is known as a "pseudo-push-pull" output stage. M6 and M7 can be output of the previously discussed two-stage op-amp. With the new pseudo-push-pull output attached, the amplifier is able to achieve high output swing with large current drive capability using very little silicon area. The transistor MQ1 is for level shifting purposes only. When the output signal needs to swing in the positive direction, Q2 behaves just like the BJT output driver shown in Fig. 19.35. When the output swings in the negative direction, Q1 drives the gate of M9 down, thus increasing I_{D9}. The increase in current is mirrored via M10 to M11, which is able to sink a large amount of current. The output voltage at its lowest voltage is approximately the same voltage as the emitter voltage of Q2. The transistor Q2 provides the needed low output impedance.

Another advantage of using BJT devices in the design is to provide large g_ms as compared to the MOS counterpart. BiCMOS circuits can be constructed, which offer high input impedance and gain bandwidth products. If both npn and pnp devices are available in the BiCMOS process, then the output stage seen in Fig. 19.37 can be used. This circuit functions as a buffer circuit with very low output impedance.

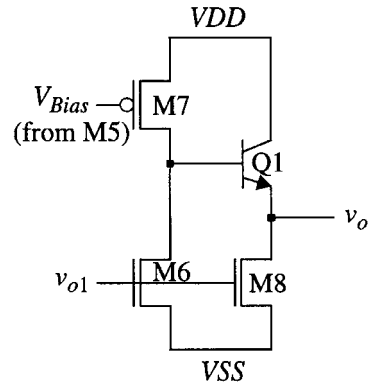

FIGURE 19.35 Using an NPN BJT as an output driver.

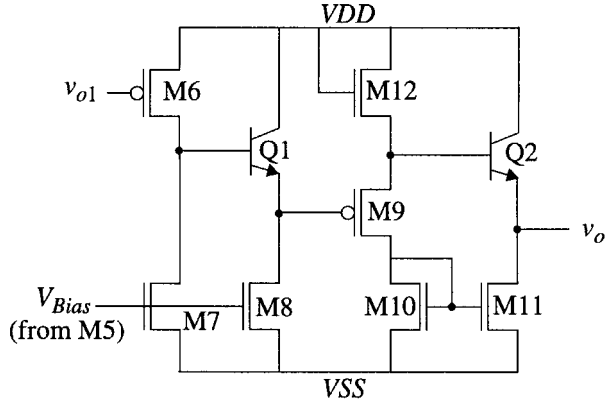

FIGURE 19.36 A "pseudo" push-pull npn only output driver.

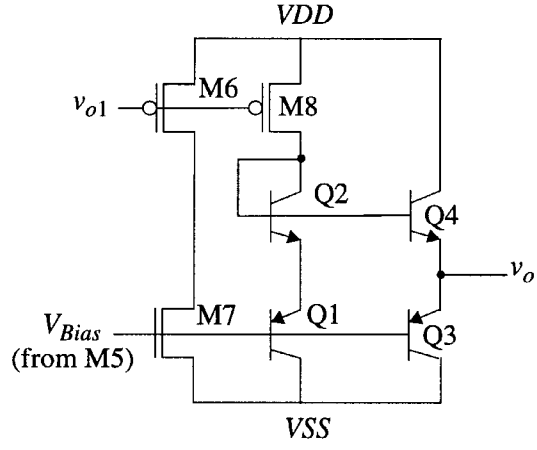

FIGURE 19.37 A low-impedance output stage using both npn and pnp devices.

High-Performance Operational-Amplifier Considerations

In the commercial world, it seems there are not many applications that require simple, easy to design op-amps. High bit rate communication systems and over-sampled data converters push the bandwidth and slew rate capabilities of CMOS op-amps, while battery-powered systems are required to squeeze just enough performance out of micro-amps of current, and a volt or two of power supply. Sensor interfaces and audio systems demand low noise and distortion. To further complicate things, CMOS analog circuits are often integrated with large digital circuits, making isolation from switching noise a major concern. This section will present solutions to some of the problems faced by op-amp designers who, because of budget constraints or digital compatibility, do not have the option to use bipolar junction transistors in their design. We will then give some hints on where the designer might use bipolar transistors if they are available.

Power Supply Rejection

Fully differential circuits like the OTA shown in Fig. 19.38 are used in mixed signal circuits because they provide good rejection of substrate noise and power supply noise. As long as the noise coupled from the substrate or power supply is equal for both outputs, the difference between the two signals is noise-free (differential component of the noise is zero). This is illustrated in Fig. 19.39. The top two traces in Fig. 19.39 are a differential signal corrupted with common-mode noise. The bottom trace is the difference between these two noisy signals. If the next circuit in the path has good common-mode rejection, the substrate and power supply noise will be ignored. In practical circuits, mismatches between the transistors of symmetrical halves of the differential circuit will lead to imperfect matching of noise on the outputs, and therefore reduced rejection of power supply noise. Common centroid layouts and large geometry transistors are necessary to minimize mismatches. Differential circuits are capable of twice the signal swing of single-ended circuits, making them especially welcome in low-voltage and low-noise applications.

Single-stage or multiple-stage op-amps can be made differential, but each stage requires a common-mode feedback circuit to give the differential output a common-mode reference. Consider the folded cascode OTA shown in Fig. 19.38. If the threshold voltage of M5A is slightly larger than the threshold voltage of M5B and M5C, the pull-down currents will be larger than the pull-up currents. This small current difference, in combination with the very high output impedance of the cascode current mirrors,

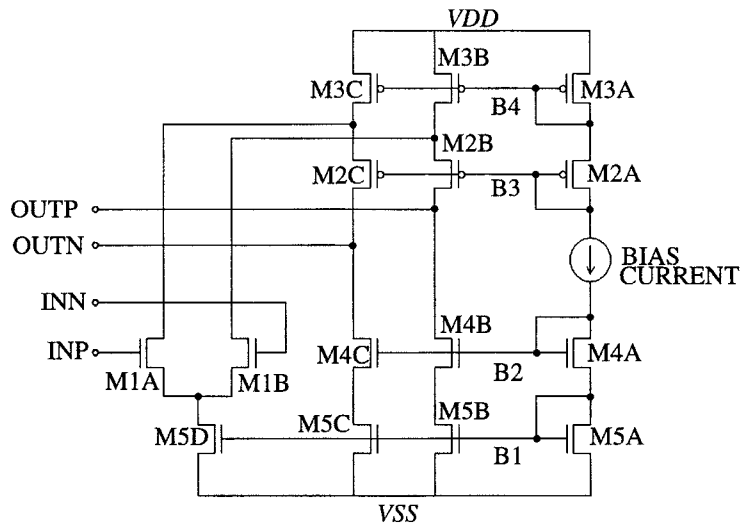

FIGURE 19.38 Folded cascode OTA.

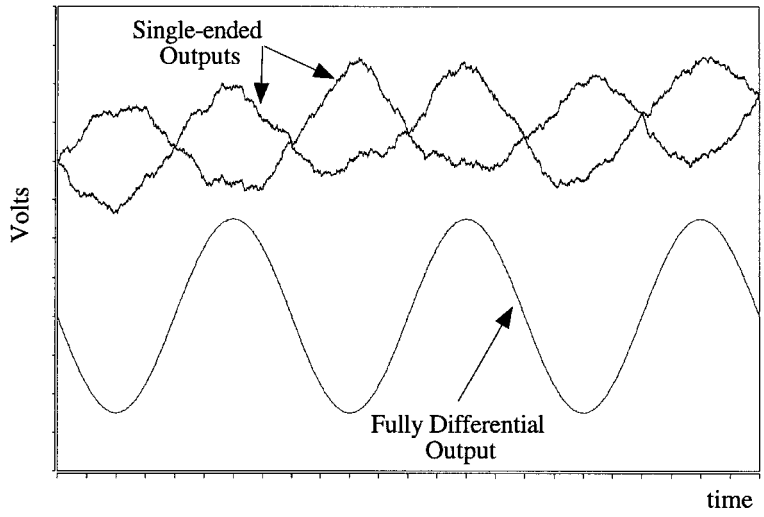

FIGURE 19.39 Simulation output illustrating the difference between single-ended and fully differential signals.

will cause the output voltages to be pegged at the negative power supply. This common-mode error cannot be corrected by applying feedback to the differential pair. A common-mode feedback circuit is needed to find the average of the output voltages, and control the pull-up or pull-down current in the outputs to maintain this average at the desired reference. A center-tapped resistor between the outputs could be used to sense the common-mode voltage if the outputs were buffered to drive such a load. Since a folded cascode OTA cannot drive resistors, a switched capacitor would be a better choice to sense the common-mode voltage as shown in Fig. 19.40. The PH1 and PH2 clock signals must be non-overlapping. When the PH1 switches are closed, C_{1A} and C_{1B} are discharged to zero, while C_{2A} and C_{2B} provide feedback to the common-mode amplifier. The PH1 switches are then opened, and a moment later, the PH2 switches closed. The charge transfer that takes place moves the center tap

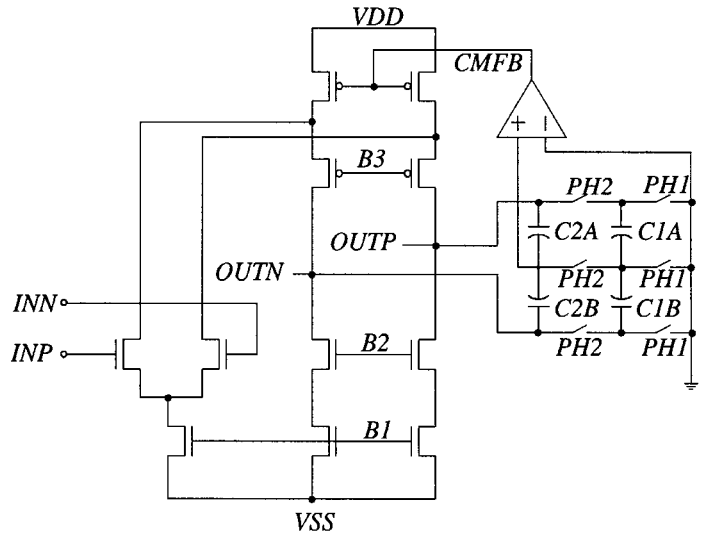

FIGURE 19.40 Folded cascode OTA using switched capacitor common mode feedback.

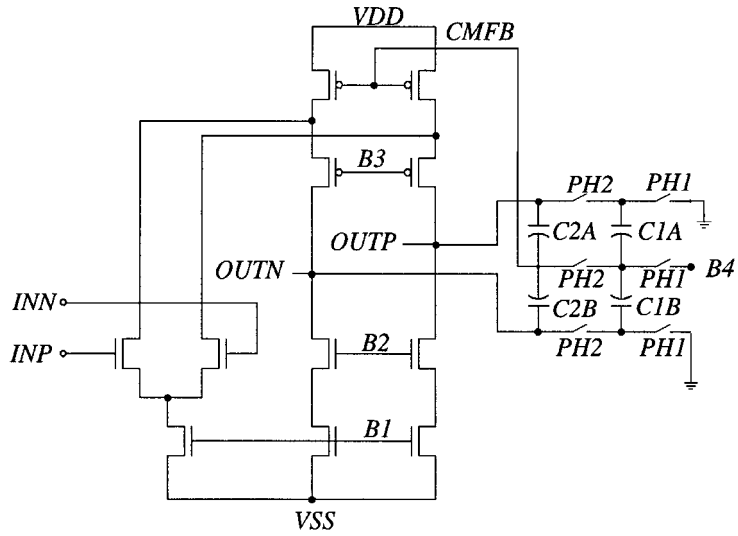

FIGURE 19.41 Using a bias voltage to precharge the switched capacitor common mode feedback capacitors.

between C_{2A} and C_{2B} toward the average of the two output voltages. After many clock cycles, the input to the common-mode feedback amplifier will be the average of the two voltages. C_{1A} and C_{1B} can be precharged to a bias voltage to provide a level shift. This allows direct feedback from the common-mode circuit to the pull-up bias as shown in Fig. 19.41.

A BiCMOS version of the folded cascode amplifier can be seen in Fig. 19.42.[6] Here, it is again assumed that only npn devices are available. Note that to best utilize the npn devices, the folded cascoded uses a diff-amp with P-channel input devices. The amplifier also uses the high swing current mirror presented in Section 19.2.

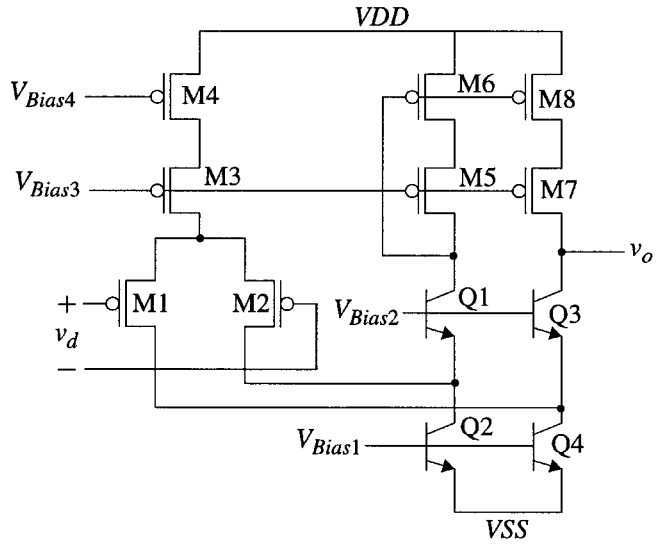

FIGURE 19.42 BiCMOS folded cascode amplifier.

Slew Rate

The slew rate of a single-stage class A OTA is the maximum current the output can source or sink, divided by the capacitive load. The slew rate is therefore proportional to the steady state power consumed. Class AB amplifiers give a better tradeoff between power and slew rate. The amplifier's maximum output current is not the same as the steady-state current. An example of a class AB single-stage op-amp is shown in Fig. 19.43. The differential pair is replaced by M1A, M1B, M2A, and M2B. A level shifter consisting of M3A, M3B, M4A, and M4B couples the input signal to M2A and M2B, and sets up the zero input bias current. If the width of M2A and M2B are three times the width of M1A and M1B, the small signal voltage on the nodes between M1 and M2 will be approximately zero. The current available from one of the input transistors is approximately

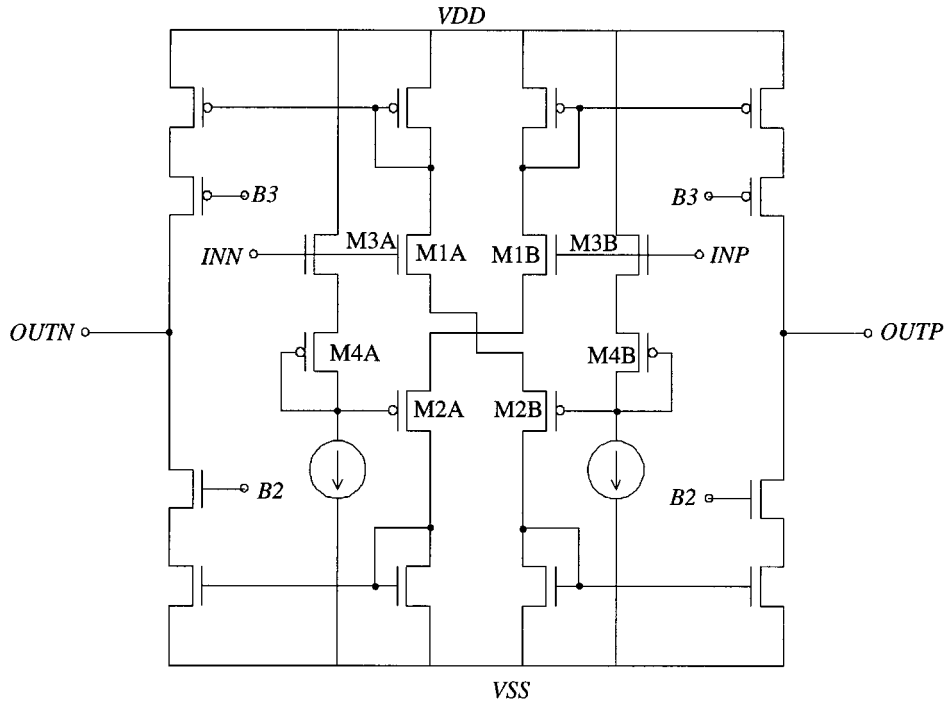

FIGURE 19.43 A class AB single stage op-amp with high slew rate capability.

$$I_{out} = KP\frac{W}{L}(V_{in} + V_{bias} + V_{THN})^2 \tag{19.59}$$

The differential current from the input stage is

$$I_{OUTP} - I_{OUTN} = 2 \cdot \beta(V_{in} + V_{BIAS} + V_{THN}) \tag{19.60}$$

It is interesting to note that the non-linearities cancel. The output current becomes non-linear again as soon as one of the input transistors turns off. The maximum current available from the input transistors is not limited by a current source as is a differential pair. It should be noted that it is impossible to keep all transistors saturated for low power supplies and large input common-mode swings. A similar BiCMOS circuit with high slew rate can be seen in Fig. 19.44.[7]

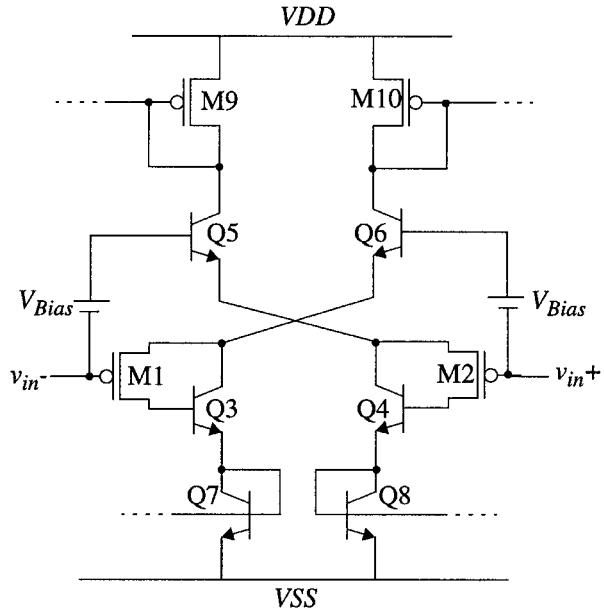

FIGURE 19.44 A BiCMOS class AB input stage.

Adaptive bias is another method to reduce the ratio of supply current to slew rate. Adaptive bias senses the current in each side of a conventional differential pair, and increases the bias current when the current on one side falls below a preset value. This guarantees that neither side of the differential pair will turn off. The side that is using most of the current must therefore be supplied with much more than the zero input amount. The differential pair current can be sensed by measuring the gate-to-source voltages as shown in Fig. 19.45, or by measuring the current in the load as shown in Fig. 19.46. Both of these adaptive

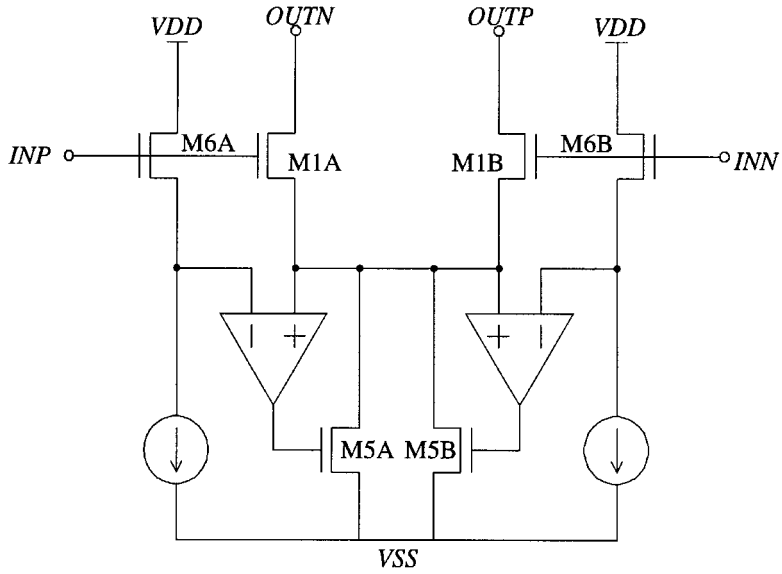

FIGURE 19.45 Adaptive biasing scheme for improved slew rate performance.

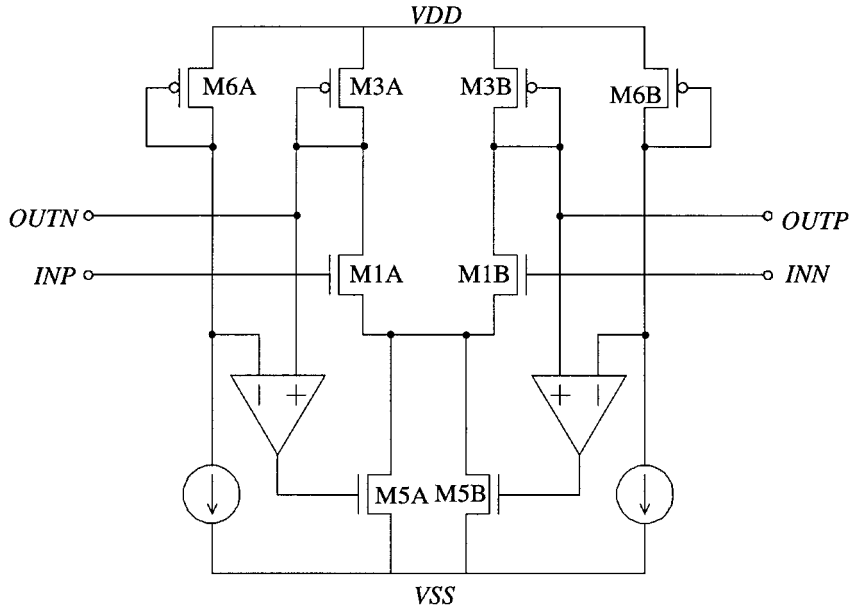

FIGURE 19.46 Another adaptive biasing circuit.

bias schemes depend on a feedback loop to control the current in the differential pair. These circuits improve settling time for low power, low bandwidth circuits, but the delay in the feedback path is a problem for high-speed circuits.

A second form of adaptive bias can be used when it is known that increased output current is needed just after clock edges, such as in switched capacitor filters. This type of adaptive bias can be realized using the switched capacitor bias boost shown in Fig. 19.47. In this circuit, $I_{D1} \cdot L_1/W_1 > I_{D2} \cdot L_2/W_2$, which makes $V_1 > V_2$. When the PH1 switches are closed, the steady-state voltage across the capacitor is $V_1 - V_2$, and

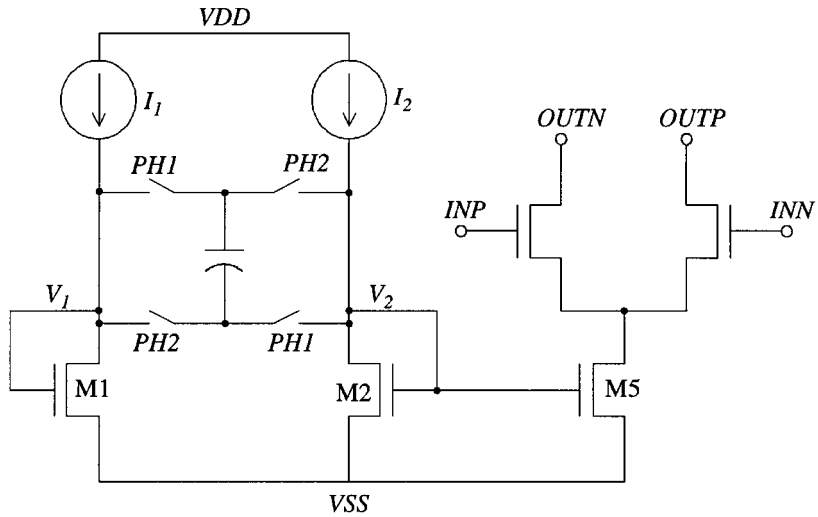

FIGURE 19.47 Adaptive biasing using a switched capacitor circuit.

the current in M3 is set by I_{D2}. When the PH2 switches close, V_2 is momentarily increased, while V_1 is decreased. The transient is repeated when the PH1 switches close. The net effect of the switched capacitor bias boost is that the current in M3 increases after both clock edges. Notice that the current is increased, whether it is needed or not. This circuit is fast because there is no feedback loop, but it is not the most efficient because it does not actually sense the current in the differential pair.

In all three approaches, the quiescent current is less than the current when the output is required to slew. Therefore, output swing and gain are not degraded when the bias current returns to its quiescent value. All three adaptive bias circuits will cause larger current spikes to be put on the supplies by the op-amps. The width of the power supply lines should be increased to compensate for the increased *IR* drop and crosstalk. Enhanced slew rate circuits are not linear time invariant systems because the transconductance and output impedance of the transistors are bias current dependent, and the bias is time varying. A transient analysis is the most dependable way to evaluate settling time in this case.

Output Swing

Decreasing power supply voltages put an uncomfortable squeeze on the design engineer. To maintain the desired signal-to-noise ratio with a smaller signal swing, circuit impedances must decrease, which often cancels any power savings that may be gained by a lower supply voltage. To get the best signal swing, differential circuits are used. If the output stages use cascode current mirrors, bias voltages must be generated, which keep both the mirror and cascode transistors in saturation with the minimum voltage on the output. Another example of a high swing bias circuit (refer also to Section 19.2) and a current mirror is shown in Fig. 19.48. First, let the *W*/*L* ratio of M2, M4, and M6 be equal, and the *W*/*L* ratio of M3 and M5 be equal. Now recall that to keep a MOSFET in saturation

$$V_{DS} \geq V_{GS} - V_{THN} \tag{19.61}$$

The minimum output voltage that will keep both M5 and M6 in saturation with proper biasing is

$$V_{out} \geq V_{GS6} - 2V_{THN} + V_{GS5} \tag{19.62}$$

ignoring the bulk effects. For a given current, the minimum drain voltage can be rewritten as

$$V_{DS} \geq \sqrt{\frac{I_D \cdot L}{K \cdot W}} \tag{19.63}$$

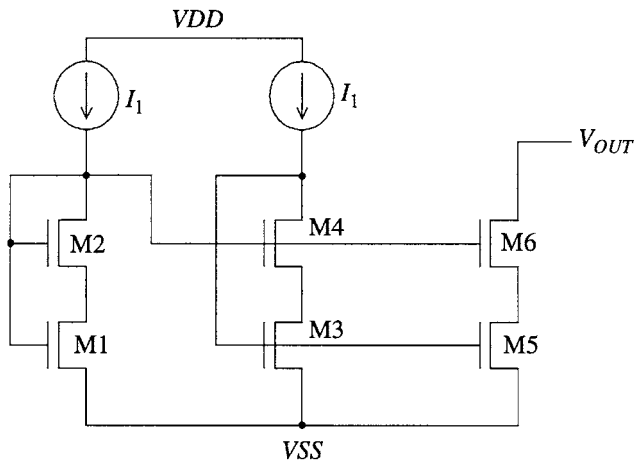

FIGURE 19.48 A high swing biasing circuit for low power supply applications.

The equation for the minimum V_{OUT} can be rewritten as

$$V_{OUT} \geq \sqrt{\frac{I_{OUT} \cdot L_6}{K_6 \cdot W_6}} + \sqrt{\frac{I_{OUT} \cdot L_5}{K_5 \cdot W_5}} \tag{19.64}$$

The trick to making this bias generator work is setting V_{DS} of M1 equal to the minimum V_{DS} required by M3 and M5. M1 is biased in the linear region, while we wish to keep M3 and M5 saturated. It is a good idea to set $L_1 = L_3 = L_5$ to match etching tolerances. A second trick is to make sure M3 and M4 stay saturated. M4 is inserted between the gate and drain connections of M3 to make $V_{DS3} = V_{DS5}$. If the W/L ratio of M3 is too small, M3 will be forced out of saturation by the source of M4. If the W/L_3 is too large, the gate voltage of M3 will not be large enough to keep M4 in saturation.

DC Gain

Start by calculating the DC gain of the folded cascode OTA in Fig. 19.38. If we assume the output impedance of the n-channel cascode current mirror is much greater than the output impedance of the individual transistors, then the DC gain is approximately

$$\frac{v_o}{v_{in}} = -g_{m1} \cdot r_{o1} \left| \right| r_{o3} \cdot g_{m2} \cdot r_{o2} \tag{19.65}$$

If we assume that the current from the M3 splits equally to M1 and M2, the gain can be written as

$$\frac{v_o}{v_{in}} \propto \frac{\sqrt{W_1 L_1 W_2 L_2}}{I_{D1}} \cdot \frac{L_3}{2L_1 + L_3} \tag{19.66}$$

We can see that the gate area of the differential pair and cascode transistors must both double each time current is doubled to maintain the same gain. We also note that it is desirable to make $L_3 > L_1$. If the current in the amplifier were raised to increase gain-bandwidth, or slew rate, it would be desirable to increase the widths of the transistors by the same factor to maintain output swing.

Regulated gate cascode outputs increase the gain of the OTA by effectively multiplying the g_m of M4 by the gain of the RGC amplifier. The stability of the RGC amplifier loop must be considered. An example of a gain boosted output stage is shown in Fig. 19.49.

Gain Bandwidth and Phase Margin

Again, start with the transfer function for the folded cascode OTA of Fig. 19.38. If we assume the output impedances of the n-channel cascode current mirrors are very large, and the gain of M2 is much greater than one, we have

$$\frac{v_o}{v_{in}} = \frac{g_{m1} r_{o1} g_{m2} r_{o2}}{(C_1 \cdot C_{out} \cdot r_{o1} \cdot r_{o2}) \left(s^2 + \left(\frac{g_{m2}}{C_1} + \frac{1}{C_1 \cdot r_{o1}} + \frac{1}{C_1 \cdot r_{o2}} + \frac{1}{C_{out} \cdot r_{o2}} \right) s + \frac{1}{C_1 \cdot C_{out} \cdot r_{o1} \cdot r_{o2}} \right)} \tag{19.67}$$

where ro_1 is now the parallel combination of r_{o1} and r_{o3}. If we further assume that the poles are spaced far apart, and that g_{m2} is much larger than $1/r_{o1}$ and $1/r_{o2}$, then the gain-bandwidth product is g_{m1}/C_{load}. The second pole, which will determine phase margin, is approximately

$$\omega = \frac{g_{m2}}{C_1} + \frac{1}{C_{out} \cdot r_{o2}}$$

The depletion capacitance of the drains of M1 and M3 will also add to this capacitance. As a first cut, let $C_1 = K_c \cdot W_2 \cdot L_2$. Now the equation for the second pole boils down to

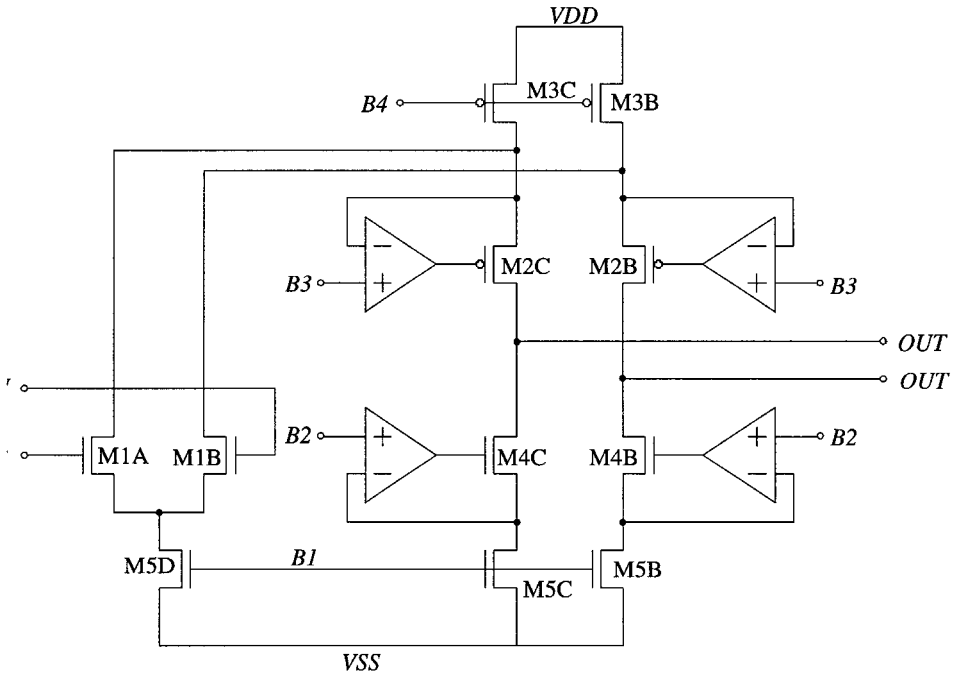

FIGURE 19.49 OTA with regulated gate cascode output.

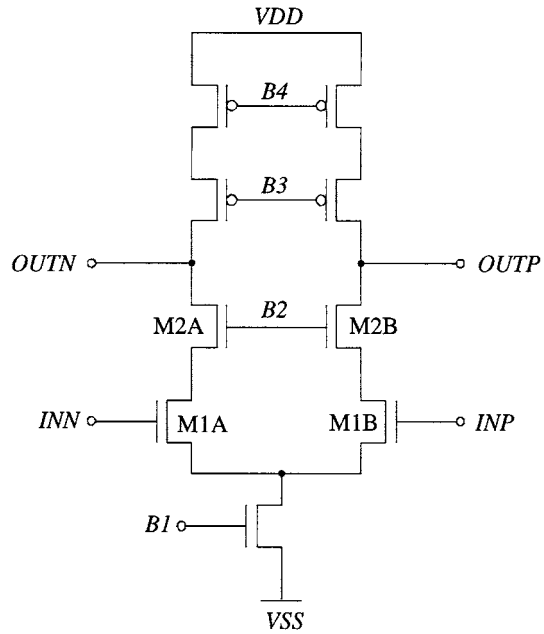

FIGURE 19.50 A telescopic OTA.

$$\omega \approx \frac{\sqrt{K \cdot I_{D2}}}{K_C \cdot L_2 \cdot \sqrt{W_2 \cdot L_2}} + \frac{I_{D2}}{L_2 \cdot C_{out}}$$

To get maximum phase margin, we clearly want to use as short a channel length as the gain specification will allow. The folded cascode OTA and two-stage OTA both have n-channel and p-channel transistors in the signal path. Since holes have lower mobility than electrons, it is necessary to make a silicon p-channel transistor about three times wider than an n-channel transistor of the same length to get the same transconductance. The added parasitic capacitance of the wider p-channel transistor is a hindrance for high-speed design. The telescopic OTA shown in Fig. 19.50 has only n-channel transistors in the signal path, and can therefore achieve very high bandwidths with acceptable phase margin. Its main drawback is that the output common-mode voltage must be more positive than the input common-mode voltage. This amplifier can achieve even wider bandwidth with acceptable phase margin if M2 is replaced by an npn bipolar transistor.

Bipolar Amplifier Design

Geert A. De Veirman
Silicon Systems, Inc.

20.1 Introduction

This chapter gives an overview of amplifier design techniques using bipolar transistors. An elementary understanding of the operation of the bipolar junction transistor is assumed. Section 20.2 reviews the basic principles of amplification and details the proper selection of an operating point. This section also introduces the three fundamental single-transistor amplifier stages: the common-emitter, the common-collector, and the common-base configurations. Section 20.3 deals with the problem of amplification of dc and difference signals. The emitter-coupled differential pair is discussed in great depth. Issues specific to output stages are presented in Section 20.4. Section 20.5 briefly touches on supply-independent biasing techniques. Next, Section 20.6 combines all the acquired building block knowledge in a condensed overview of operational amplifiers. A short conclusion is presented in Section 20.7, followed by a list of references.

20.2 Single-Transistor Amplifiers

Basic Principles

Bipolar Transistor Operation

Although prior exposure to bipolar transistor fundamentals is expected, a few elementary concepts are briefly reviewed here. The *bipolar junction transistor* (BJT) contains two back-to-back pn junctions,

known as the base–emitter and base–collector junctions. In this chapter, it is assumed that the BJT is operated in the so-called normal mode with a forward-bias applied at the base–emitter junction and a reverse voltage across the base–collector interface. Then, the collector current I_C, which is β times the base current I_B, is exponentially related to the base–emitter voltage V_{BE}. The mathematical expression of this dependency is known as the *Ebers-Moll equation.* For small signal variations, the relationship between the current *through* the transistor (I_C) and the *control input* voltage (V_{BE}) is expressed by the *transconductance* g_m.

When designing bipolar transistor amplifiers, it is also essential to understand the relationship between I_C and the voltage *across* the transistor (the collector-emitter voltage V_{CE}). For each input voltage V_{BE}, a different characteristic exists in the I_C-V_{CE} diagram, as shown in Fig. 20.1. As long as V_{CE} is high enough to keep the transistor in the linear region, the I_C vs. V_{CE} characteristics are fairly flat. When V_{BE} is held constant, increasing V_{CE} corresponds to applying more reverse voltage across the base–collector junction. As a result, the base width is modulated and this causes the I_C curves to increase approximately linearly with V_{CE}. When the I_C curves are extrapolated to negative V_{CE} values, they eventually all go through a single pivot point, which is referred to as the transistor's *Early voltage* V_A. For very small values of V_{CE}, the base–collector junction becomes forward-biased. As a result, the transistor saturates and the collector current drops off rapidly.

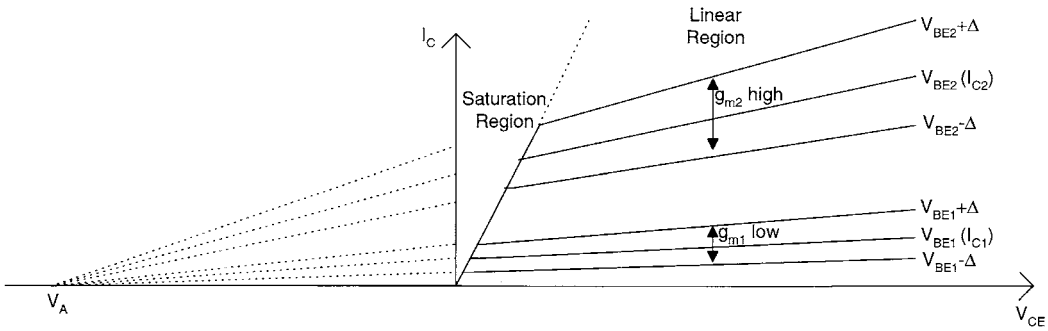

FIGURE 20.1 $I_C(I_{through})$ vs. $V_{CE}(V_{across})$ characteristics of the npn bipolar junction transistor.

In Fig. 20.1, V_{BE1} is less than V_{BE2}. In the linear operating region, the exponential nature of the BJT renders $g_{m1} < g_{m2}$, which means that for an identical incremental input voltage Δ, I_{C2} changes by a larger amount than I_{C1}. Also, since both curves merge at V_A, I_{C2} is a stronger function of V_{CE} than I_{C1}.

Mathematical expressions for the relationships discussed above will be introduced as needed in the following sections.

Basic Bipolar Amplifier Concepts

In order to amplify a voltage with a bipolar transistor, a load is placed in series with the device. In its simplest form, this load consists of a resistor R_L. Taking into account the polarity of electrons and the direction of current flow, one ends up with a transistor and supply arrangement as shown in Fig. 20.2, where the voltage to be amplified (V_i) drives the base. Hence, the only available output node (V_o) in Fig. 20.2 is the voltage between the transistor and the load resistor. This voltage can be determined in the I_C–V_{CE} diagram of Fig. 20.1 by subtracting the voltage drop across R_L from the supply voltage V_{CC}. The result is a straight line, which is known as the *load line.* The load line, shown in Fig. 20.3, graphically represents the possible operating points of the bipolar transistor. The line is straight simply because the resistor R_L is a linear element. Every point on the load line represents a state, which is determined by the voltage at the transistor's base. This state in turn determines how much current flows through the transistor and how much voltage there exists across this device.

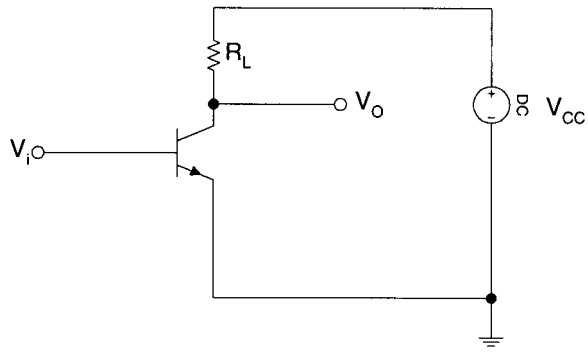

FIGURE 20.2 Conceptual schematic of single-transistor amplifier.

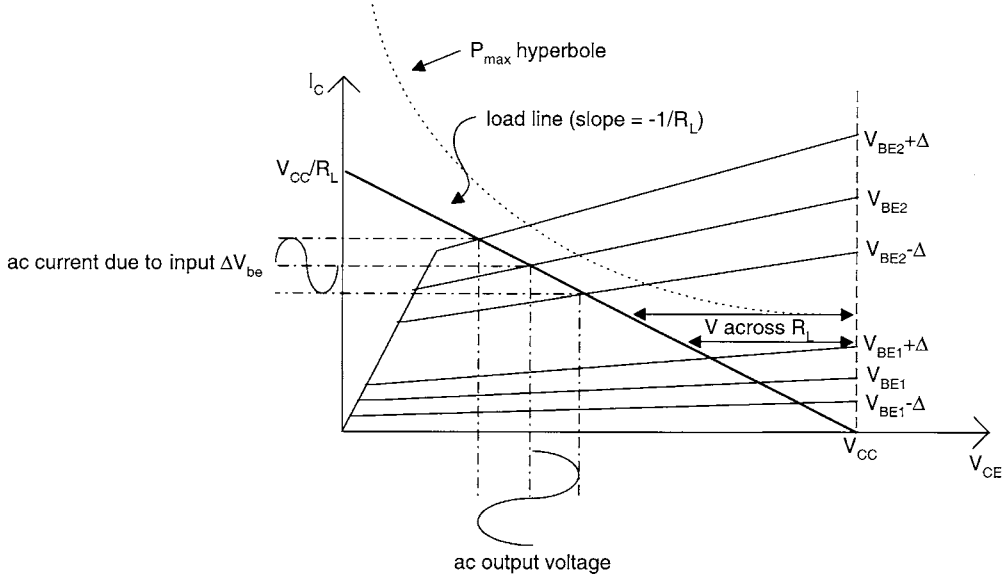

FIGURE 20.3 Load line characteristic.

To determine the circuit's voltage amplification, all one has to do is to plot the output voltage as a function of the input voltage. For different values of R_L, this process results in the *transfer characteristics* depicted in Fig. 20.4. The transfer characteristics allow us to visually determine two important items: first, the range in which the input voltage V_i should lie in order to obtain the maximum possible voltage variation at the output; and second, the optimum value of R_L. Since the transfer characteristics in Fig. 20.4 are far from linear, the best one can do is to identify a region where the curves can be linearized, provided the signal swings are not too large. Also, note that the transfer curves do not pass through the (0,0) coordinate. This means that the desired proportionality between input and output is not present. Consequently, one would want to move the V_o and V_i axes, so that their origin coincides with a desired point on the curves, as is the case for the V_o'/V_i' coordinate system illustrated in Fig. 20.4. The next subsection will discuss how such a suitable *operating point* (or *quiescent point*) can be established.

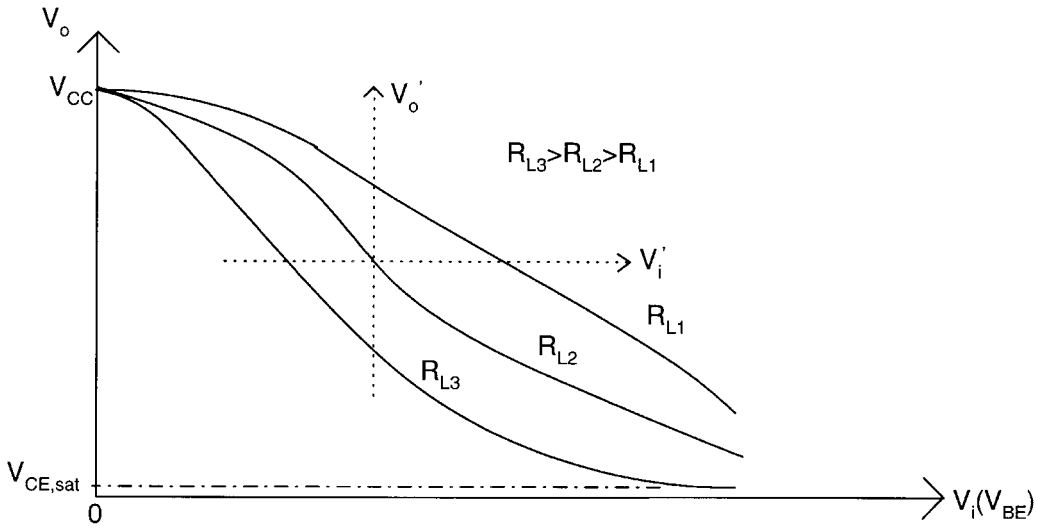

FIGURE 20.4 Transfer characteristics.

Figure 20.4 furthermore graphically clarifies how the bipolar transistor can be used in three distinct ways: first, as a switch; second, as a linear amplifier for small signals; and third, as a linear amplifier for large signals. When operating the BJT as a switch, the (logic) designer is primarily concerned about the speed of the transitions between the OFF and ON states. Such obviously non-linear modus operandi is a topic outside the scope of this chapter. Large signals pose particular difficulties, which will be covered a bit later in the sections on differential pairs and output stages. In the next several sections, we will deal mainly with linear small-signal operation.

Setting a Suitable Operating Point

The choice of a proper operating point depends on several factors. Three key decision criteria are:

1. Maximum allowable power dissipation of the active element. Each transistor has a maximum power limit. If this limit is exceeded, permanent damage (e.g., degradation of β) occurs or, in the worst case, the device may be destroyed. (Actually, maximum power ratings can be temporarily exceeded, as long as such transgressions are very fast. But such operation goes beyond this discussion.) In the I_C–V_{CE} diagram, constant power curves are represented by hyperboles. One such hyperbole, representing the maximum allowable power dissipation P_{max}, is included in Fig. 20.3. The designer must guarantee that excursions from the operating point along the amplifier's load line do not cross into the forbidden zone above the P_{max} curve.
2. Proper location on the transfer curve. As mentioned above during the discussion of Fig. 20.4, this choice directly affects the achievable linearity and signal swing.
3. Bias current. Figure 20.5 illustrates how the vertical axis in the V_o/V_i diagram can be moved. All one has to do is apply a proper dc bias voltage and superpose a small signal input. Making use of a separate bias voltage, as shown in Fig. 20.5(a), is one possibility. Alternatively, the dc voltage at the base can be set by means of a resistive divider from V_{CC}, and the ac signal can be capacitively coupled through C_{ci}, as depicted in Fig. 20.5(b). Similarly, a coupling capacitor C_{co} can be employed to separate the dc bias at V_o from the ac signal swing. As such, C_{co} moves the horizontal axis in the V_o/V_i diagram.

In Fig. 20.6(a), a second load resistor R_L' is added. Since the capacitor C_{co} acts as an open circuit for dc signals, the operating point remains solely determined by the intersection of the chosen transistor characteristic and the *static* load line, which results from the combination of V_{CC} and R_L. Assuming C_{co}

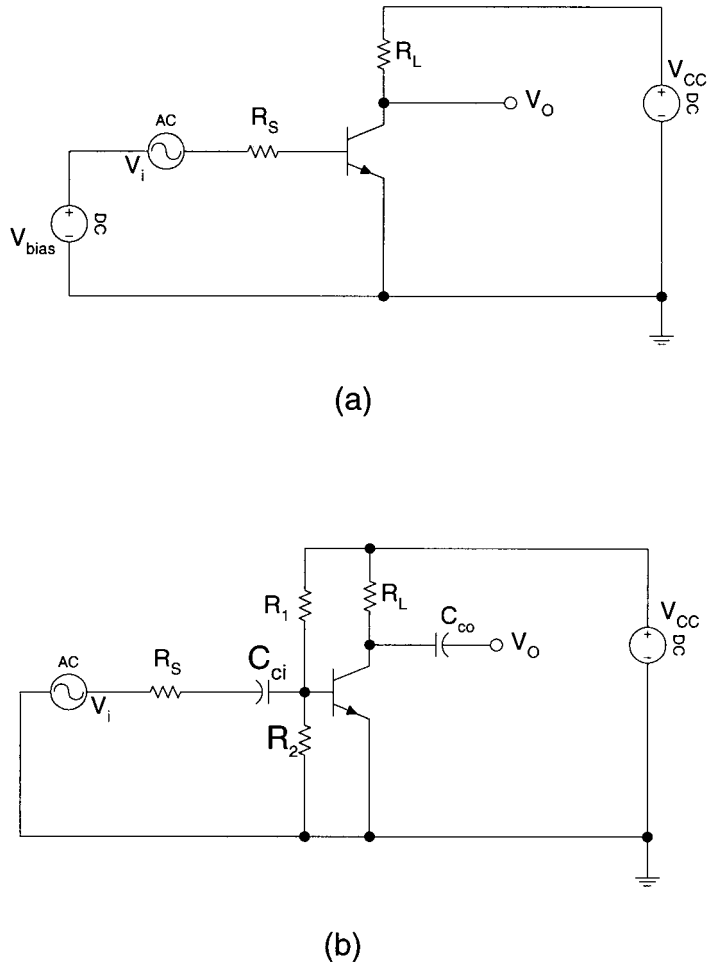

FIGURE 20.5 Common-emitter amplifier: (a) V_{bias} in series with ac signal source, (b) arrangement with coupling capacitors.

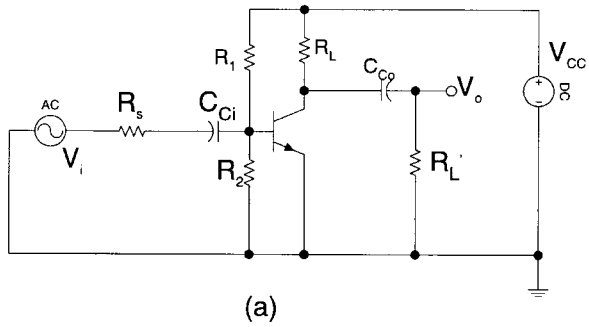
is large, this coupling capacitor behaves as a short-circuit for ac signals. Hence, R_L' is effectively in parallel with R_L. Therefore, signal excursions occur along a new *dynamic* load line, as illustrated in Fig. 20.6(b).

Common-Emitter Amplifier

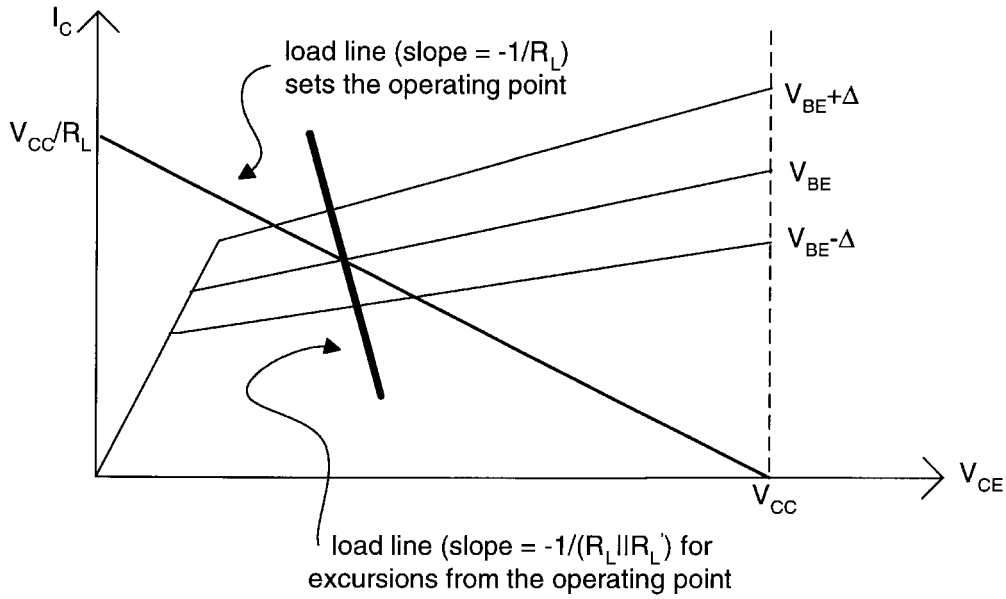
The circuits in Figs. 20.5 or 20.6(a) are known as *common-emitter amplifiers.* This name is derived from the fact that the emitter terminal is common with the ground node.

Small-Signal Gain

The small-signal equivalent circuit of the common-emitter amplifier is shown in Fig. 20.7. This circuit is derived based on the observation that for ac signals, fixed dc bias sources are identical to ac ground. We have also assumed (for now) that the coupling capacitors C_{ci} and C_{co} are so large that for any frequencies of interest, they effectively behave as short-circuits. Moreover, parasitic capacitances internal to the transistor are ignored. R_L' has been eliminated for simplicity (or one could assume that R_L represents the effective parallel resistance). R_S is the series output resistance of the ac source V_i and r_b stands for the physical resistance of the base. r_π models the linearized input voltage–current characteristic



(a)



(b)

FIGURE 20.6 (a) common-emitter amplifier with ac coupled load R'_L, (b) I_C vs. V_{CE} diagram with static and dynamic load lines.

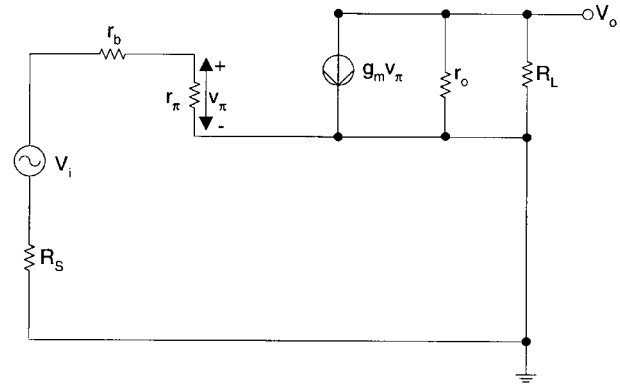


FIGURE 20.7 Small-signal equivalent circuit for the common-emitter amplifier.

of the base–emitter junction. In other words, r_π is the ratio between v_{be} and i_b for small-signal excursions from the operating point set by V_{BE}. Although the parallel combination of R_1 and R_2 shunts r_π, we assume here that both resistors have such high ohmic values that their effect on r_π can be regarded as immaterial. From the Ebers-Moll equation (with $V_{BE} >> V_T$),

$$I_C = \beta I_B = I_S \exp\left(\frac{V_{BE}}{V_T}\right)\left(1 + \frac{V_{CE}}{V_A}\right) \tag{20.1}$$

where I_S is the transistor's saturation current and $V_T = kT/q$ the thermal voltage, one readily derives the following expressions for the transconductance g_m, the input resistance r_π, and the output resistance r_o.

$$g_m = \frac{dI_C}{dV_{BE}} = \frac{I_C}{V_T} \tag{20.2}$$

$$r_\pi = \left(\frac{dI_B}{dV_{BE}}\right)^{-1} = \left(\frac{I_C}{\beta V_T}\right)^{-1} = \frac{\beta}{g_m} \tag{20.3}$$

$$r_o = \left(\frac{dI_C}{dV_{CE}}\right)^{-1} = \left(\frac{I_S}{V_A}\exp\left(\frac{V_{BE}}{V_T}\right)\right)^{-1} \tag{20.4}$$

In general, $V_A >> V_{CE}$. Therefore,

$$r_o \approx \frac{V_A}{I_C} \tag{20.5}$$

The following two equations can be written for the circuit in Fig. 20.7.

$$v_\pi = V_i \frac{r_\pi}{r_b + R_S + r_\pi} \tag{20.6}$$

$$V_o = -g_m v_\pi (r_o \parallel R_L) \tag{20.7}$$

where $\parallel$ denotes the parallel combination of two resistors. Combining Eqs. (20.6) and (20.7) leads to the expression for the small-signal gain

$$A = \frac{V_o}{V_i} = -g_m \frac{r_\pi}{r_b + R_S + r_\pi} \frac{r_o R_L}{r_o + R_L} \tag{20.8}$$

Assuming $r_b + R_S << r_\pi$ and $R_L << r_o$,

$$A \approx -g_m R_L \tag{20.9}$$

Equation (20.9) implies that selecting a higher-valued load resistor R_L results in higher gain. However, this conclusion is only valid as long as $R_L << r_o$. Conversely, for a given R_L, the gain can be increased by choosing a higher g_m. According to Eq. (20.2), this corresponds to a higher I_C. However, r_o goes down with increasing I_C (see Eq. (20.5) and Fig. 20.1), causing some reduction in gain. Furthermore, assuming β is constant over the range of operating points, Eq. (20.3) specifies that r_π also decreases with increasing g_m, augmenting the reduction in gain. To compound the problem, β actually starts rolling off at high current levels.

The best choice of operating point is most often determined by ensuring the largest possible output signal swing. In that case,

The best choice of operating point is most often determined by ensuring the largest possible output signal swing. In that case,

$$I_C R_L = \frac{V_{CC} - V_{CE,\,sat}}{2} \approx \frac{V_{CC}}{2} \tag{20.10}$$

Under this condition, the gain expression reduces to

$$A \approx -\frac{V_{CC}}{2\,V_T} \tag{20.11}$$

Since V_T is about 25 mV at room temperature, a 5-V supply yields a gain A approximately equal to 100.

The apparent paradox (a high R_L limits g_m and vice versa) could be circumvented if a scheme were conceived that combined a static low-R_L load line (allowing a high bias current and hence g_m) with a dynamic high-R_L load line. One potential solution is to steer some dc current away from R_L by means of a current source, as illustrated in Fig. 20.8(a). Figure 20.8(b) depicts the corresponding vertical movement of the load line. The current source can be made with a pnp transistor and three resistors, as shown in Fig. 20.8(c). Why this particular configuration makes a good current source will become clear later from the discussion of the reciprocal npn circuit.

The logical next step consists of the complete removal of R_L and replacing this *passive* component with an *active* pnp load. A conceptual drawing, including a current generator and mirror, is given in Fig. 20.9(a). Figure 20.9(b) shows that the operating point is now determined by the intersection of the npn and pnp I_C–V_{CE} curves. For the amplifier in Fig. 20.9(a),

$$A \approx -g_m(r_{o,n} \parallel r_{o,p}) \approx -\frac{I_C}{V_T}\left(\frac{V_{A,n}}{I_C} \parallel \frac{V_{A,p}}{I_C}\right) \approx -\frac{V_{A,n}\,V_{A,p}}{V_T(V_{A,n} + V_{A,p})} \tag{20.12}$$

Similar to Eq. (20.11), the gain expressed by Eq. (20.12) is independent of the bias current I_C. Furthermore, A no longer depends on the supply voltage V_{CC}. The circuit in Fig. 20.9(a), however, is only conceptual in nature. In practice, it is dc unstable. Indeed, due to the small slopes of the intersecting transistor characteristics (or, equivalently, the high output resistances of both transistors), minor mismatches between the two currents, small temperature differences, or simply basic variations in processing will cause a sizable shift of the operating point. Intuitively, some kind of feedback network is needed to guarantee quiescent stability. The discussion of such circuitry is deferred to Section 20.3 and Fig. 20.32.

Stabilizing the Common-Emitter's Operating Point

Up to this point, we have (implicitly) assumed that the operating point is set by means of a fixed dc voltage V_B at the base of the transistor. However, due to the exponential nature of the BJT, such arrangement leaves both I_C and the operating point very sensitive to even small changes in this base voltage. Indeed,

$$\frac{dI_C}{dV_{BE}} = \frac{d\left(I_S \exp\left(\frac{V_{BE}}{V_T}\right)\right)}{dV_{BE}} = \frac{I_S}{V_T}\exp\left(\frac{V_{BE}}{V_T}\right) = \frac{I_C}{V_T} \tag{20.13}$$

Therefore, $\Delta I_C/I_C = \Delta V_{BE}/V_T = \Delta V_B/V_T$. At room temperature, a 1-mV change in V_B translates into a 4% collector current change. Furthermore, the strong temperature dependence of V_T as well as I_S requires V_B to decrease by about 2 mV per degree rise in temperature if a constant current I_C is to be

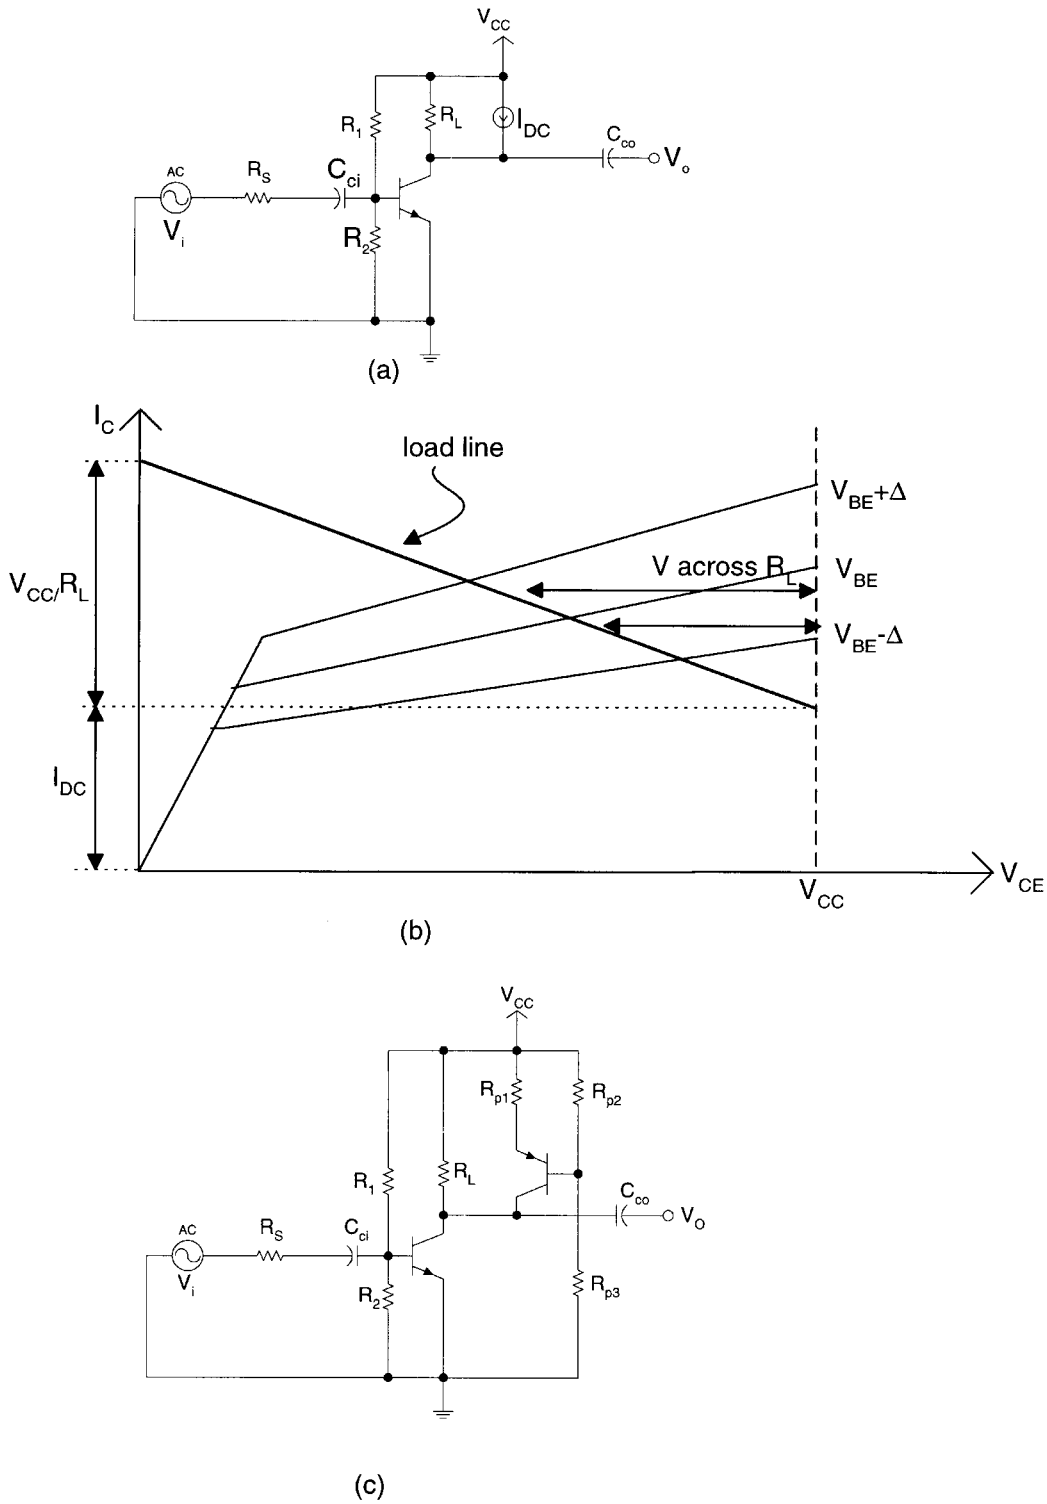

FIGURE 20.8 (a) Common-emitter amplifier with dc current bypass of R_L; (b) I_C vs. V_{CE} diagram with load line; (c) current source implemented by means of pnp and three resistors.

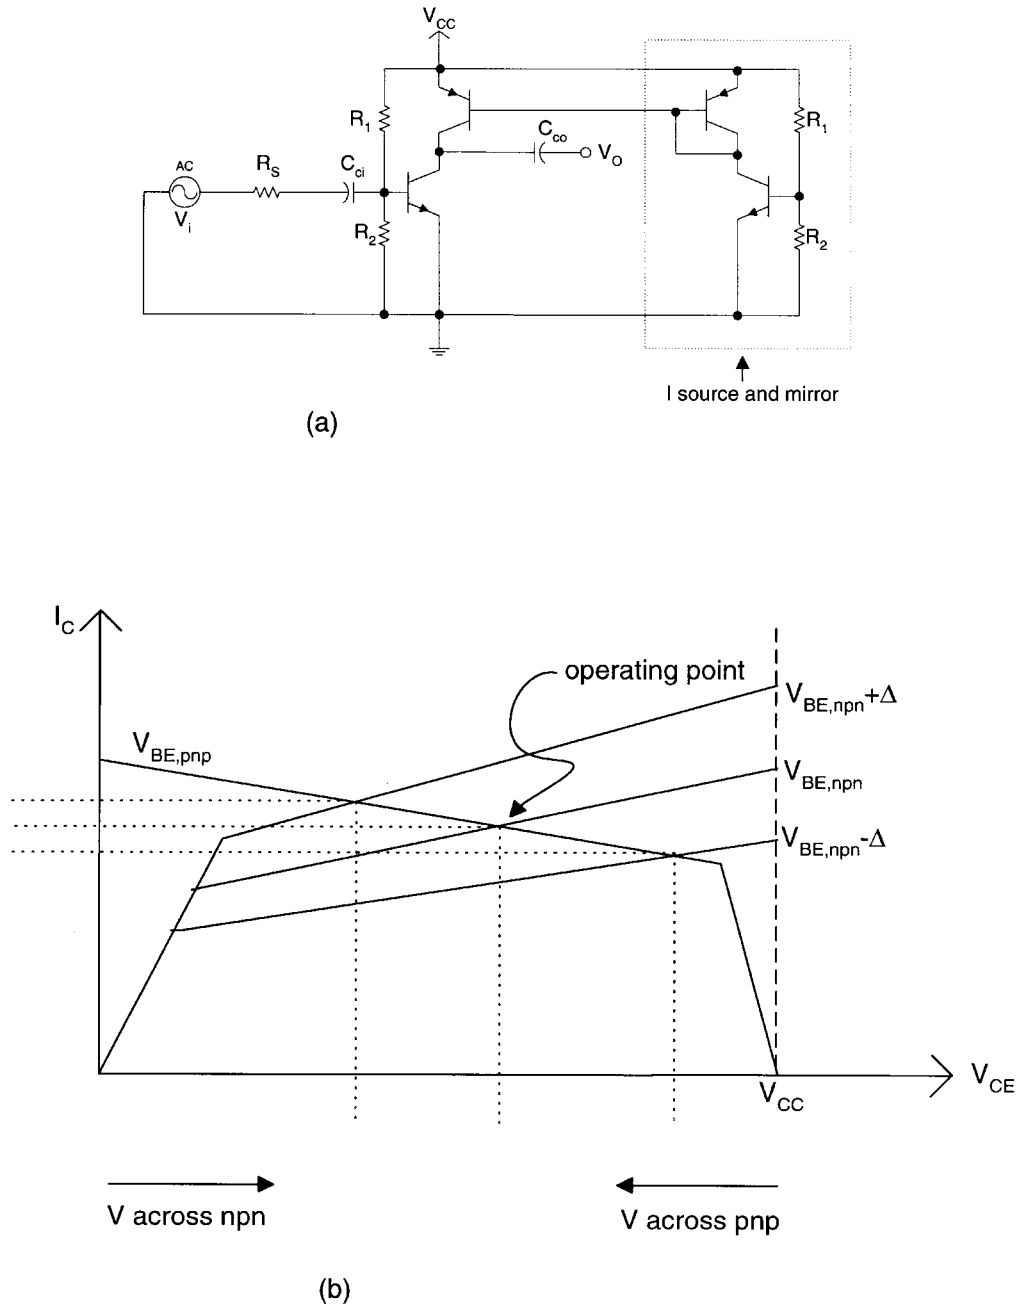

FIGURE 20.9 (a) Common-emitter amplifier with active load; (b) I_C vs. V_{CE} diagram.

maintained. Rather than fixing the voltage V_B at the base, one could try to force a fixed base current I_B and rely on the $I_C = \beta I_B$ relationship to set the collector current. However, β is strongly temperature dependent as well as subject to wide process variations. Moreover, β varies according to the transistor's current bias.

Consequently, the only way a stable operating point can be secured is by fixing the emitter current I_E. Since

$$I_C = \alpha I_E = \frac{\beta}{\beta + 1} I_E \approx I_E \tag{20.14}$$

fixing I_E yields a predictable collector current I_C. In discrete realizations, the value of R_L is well-determined (e.g., better than 1%). In integrated circuits (ICs), on the other hand, resistors are subject to wide absolute value tolerances. However, resistor ratios are usually tightly controlled. If one is able to set $I_C = V_{ref}/R_C$, where V_{ref} is a well-defined voltage, such as a bandgap reference (see Section 20.5), the product $I_C R_L$ only depends on V_{ref} and a resistor ratio. Thus, the operating point can be firmly established.

A simple way to set I_E consists of inserting a resistor R_E in series with the emitter, as shown in Fig. 20.10. The insertion of R_E introduces negative feedback, which makes the biasing circuit self-correcting. By inspection,

$$V_B = V_{BE} + R_E I_E \approx V_{BE} + R_E I_C \tag{20.15}$$

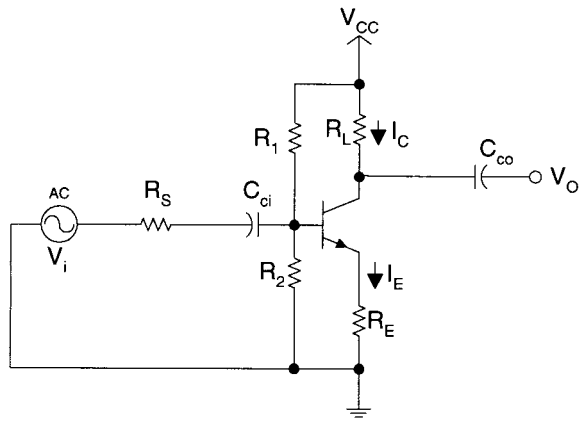

FIGURE 20.10 Common-emitter amplifier with degeneration resistor.

If the base current I_B is assumed to be much smaller than the current through the resistive divider network consisting of R_1 and R_2, then

$$V_B \approx \frac{R_2}{R_1 + R_2} V_{CC} \tag{20.16}$$

Combined with the Ebers-Moll identity

$$V_{BE} = V_T \ln\left(\frac{I_C}{I_S}\right) \tag{20.17}$$

Eqs. (20.15) and (20.16) can be solved for I_C. However, no closed-form solution is possible and numerical iterations must be performed. Intuitively, when I_C increases, the voltage drop across R_E also increases. Since V_B is constant, V_{BE} must go down, forcing I_C to decrease instead. Conversely, when I_C begins to decrease, the voltage across R_E goes down, V_{BE} is increased, which in turn leads to a reversal in the direction of the change in I_C. Eventually, an equilibrium point is reached. The dc voltage at the output can be expressed as

$$V_{o,dc} = V_{CC} - I_C R_C = V_{CC} - (V_B - V_{BE})\frac{R_L}{R_E} \tag{20.18}$$

Apparently, the arrangement of R_1, R_2, R_E and the npn transistor approximates a current source quite well. The approximation more closely approaches an ideal current source as the voltage drop across R_E is increased. In practice, however, the available supply voltage V_{CC} is fixed (or at least limited) and the emitter degeneration voltage subtracts from the achievable signal swing. Consequently, an acceptable compromise must be made.

The fact that the transistor's collector current is more or less constant, independent of the voltage at the output, implies that the configuration possesses a high output impedance. A mathematical expression for the output resistance of the degenerated common-emitter configuration can be derived from the small-signal equivalent circuit depicted in Fig. 20.11. If a test voltage V_{test} and a test current I_{test} are applied, the following equations can be written

$$I_{test} = g_m v_\pi + \frac{V_{test} - V_E}{r_o} \tag{20.19}$$

$$I_{test} = \frac{V_E}{R_E} + \frac{V_E}{r_b + R_S + r_\pi} \tag{20.20}$$

$$v_\pi = -\frac{r_\pi}{r_b + R_S + r_\pi} V_E \tag{20.21}$$

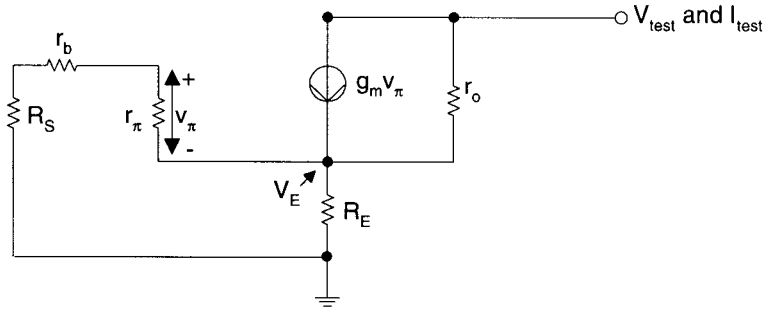

FIGURE 20.11 Small-signal equivalent circuit for calculation of the output resistance of the common-emitter configuration with degeneration.

The output resistance R_o is simply the ratio of V_{test} and I_{test}. Thus,

$$R_o = \frac{V_{test}}{I_{test}} = r_o\left(1 + \frac{g_m r_\pi R_E}{r_b + R_S + r_\pi + R_E} + \frac{R_E(r_b + R_S + r_\pi)}{r_o(r_b + R_S + r_\pi + R_E)}\right) \tag{20.22}$$

Assuming typical values for each of the resistances, Eq. (20.22) can be simplified to

$$R_o \approx r_o\left(1 + g_m R_E + \frac{R_E}{r_o}\right) \approx r_o(1 + g_m R_E) \tag{20.23}$$

In conclusion, the applied degeneration significantly boosts the transistor's output resistance r_o, more specifically by a multiplication factor $(1 + g_m R_E)$. The reader should take note that Fig. 20.11 and

Eq. (20.23) only represent the degenerated transistor. The output resistance of the complete degenerated common-emitter amplifier of Fig. 20.10 is the shunt combination of R_o and R_L.

The effect of R_E on the input impedance can similarly be derived from the small-signal equivalent circuit in Fig. 20.12.

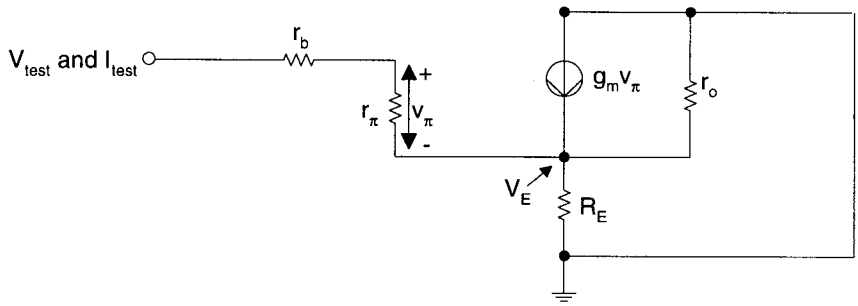

FIGURE 20.12 Small-signal equivalent circuit for calculation of the input resistance of the common-emitter configuration with degeneration.

$$I_{test} = \frac{V_E}{R_E} + \frac{V_E}{r_o} - g_m v_\pi \tag{20.24}$$

$$V_{test} = (r_b + r_\pi) I_{test} + V_E \tag{20.25}$$

$$v_\pi = r_\pi I_{test} \tag{20.26}$$

Combining Eqs. (20.24) through (20.26) yields

$$R_i = \frac{V_{test}}{I_{test}} = r_b + r_\pi + (1 + g_m r_\pi)\frac{r_o R_E}{r_o + R_E} \approx r_b + r_\pi + (\beta + 1)R_E \tag{20.27}$$

$$\approx r_\pi + \beta R_E \approx r_\pi(1 + g_m R_E)$$

The desirable multiplication factor found in Eq. (20.23) is likewise recognized in Eq. (20.27).

Lastly, the effect of R_E on the small-signal gain is calculated from the circuit in Fig. 20.13.

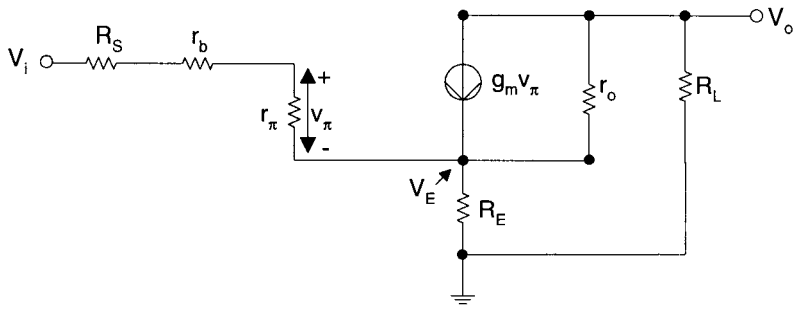

FIGURE 20.13 Small-signal equivalent circuit for calculation of the gain of the common-emitter amplifier with degeneration.

$$\frac{V_E}{R_E} + \frac{V_E - V_i}{r_b + R_S + r_\pi} + \frac{V_E - V_o}{r_o} - g_m v_\pi = 0 \tag{20.28}$$

$$\frac{V_o}{R_L} + \frac{V_o - V_E}{r_o} + g_m v_\pi = 0 \tag{20.29}$$

$$v_\pi = (V_i - V_E)\frac{r_\pi}{r_b + R_S + R_\pi} \tag{20.30}$$

After some manipulation, and assuming r_o is quite high, as well as r_π being much larger than either r_b, R_S, or R_L, one finds

$$A = \frac{V_o}{V_i} \approx -\frac{g_m R_L}{1 + g_m R_E} \approx -\frac{R_L}{R_E} \tag{20.31}$$

Again, the factor $(1 + g_m R_E)$ shows up. However, this time it appears in the denominator, which translates into a large unwanted reduction in gain. A possible solution lies in the use of a decoupling capacitor C_E placed in parallel with R_E. Then, Eq. (20.31) becomes

$$A \approx -\frac{g_m R_L (1 + sC_E R_E)}{1 + g_m R_E + sC_E R_E} \tag{20.32}$$

Eq. (20.32) has a zero at

$$s_z = -\frac{1}{C_E R_E} \tag{20.33}$$

and a pole at a higher frequency given by

$$s_p = -\frac{1 + g_m R_E}{C_E R_E} \approx -\frac{g_m}{C_E} \tag{20.34}$$

If C_E is chosen sufficiently large, the desirable dc degeneration resistance properties can be combined with a small-signal gain, which for the frequencies of interest approaches the $-g_m R_L$ value realized by the undegenerated common-emitter amplifier.

The stabilization method shown in Fig. 20.10 is very commonly used in discrete amplifier realizations. As mentioned before, integrated circuit implementations have the advantage of near-perfect matching between like components. Rather than stabilizing the current in each transistor by the method described above, usually a single accurate bias current generator is incorporated on a chip and the resulting reference current is mirrored throughout. The discussion of suitable voltage and current reference generators is postponed until Section 20.5. Figure 20.14(a) shows how a reference current I_{REF} is mirrored to the common-emitter amplifier by means of a basic npn current mirror. Following the previous derivations

$$R_{E,\,\text{eff}} = r_o(1 + g_m R_{E2}) = r_o\left(1 + \frac{I_{REF}}{V_T} R_{E2}\right) = \frac{V_A}{I_{REF}}\left(1 + \frac{I_{REF}}{V_T} R_{E2}\right) \approx \frac{V_A}{V_T} R_{E2} \tag{20.35}$$

$R_{E,\text{eff}}$ is much higher than could be obtained by a resistor only, under the restriction of an equal voltage drop. Thus, we have a higher performance current source. Also, for a given C_E, the pole and zero, which obey Eqs. (20.33) and (20.34), move to lower frequencies. Conversely, a lower valued C_E could be used.

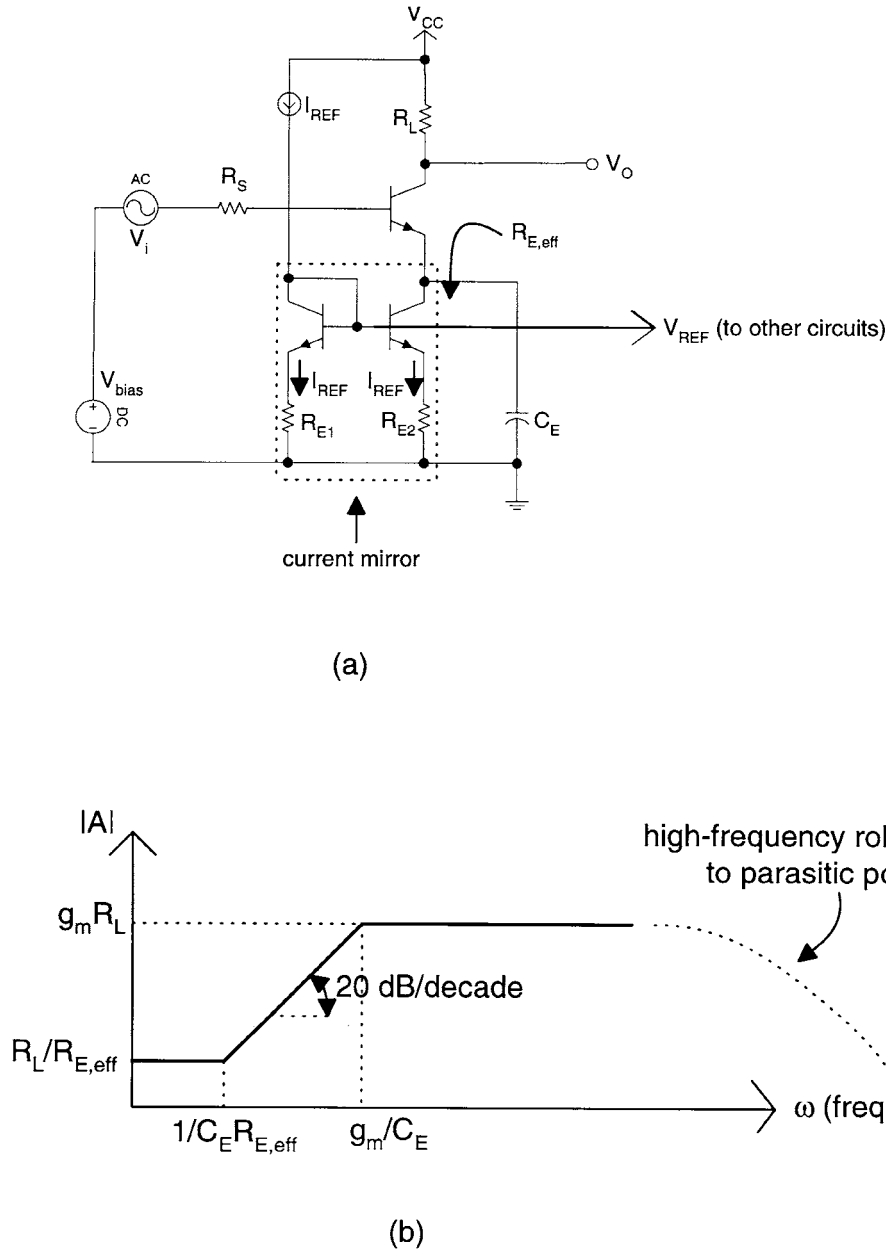

FIGURE 20.14 (a) Common-emitter amplifier with bias current generator and mirror, and (b) magnitude response vs. frequency.

This property is quite useful since integrated circuit capacitors consume a rather large amount of silicon real estate, and die size directly relates to cost.

Frequency Response of the Common-Emitter Amplifier

With the exception of C_E, we have thus far ignored the effect of the capacitors. At low frequencies, the ac coupling capacitances C_{ci} and C_{co} result in a gain reduction. In that sense, they behave similarly to C_E. At high frequencies, the internal transistor parasitics lead to a decrease in gain. Three parasitic

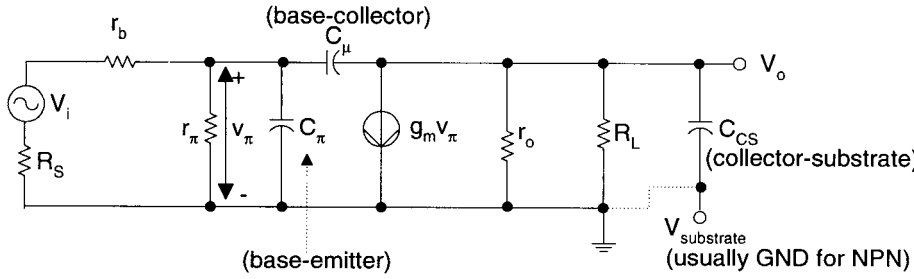

FIGURE 20.15 High-frequency small-signal equivalent circuit for the common-emitter amplifier.

capacitors must be accounted for: the emitter–base capacitance C_π, the collector–base capacitance C_μ, and the collector–substrate capacitance C_{cs}. Figure 20.15 shows the high-frequency small-signal equivalent circuit of the common-emitter amplifier. With R_i representing the parallel combination of $(R_S + r_b)$ with r_π, and R_C similarly designating the parallel combination of R_L with r_o, Eq. (20.9) must be rewritten as

$$A = -\frac{g_m R_i R_C}{R_S + r_b}\frac{N(s)}{D(s)} \tag{20.36}$$

where

$$\frac{N(s)}{D(s)} = \left(1 - \frac{sC_\mu}{g_m}\right)\Big/\left(1 + s(C_\pi R_i + C_\mu R_i + C_\mu R_C + C_\mu R_i R_C g_m + C_{cs} R_C) + s^2(C_\pi C_{cs} R_i R_C + C_\pi C_\mu R_i R_C + C_\mu C_{cs} R_i R_C)\right) \tag{20.37}$$

One observes that Eq. (20.37) contains a right half-plane zero located at $s_z = g_m/C_\mu$, resulting from the capacitive feedthrough from input to output. However, this right half-plane zero is usually at such a high frequency that it can be ignored in most applications. Furthermore, in most cases, one can assume that $D(s)$ contains a dominant pole p_1 and a second pole p_2 at a substantially higher frequency. If the dominant pole assumption is valid, $D(s)$ can be factored in the following manner

$$D(s) = \left(1 - \frac{s}{p_1}\right)\left(1 - \frac{s}{p_2}\right) \approx 1 - \frac{s}{p_1} + \frac{s^2}{p_1 p_2} \tag{20.38}$$

Equating Eqs. (20.37) and (20.38) yields

$$p_1 = -\frac{1}{R_i}\frac{1}{C_\pi + C_{cs}\dfrac{R_C}{R_i} + C_\mu\left(1 + g_m R_C + \dfrac{R_C}{R_i}\right)} \tag{20.39}$$

$$p_2 = -\frac{1}{R_C(C_\mu + C_{cs})}\frac{C_\pi + C_{cs}\dfrac{R_C}{R_i} + C_\mu\left(1 + g_m R_C + \dfrac{R_C}{R_i}\right)}{C_\pi + \dfrac{C_\mu C_{cs}}{C_\mu + C_{cs}}} \tag{20.40}$$

In Eqs. (20.39) and (20.40), the collector–base capacitance C_μ appears with a multiplication factor. One readily recognizes that this factor is dominated by the term $g_m R_C$, which is equal to the amplifier's gain A. A very important conclusion is that, looking into the common-emitter amplifier's input, the base–collector capacitance C_μ appears approximately A times larger than its actual physical value. This phenomenon is widely referred to as the *Miller effect*. As a result, C_μ often constitutes the predominant frequency limiter in high-gain common-emitter amplifiers.

If the dominant pole assumption is a valid model for the amplifier's high-frequency response, the –3 dB frequency can be more easily calculated by the method of *time constants*, rather than by deriving the complete transfer function. Indeed, it can be shown that

$$\omega_{3dB,HF} = \frac{1}{\sum_{n} C_i R_i} \tag{20.41}$$

where C_i are the capacitors in the high-frequency equivalent scheme (Fig. 20.15) and R_i are the resistances measured across each C_i when all other capacitors are replaced by open circuits. The reader can quickly verify that

$$R_\pi = r_\pi \| (r_b + R_S) = R_i \tag{20.42}$$

$$R_\mu = (r_\pi \| (r_b + R_S)) + (R_L \| r_o)(1 + g_m(r_\pi \| (r_b + R_S))) = R_i + R_C(1 + g_m R_i) \tag{20.43}$$

$$R_{Ccs} = R_L \| r_o = R_C \tag{20.44}$$

Then, according to Eq. (20.41),

$$\omega_{3dB,HF} = \frac{1}{R_\pi C_\pi + R_\mu C_\mu + R_{Ccs} C_{cs}} \tag{20.45}$$

which is identical to Eq. (20.39).

Likewise, one can show that if the low-frequency behavior can be described by a single-pole model,

$$\omega_{3dB,LF} = \sum_{j=1}^{m} \frac{1}{C_j R_j} \tag{21.46}$$

where C_j are the decoupling and coupling capacitors C_E, C_{ci}, C_{co}, and R_j are the resistances individually measured across their terminals when all other capacitors are simultaneously shorted.

This concludes the analysis of the common-emitter amplifier. The bipolar transistor, however, is a three-terminal device (actually there are four terminals if the substrate node is included), so there are obviously different ways to hook the BJT up into a circuit. Based on an understanding of the transistor's operation, it clearly does not make much sense to consider the base as an output, nor to use the collector as an input. This leaves us with two other meaningful possibilities, which will be studied in further detail.

Common-Collector Amplifier (Emitter Follower)

In the amplifier of Fig. 20.16, the input signal is provided to the base of the transistor, while the output is taken at the emitter. Similar to the common-emitter amplifier, this circuit configuration derives its name based on the terminal tied to a common ac ground node. In Fig. 20.16, the collector is connected directly to the supply voltage V_{CC}, hence the name *common-collector* amplifier.

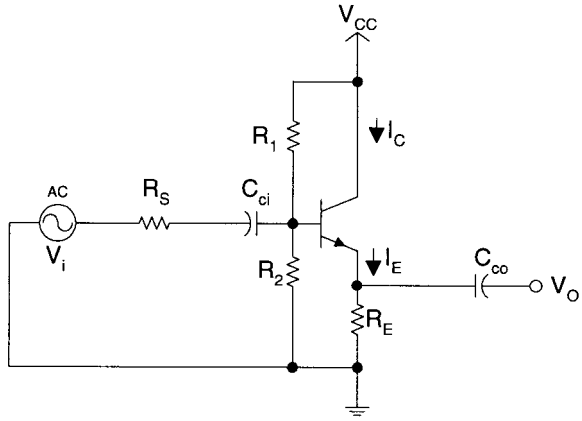

FIGURE 20.16 Common-collector amplifier (emitter follower).

Small-Signal Gain

The common-collector amplifier's mid-frequency small-signal equivalent circuit is shown in Fig. 20.17. By inspection,

$$\frac{V_o}{R_E} + \frac{V_o - V_i}{r_b + R_S + r_\pi} + \frac{V_o}{r_o} - g_m v_\pi = 0 \tag{20.47}$$

$$v_\pi = (V_i - V_o)\frac{r_\pi}{r_b + R_S + r_\pi} \tag{20.48}$$

$$A = \frac{V_o}{V_i} = \frac{1}{1 + \dfrac{r_b + R_S + r_\pi}{(\beta + 1)(R_E \parallel r_o)}} \tag{20.49}$$

$$A \approx \frac{1}{1 + \dfrac{r_\pi}{\beta R_E}} \approx \frac{g_m R_E}{1 + g_m R_E} \tag{20.50}$$

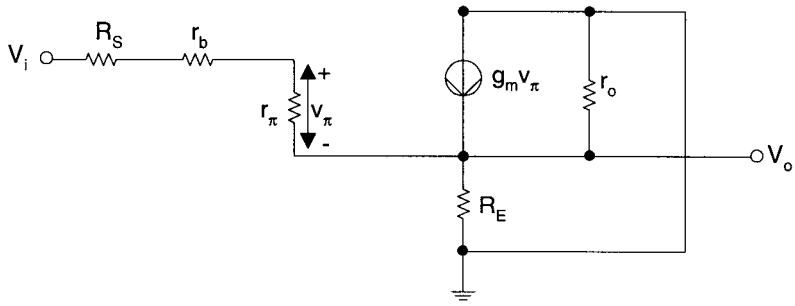

FIGURE 20.17 Small-signal equivalent circuit for calculation of the gain of the common-collector amplifier (emitter follower).

In most cases, $g_m R_E >> 1$ and, thus,

$$A \approx 1 \tag{20.51}$$

This means that the output voltage at the emitter nearly follows the input at the base. Eq. (20.51) is the reason why the common-collector amplifier is most often referred to as the *emitter follower* configuration.

The emitter follower's input resistance is identical to that of the degenerated common-emitter's. Thus, R_i is high and given by Eq. (20.27). Its output resistance R_o can be calculated from Fig. 20.17 by applying V_{test} and I_{test}, as demonstrated previously for the common-emitter circuit.

$$R_o = R_E \parallel r_o \parallel \frac{r_b + R_S + r_\pi}{\beta + 1} \approx \frac{1}{g_m} + \frac{R_S}{\beta} \tag{20.52}$$

Generally, Eq. (20.52) means that R_o is low. When the emitter follower is driven from a low-impedance (near-ideal) voltage source, R_o approaches its lower limit $1/g_m$. At room temperature, for example, a 1-mA bias current yields $R_o \approx 25\ \Omega$.

Since there is no gain, the emitter follower does not experience the aforementioned Miller effect and, correspondingly, has a wide bandwidth.

At this time, the reader may interject, "Why not use a (non-degenerated) common-emitter amplifier with a $1/g_m$ load, rather than the emitter follower?" Indeed, both circuits have identical input and output resistances as well as a gain of 1. The answer, however, does not lie in these small-signal parameters, but depends on the signal level. For example, for the common-emitter, a 1-V input is large (actually it would steer the transistor from the OFF state all the way into saturation). For the emitter follower, on the other hand, such a signal is considered small. Thus, the emitter follower is particularly suited as an output stage for large signals. As such, the emitter follower circuit will be revisited in Section 20.4.

In Fig. 20.18, R_E is replaced by a current source. As derived above, the effective degeneration resistor is now equal to $r_o(1 + g_m R_E)$, and thus much higher. According to Eq. (20.50), the circuit's gain is therefore even closer to 1. The drawback of using a current source is the introduction of the parasitic capacitor C_E, which adversely affects the frequency response.

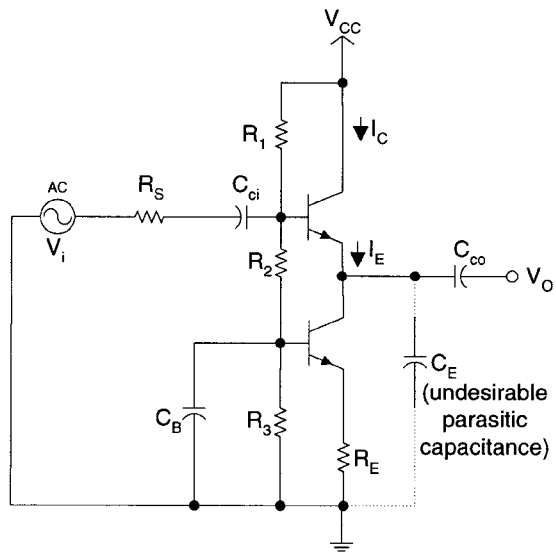

FIGURE 20.18 Common-collector amplifier (emitter follower) with current source bias.

Common-Base Amplifier

Figure 20.19 introduces an amplifier, where the input is applied at the emitter and the output taken at the collector. Since the base is connected to ac ground, this circuit is known as a *common-base* configuration.

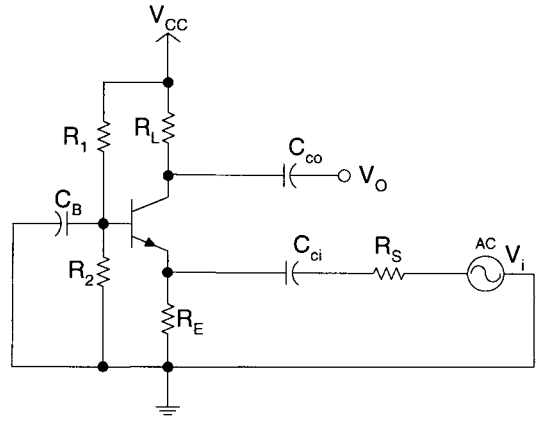

FIGURE 20.19 Common-base amplifier.

Subsequent to the analysis of the common-emitter and emitter follower configurations, it is straightforward to derive an expression for the input resistance R_i.

$$R_i \approx \frac{r_b + r_\pi}{\beta + 1} \approx \frac{1}{g_m} \tag{20.53}$$

According to Eq. (20.53), R_i is very low. Thus, it seems logical that the common-base circuit should be driven by a source with an equally low impedance. As we have seen above, such a source exists in the form of an emitter follower. Figure 20.20 shows the resulting combined circuit. Especially noteworthy in Fig. 20.20 is the symmetry in the arrangement of both transistors and the resistor R_E. This particular building block is called an *emitter-coupled pair*, as the reader might have expected based on the device connections. The emitter-coupled pair is by far the most frequently used configuration in integrated circuit bipolar amplifiers. It forms the cornerstone in the amplification of dc and difference signals and, as such, is the subject of an in-depth study in Section 20.3.

The common-base amplifier, however, can also be driven from a high-impedance source, as illustrated in Fig. 20.21. There, the outlined two-transistor arrangement is known as a *cascode* configuration. In Fig. 20.21, the common-emitter circuit at the bottom is loaded by the low-input impedance $(1/g_m)$ of the cascode common-base stage. Therefore, it provides no voltage amplification, but only current gain. The common-base stage, in turn, has a current gain approximately equal to 1 (to be exact, $\alpha = \beta/(\beta + 1)$), but contributes voltage gain by means of the load resistor R_L. The overall voltage transfer function is

$$A = \frac{V_o}{V_i} \approx -g_m R_L \tag{20.54}$$

The gain expressed in Eq. (20.54) is identical to the gain realized by the single-transistor common-emitter circuit. The reader may wonder, "What is the benefit of adding a second transistor in the common-base configuration?" The answer and advantage are related to the circuit's high-frequency response. Indeed, the common-base cascode stage effectively eliminates the Miller effect and, thereby, broadbands the circuit.

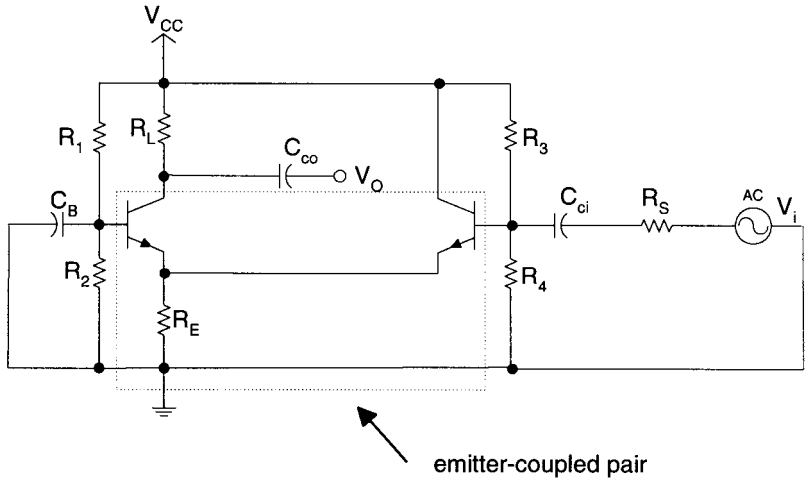

FIGURE 20.20 Common-base amplifier driven by an emitter follower.

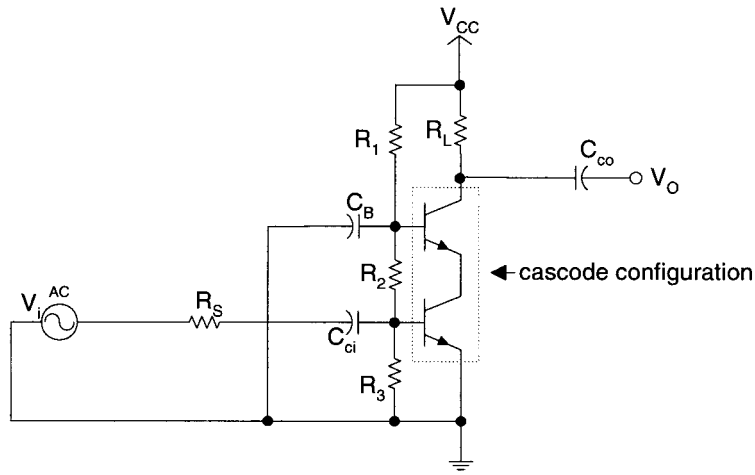

FIGURE 20.21 Common-base amplifier driven from common-emitter stage.

Darlington And Pseudo-Darlington Pairs

Whereas this chapter section was entitled single-transistor amplifiers, two two-transistor configurations, namely the emitter-coupled pair and the cascode arrangement, were briefly presented. Figure 20.22 introduces two other important two-transistor combinations: the *Darlington* and *pseudo-Darlington pairs*. The Darlington pair consists of two npn transistors connected as shown in Fig. 20.22(a). Combined, the two transistors effectively behave as a single npn with a (high) current gain $\beta = \beta_1\beta_2$. This improved current gain is traded off against a higher voltage requirement: the base–emitter voltage is twice that of a single transistor and the minimum base–collector voltage equals $(V_{CE,sat} + V_{BE})$. The pseudo-Darlington pair, shown in Fig. 20.22(b), is made out of the combination of a *npn* and a *pnp*. Both transistors jointly act as a single *pnp* with $\beta = \beta_1\beta_2$. The pseudo-Darlington's improved current gain is an important positive feature, as pnp's are generally far inferior in this respect compared to npn's. similar to the Darlington pair, the required collector–emitter voltage of the pseudo configuration is equal to $(V_{CE,sat} + V_{BE})$. Its

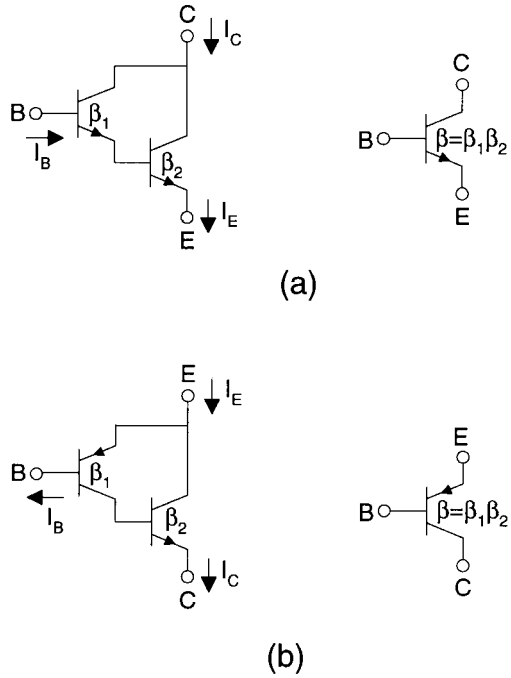

FIGURE 20.22 (a) Darlington pair, and (b) pseudo-Darlington pair.

base–emitter voltage requirement equals (V_{BE} + $V_{CE,sat}$). While higher than for a single transistor, this is not quite as high as needed by the cascade of two transistors.

20.3 Differential Amplifiers[1]

Introduction: Amplification of dc and Difference Signals

Differential amplifiers represent a class of amplifiers that amplify the difference between two signals, including dc. We will show that to obtain their desired characteristics, differential amplifiers critically depend on component matching. Therefore, discrete implementations necessitate careful component pairing, which is not only painstaking to the design engineer, but also significantly raises the amplifier's cost. In contrast, integrated circuit technology with its inherent small relative component tolerances is particularly suited for this application.

Section 20.2 emphasized that the active elements used for amplification are far from linear devices. To circumvent the problems associated with the bipolar transistor's non-linear input–output relationship, the amplifier circuits were linearized through the selection of a suitable operating point. Recalling Fig. 20.10, the input bias and dc level at the output were separated from the desired input–output signals by means of coupling capacitors C_{ci} and C_{co}. Further, an emitter degeneration resistor R_E reduced the drift of the operating point and a decoupling capacitor C_E was added to counteract the associated undesired gain reduction.

Obviously, the presence of coupling and decoupling capacitors makes the circuit in Fig. 20.10 unsuitable for dc amplification. But, even at low frequencies, this amplifier scheme is not usable due to the

[1] This section largely parallels the bipolar technology part of Ref. 12 by the same author.

large capacitor values required, which in turn give rise to large RC time constants and, consequently, slow recovery times from any transient disturbances.

The requirement to avoid capacitors in low-frequency or dc amplifiers unavoidably leads to a mixing of the concepts of bias and signal. A second characteristic of such amplifiers, as will become evident, is the application of symmetry to compensate for the drift of the active components.

An intuitive solution appears to lie in the use of two amplifiers connected in a difference configuration, as illustrated in Fig. 20.23. For this circuit, one can write the following equations

$$V_3 = A_1 V_1 \tag{20.55}$$

$$V_4 = A_2 V_2 \tag{20.56}$$

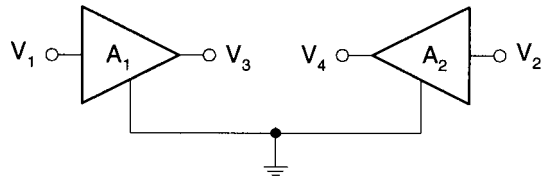

FIGURE 20.23 Initial concept of difference amplifier.

Assuming A_1 approximately equal to A_2 (i.e., $A_1 = A + \Delta/2$ and $A_2 = A - \Delta/2$) yields

$$V_3 - V_4 = A(V_1 - V_2) + \frac{\Delta}{2}(V_1 + V_2) \tag{20.57}$$

$$V_3 + V_4 = A(V_1 + V_2) + \frac{\Delta}{2}(V_1 - V_2) \tag{20.58}$$

Clearly, when both amplifiers are perfectly matched or $\Delta = 0$, the difference mode is completely separated from the sum mode.

Upon further reflection, however, the difference amplifier of Fig. 20.23 is not really the solution to the amplification problem under consideration. Indeed, in many instances, small signals, which sit on top of large pedestal voltages, need to be amplified. For example, assume $A = 100$, a difference signal of 10 mV, and a bias voltage equal to 10 V. The amplifier scheme of Fig. 20.23 would result in a 1-V difference signal in addition to a 1000-V output voltage common to both amplifiers. It is clearly unrealistic to assume that both amplifiers will remain linear and matched over such an extended voltage range. Instead, the real solution is obtained by coupling the amplifiers. The resulting arrangement is known as the *differential pair* amplifier.

In the mathematical description of the differential pair, four amplification factors are generally defined to express the relationship between the differential or difference (subscript D) and common or sum mode (subscript C) input and output signals. Applied to the circuit in Fig. 20.23, one can write

$$V_3 - V_4 = V_{oD} = A_{DD} V_{iD} + A_{DC} V_{iC} \tag{20.59}$$

$$V_3 + V_4 = 2V_{oC} = 2A_{CC} V_{iC} + 2A_{CD} V_{iD} \tag{20.60}$$

where $V_{iD} = V_1 - V_2$ and $V_{iC} = (V_1 + V_2)/2$.

The ratio A_{DD}/A_{CC} is commonly referred to as the amplifier's *common-mode rejection ratio* or CMRR. While an amplifier's CMRR is an important characteristic, maximizing its value is not a designer's goal

in itself. Rather, the real purpose is to suppress large sum signals so that the two amplifiers exhibit a small output swing and, thereby, indeed operate as a matched pair. Furthermore, the ultimate goal is to avoid that the application of a common-mode input signal results in a differential signal at the output. This objective can only be accomplished through a combination of careful device matching, precise selection of the amplifier's bias and operating point, as well as by a high common-mode rejection. While we have only considered differential output signals up to this point, in some instances a single-ended output is desired. Eqs. (20.59) and (20.60) can be rearranged as

$$V_3 = V_{oC} + \frac{1}{2}V_{oD} = \left(A_{CD} + \frac{1}{2}A_{DD}\right)V_{iD} + \left(A_{CC} + \frac{1}{2}A_{DC}\right)V_{iC} \tag{20.61}$$

$$V_4 = V_{oC} - \frac{1}{2}V_{oD} = \left(A_{CD} - \frac{1}{2}A_{DD}\right)V_{iD} + \left(A_{CC} - \frac{1}{2}A_{DC}\right)V_{iC} \tag{20.62}$$

One concludes that in the single-ended case, all three ratios A_{DD}/A_{CC}, A_{DD}/A_{CD}, and A_{DD}/A_{DC} must be high to yield the desired result.

Bipolar Differential Pairs (Emitter-Coupled Pairs)

Emitter-Coupled Pairs

Figure 20.24 depicts the basic circuit diagram of a bipolar differential pair. A differential signal V_{iD} is applied between the bases of two transistors, which, unless otherwise noted, are assumed to be identical. The dc bias voltage V_{bias} and a common-mode signal V_{iC} are also present. The transistors' common-emitter node (hence the name *emitter-coupled pair*) is connected to ground through a biasing network, which for simplicity is represented by a single resistor R_O. The amplifier output is taken differentially across the two collectors, which are tied to the power supply V_{CC} by means of a matched pair of load resistors R_L.

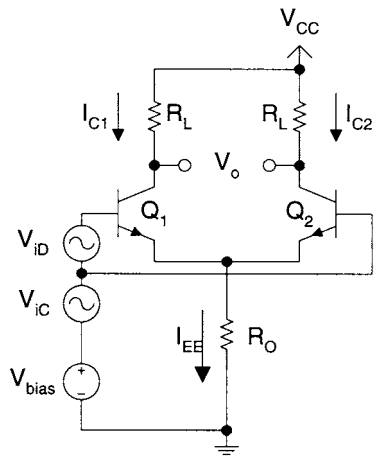

FIGURE 20.24 Emitter-coupled pair.

Low-Frequency Large-Signal Analysis

Applying the bipolar transistor's Ebers-Moll relationship with $V_{BE} >> V_T$ (where $V_T = kT/q$ is the thermal voltage) and assuming that both transistors are matched (i.e., the saturation currents $I_{S1} = I_{S2}$), the difference voltage V_{iD} can be expressed as follows

$$V_{iD} = V_{BE1} - V_{BE2} = V_T \ln\left(\frac{I_{C1}}{I_{C2}}\right) \tag{20.63}$$

After some manipulation and substituting $I_{C1} + I_{C2} = \alpha I_{EE}$ (the total current flowing through R_O), one gets

$$I_{C1} = \frac{\alpha I_{EE}}{1 + \exp\left(\frac{-V_{iD}}{V_T}\right)} \tag{20.64}$$

$$I_{C2} = \frac{\alpha I_{EE}}{1 + \exp\left(\frac{V_{iD}}{V_T}\right)} \tag{20.65}$$

where α is defined as $\beta/(\beta + 1)$.

Since $V_{oD} = -R_L (I_{C1} - I_{C2})$, the expression for the differential output voltage V_{oD} becomes

$$V_{oD} = -\alpha R_L I_{EE} \frac{\exp\left(\frac{V_{iD}}{2V_T}\right) - \exp\left(\frac{-V_{iD}}{2V_T}\right)}{\exp\left(\frac{V_{iD}}{2V_T}\right) + \exp\left(\frac{-V_{iD}}{2V_T}\right)} = -\alpha R_L I_{EE} \tanh\left(\frac{V_{iD}}{2V_T}\right) = -\alpha R_L I_{EE} \tanh x \tag{20.66}$$

The transfer function expressed in Eq. (20.66) is quite non-linear. A graphical representation is given in Fig. 20.25. When $V_{iD} > 2V_T$, the current through one of the two transistors is almost completely cut off and for further increases in V_{iD} the differential output signal eventually clips at $-\alpha R_L I_{EE}$. On the other hand, for small values of x, $\tanh x \approx x$. Under this small-signal assumption,

$$A_{DD} = \frac{V_{oD}}{V_{iD}} = -\frac{\alpha I_{EE}}{2V_T} R_L = -g_m R_L \tag{20.67}$$

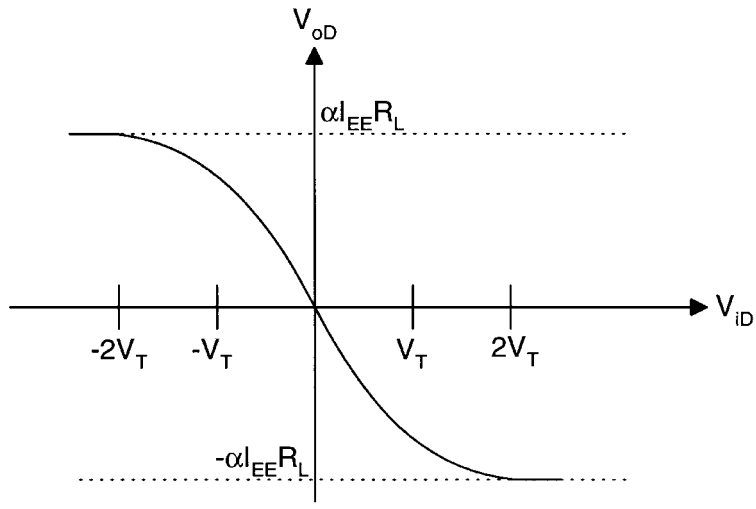

FIGURE 20.25 Emitter-coupled pair's dc transfer characteristic.

While the next subsection contains a more rigorous small-signal analysis, a noteworthy observation here is that, under conditions of equal power dissipation, the differential amplifier of Fig. 20.24 has only one half the transconductance value and hence only one half the gain of a single-transistor common-emitter amplifier. From Eq. (20.67), one furthermore concludes that when the tail current I_{EE} is derived from a voltage source, which is proportional to absolute temperature (PTAT), and a resistor of the same type as R_L, the transistor pair's differential gain is determined solely by a resistor ratio. As such, the gain is well-controlled and insensitive to absolute process variations. A similar observation was made in Section 20.2 during the discussion of the common-emitter amplifier's operating point stability. In Section 20.5, a suitable PTAT reference will be presented.

An intuitive analysis of the common-mode gain can be carried out under the assumption that R_O is large (e.g., assume R_O represents the output resistance of a current source). Then, a common-mode input signal V_{iC} results only in a small current change i_C through R_O and therefore V_{BE} remains approximately constant. With $i_C \approx V_{iC}/R_O$ and $V_{oC} = -R_L i_C/2$, the common-mode gain can be expressed as

$$A_{CC} = \frac{V_{oC}}{V_{iC}} \approx -\frac{R_L}{2R_o} \tag{20.68}$$

Combining Eqs. (20.67) and (20.68) yields

$$\text{CMRR} = \frac{A_{DD}}{A_{CC}} \approx 2g_m R_O \tag{20.69}$$

Half-Circuit Equivalents

Figure 20.26 illustrates the derivation of the emitter-coupled pair's differential mode half-circuit equivalent representation. For a small differential signal, the sum of the currents through both transistors remains constant and the current through R_O is unchanged. Therefore, the voltage at the emitters remains constant. The transistors operate as if no degeneration resistor were present, resulting in a high gain. In sum mode, on the other hand, the common resistor R_O provides negative feedback, which significantly lowers the common-mode gain. In fact, with identical signals at both inputs, the symmetrical circuit can be split into two halves, each with a degeneration resistor $2R_O$ as depicted in Fig. 20.27.

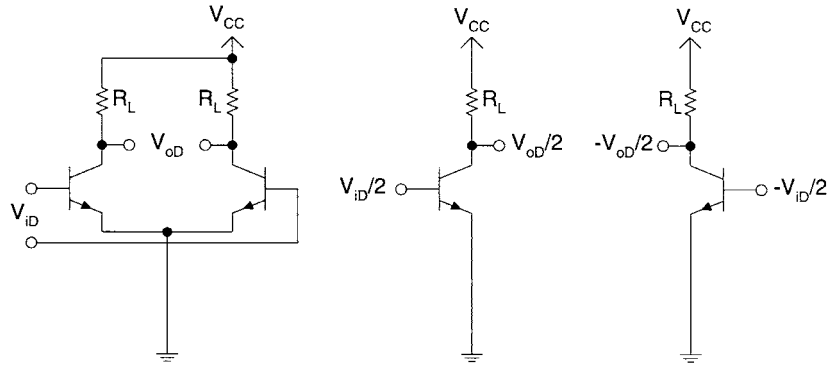

FIGURE 20.26 Difference mode.

Low-Frequency Small-Signal Analysis

Figure 20.28 represents the low-frequency small-signal differential mode equivalent circuit wherein R_{SD} models the corresponding source impedance. Under the presumption of matched devices,

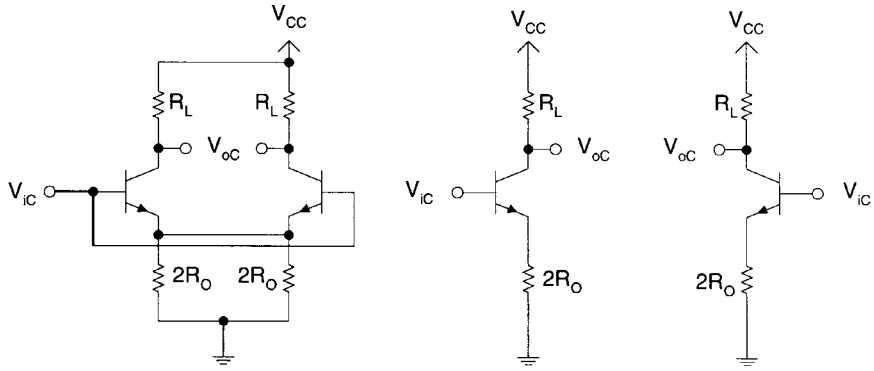

FIGURE 20.27 Sum mode.

$$A_{DD} = \frac{V_{oD}}{V_{iD}} = -g_m R_L \frac{r_\pi}{r_\pi + r_b + \frac{1}{2}R_{SD}} \tag{20.70}$$

With $r_b << r_\pi$ and assuming a low-impedance voltage source, Eq. (20.70) can be simplified to $-g_m R_L$ as was previously derived in Eqs. (20.67) or (20.9).

The low-frequency common-mode equivalent circuit is shown in Fig. 20.29. Under similar assumptions as in Eq. (20.70) and with R_{SC} representing the common-mode source impedance, one finds

$$A_{CC} = \frac{V_{oC}}{V_{iC}} = -g_m R_L \frac{r_\pi}{r_\pi + r_b + 2R_{SC} + 2(\beta + 1)R_O} \tag{20.71}$$

Upon substitution of $\beta = g_m r_\pi >> 1$, Eq. (20.71) reduces to $-R_L/2R_O$, the intuitive result obtained earlier in Eq. (20.68). For $R_E = 2R_O$, this result is also identical to Eq. (20.31).

The combination of Eqs. (20.70) and (20.71) leads to

$$\text{CMRR} = \frac{A_{DD}}{A_{CC}} = \frac{r_\pi + r_b + 2R_{SC} + 2(\beta + 1)R_O}{r_\pi + r_b + \frac{1}{2}R_{SD}} \approx 2g_m R_O \tag{20.72}$$

Let us consider the special case where R_O models the output resistance of a current source, implemented by a single bipolar transistor. Then, $R_O = V_A/I_{EE}$, where V_A is the transistor's Early voltage. With $g_m = \alpha I_{EE}/2V_T$,

$$\text{CMRR} = \frac{\alpha V_A}{V_T} \tag{20.73}$$

which is independent of the amplifier's bias conditions, but only depends on the process technology and temperature. At room temperature, with $\alpha \approx 1$ and $V_A \approx 25$ V, the amplifier's CMRR would be approximately 60 dB. The use of an improved current source, for example a bipolar transistor in series with an emitter degeneration resistor R_D, can significantly increase the CMRR. More specifically,

$$\text{CMRR} = \frac{\alpha V_A}{V_T}\left(1 + \frac{I_{EE}R_D}{V_T}\right) \tag{20.74}$$

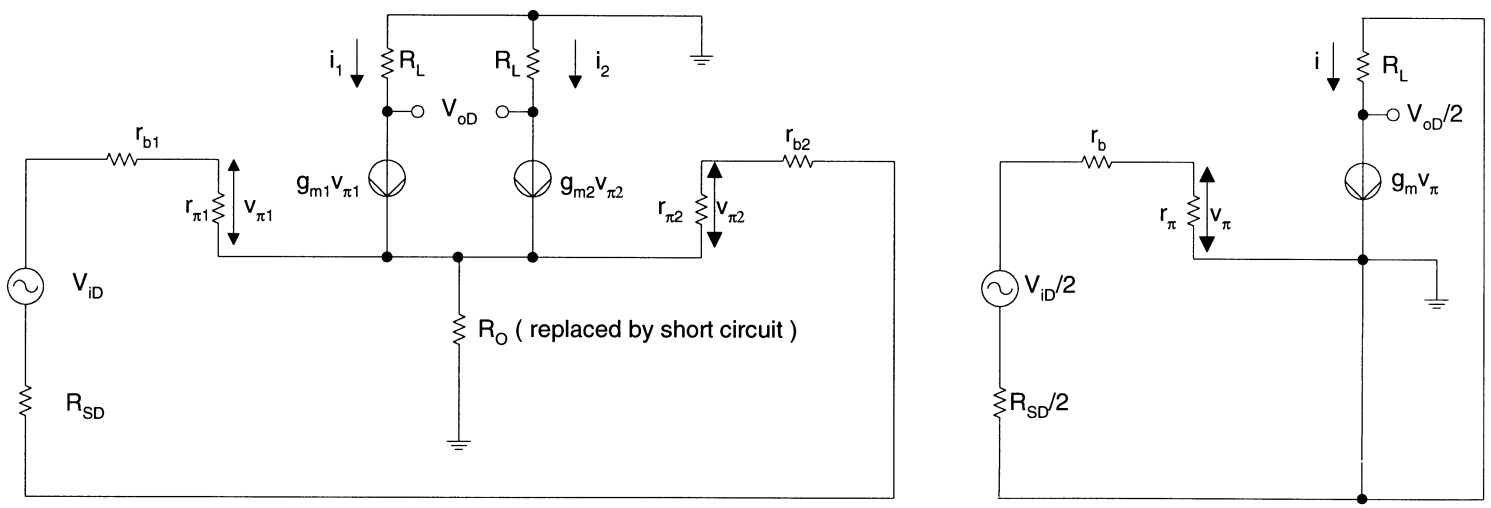

FIGURE 20.28 Small-signal equivalent circuit for difference mode.

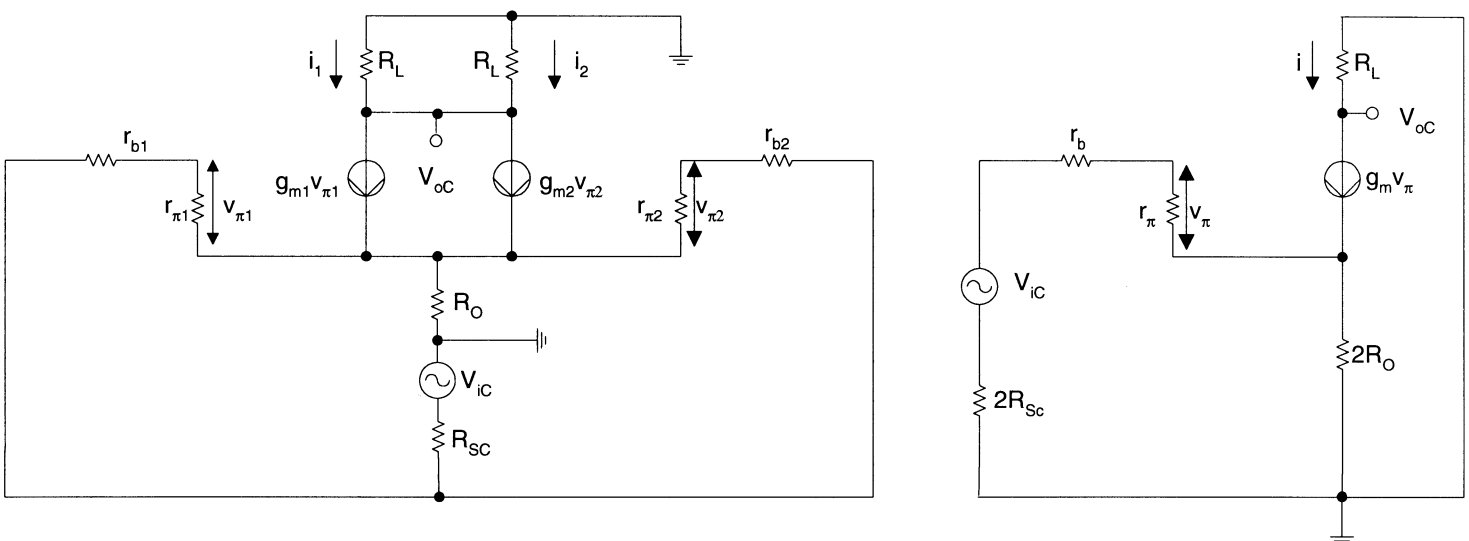

FIGURE 20.29 Small-signal equivalent circuit for sum mode.

For $I_{EE}R_D$ = 250 mV, the CMRR in Eq. (20.74) is eleven times higher than in Eq. (20.73).

In addition to expressions for the gain, the emitter-coupled pair's differential and common-mode input resistances can readily be derived from the small-signal circuits in Figs. 20.28 and 20.29.

$$R_{inD} = 2r_\pi \tag{20.75}$$

$$R_{inC} = \frac{1}{2}r_\pi + R_O(\beta + 1) \tag{20.76}$$

Taking into account the thermal noise of the transistors' base resistances and the load resistors R_L, as well as the shot noise caused by the collector currents, the emitter-coupled pair's total input referred squared noise voltage per Hertz is given by

$$\frac{V_{iN}^2}{\Delta f} = 8kT\left(r_b + \frac{1}{2g_m} + \frac{1}{g_m^2 R_L}\right) \tag{20.77}$$

Due to the presence of base currents, there is also a small input noise current, which however will be ignored here and in further discussions.

Small-Signal Frequency Response

When the emitter-base capacitance C_π, the collector-base capacitance C_μ, the collector-substrate capacitance C_{cs}, and the transistor's output resistance r_o are added to the transistor's hybrid-π small-signal model in Fig. 20.28, the differential gain transfer function becomes frequency dependent. Although the differential-mode small-signal equivalent circuit is identical to that of the non-degenerated common-emitter amplifier analyzed in Section 20.2, the high-frequency analysis is repeated here for the sake of completeness. With R_i representing the parallel combination of $(R_{SD}/2 + r_b)$ with r_π, and R_C similarly designating the parallel combination of R_L with r_o, Eq. (20.70) must be rewritten as

$$A_{DD} = -\frac{g_m R_i R_C}{\frac{1}{2}R_{SD} + r_b}\frac{N(s)}{D(s)} \tag{20.78}$$

where

$$\frac{N(s)}{D(s)} = \left(1 - \frac{sC_\mu}{g_m}\right)/(1 + s(C_\pi R_i + C_\mu R_i + C_\mu R_C + C_\mu R_i R_C g_m + C_{cs}R_C) + s^2(C_\pi C_{cs} R_i R_C + C_\pi C_\mu R_i R_C + C_\mu C_{cs} R_i R_C)) \tag{20.79}$$

As mentioned before, the right half-plane zero located at $s_z = g_m/C_\mu$ results from the capacitive feedthrough from input to output. This right half-plane zero is usually at such a high frequency that it can be ignored in most applications. Unlike in a single-ended amplifier, in a differential pair this zero can easily be canceled. One only has to add two capacitors $C_C = C_\mu$ between the bases of the transistors and the opposite collectors, as illustrated in Fig. 20.30(a). Rather than using physical capacitors, perfect tracking can be achieved by making use of the base–collector capacitances of transistors, whose emitters are either floating or shorted to the bases, as illustrated in Figs. 20.30(b) and (c). Note, however, that the compensating transistors contribute additional collector-substrate parasitics, which to some extent counteract the intended broadbanding effect.

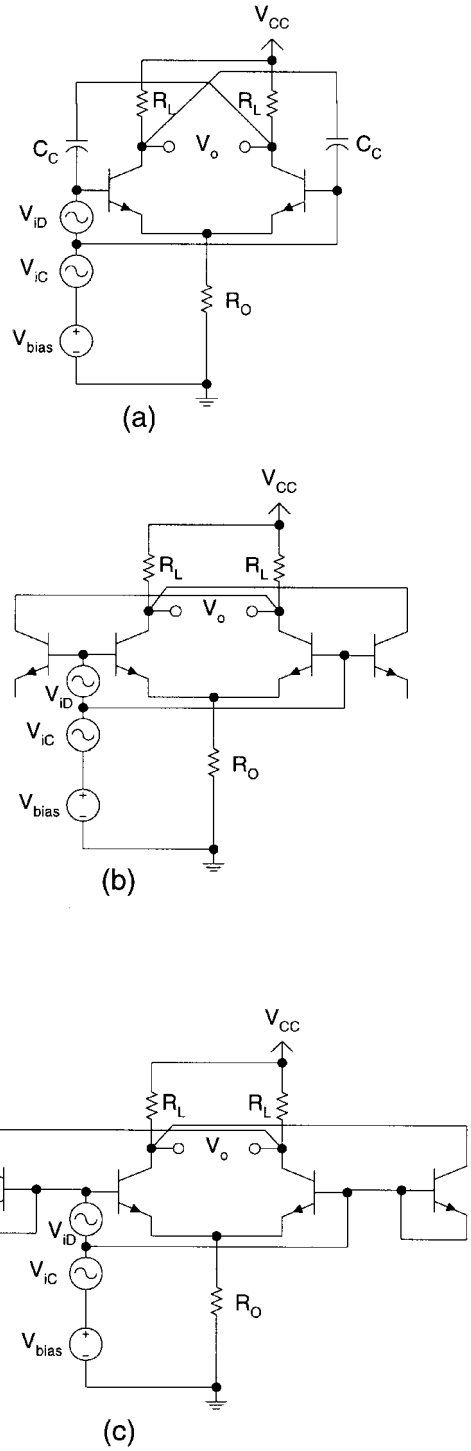

FIGURE 20.30 C_μ cancellation: (a) capacitor implementation, (b) transistor with floating emitter, and (c) transistor with shorted base–emitter junction.

If the dominant pole assumption is valid, $D(s)$ can be factored in the following manner

$$D(s) = \left(1 - \frac{s}{p_1}\right)\left(1 - \frac{s}{p_2}\right) \approx 1 - \frac{s}{p_1} + \frac{s^2}{p_1 p_2} \tag{20.80}$$

Equating Eqs. (20.79) and (20.80) yields

$$p_1 = -\frac{1}{R_i} \frac{1}{C_\pi + C_{cs}\frac{R_C}{R_i} + C_\mu\left(1 + g_m R_C + \frac{R_C}{R_i}\right)} \tag{20.81}$$

$$p_2 = -\frac{1}{R_C(C_\mu + C_{cs})} \frac{C_\pi + C_{cs}\frac{R_C}{R_i} + C_\mu\left(1 + g_m R_C + \frac{R_C}{R_i}\right)}{C_\pi + \frac{C_\mu C_{cs}}{C_\mu + C_{cs}}} \tag{20.82}$$

Rather than getting into a likewise detailed analysis, the discussion of the emitter-coupled pair's common-mode frequency response is limited here to the effect of the unavoidable capacitor C_O (representing, for instance, the collector–base and collector–substrate parasitic capacitances of the BJT), which shunts R_O. The parallel combination of R_O and C_O yields a zero in the common-mode transfer function. Correspondingly, a pole appears in the expression for the amplifier's CMRR. Specifically,

$$\text{CMRR} = 2g_m \frac{R_O}{1 + sC_O R_O} \tag{20.83}$$

The important conclusion from Eq. (20.83) is that at higher frequencies, the amplifier's CMRR rolls off by 20 dB per decade.

dc Offset

Input Offset Voltage

Until now, perfect matching between like components has been assumed. While ratio tolerances in integrated circuit technology can be very tightly controlled, minor random variations between "equal" components are unavoidable. These minor mismatches result in a differential output voltage, even if no differential input signal is applied. When the two bases in Fig. 20.24 are tied together, but the transistors and load resistors are slightly mismatched, the resulting differential output offset voltage can be expressed as

$$\begin{aligned} V_{oO} &= -(R_L + \Delta R_L)(I_C + \Delta I_C) + R_L I_C = \\ &-(R_L + \Delta R_L)(I_S + \Delta I_S)\exp\left(\frac{V_{BE}}{V_T}\right) + R_L I_S \exp\left(\frac{V_{BE}}{V_T}\right) \end{aligned} \tag{20.84}$$

or

$$V_{oO} \approx -\left(\frac{\Delta R_L}{R_L} + \frac{\Delta I_S}{I_S}\right) R_L I_S \exp\left(\frac{V_{BE}}{V_T}\right) = -\left(\frac{\Delta R_L}{R_L} + \frac{\Delta I_S}{I_S}\right) R_L I_C \tag{20.85}$$

Conversely, the output offset can be referred back to the input through a division by the amplifier's differential gain.

$$V_{iO} = \frac{V_{oO}}{-g_m R_L} = V_T\left(\frac{\Delta R_L}{R_L} + \frac{\Delta I_S}{I_S}\right) \tag{20.86}$$

The input referred offset voltage V_{iO} represents the voltage that must be applied between the input terminals in order to nullify the differential output voltage. In many instances, the absolute value of the offset voltage is not important because it can easily be measured and canceled, either by an auto-zero technique or by trimming. Rather, when offset compensation is applied, the offset stability under varying environmental conditions becomes the primary concern. The drift in offset voltage over temperature can be calculated by differentiating Eq. (20.86):

$$\frac{dV_{iO}}{dT} = \frac{V_{iO}}{T} \tag{20.87}$$

From Eq. (20.87), one concludes that the drift is proportional to the magnitude of the offset voltage and inversely related to the change in temperature.

Input Offset Current

Since in most applications the differential pair is driven by a low-impedance voltage source, its input offset voltage is an important parameter. Alternatively, the amplifier can be controlled by high-impedance current sources. Under this condition, the input offset current I_{iO}, which originates from a mismatch in the base currents, is the offset parameter of primary concern.

Parallel to the definition of V_{iO}, I_{iO} is the value of the current source that must be placed between the amplifier's open-circuited input terminals to reduce the differential output voltage to zero.

$$I_{iO} = \frac{I_C + \Delta I_C}{\beta + \Delta\beta} - \frac{I_C}{\beta} \approx \frac{I_C}{\beta}\left(\frac{\Delta I_C}{I_C} - \frac{\Delta\beta}{\beta}\right) \tag{20.88}$$

The requirement of zero voltage difference across the output terminals can be expressed as

$$(R_L + \Delta R_L)(I_C + \Delta I_C) = (R_L I_C) \tag{20.89}$$

Eq. (20.89) can be rearranged as

$$\frac{\Delta I_C}{I_C} \approx -\frac{\Delta R_L}{R_L} \tag{20.90}$$

Substituting Eq. (20.90) into Eq. (20.88) yields

$$I_{iO} = -\frac{I_{EE}}{2\beta}\left(\frac{\Delta R_L}{R_L} + \frac{\Delta\beta}{\beta}\right) \tag{20.91}$$

I_{iO}'s linear dependence on the bias current and its inverse relationship to the transistors' current gain β as expressed by Eq. (20.91) intuitively make sense.

Gain Enhancement Techniques

From Eq. (20.67), one concludes that there are two ways to increase the emitter-coupled pair's gain: namely, an increase in the bias current or the use of a larger valued load resistor. Similar to the earlier discussion of the common-emitter amplifier, practical limitations of the available supply voltage and the corresponding limit on the allowable I-R voltage drop across the load resistors (in order to avoid saturating either of the two transistors), however, limit the maximum gain that can be achieved by a single stage.

This section introduces two methods that generally allow the realization of higher gain while avoiding the dc bias limitations.

Negative Resistance Load

In the circuit of Fig. 20.31, a gain boosting positive feedback circuit is connected between the output terminals. The output dc bias voltage is simply determined by V_{CC}, together with the product of R_L and the current flowing through it, which is now equal to $(I_E + I_R)/2$. However, for ac signals, the added circuit — consisting of two transistors with cross-coupled base–collector connections and the resistors R_C between the emitters — represents a negative resistance of value $-2(R_C + 1/g_{mc})$, where $g_{mc} = \alpha I_R/2V_T$. The amplifier's differential gain can now be expressed as

$$A_{DD} \approx -g_m R_L \frac{1}{1 - \dfrac{g_{mc} R_L}{1 + g_{mc} R_C}} \tag{20.92}$$

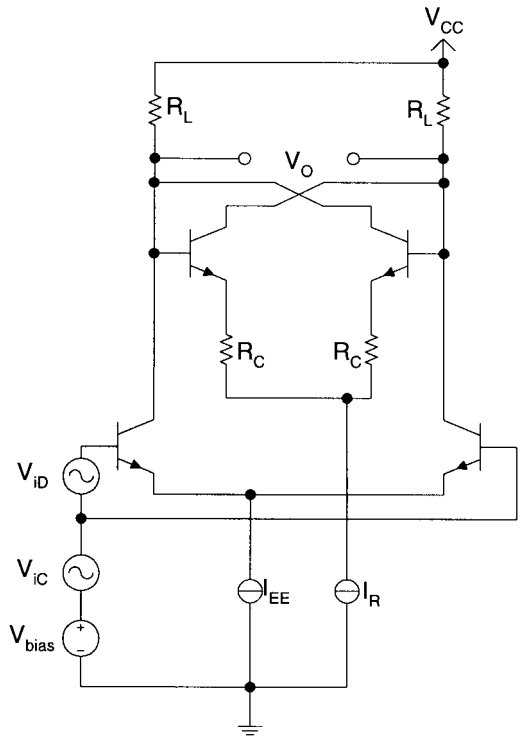

FIGURE 20.31 Emitter-coupled pair with negative resistor load.

Active Load

Another approach to increase the gain consists of replacing the load resistors by active elements, such as pnp transistors. Figure 20.32 shows a fully differential realization of an emitter-coupled pair with active loads. The differential gain is determined by the product of the transconductance of the input devices and the parallel combination of the output resistances of the npn and pnp transistors. Since $g_m = I_C/V_T$, $r_{on} = V_{An}/I_C$, and $r_{op} = V_{Ap}/I_C$, the gain becomes

$$A_{DD} = -g_m \frac{V_{An} V_{Ap}}{(V_{An} + V_{Ap}) I_C} = -\frac{1}{V_T} \frac{V_{An} V_{Ap}}{V_{An} + V_{Ap}} \tag{20.93}$$

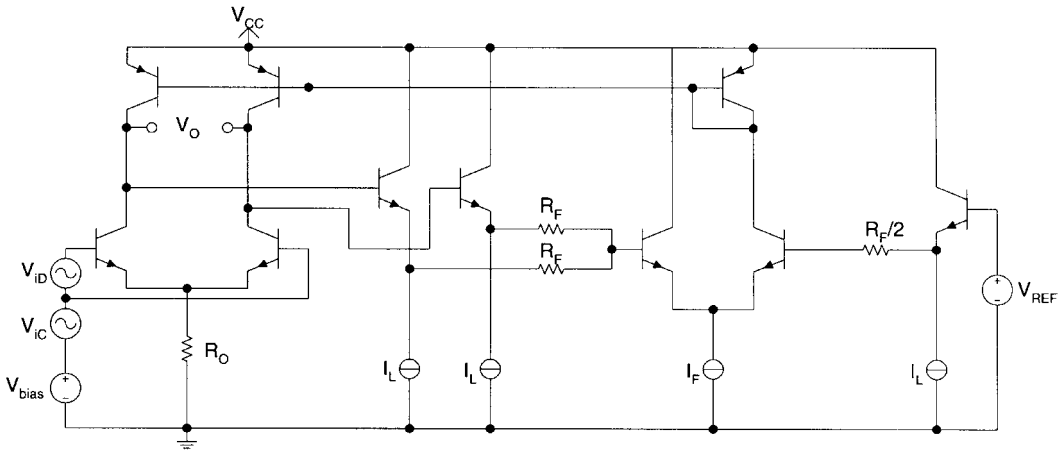

FIGURE 20.32 Emitter-coupled pair with active pnp load.

Consequently, the gain is relatively high and independent of the bias conditions. The disadvantage of the fully differential realization with active loads is that the output common-mode voltage is not well-defined. This problem also exists for the corresponding single-ended implementation (see Fig. 20.9(a)), as mentioned in Section 20.2. If one were to use a fixed biasing scheme for both types of transistors in Fig. 20.32, minor, but unavoidable mismatches between the currents in the npn and pnp transistors will result in a significant shift of the operating point. The solution lies in a common-mode feedback (CMFB) circuit that controls the bases of the active loads and forces a predetermined voltage at the output nodes. The CMFB circuit has high gain for common-mode signals, but does not respond to differential signals present at its inputs. A possible realization of such a CMFB circuit is seen in the right portion of Fig. 20.32. Via emitter followers and resistors R_P the output nodes are connected to one input of a differential pair, whose other input terminal is similarly tied to a reference voltage V_{REF}. The negative feedback provided to the pnp load transistors forces an equilibrium state where the dc voltages at the output terminals of the differential pair gain stage are equal to V_{REF}. An alternative active load implementation with a single-ended output is shown in Fig. 20.33. Contrary to the low CMRR of a single-ended realization

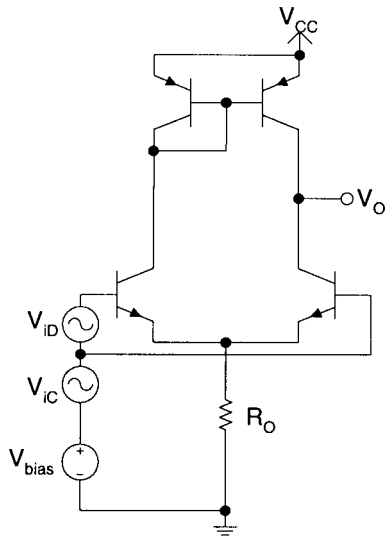

FIGURE 20.33 Emitter-coupled pair with active load and single-ended output.

with resistive loads, the circuit in Fig. 20.33 inherently possesses the same CMRR as a differential realization since the output voltage depends on a current differencing as a result of the pnp mirror configuration. The drawback of the single-ended circuit is a lower frequency response, particularly when low-bandwidth lateral pnp transistors are used.

Linearization Techniques

As derived previously, the linear range of operation of the emitter-coupled pair is limited to approximately $V_{iD} \approx 2V_T$. This section describes two techniques that can be used to extend the linear range of operation.

Emitter Degeneration

The most common technique to increase the linear range of the emitter-coupled pair relies on the inclusion of emitter degeneration resistors, as shown in Fig. 20.34. The analysis of the differential gain transfer function proceeds as before; however, no closed-form expression can be derived. Intuitively, the inclusion of R_E introduces negative feedback, which lowers the gain and extends the amplifier's linear operating region to a voltage range approximately equal to the product of $R_E I_E$. The small-signal differential gain can be expressed as

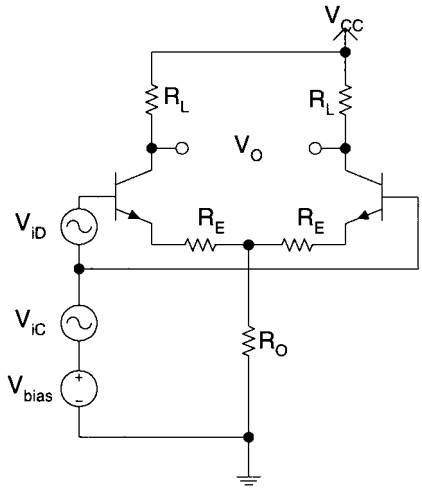

FIGURE 20.34 Differential pair with degeneration resistors.

$$A_{DD} \approx -G_M R_L \tag{20.94}$$

where G_M is the effective transconductance of the degenerated input stage. Therefore,

$$G_M = \frac{g_m}{1 + g_m R_E} \approx \frac{1}{R_E} \tag{20.95}$$

Consequently,

$$A_{DD} \approx -\frac{g_m R_L}{1 + g_m R_E} \tag{20.96}$$

In case $g_m R_E >> 1$,

$$A_{DD} \approx -\frac{R_L}{R_E} \tag{20.97}$$

In comparison to the undegenerated differential pair, the gain is reduced by an amount $(1 + g_m R_E) \approx g_m R_E$, which is proportional to the increase in linear input range. The common-mode gain transfer function for the circuit in Fig. 20.34 is

$$A_{CC} \approx -\frac{R_L}{2R_O + R_E} \tag{20.98}$$

For practical values of R_E, A_{CC} remains relatively unchanged compared to the undegenerated prototype. As a result, the amplifier's CMRR is reduced approximately by the amount $g_m R_E$. Also, the input referred squared noise voltage per Hertz can be derived as

$$\frac{V_{iN}^2}{\Delta f} = 8kT\left[r_b + \frac{1}{2g_m}(g_m^2 R_E^2) + \frac{1}{g_m^2 R_L}(g_m^2 R_E^2) + R_E\right] \tag{20.99}$$

This means that, to a first order, the noise also increases by the factor $g_m R_E$. Consequently, although the amplifier's linear input range is increased, its signal-to-noise ratio (SNR) remains unchanged. To complete the discussion of the emitter degenerated differential pair, the positive effect emitter degeneration has on the differential input resistance R_{inD}, and, to a lesser extent, on R_{inC} should be mentioned. For the circuit in Fig. 20.34,

$$R_{inD} = 2[r_\pi + (\beta + 1)R_E] \tag{20.100}$$

$$R_{inC} = \frac{1}{2}r_\pi + \frac{(\beta + 1)R_E}{2} + R_O(\beta + 1) \tag{20.101}$$

Parallel Combination of Asymmetrical Differential Pairs

A second linearization technique consists of adding the output currents of two parallel asymmetrical differential pairs with respective transistor ratios 1:r and r:1 as shown in Fig. 20.35. The reader will

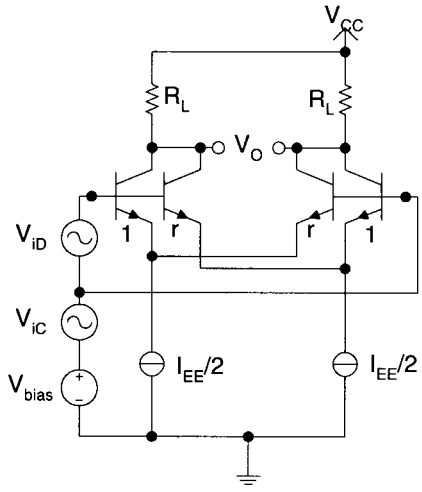

FIGURE 20.35 Parallel asymmetrical pairs.

observe that each differential pair in Fig. 20.35 is biased by a current source of magnitude $I_{EE}/2$ so that the power dissipation as well as the output common-mode voltage remain the same as for the prototype circuit in Fig. 20.24. Assuming, as before, an ideal exponential input voltage–output current relationship for the bipolar transistors, the following voltage transfer function can be derived:

$$V_{oD} = -\frac{\alpha}{2} I_{EE} R_L \left[\tanh\left(\frac{V_{iD}}{2V_T} - \frac{\ln r}{2} \right) + \tanh\left(\frac{V_{iD}}{2V_T} + \frac{\ln r}{2} \right) \right] \tag{20.102}$$

After Taylor series expansion and some manipulation, Eq. (20.102) can be rewritten as

$$V_{oD} = -\alpha I_{EE} R_L (1 - d) \left[\frac{V_{iD}}{2V_T} + \left(d - \frac{1}{3} \right) \left(\frac{V_{iD}}{2V_T} \right)^3 + \ldots \right] \tag{20.103}$$

where

$$d = \left(\frac{r-1}{r+1} \right)^2 \tag{20.104}$$

Equation (20.103) indicates that the dominant third-harmonic distortion component can be canceled by setting $d = 1/3$ or $r = 2 + \sqrt{3} = 3.732$. The presence of parasitic resistances within the transistors tends to require a somewhat higher ratio r for optimum linearization. In practice, the more easily realizable ratio $r = 4$ (or $d = 9/25$) is frequently used. When the linear input ranges at a 1% total harmonic distortion (THD) level of the single symmetrical emitter-coupled pair in Fig. 20.24 and the dual circuit with $r = 4$ in Fig. 20.35 are compared, a nearly threefold increase is noted. For $r = 4$ and neglecting higher-order terms, Eq. (20.103) becomes

$$A_{DD} \approx -0.64 g_m R_L \tag{20.105}$$

where $g_m = \alpha I_{EE}/2V_T$ as before. Equation (20.105) means that the tradeoff for the linearization is a reduction in the differential gain to 64% of the value obtained by a single symmetrical emitter-coupled pair with equal power dissipation. The squared input referred noise voltage per Hertz for the two parallel asymmetrical pairs can be expressed as

$$\frac{V_{iN}^2}{\Delta f} = \frac{8kT}{(0.64)^2} \left(\frac{r_b}{5} + \frac{1}{2g_m} + \frac{1}{g_m^2 R_L} \right) \tag{20.106}$$

The factor $r_b/5$ appears because of an effective reduction in the base resistance by a factor $(r + 1)$ due to the presence of five transistors vs. one in the derivation of Eq. (20.77). If the unit transistor size in Fig. 20.35 is scaled down accordingly, a subsequent comparison of Eqs. (20.77) and (20.106) reveals that the input referred noise for the linearized circuit of Fig. 20.35 is 1/0.64, or 1.56 times higher than for the circuit in Fig. 20.24. Combined with the nearly threefold increase in linear input range, this means that the SNR nearly doubles. The approximately 6-dB increase in SNR is a distinct advantage over the emitter degeneration linearization technique. Moreover, the linearization approach introduced in this section can be extended to a summation of the output currents of three, four, or more parallel asymmetrical pairs. However, there is a diminished return in the improvement. Also, for more than two pairs, the required device ratios become quite large and the sensitivity of the linear input range to small mismatches in the actual ratios versus their theoretical values increases as well.

Rail-to-Rail Common-Mode Inputs and Minimum Supply Voltage Requirement

With the consistent trend toward lower power supplies, the usable input common-mode range as a percentage of the supply voltage is an important characteristic of differential amplifiers. Full rail-to-rail input compliance is a highly desirable property. Particularly for low-power applications, the ability to operate from a minimal supply voltage is equally important. For the basic emitter-coupled pair in Fig. 20.24, the input is limited on the positive side when the npn transistors saturate. Therefore,

$$V_{\text{iC, pos}} = VCC - \frac{1}{2} R_{\text{L}} I_{\text{EE}} + V_{\text{bc, forward}} \tag{20.107}$$

If one limits $R_{\text{L}} I_{\text{EE}}/2 < V_{\text{bc,forward}}$, $V_{\text{iC,pos}}$ can be as high as V_{CC} or even slightly higher. On the negative side, the common-mode input voltage is limited to that level, where the tail current source starts saturating. Assuming a single bipolar transistor is used as the current source,

$$V_{\text{iC, neg}} > V_{\text{BE}} + V_{\text{CE, sat}} \approx 1 \text{ V} \tag{20.108}$$

The opposite relationships hold for the equivalent pnp transistor-based circuit. As a result, the rail-to-rail common-mode input requirement can be resolved by putting two complementary stages in parallel. In general, as the input common-mode traverses between V_{CC} and ground, three distinct operating conditions can occur: (1) at high voltage levels, only the npn stage is active; (2) at intermediate voltage levels, both the npn and pnp differential pairs are enabled; and finally, (3) for very low input voltages, only the pnp stage is operating. If care is not taken, three distinct gain ranges can occur: based on g_{mn} only; resulting from $g_{\text{mn}} + g_{\text{mp}}$; and, contributed by g_{mp} only. Non-constant g_{m} and gain that depends on the input common-mode is usually not desirable for several reasons, not the least of which is phase compensation if the differential pair is used as the first stage in an operational amplifier. Fortunately, the solution to this problem is straightforward if one recognizes that the transconductance of the bipolar transistor is proportional to its bias current. Therefore, the only requirement for a bipolar constant-g_{m} complementary circuit with full rail-to-rail input compliance is that under all operating conditions the sum of the bias currents of the npn and pnp subcircuits remains constant. A possible implementation is shown in Fig. 20.36. If $V_{\text{iC}} < V_{\text{REF}}$, the pnp input stage is enabled and the npn input transistors are off. When $V_{\text{iC}} > V_{\text{REF}}$, the bias current is switched to the npn pair and the pnp input devices turn off. For $R_{\text{L}} I_{\text{EE}}/2 < V_{\text{cb,forward,n}}$, the minimum required power supply voltage is $V_{\text{BE,n}} + V_{\text{BE,p}} + V_{\text{CE,sat,n}} + V_{\text{CE,sat,p}}$, which is lower than 2 V.

20.4 Output Stages

Output stages are specially designed to deliver large signals (as close to rail-to-rail as possible) and a significant amount of power to a specified load. The load to be driven is often very low-ohmic in nature; for example, 4 to 8 ohms in the case of audio loudspeakers. Therefore, output stages must possess a low output impedance and be able to supply high amounts of current — without distorting the signal. The output stage also needs to have a relatively wide bandwidth, so that it does not contribute major frequency limitations to the overall amplifier. Equally desirable is a high efficiency in the power transfer. Preferably, the output stage consumes no (or very little) power in the quiescent state, when no input signal is present. In this section, two major classes of amplifiers, distinguished by their quiescent power needs, are discussed. *Class A amplifiers* consume the same amount of power regardless of the presence of an ac signal. *Class B amplifiers*, on the other hand, only consume power while activated by an input signal and dissipate absolutely no power in stand-by mode. A hybrid between these two distinct cases is *Class AB* operation, which consumes only a small amount of quiescent power. Because output stages deliver high power levels, care must be taken to guarantee

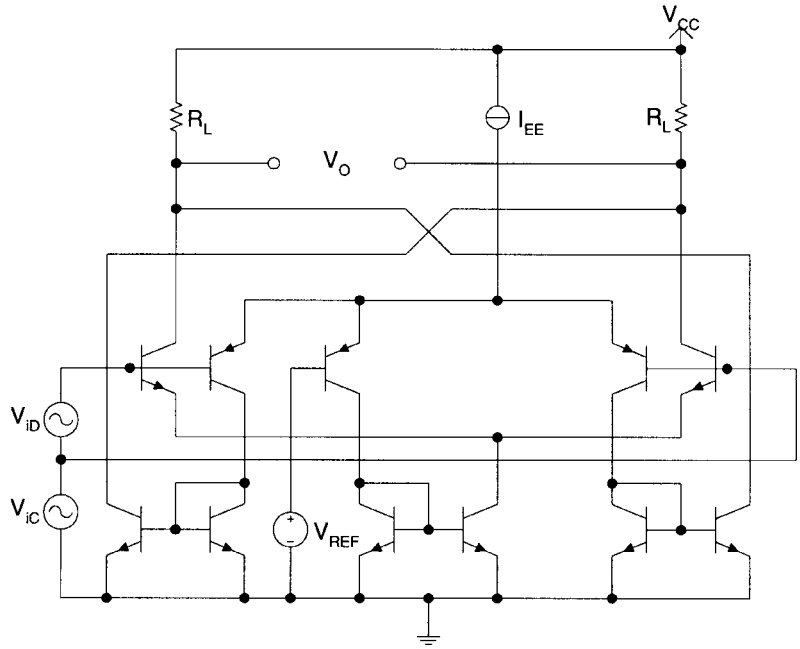

FIGURE 20.36 Low-voltage rail-to-rail input circuit.

that the transistors do not exceed their maximum power ratings, even under unintended operating conditions, such as when the output is shorted to ground. To avoid permanent damage or total destruction, output stages often include some sort of overload protection circuitry.

Class A Operation

The emitter follower, analyzed in Section 20.2, immediately comes to mind as a potential output stage configuration. The circuit is revisited here with an emphasis on its signal-handling capability and power efficiency. Figure 20.37(a) shows an emitter follower transistor Q_1 biased by a current source Q_2 and loaded by a resistor R_L. For generality, separate positive (V_{CC}) and negative ($-V_{EE}$) supplies, as well as ground are used in Fig. 20.37(a) and the analysis below.

The following identities can readily be derived

$$V_i = V_{BE,1} + V_o \tag{20.109}$$

$$V_i = V_T \ln \frac{I_1}{I_S} + V_o = V_T \ln \frac{I_Q + \dfrac{V_o}{R_L}}{I_S} + V_o \tag{20.110}$$

where I_Q is the quiescent current supplied by the current source Q_2.

If one assumes that R_L is quite large, the output current $I_o = V_o/R_L$ is relatively small and $V_{BE,1}$ is approximately constant. Then,

$$V_o \approx V_i - V_T \ln \frac{I_Q}{I_S} \tag{20.111}$$

or there is approximately a fixed voltage drop between input and output.

(b)

FIGURE 20.37 (a) Emitter-follower output stage (Class A), and (b) voltage transfer diagram.

The positive output excursion is limited by the eventual saturation of Q_1. This means that V_o cannot exceed ($V_{CC} - V_{CEsat,1}$). $V_{Cesat,1}$ is less than $V_{BE,1}$. However, since V_i is most often provided by a previous gain stage, its voltage level can generally not be raised above the supply. In practice, this means that the maximum output voltage is limited to

$$V_{o,\,max} = V_{CC} - V_{BE,\,1} \approx V_{CC} - V_T \ln \frac{I_Q}{I_S} \tag{20.112}$$

Similarly, the negative excursion is limited by the saturation of Q_2. Therefore,

$$V_{o,\,min} = -V_{EE} + V_{CEsat,\,2} \tag{20.113}$$

If the assumption about the load resistor is not valid and R_L is small, the slope of the transfer characteristic is not exactly 1 and some curvature occurs for larger signal excursions. Also, negative output clipping can occur sooner. Indeed, the maximum current flow through R_L during the negative excursion is bounded by the bias I_Q. Consequently,

$$V_{o,\,min} = -I_Q R_L \tag{20.114}$$

Figure 20.37(b) graphically represents the emitter follower's transfer characteristic for both R_L assumptions.

If V_{CC} and V_{EE} are much larger than V_{BE} and V_{CEsat}, the maximum symmetrical swing one can obtain is

$$V_{o,\,peak} \approx \frac{V_{CC} + V_{EE}}{2} \tag{20.115}$$

provided V_i has the proper dc bias and the quiescent current is equal to or greater than the optimum value

$$I_{Q,\,opt} = I_{o,\,peak} = \frac{V_{o,\,peak}}{R_L} \tag{20.116}$$

Under the conditions of Eqs. (20.115) and (20.116), the emitter follower's power dissipation is

$$P_{supply} = (V_{CC} + V_{EE}) I_{Q,\,opt} \approx 2\, V_{o,\,peak} I_{o,\,peak} \tag{20.117}$$

For sinusoidal input conditions, the average power delivered to the load is expressed as

$$P_{load} = \frac{1}{2} V_{o,\,peak} I_{o,\,peak} \tag{20.118}$$

Therefore, the highest achievable power efficiency is limited to

$$\eta = \frac{P_{load}}{P_{supply}} \approx 25\% \tag{20.119}$$

In conclusion, while the emitter follower can be used as an output stage, it suffers from two major limitations. First, the output swing is asymmetrical and not rail-to-rail. Second, the operation is Class A and thus consumes dc power. The emitter follower's maximum power efficiency, which is only reached at full signal swing, is very poor.

Class B and Class AB Operation

Figure 20.38(a) shows a symmetrical configuration with the emitters of an npn and a pnp transistor tied together at the output node, while the input is provided to their joint bases. This dual emitter follower combination is frequently referred to as a *push-pull* arrangement. When no input is applied, clearly no current flow is possible and, thus, the operation is Class B. The push-pull configuration, however, does not solve all the problems of the single-ended emitter follower. Indeed, the output swing is still not rail-to-rail, but is limited to one V_{BE} drop from either supply rail (assuming V_i cannot exceed V_{CC} or V_{EE}). The circuit's transfer characteristic is shown in Fig. 20.38(b). Note that both transistors are off, not just for zero input as desired, but they also do not turn on when small inputs are applied. In effect, for $V_{BE,p} < V_i < V_{BE,n}$, the output has a dead zone. Such *hard non-linearity* leads to undesirable *cross-over distortion*. A method to overcome this problem will be discussed shortly. For larger inputs, only one of the transistors conducts.

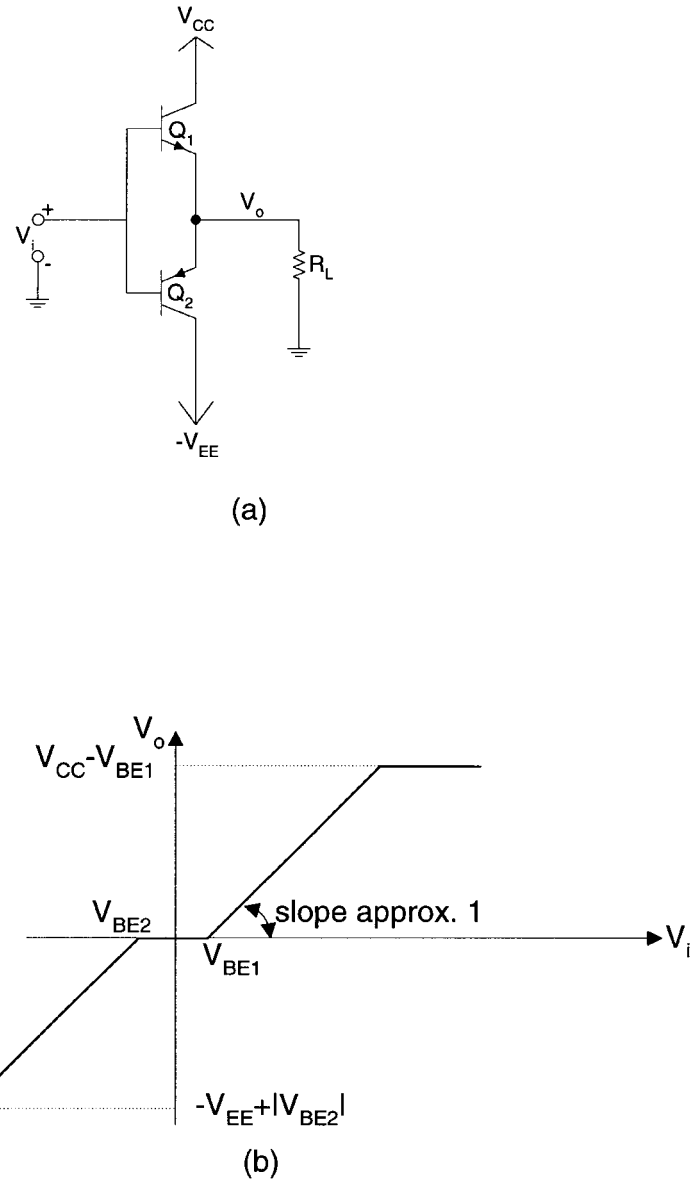

FIGURE 20.38 (a) Emitter-follower push-pull output stage (Class B), and (b) voltage transfer diagram.

The push-pull configuration's power efficiency under sinusoidal input conditions can be derived as follows. The dissipated power is equal to

$$P_{\text{supply}} = (V_{\text{CC}} + V_{\text{EE}})I_{\text{supply}} = (V_{\text{CC}} + V_{\text{EE}})\frac{V_{\text{o, peak}}}{\pi R_{\text{L}}} \tag{20.120}$$

while the power delivered to the load is expressed as

$$P_{\text{load}} = \frac{V_{\text{o, peak}}^2}{2R_{\text{L}}} \tag{20.121}$$

Thus,

$$\eta = \frac{P_{\text{load}}}{P_{\text{supply}}} = \frac{\pi}{2}\frac{V_{\text{o, peak}}}{V_{\text{CC}} + V_{\text{EE}}} \tag{20.122}$$

Equation (20.122) says that the efficiency is directly proportional to the peak output amplitude. In case the base–emitter voltage can be neglected relative to the supply voltages,

$$V_{\text{o, peak, max}} = \frac{V_{\text{CC}} + V_{\text{EE}} - V_{\text{BE, n}} - V_{\text{BE, p}}}{2} \approx \frac{V_{\text{CC}} + V_{\text{EE}}}{2} \tag{20.123}$$

The power efficiency's upper bound is therefore given by

$$\eta_{\text{max}} \approx \frac{\pi}{4} \approx 78.6\% \tag{20.124}$$

The dead zone and resulting cross-over distortion can be eliminated by inserting two conducting diodes between the bases of the npn and pnp output devices, as shown in Fig. 20.39(a). Strictly speaking, the push-pull circuit is then no longer Class A, but rather becomes Class AB as a small stand-by current constantly flows through both output devices. The resulting linear transfer characteristic is shown in Fig. 20.39(b). One should, however, note that the actual quiescent current is not well-defined, as it depends on matching between the base–emitter voltage drops of the diodes and the output transistors. For discrete implementations, this configuration would clearly be too sensitive. Even in integrated circuits, it is often desirable to stabilize the operating point through the inclusion of degeneration resistors, as illustrated in Fig. 20.40(a). In addition, these series resistors act as passive current limiters. Indeed, a potential problem occurs in the circuit of Fig. 20.39(a) when the output node is shorted to ground ($R_L = 0$). If the input voltage is large and positive, Q_2 and the diode string are off, forcing all the current I_B to flow into the base of Q_1, where it gets multiplied by the (high) current gain β_1. The resulting collector current may be so large as to cause Q_1 to self-destruct. Obviously, the voltage drop, which builds across either degeneration resistor, limits the maximum current and, as such, can prevent damage. Unfortunately, the inclusion of series resistors is a far from perfect solution as the values needed for quiescent current stabilization and overdrive protection are often unacceptably large. Thus, the degeneration resistors reduce the power efficiency, limit the output swing, and raise the circuit's output resistance. Fortunately, this issue can be circumvented if a diode is added in parallel with the degeneration resistor, as shown in Fig. 20.40(a). For low current values, the diode is off and the circuit is characterized by the high resistance of R_1 (R_2). At higher current levels, the diode turns on and provides a low dynamic resistance. For small input signals, the degeneration resistor is in series with the load and voltage division occurs. At higher input levels when the diode is on, the output again follows the input. The transfer characteristic, illustrated in Fig. 20.40(b), shows that rather than being completely eliminated as in the circuit of Fig. 20.39, the dead zone is replaced by a "slow zone." In other words, the hard non-linearity of the simple push-pull circuit in Fig. 20.38 is transformed into a more acceptable *soft non-linearity*. The transfer characteristics can be further linearized by applying negative feedback around the complete amplifier. The reader should observe, however, that the diode voltage drop further limits the maximum signal swing. While the diodes may reduce the passive current limiting provided by the resistors, superior active limiting is achieved when they are replaced by transistors, as depicted in Fig. 20.40(c). When the voltage drop across R_1 becomes high enough to forward-bias the base–emitter junction of Q_{D1}, the transistor starts to pull current away from the base of Q_1, delivering it harmlessly to the load, without additional multiplication. One should note that the limiting effect for large negative currents is not nearly as effective in this scheme, since this is largely determined by the current sinking capability of the driving transistor (not shown in Fig. 20.40), which pulls current out of the base of Q_2. On the other hand, pnp transistors are usually lateral or substrate devices with relatively low current gain, which furthermore rolls off very quickly at higher current

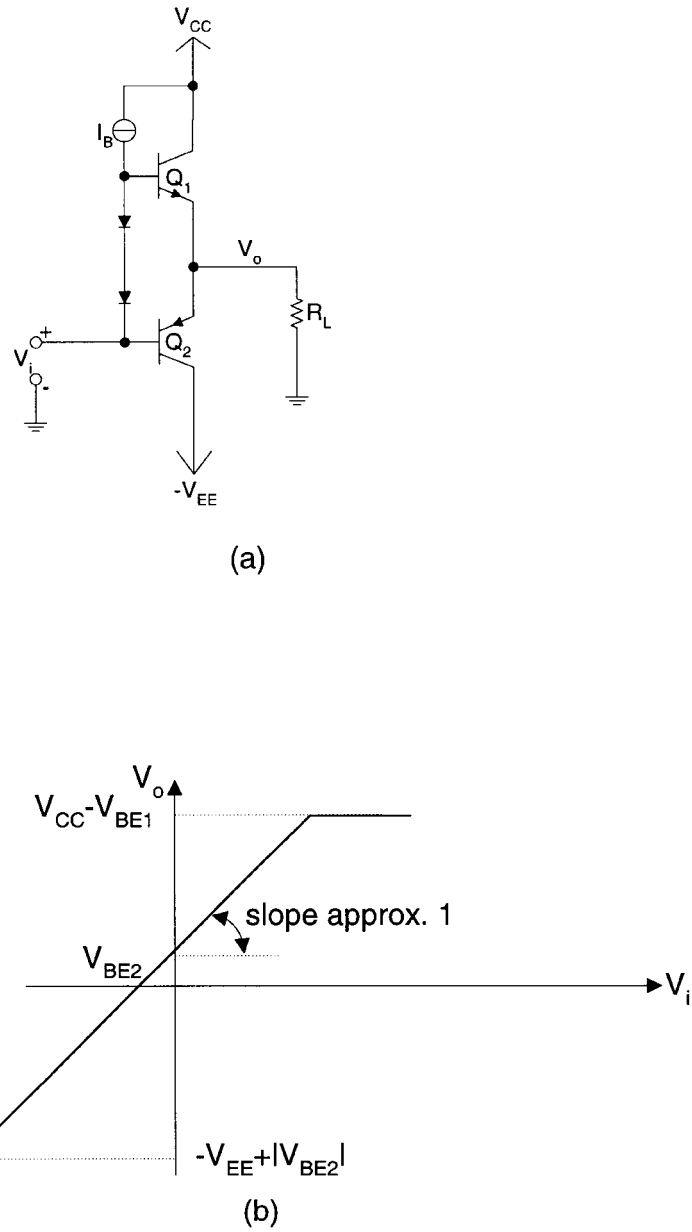

FIGURE 20.39 (a) Emitter-follower push-pull output stage (Class AB), and (b) voltage transfer diagram.

levels. Consequently, the potential problem of negative current overload is inherently less severe. Whereas these lateral or substrate pnp's are generally adequate for low to moderate power applications, if high power must be delivered, a complementary bipolar process with isolated vertical pnp's is required. When such a more complicated and expensive process is not available, alternatively quasi-complementary structures can be used. In Fig. 20.41, for example, the pnp transistor is replaced by a pseudo-Darlington pair (see Section 20.2).

In summary, the Class AB push-pull configuration meets the requirements of an output stage with relatively high efficiency in its power transfer and low stand-by dissipation. For very low voltage

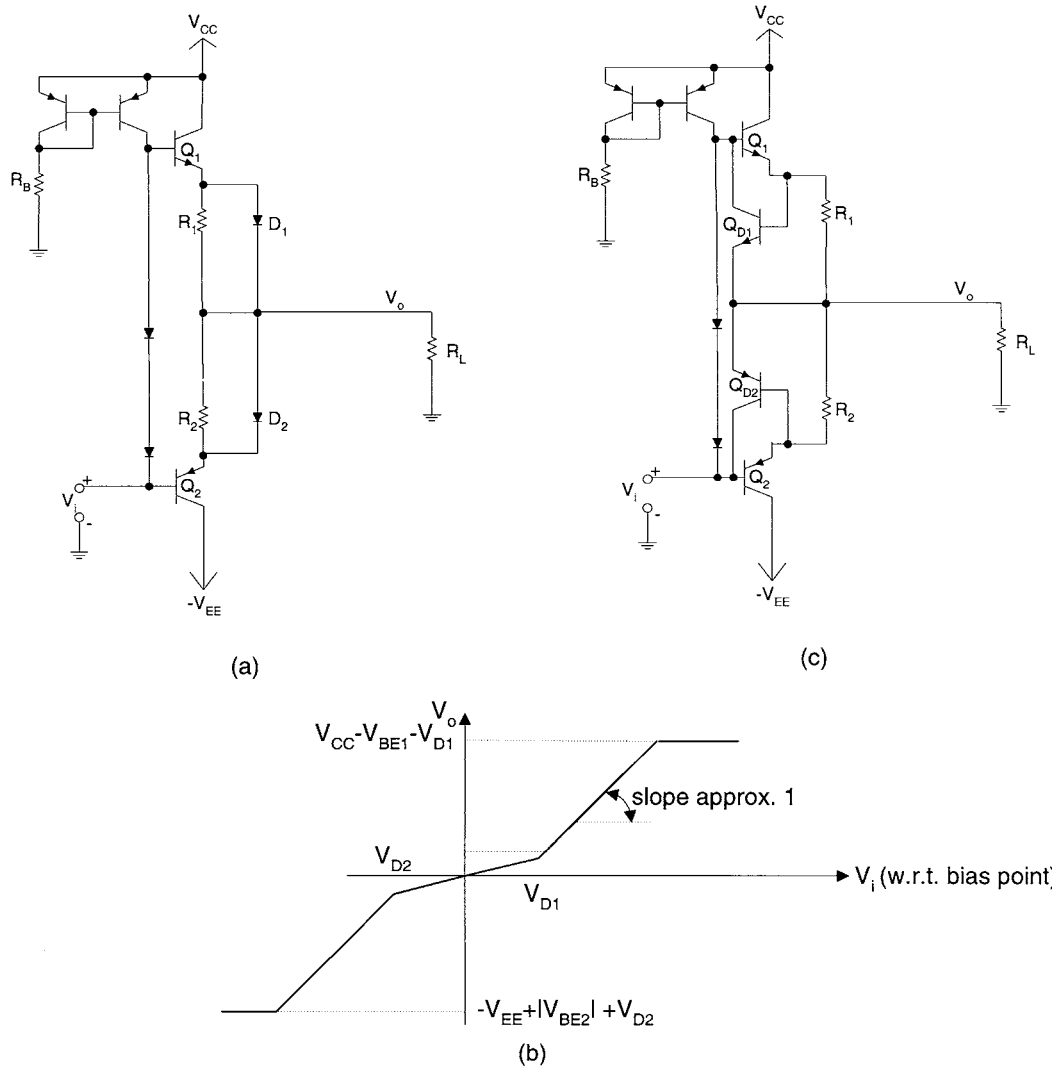

FIGURE 20.40 (a) Emitter-follower push-pull output stage (Class AB) with resistors and diodes; (b) voltage transfer diagram; and (c) emitter-follower push-pull output stage (Class AB) with resistors and transistors.

applications, however, the voltage drop across the base–emitter junction (and the series diodes) constitutes a serious limitation. A true rail-to-rail output swing (apart from an unavoidable, but low V_{CEsat}) can only be achieved by a complementary common-emitter output stage, as drawn in Fig. 20.42. Following the discussion in Section 20.2, the reader will likely interject that this arrangement suffers from a high output impedance and potential frequency limitations. An in-depth treatment of low-voltage common-emitter output configurations is beyond the scope of this chapter. The interested reader is referred to Ref. 5.

20.5 Bias Reference

It is definitely not the author's intention to present an in-depth discussion of voltage and current reference design. However, on several occasions, the terms "bandgap voltage" and "PTAT voltage" were mentioned.

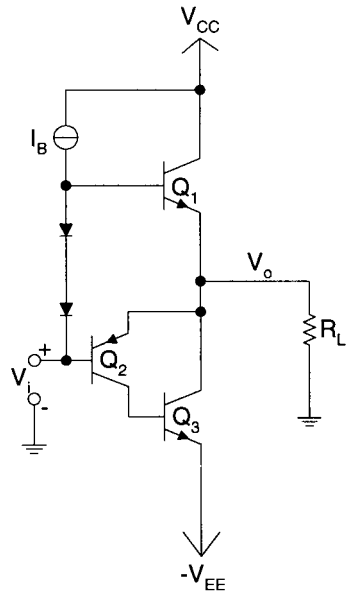

FIGURE 20.41 Quasi-complementary push-pull output stage.

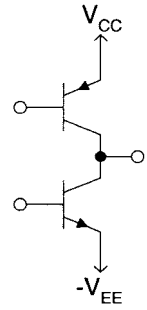

FIGURE 20.42 Rail-to-rail complementary common-emitter output stage.

It was also noted that a current, which is proportional to absolute temperature and inversely related to a resistor, is quite often desired in order to stabilize an amplifier's gain. A circuit that provides such supply-independent voltages and currents is shown in Fig. 20.43. By inspection,

$$V_{BG} = V_{BE1} + R_2 I = V_{BE1} + V_{PTAT} \tag{20.125}$$

The current mirror consisting of Q_3 and Q_4 forces the current I to split evenly between Q_1 and Q_2. As a result, the following identity is valid:

$$V_{BE1} = V_{BE2} + R_1 \frac{I}{2} \tag{20.126}$$

Substituting the Ebers-Moll identity into Eq. (20.126), where I_{S2} is N times I_{S1}, yields

$$I = \frac{2}{R_1}\left(V_T \ln\frac{I}{2I_{S1}} - V_T \ln\frac{I}{2I_{S2}}\right) = \frac{2}{R_1} V_T \ln N \tag{20.127}$$

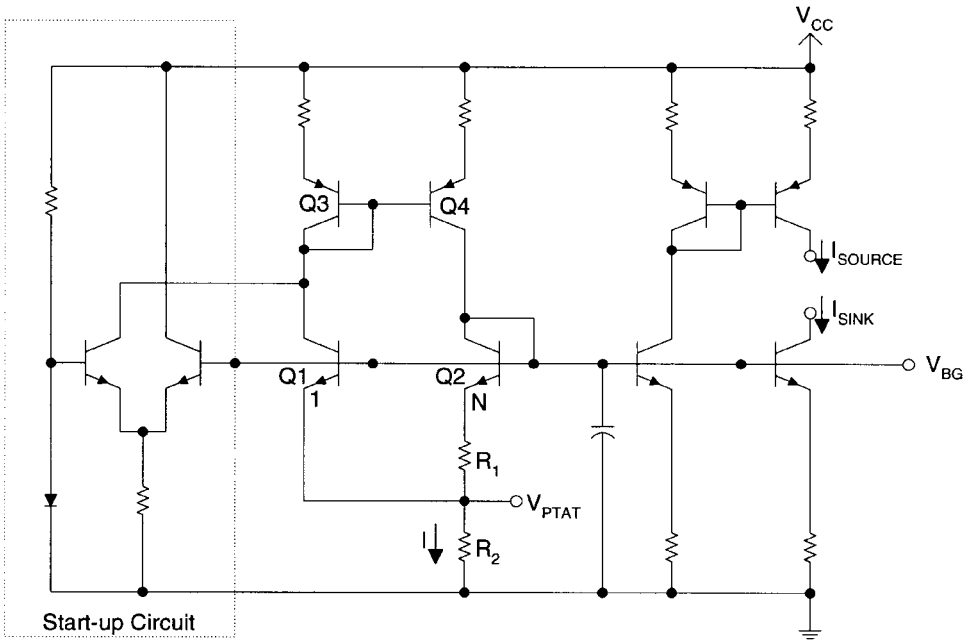

FIGURE 20.43 Bias reference.

By combining Eqs. (20.125) and (20.127), one gets

$$V_{BG} = V_{BE1} + 2\frac{R_2}{R_1}V_T \ln N \tag{20.128}$$

Also,

$$V_{PTAT} = 2\frac{R_2}{R_1}V_T \ln N = 2\frac{R_2}{R_1}\frac{kT}{q}\ln N \tag{20.129}$$

From Eq. (20.129), one concludes that V_{PTAT} is indeed proportional to absolute temperature. Apart from the absolute temperature T, V_{PTAT} only depends on physical constants (k and q), an area multiple N, and the ratio of two resistors. In addition to V_{PTAT}, the expression for V_{BG} (Eq. (20.128)) contains the term V_{BE1}, which decreases by 2 mV per degree increase in temperature. Through an appropriate selection of the resistors R_1 and R_2, the voltage V_{BG} can be made temperature independent. This occurs for $V_{BG} \approx$ 1.25 V, known as the BJT bandgap voltage. The currents I_{SOURCE} and I_{SINK} in Fig. 20.43 are simply mirrored copies of I, and thus exhibit the desired PTAT and resistor dependence.

Further observation of the circuit in Fig. 20.43 reveals that it possesses a second (although unstable) operating point. Indeed, the circuit is also in equilibrium when $V_{BG} = V_{PTAT} = 0$ V and there is no current flow. To prevent the bias reference from being stuck in this undesired state, an initial start-up circuit is added as shown. When power is first applied, the start-up circuit injects a small current into the mirror Q_3-Q_4, forcing the circuit to wake up and drift away from the zero state. As V_{BG} increases toward 1.25 V, the differential pair eventually switches and the start-up current is simply thrown away. The reader should realize that the circuit in Fig. 20.43 is conceptual in nature and specifically drawn to show that a supply voltage $V_{CC} < 2$ V suffices. However, it suffers from non-idealities due to base currents and poor supply rejection resulting from the simple current mirrors with relatively low output impedances. At the expense of added circuit complexity and the need for a higher supply voltage, significant improvements can be made. Such specialized bias reference discussion, however, goes beyond the scope of this chapter.

20.6 Operational Amplifiers

Introduction

Operational amplifiers (or op-amps) are key analog circuit building blocks that find widespread use in a variety of applications, such as precision amplification circuits (e.g., instrumentation amplifiers), continuous-time and switched-capacitor filters, etc. The traditional symbolic representation of the operational amplifier is shown in Fig. 20.44. The op-amp is a five-terminal device, with inverting and non-inverting input terminals (hence, accommodating a differential input signal), a single-ended output terminal, as well as positive and negative supply terminals. Most commercially available op-amps require a dual supply system of equal, but opposite value (e.g. ±15 V or ±5 V); however, asymmetrical or single-supply circuits are also available (e.g., +5 V and ground). Special-purpose operational amplifiers with differential or fully balanced outputs also exist. The internal circuitry of op-amps combines the different building blocks, which were previously discussed. Op-amps typically consist of two or three stages. The input stage, based on a differential pair, provides the initial amplification. A second or intermediate stage may be included to boost the amplifier's gain. Differential to single-ended conversion is also accomplished in the first stage, or, if applicable, in the second stage. The output stage, typically an emitter follower push-pull configuration, provides a low impedance, large swing, and high current drive. An elementary op-amp schematic can be found in Fig. 20.47(a).

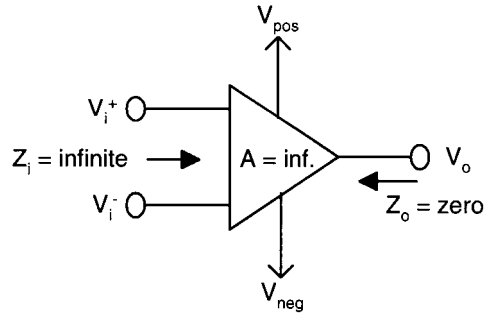

FIGURE 20.44 Op-amp symbol.

Ideal Op-Amps

The op-amp's input–output relationship can be expressed as

$$V_o = A(V_i^+ - V_i^-) \tag{20.130}$$

In the case of an ideal op-amp, A is assumed to have infinite magnitude as well as bandwidth. As such, there is no phase shift over frequency, as illustrated in Fig. 20.45(a). Since the output V_o must remain bounded, the assumption of infinite gain leads to the fundamental principle of *virtual ground* (virtual short). In other words, if the op-amp is ideal, there cannot exist a voltage difference between the input terminals, and V_i^+ must equal V_i^-. The assumption of ideality also calls for an infinite input impedance (i.e., the op-amp does not load the driving source) and a zero output impedance (i.e., the op-amp can accommodate arbitrarily small loads).

Op-Amp Non-idealities

Real operational amplifiers generally approximate the ideal op-amp model reasonably well; however, they naturally have finite gain, finite bandwidth, and finite input as well as output impedances. Specific non-idealities are itemized below.

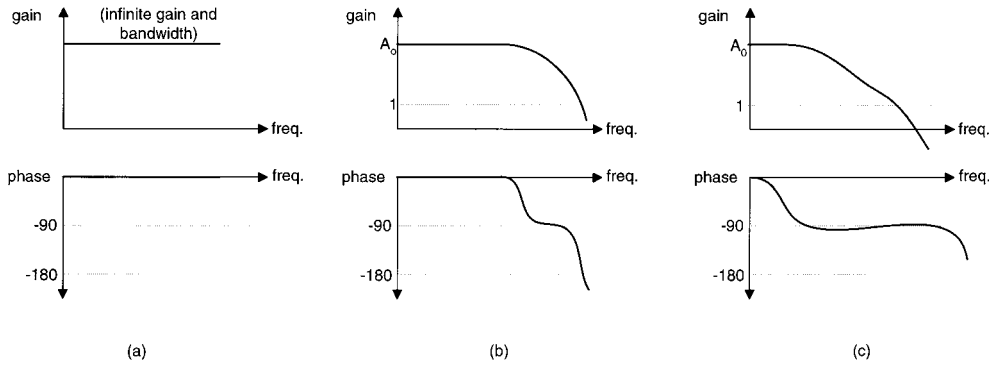

FIGURE 20.45 Magnitude and phase responses: (a) ideal op-amp; (b) real op-amp (potentially unstable in unity-gain feedback loop); (c) real op-amp with internal compensation (guaranteed stable, phase margin approx. 90 degrees).

Finite Gain

The op-amp's (low-frequency) gain can be made quite high, particularly when multiple gain stages are cascaded. The absolute gain value, however, is not very well-defined as it depends on widely varying process parameters, such as the transistor's current gain β. If a precise gain is required, the op-amp must be configured into a feedback network; for example, the non-inverting and inverting gain stages shown in Figs. 20.46(a) and (b), respectively. Assuming finite op-amp gain but infinite input impedance, the gain of the non-inverting amplifier in Fig. 20.46(a) can be expressed as

$$\frac{V_o}{V_i} = A\frac{R_i + R_f}{R_i + R_f + AR_i} \tag{20.131}$$

If A is high, Eq. (20.131) can be approximated by

$$\frac{V_o}{V_i} \approx \frac{A}{A+1}\frac{R_i + R_f}{R_i} \approx 1 + \frac{R_f}{R_i} \tag{20.132}$$

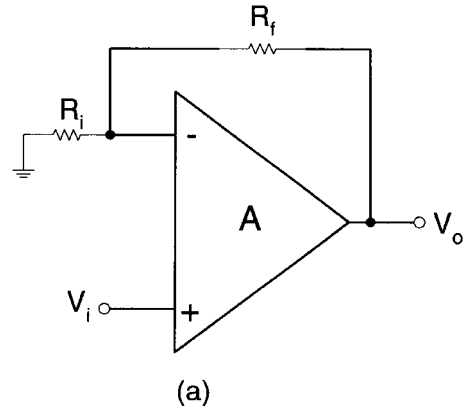
For practical resistor values, the *closed-loop* gain in Eq. (20.132) is not very high (at least compared to the op-amp's open-loop gain A), but it can be accurately set, even over process corners, by the ratio of two like components. Similarly, the inverting amplifier of Fig. 20.46(b) provides a closed-loop gain

$$\frac{V_o}{V_i} = -A\frac{R_f}{R_i + R_f + AR_i} \approx -\frac{A}{A+1}\frac{R_f}{R_i} \approx -\frac{R_f}{R_i} \tag{20.133}$$

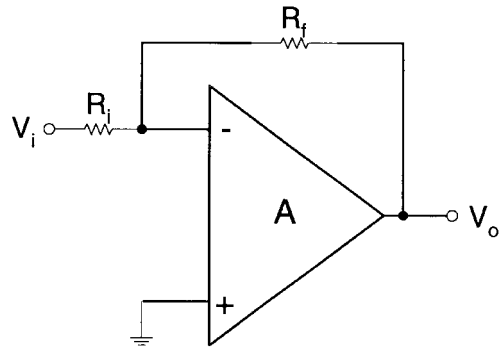
An important building block in active filter design is the inverting integrator circuit displayed in Fig. 20.46(c). By inspection,

$$\frac{V_o}{V_i} = \frac{-A}{(A+1)sR_iC_f + 1} \approx \frac{-1}{sR_iC_f} \tag{20.134}$$

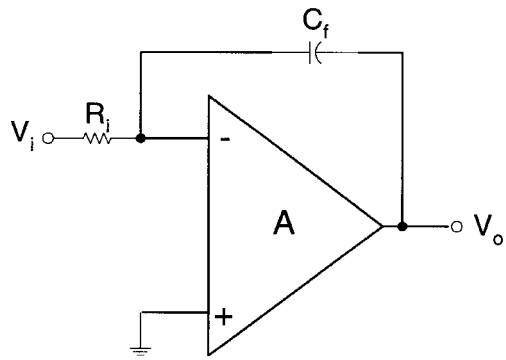
Unlike for the previous two amplifiers, the gain in Eq. (20.134) depends on the product of absolute resistor and capacitor values. When implemented as a monolithic circuit, the integrator's time constant is therefore subject to large tolerances, which need to be compensated for by trimming or an automatic tuning loop.



(a)



(b)



(c)

FIGURE 20.46 (a) Noninverting amplifier; (b) inverting amplifier; and (c) inverting integrator.

Finite Bandwidth

The op-amp's internal electronics are characterized by parasitic poles and/or zeros. As previously discussed, these unavoidable parasitics cause the gain to roll off at high frequencies and also introduce phase shifts. A typical op-amp's magnitude and phase responses are shown in Fig. 20.45(b). Assuming the op-amp has a dominant pole, the gain initially decreases by 20 dB/decade and the phase shift approaches –90°. At higher frequencies, the gain starts to decrease faster due to the combined effect of additional non-dominant parasitics and the phase increases as well. Since op-amps are used in gain stabilizing negative feedback circuits, as discussed in the previous sub-section, this high-frequency behavior can lead to instability. The worst possible situation occurs for unity feedback configurations. To avoid potential oscillation problems even under these conditions, commercial op-amps are nearly always internally compensated. Typically, a low-frequency dominant pole is introduced, which causes the gain to drop below unity at the –180° phase cross-over frequency, as shown in Fig. 20.45(c). The difference between the actual phase shift at the op-amp's unity-gain frequency and –180° is referred to as the *phase margin*. Whereas an op-amp is unconditionally stable when its phase margin is positive, values well above 45° are highly desirable to obtain quick settling to input transients. Conversely, the ratio between unity and the actual gain at the frequency corresponding to –180° phase shift is called the *gain margin*. If the dominant pole assumption is valid, the op-amp's gain A should be rewritten as

$$A(s) = A(j\omega) = \frac{A_o\omega_o}{s+\omega_o} \approx \frac{A_o\omega_o}{s} \tag{20.135}$$

where A_o is the dc gain and ω_o is the radial –3 dB frequency. $A_o\omega_o$ is referred to as the op-amp's *gain–bandwidth product*. When Eq. (20.135) is substituted into Eqs. (20.133) and (20.134), the latter gain expressions become frequency dependent. If Eq. (20.135) is likewise combined with the integrator gain in Eq. (20.134), the latter's denominator turns into a second-order polynomial.

Finite Input Impedance

An op-amp's input stage is usually a differential pair. Expressions for its differential and common-mode input resistances have been previously derived. If a high differential input resistance is desired, several design options exist. First, npn input pairs are better than pnp's, thanks to the higher β. Also, the input impedance increases as the input transconductance is lowered, either by reducing the bias current or by adding degeneration resistors. A Darlington pair can be used when an even higher input resistance is required. At high frequencies, the input impedance becomes capacitive (and thus decreases) due to the BJT's C_π and C_μ.

Input Bias Current

The bipolar transistors in the input differential pair require base current. For npn transistors, the current flows into the base, whereas current must be pulled out of the base in the case of pnp transistors. As a result of the higher β, for a given transconductance, the required input bias current is lower in absolute value in the case of an npn input stage compared to a pnp. Darlington or pseudo-Darlington input pairs can further reduce the input bias current requirement. Alternatively, input bias or base current cancellation techniques are sometimes applied.

Input Offset Voltage

Unavoidable device mismatches require the application of a small difference voltage between the input terminals in order to get zero volts at the output terminal. The reader is referred back to Section 20.3 (Input Offset Voltage).

Input Offset Current

Similar to the input offset voltage, when the inputs are currents rather than voltages, small component mismatches require the application of a small input difference current in order to get zero volts at the output node. See Section 20.3 (Input Offset Current) for more details.

Finite Output Impedance

A typical output stage consists of an emitter follower push-pull configuration. Hence, the output resistance depends on $1/g_m$, plus the resistance of the driving stage divided by β. Since β rolls off at high frequencies, R_o increases accordingly. As such, the output impedance appears inductive. This phenomenon can lead to stability problems when driving capacitive loads.

Finite Common-Mode Rejection Ratio

In Section 20.3, the common-mode rejection ratio was defined as the ratio between the differential and common-mode gains. However, an op-amp's CMRR can be more meaningfully explained in terms of the input offset voltage. In this way, the CMRR can be defined as the change in input offset voltage due to a unit change in common-mode input voltage. The CMRR of commercial op-amps typically measures 100 to 120 dB.

Finite Power Supply Rejection Ratio

Similar to the CMRR, the *power supply rejection ratio* (PSRR) is defined as the change in input offset voltage due to a unit change in the supply voltage. An op-amp's PSRR is nearly always different with respect to its positive and negative supplies. Hence, two individual performance numbers are specified. Typical values are in the range of the CMRR.

Slew Rate, Full-Power Bandwidth, and Unity-Gain Frequency

When a step input is applied, the op-amp's output cannot change instantaneously. Rather, a finite transition time is needed. The maximum rate of change in output voltage is referred to as the opamp's *slew rate* (SR). To determine an expression for the slew rate, consider the elementary op-amp in Fig. 20.47(a). This basic circuit consists of an input differential pair gain stage, which also converts the input to a single-ended signal. An intermediate stage provides additional gain. In addition, a dominant pole is introduced by means of the Miller capacitor C_c. The output stage is a Class AB emitter follower push-pull configuration. For the purpose of slew rate calculation, the elementary op-amp can be replaced by the equivalent circuit in Fig. 20.47(b). Then,

$$SR = \left.\frac{dV_o}{dt}\right|_{max} = \left.\frac{g_m V_i}{C_c}\right|_{max} \tag{20.136}$$

The maximum value of $g_m V_i$ is equal to α times the tail current source I_{EE}. Thus,

$$SR = \frac{\alpha I_{EE}}{C_c} \tag{20.137}$$

Based on the equivalent circuit in Fig. 20.47(b), the op-amp's radial unity-gain frequency is readily determined as

$$\omega_u = \frac{g_m}{C_c} \tag{20.138}$$

By combining Eqs. (20.137) and (20.138), the following relationship can be identified between the op-amp's slew rate and its unity-gain frequency

$$SR = \frac{\alpha I_{EE}}{g_m}\omega_u \tag{20.139}$$

From Eq. (20.137), one could conclude that to improve the slew rate, I_{EE} must be increased and/or C_c lowered. However, for the elementary opamp in Fig. 20.47(a), I_{EE} is also directly proportional to g_m.

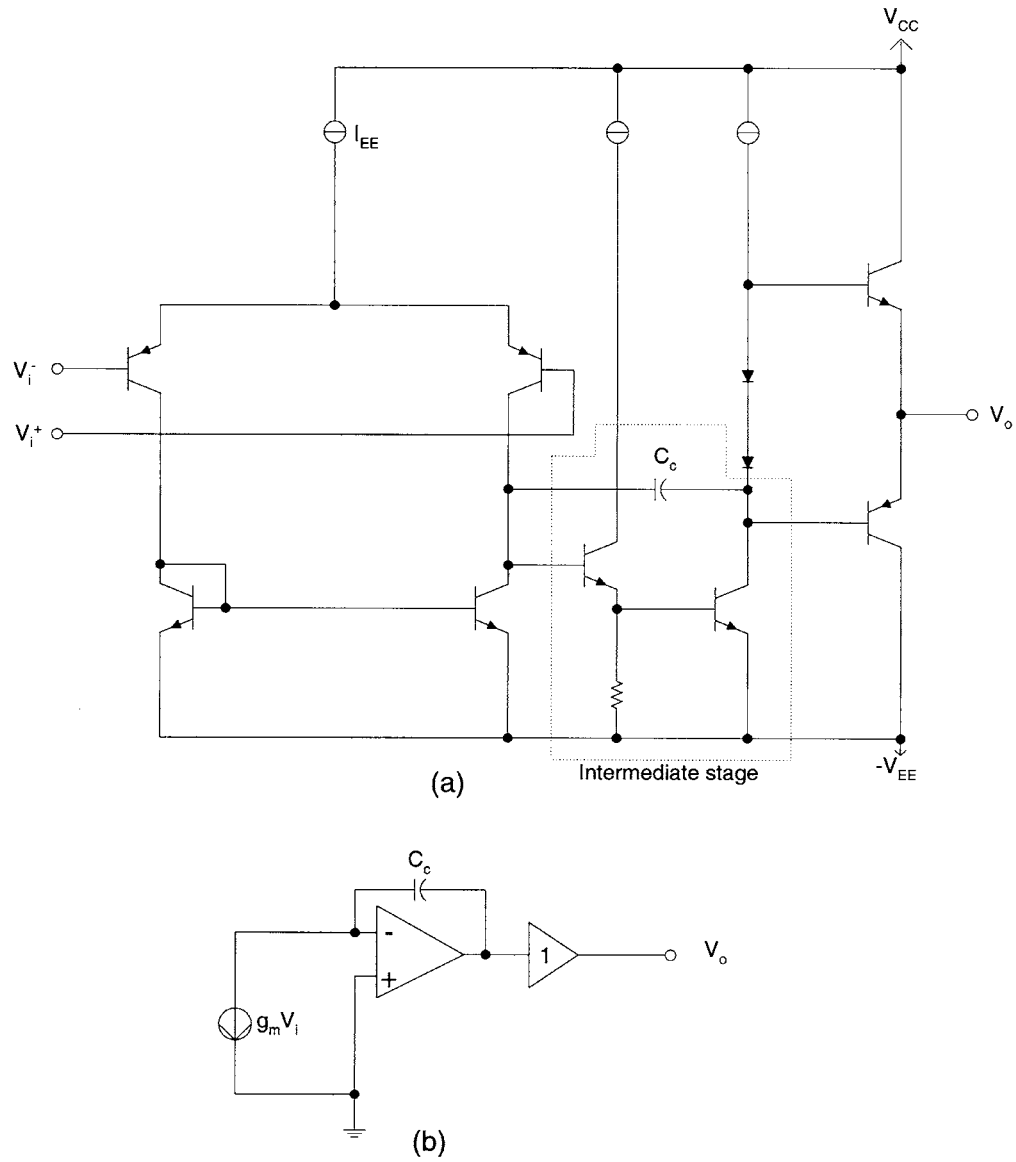


FIGURE 20.47 (a) Elementary op-amp, and (b) equivalent circuit for slew rate calculation.

Thus, both methods of increasing the slew rate at the same time increase the unity-gain bandwith ω_u. Obviously, a higher ω_u would also be desirable. However, ω_u has an upper limit, which is determined by the op-amp's non-dominant poles. Indeed, less than –180° phase shift must be maintained at ω_u in order to guarantee stability when external feedback is applied. This requirement for ω_u severely limits our flexibility to enhance the op-amp's slew rate. For a given ω_u, Eq. (20.139) suggests that the slew rate can be improved by increasing the I_{EE}/g_m ratio. Two approaches that fall into this category have been previously described in Section 20.3 on differential pair linearization. First, instead of a simple emitter-coupled pair, a differential pair with degeneration resistors can be used. Unfortunately, as pointed out before, the degeneration resistors negatively impact the circuit's noise and also degrade its offset performance. A better approach for improved slew rate is the use of parallel asymmetrical differential pairs,

such as two pairs with a 1:r emitter ratio. Although the emphasis in Section 20.3 was on linearization, and a ratio $r = 4$ was chosen specifically to eliminate the third harmonic distortion, the reader may recall that the tradeoff was a reduction in current efficiency (g_m/I_{EE}) to 64% of that of a simple differential pair. In case of an op-amp, a wide linear input range is of lesser or no concern (when feedback is applied, there is virtually no differential signal across the input terminals) and therefore different emitter ratios can be chosen. g_m/I_{EE} further decreases with larger r values. As such, the slew rate can be improved, while keeping ω_u constant. The reader is referred to Ref. 7 for further details.

Another parameter that can directly be correlated to the slew rate is the full-power bandwidth ω_{max}. The full-power bandwidth is defined as the maximum radian frequency for which the op-amp achieves a full output swing under the assumption of a sinusoidal signal. Let

$$V_o = \hat{V}\sin\omega t \tag{20.140}$$

Then,

$$\frac{dV_o}{dt} = \hat{V}\omega\cos\omega t \tag{20.141}$$

and

$$\left.\frac{dV_o}{dt}\right|_{max} = \hat{V}\omega_{max} \tag{20.142}$$

The left-hand side in Eq. (20.142) is, per definition, the slew rate. Hence, the slew rate and full-power bandwidth are simply related by the amplitude of the sinusoidal output signal.

20.7 Conclusion

In this chapter, the basic concepts behind signal amplification using bipolar transistors were introduced. Different circuit configurations, which fulfill distinct roles as building blocks in multi-stage designs or operational amplifiers, were presented. During their analysis, no parallel was drawn nor was a comparison made with respect to competing CMOS designs. This chapter would, however, not be complete if the main pros and cons of bipolar amplifiers are not very briefly mentioned. Bipolar amplifiers typically enjoy an advantage by offering higher gain, wider bandwidth, lower noise, and smaller offsets compared to their CMOS counterparts. The transconductance of an MOS transistor, while proportional to the device's size, is generally much lower than for bipolar and, rather than linearly, only increases with the square root of the bias current.

One disadvantage of bipolar amplifiers is the need for input bias currents, coupled with unavoidable input offset currents. Second, MOS transistors in saturation approximate a square-law I–V relationship and are therefore inherently more linear than bipolar devices, which are exponential in nature. Additionally, the linearity of MOS designs can be improved simply by proper device sizing. But, perhaps the most significant drawback of bipolar technology is a more complicated and expensive process (especially in the case of a complementary process with true isolated pnp transistors). Furthermore, bipolar's incompatibility with mainstream VLSI processes prevents higher levels of system integration.

Imperial College, University of London

21.1 Introduction

As the operating frequency of communication channels for both video and wireless increases, there is an ever-increasing demand for high-frequency amplifiers. Furthermore, the quest for single-chip integration has led to a whole new generation of amplifiers predominantly geared toward CMOS VLSI. In this chapter, we will focus on the design of high-frequency amplifiers for potential applications in the front-end of video, optical, and RF systems. Figure 21.1 shows, for example, the architecture of a typical mobile phone transceiver front-end. With channel frequencies approaching the 2-GHz range, coupled with demands for reduced chip size and power consumption, there is an increasing quest for VLSI at microwave frequencies. The shrinking feature size of CMOS has facilitated the design of complex analog circuits and systems in the 1- to 2-GHz range, where more traditional low-frequency lumped circuit techniques are now becoming feasible. Since the amplifier is the core component in such systems, there has been an abundance of circuit design methodologies for high-speed, low-voltage, low-noise, and low distortion operation.

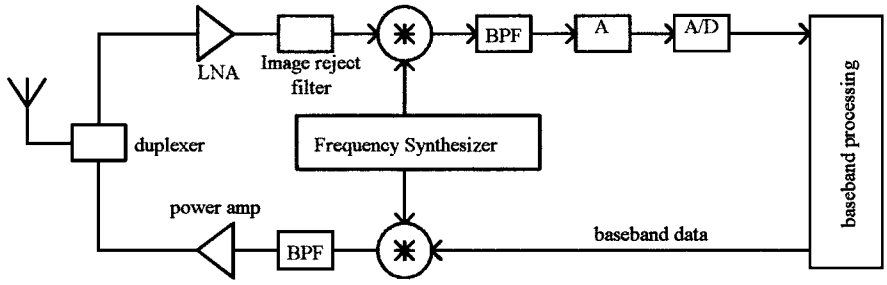

FIGURE 21.1 Generic wireless transceiver architecture.

This chapter will present various amplifier designs that aim to satisfy these demanding requirements. In particular, we will review, and in some cases present new ideas for power amps, LNAs, and transconductance cells, which form core building blocks for systems such as Fig. 21.1. Section 21.2 begins by reviewing the concept of current-feedback, and shows how this concept can be employed in the development of low-voltage, high-speed, constant-bandwidth CMOS amplifiers. The next two sections of the chapter focus on amplifiers for wireless receiver applications, investigating performance requirements and design strategies for optical receiver amplifiers (Section 21.3) and high-frequency low-noise amplifiers (Section 21.4). Section 21.5 considers the design of amplifiers for the transmitter side, and in particular the design and feasibility of Class E power amps are discussed. Finally, Section 21.6 reviews a very recent low-distortion amplifier design strategy termed "log-domain," which has shown enormous potential for high-frequency, low-distortion tunable filters.

21.2 The Current Feedback Op-Amp

Current Feedback Op-Amp Basics

The operational amplifier (op-amp) is one of the fundamental building blocks of analog circuit design.[1,2] High-performance signal processing functions such as amplifiers, filters, oscillators, etc. can be readily implemented with the availability of high-speed, low-distortion op-amps. In the last decade, the development of complementary bipolar technology has enabled the implementation of single-chip video op-amps.[3–7] The emergence of op-amps with non-traditional topologies, such as the current feedback op-amp, has improved the speed of these devices even further.[8–11] Current feedback op-amp structures are well known for their ability to overcome (to a first-order approximation) the gain-bandwidth tradeoff and slew rate limitation that characterizes traditional voltage feedback op-amps.[12]

Figure 21.2 shows a simple macromodel of a current feedback op-amp (CFOA), along with a simplified circuit diagram of the basic architecture. The topology of the current feedback op-amp differs from the conventional voltage feedback op-amp (VOA) in two respects. First, the input stage of a CFOA is a unity-gain voltage buffer connected between the inputs of the op-amp. Its function is to force V_n to follow V_p, very much like a conventional VOA does via negative feedback. In the case of the CFOA, because of the low output impedance of the buffer, current can flow in or out of the inverting input, although in normal operation (with negative feedback) this current is extremely small. Secondly, a CFOA provides a high open-loop transimpedance gain $Z(j\omega)$, rather than open-loop voltage gain as with a VOA. This is shown in Fig. 21.2, where a current-controlled current source senses the current I_{INV} delivered by the buffer to the external feedback network, and copies this current to a high impedance $Z(j\omega)$. The voltage conveyed to the output is given by Eq. 21.1:

$$V_{OUT} = Z(j\omega) \cdot I_{INV} \Rightarrow \frac{V_{OUT}}{I_{INV}}(j\omega) = Z(j\omega) \tag{21.1}$$

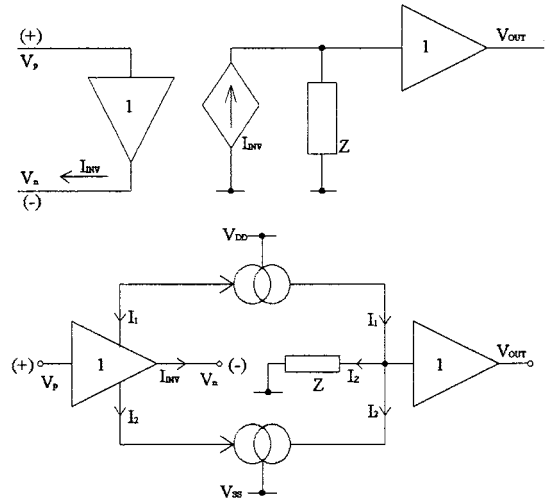

FIGURE 21.2 Current feedback op-amp macromodel.

When the negative feedback loop is closed, any voltage imbalance between the two inputs due to some external agent, will cause the input voltage buffer to deliver an error current I_{INV} to the external network. This error current $I_{INV} = I_1 - I_2 = I_Z$ is then conveyed by the current mirrors to the impedance Z, resulting in an ouput voltage as given by Eq. 21.1. The application of negative feedback ensures that V_{OUT} will move in the direction that reduces the error current I_{INV} and equalizes the input voltages.

We can approximate the open-loop dynamics of the current feedback op-amp as a single pole response. Assuming that the total impedance $Z(j\omega)$ at the gain node is the combination of the output resistance of the current mirrors R_o in parallel with a compensation capacitor C, we can write:

$$Z(j\omega) = \frac{R_o}{1 + j\omega R_o C} = \frac{R_o}{1 + j\dfrac{\omega}{\omega_o}} \tag{21.2}$$

where $\omega_o = 1/R_o \cdot C$ represents the frequency where the open-loop transimpedance gain is 3 dB down from its low frequency value R_o. In general, R_o is designed to be very high in value.

Referring to the non-inverting amplifier configuration shown in Fig. 21.3:

$$I_{INV} = \frac{V_{IN}}{R_G} - \frac{V_{OUT} - V_{IN}}{R_F} = \frac{V_{IN}}{R_G // R_F} - \frac{V_{OUT}}{R_F} \tag{21.3}$$

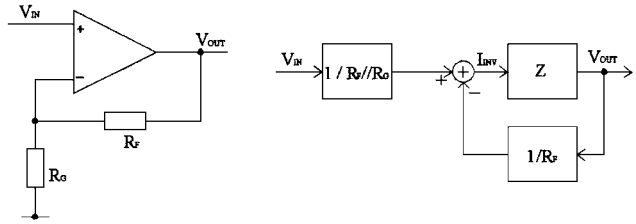

FIGURE 21.3 CFOA non-inverting amplifier configuration.

Substituting Eq. 21.1 into Eq. 21.3 yields the following expression for the closed-loop gain:

$$A_{CL}(j\omega) = \left(1 + \frac{R_F}{R_G}\right) \cdot \frac{Z(j\omega)}{R_F + Z(j\omega)} = \left(1 + \frac{R_F}{R_G}\right) \cdot \frac{1}{1 + \frac{R_F}{Z(j\omega)}} \tag{21.4}$$

Combining Eqs. 21.2 and 21.4, and assuming that the low frequency value of the open-loop transimpedance is much higher than the feedback resistor ($R_o >> R_F$) gives:

$$A_{CL}(j\omega) = \left(1 + \frac{R_F}{R_G}\right) \cdot \frac{1}{1 + j\frac{R_F \cdot \omega}{R_o \cdot \omega_o}} = \frac{A_{Vo}}{1 + j\frac{\omega}{\omega_\alpha}} \tag{21.5}$$

Referring to Eq. 21.5, the closed-loop gain $A_{Vo} = 1 + R_F/R_G$, while the closed-loop –3 dB frequency ω_α is given by:

$$\omega_\alpha = \frac{R_o}{R_F} \cdot \omega_o \tag{21.6}$$

Eq. 21.6 indicates that the closed-loop bandwidth does not depend on the closed-loop gain as in the case of a conventional VOA, but is determined by the feedback resistor R_F. Explaining this intuitively, the current available to charge the compensation capacitor at the gain node is determined by the value of the feedback resistor R_F and not R_o, provided that$R_o >> R_F$. So, once the bandwidth of the amplifier is set via R_F, the gain can be independently varied by changing R_G. The ability to control the gain independently of bandwidth constitutes a major advantage of current feedback op-amps over conventional voltage feedback op-amps.

The other major advantage of the CFOA compared to the VFOA is the inherent absence of slew rate limiting. For the circuit of Fig. 21.3, assume that the input buffer is very fast and thus a change in voltage at the non-inverting input is instantaneously converted to the inverting input. When a step ΔV_{IN} is applied to the non-inverting input, the buffer output current can be derived as:

$$I_{INV} = \frac{V_{IN} - V_{OUT}}{R_F} + \frac{V_{IN}}{R_G} \tag{21.7}$$

Eq. 21.7 indicates that the current available to charge/discharge the compensation capacitor is proportional to the input step regardless of its size, that is, there is no upper limit. The rate of change of the output voltage is thus:

$$\frac{dV_{OUT}}{dt} = \frac{I_{INV}}{C} \Rightarrow V_{OUT}(t) = \Delta V_{IN} \cdot \left(1 + \frac{R_F}{R_G}\right) \cdot (1 - e^{-t/R_f \cdot C}) \tag{21.8}$$

Eq. 21.8 indicates an exponential output transition with time constant $\tau = R_F \cdot C$. Similar to the small-signal frequency response, the large-signal transient response is governed by R_F alone, regardless of the magnitude of the closed-loop gain. The absence of slew rate limiting allows for faster settling times and eliminates slew rate-related non-linearities.

In most practical bipolar realizations, Darlington-pair transistors are used in the input stage to reduce input bias currents, which makes the op-amp somewhat noisier and increases the input offset voltage. This is not necessary in CMOS realizations due to the inherently high MOSFET input impedance. However, in a closed-loop CFOA, R_G should be much larger than the output impedance of the buffer. In bipolar realizations, it is fairly simple to obtain a buffer with low output resistance, but this becomes more of a

problem in CMOS due to the inherently lower gain of MOSFET devices. As a result, R_G typically needs to be higher in a CMOS CFOA than in a bipolar realization, and consequently, R_E needs to be increased above the value required for optimum high-frequency performance. Additionally, the fact that the input buffer is not in the feedback loop imposes linearity limitations on the structure, especially if the impedance at the gain node is not very high. Regardless of these problems, current feedback op-amps exhibit excellent high-frequency characteristics and are increasingly popular in video and communications applications.[13]

The following sections outline the development of a novel low-output impedance CMOS buffer, which is then employed in a CMOS CFOA to reduce the minimum allowable value of R_G.

CMOS Compound Device

A simple PMOS source follower is shown in Fig. 21.4. The output impedance seen looking into the source of M1 is approximately $Z_{out} = 1/g_m$, where g_m is the small signal transconductance of M1. To increase g_m, the drain current of M1 could be increased, which leads to an increased power dissipation. Alternatively, the dimensions of M1 can be increased, resulting in additional parasitic capacitance and hence an inferior frequency response. Figure 21.5 shows a configuration that achieves a higher transconductance than the simple follower of Fig. 21.3 for the same bias current.[11] The current of M2 is fed back to M1 through the a:1 current mirror. This configuration can be viewed as a compound transistor whose gate is the gate of M1 and whose source is the source of M2. The impedance looking into the compound source can be approximated as $Z_{out} = (g_{m1} - a \cdot g_{m2})/(g_{m1} \cdot g_{m2})$, where g_{m1} and g_{m2} represent the small signal transconductance of M1 and M2, respectively. The output impedance can be made small by setting the current mirror transfer ratio $a = g_{m1}/g_{m2}$.

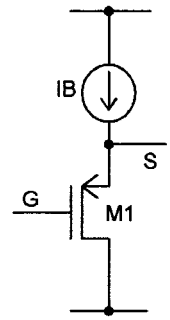

FIGURE 21.4 Simple PMOS source follower.

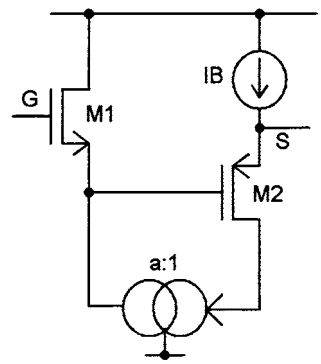

FIGURE 21.5 Compound MOS device.

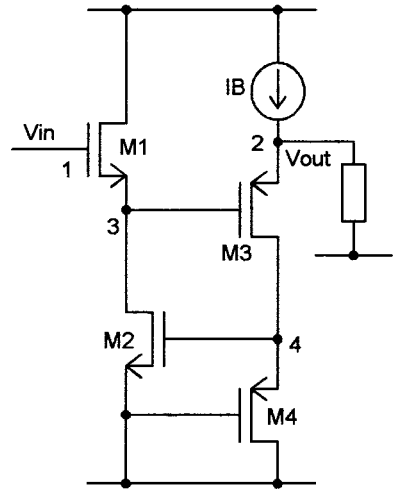

FIGURE 21.6 Actual p-compound device implementation.

The p-compound device is practically implemented as in Fig. 21.6. In order to obtain a linear voltage transfer function from node 1 to 2, the gate-source voltages of M1 and M3 must cancel. The current mirror (M4-M2) acts as an NMOS-PMOS gate-source voltage matching circuit[14] and compensates for the difference in the gate-source voltages of M1 and M3, which would normally appear as an output offset. DC analysis, assuming a square law model for the MOSFETs, shows that the output voltage exactly follows the input voltage. However, in practice, channel length modulation and body effects preclude exact cancellation.[15]

Buffer and CFOA Implementation

The current feedback op-amp shown in Fig. 21.7 has been implemented in a single-well 0.6-μm digital CMOS process[11]; the corresponding layout plot is shown in Fig. 21.8. The chip has an area of 280 μm by

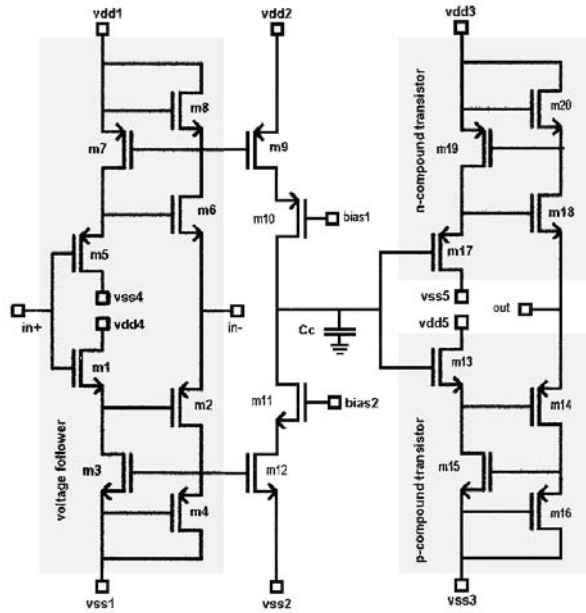

FIGURE 21.7 Current feedback op-amp schematic.

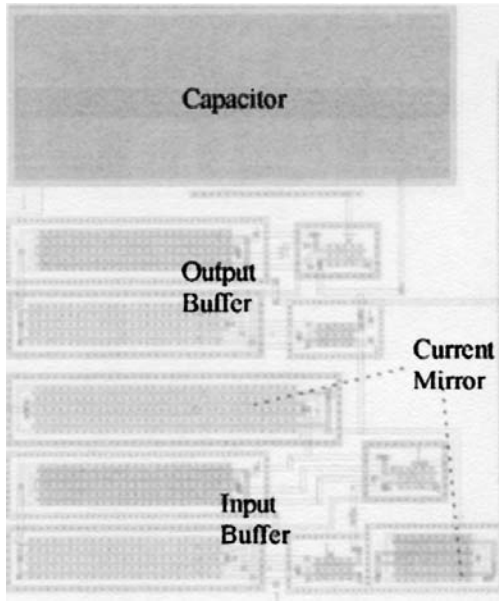

FIGURE 21.8 Current feedback op-amp layout plot.

330 μm and a power dissipation of 12 mW. The amplifier comprises two voltage followers (input and output) connected by cascoded current mirrors to enhance the gain node impedance. A compensation capacitor (Cc = 0.5 pF) at the gain node ensures adequate phase margin and thus closed-loop stability. The voltage followers have been implemented with two compound transistors, p-type and n-type, in a push-pull arrangement. Two such compound transistors in the output stage are shown shaded in Fig. 21.7. The input voltage follower of the current feedback op-amp was initialy tested open-loop, and measured results are summarized in Table 21.1. The load is set to 10 kΩ/10 pF, except where mentioned otherwise, 10 kΩ being a limit imposed by overall power dissipation of the chip. Intermodulation distortion was measured with two tones separated by 200 kHz. The measured output impedance of the buffer is given in Fig. 21.9. It remains below 80 Ω up to a frequency of about 60 MHz, when it enters an inductive region. A maximum impedance of 140 Ω is reached around 160 MHz. Beyond this frequency, the output impedance is dominated by parasitic capacitances. The inductive behavior is characteristic of the use of feedback to reduce output impedance, and can cause stability problems when driving capacitive loads. Small-signal analysis (summarized in Table 21.2) predicts a double zero in the output impedance.[15]

TABLE 21.1 Voltage Buffer Performance

Power Supply	5 V	Dissipation	5 mW
DC gain (no load)	–3.3dB	Bandwidth	140 MHz
Output impedance	75Ω	Min. load resistance	10 KΩ
HD2 (V_{in} = 200 mV_{rms})	1 MHz	–50 dB	
	10 MHz	–49 dB	
	20 MHz	–45 dB	
IM3 (V_{in}=200 mV_{rms})	20 MHz, Δf = 200 KHz	–53 dB	
Slew rate	(Load = 10 pF)	+ 130 V/μs	-72 V/μs
Input referred noise	10 $nV\sqrt{Hz}$		

Note: Load = 10 kΩ/10 pF, except for slew rate measurement.

Making factor G in Table 21.2 small will reduce the output impedance, but also moves the double zero to lower frequencies and intensifies the inductive behavior. The principal tradeoff in this configuration is between output impedance magnitude and inductive behavior. In practice. the output impedance

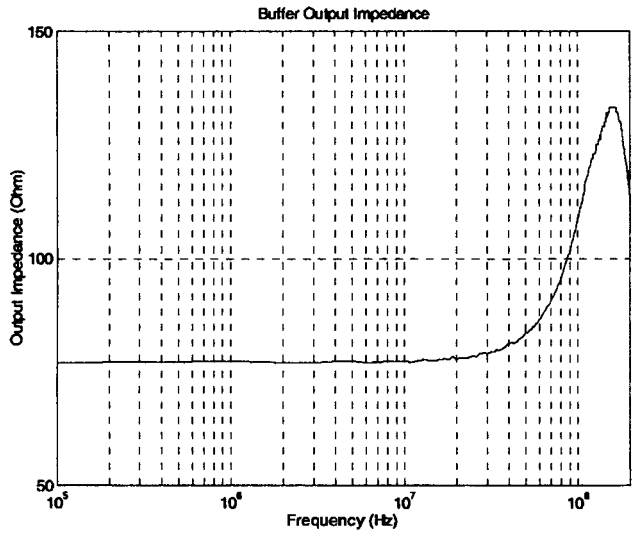

FIGURE 21.9 Measured buffer output impedance characteristics.

TABLE 21.2 Voltage Transfer Function and Output Impedance of Compound Device

$$Z_{out} = \frac{G}{(g_{m1} + g_{ds1} + g_{ds2}) \cdot (g_{m3} + g_{ds3}) \cdot (g_{m4} + g_{ds4})}$$

$$\frac{V_{out}}{V_{in}} = \frac{g_{m1} \cdot g_{m3} \cdot (g_{m4} + g_{ds4})}{(g_{m1} + g_{ds1} + g_{ds2}) \cdot (g_{m3} + g_{ds3}) \cdot (g_{m4} + g_{ds4}) + g_L \cdot G}$$

$$G = (g_{m1} + g_{ds1} + g_{ds2}) \cdot (g_{m4} + g_{ds4} + g_{ds3}) - g_{m2} \cdot g_{m3}$$

can be reduced by a factor of 3 while still maintaining good stability when driving capacitive loads. Figure 21.10 shows the measured frequency response of the buffer. Given the low power dissipation, excellent slew rates have been achieved (Table 21.2).

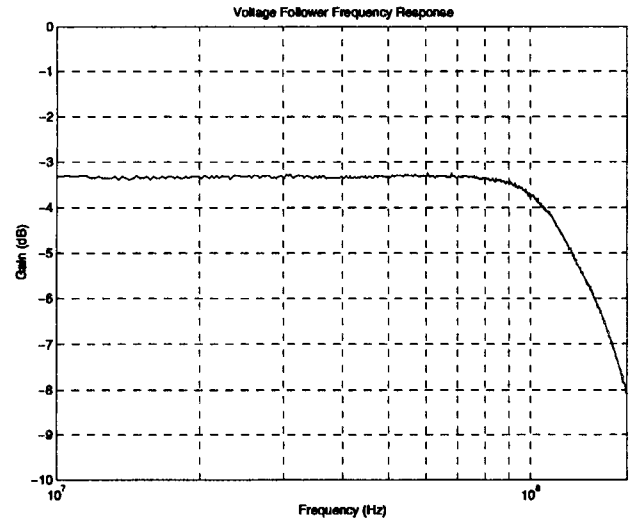

FIGURE 21.10 Measured buffer frequency response.

After the characterization of the input buffer stage, the entire CFOA was tested to confirm the suitability of the compound transistors for the implementation of more complex building blocks. Open-loop transimpedance measurements are shown in Fig. 21.11. The bandwidth of the amplifier was measured at gain settings of 1, 2, 5, and 10 in a non-inverting configuration, and the feedback resistor was trimmed to achieve maximum bandwidth at each gain setting separately. CFOA measurements are summarized in Table 21.3, loading conditions are again 10 kΩ/10 pF.

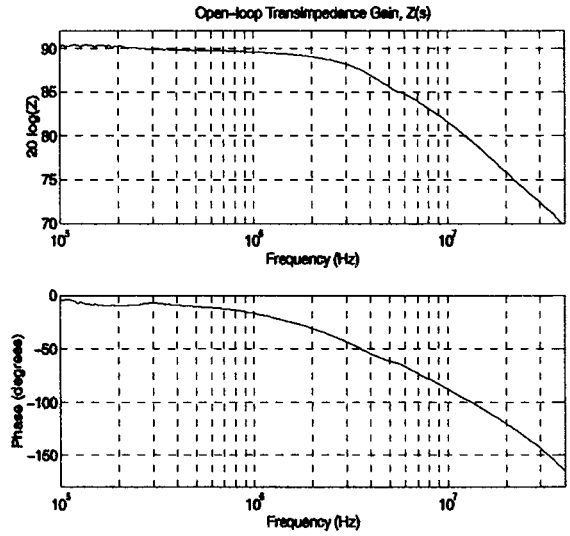

FIGURE 21.11 Measured CFOA open-loop transimpedance gain.

TABLE 21.3 Current Feedback Op-Amp Measurement Summary

Power Supply	5 V	Power Dissipation	12 mW
Gain	Bandwidth (MHz)		
1	117		
2	118		
5	113		
10	42		
Frequency	Input (mV rms)	Gain	HD2 (dB)
1 MHz	140	2	–51
	40	5	–50
	10	10	–49
10 MHz	80	2	–42
	40	5	–42
	13	10	–43

Fig. 21.12 shows the measured frequency response for various gain settings. The bandwidth remains constant at 110 MHz for gains of 1, 2, and 5, consistent with the expected behavior of a CFOA. The bandwidth falls to 42 MHz for a gain of 10 due to the finite output impedance of the input buffer stage which series as the CFOA inverting input. Figure 21.13 illustrates the step response of the CFOA driving a 10 kΩ/10 pF load at a voltage gain of 2. It can be seen that the inductive behavior of the buffers has little effect on the step response. Finally, distortion measurements were carried out for the entire CFOA for gain settings 2, 5, and 10 and are summarized in Table 21.3. HD2 levels can be further improved by employing a double-balanced topology. A distortion spectrum is shown in Fig. 21.14; the onset of HD3 is due to clipping at the test conditions.

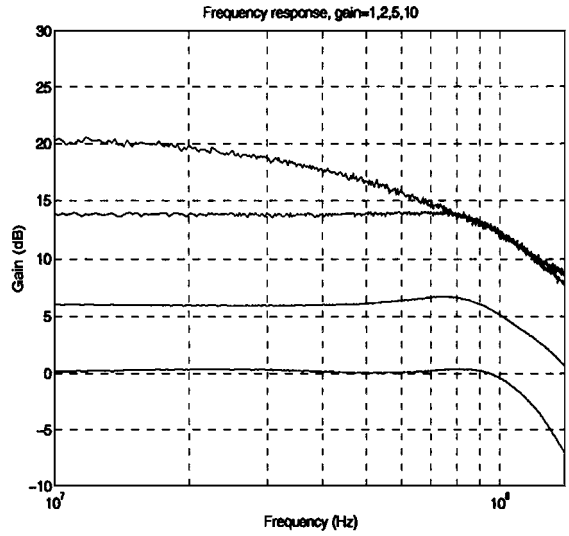

FIGURE 21.12 Measured CFOA closed-loop frequency response.

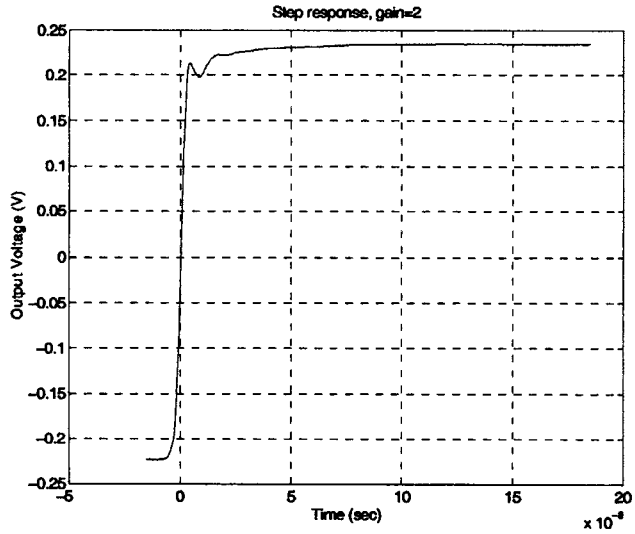

FIGURE 21.13 Measured CFOA step response.

21.3 RF Low-Noise Amplifiers

This section reviews the important performance criteria demanded of the front-end amplifier in a wireless communication receiver. The design of CMOS LNAs for front-end wireless communication receiver applications is then addressed. Section 21.4 considers the related topic of low-noise amplifiers for optical receiver front-ends.

Specifications

The front-end amplifier in a wireless receiver must satisfy demanding requirements in terms of noise, gain, impedance matching, and linearity.

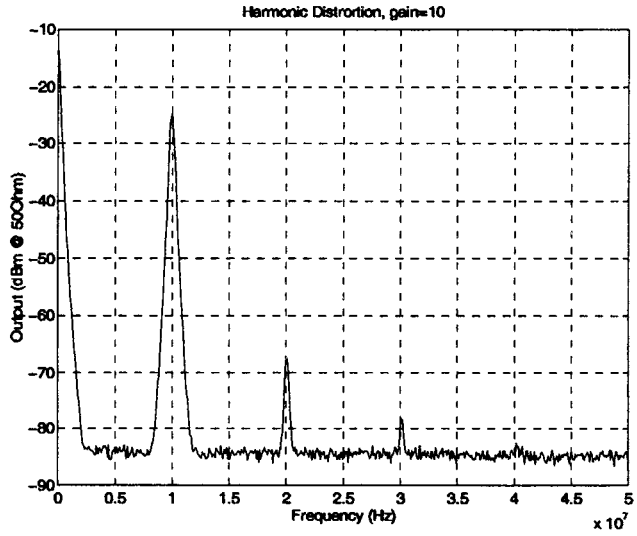

FIGURE 21.14 CFOA harmonic distortion measurements.

Noise

Since the incoming signal is usually weak, the front-end circuits of the receiver must possess very low noise characteristics so that the original signal can be recovered. Provided that the gain of the front-end amplifier is sufficient so as to suppress noise from the subsequent stages, the receiver noise performance is determined predominantly by the front-end amplifier. Hence, the front-end amplifier should be a low-noise amplifier (LNA).

Gain

The voltage gain of the LNA must be high enough to ensure that noise contributions from the following stages can be safely neglected. As an example, Fig. 21.15 shows the first three stages in a generic front-end receiver, where the gain and output-referred noise of each stage are represented by G_i and N_i ($i = 1, 2, 3$), respectively. The total noise at the third stage output is given by:

$$N_{out} = N_{in}G_1G_2G_3 + N_1G_2G_3 + N_2G_3 + N_3 \tag{21.9}$$

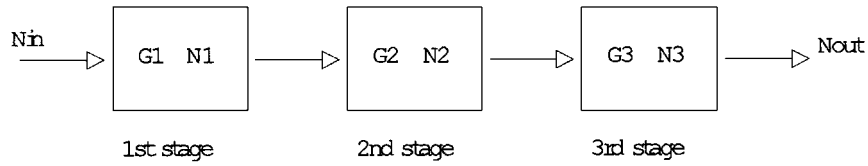

FIGURE 21.15 Three-stage building block with gain G_i and noise N_i per stage.

This output noise (N_{out}) can be referred to the input to derive an equivalent input noise (N_{eq}):

$$N_{eq} = \frac{N_{out}}{Gain} = \frac{N_{out}}{G_1G_2G_3} = N_{in} + \frac{N_1}{G_1} + \frac{N_2}{G_1G_2} + \frac{N_3}{G_1G_2G_3} \tag{21.10}$$

According to Eq. 22.10, the gain of the first stage should be high in order to reduce noise contributions from subsequent stages. However, if the gain is too high, a large input signal may saturate the

subsequent stages, yielding intermodulation products which corrupt the desired signal. Thus, optimization is inevitable.

Input Impedance Matching

The input impedance of the LNA must be matched to the antenna impedance over the frequency range of interest, in order to transfer the maximum available power to the receiver.

Linearity

Unwanted signals at frequencies fairly near the frequency band of interest may reach the LNA with signal strengths many times higher than that of the wanted signal. The LNA must be sufficiently linear to prevent these out-of-band signals from generating intermodulation products within the wanted frequency band, and thus degrading the reception of the desired signal. Since third-order mixing products are usually dominant, the linearity of the LNA is related to the "third-order intercept point" (IP3), which is defined as the input power level that results in equal power levels for the output fundamental frequency component and the third-order intermodulation components. The dynamic range of a wireless receiver is limited at the lower bound by noise and at the upper band by non-linearity.

CMOS Common-Source LNA: Simplified Analysis

Input Impedance Matching by Source Degeneration

For maximum power transfer, the input impedance of the LNA must be matched to the source resistance, which is normally 50 Ω. Impedance-matching circuits consist of reactive components and therefore are (ideally) lossless and noiseless. Figure 21.16 shows the small signal equivalent circuit of a CS LNA input stage with impedance-matching circuit, where the gate-drain capacitance C_{gd} is assumed to have negligible effect and is thus neglected.[16,17] The input impedance of this CS input stage is given by:

$$Z_{in} = j\omega(L_g + L_s) + \frac{1}{j\omega C_{gs}} + \frac{g_m}{C_{gs}}L_s \tag{21.11}$$

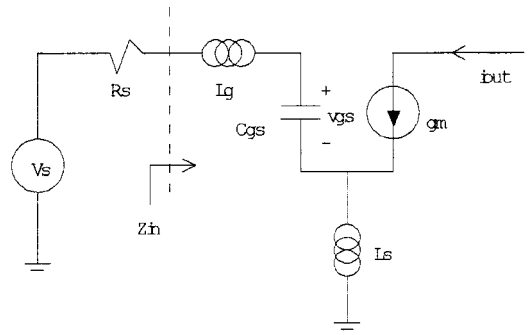

FIGURE 21.16 Simplified small-signal equivalent circuit of the CS stage.

Thus, for matching, the two conditions below must be satisfied:

$$\text{(i)} \quad \omega_o^2 = \frac{1}{(L_g + L_s)C_{gs}} \quad \text{and} \quad \text{(ii)} \quad \frac{g_m}{C_{gs}}L_s = Rs \tag{21.12}$$

Noise Figure of CS Input Stage

Two main noise sources exist in a CS input stage as shown in Fig. 21.17; thermal noise from the source resistor R_s (denoted $\overline{v_{Rs}^2}$) and channel thermal noise from the input transistor (denoted $\overline{i_d^2}$). The output noise current due to $\overline{v_{Rs}^2}$ can be determined from Fig. 21.17 as:

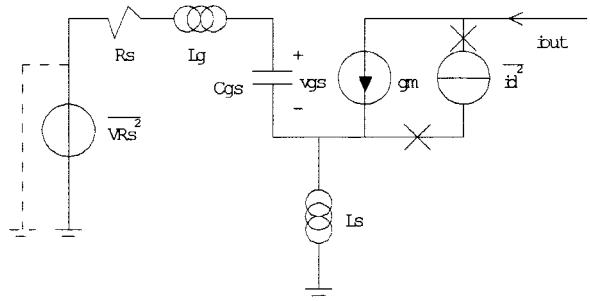

FIGURE 21.17 Simplified noise equivalent circuit of the CS stage. $\overline{V_{Rs}^2} = 4kT_{Rs}$; $\overline{id^2} = KT\Gamma g_{dc}$.

$$\overline{i_{nout1}^2} = \frac{g_m^2 \overline{v_{Rs}^2}}{\omega^2 (g_m L_s + R_s C_{gs})^2} = \frac{g_m^2}{4\omega^2 R_s^2 C_{gs}^2} \overline{v_{Rs}^2} \tag{21.13}$$

while the output noise current due to $\overline{i_d^2}$ can be evaluated as:

$$\overline{i_{nout2}} = \frac{\overline{i_d}}{\left(1 + \frac{g_m L_s}{R_s C_{gs}}\right)} = \frac{1}{2}\overline{i_d} \qquad \therefore \overline{i_{nout2}^2} = \frac{1}{4}\overline{i_d^2} \tag{21.14}$$

From Eqs. 21.13 and 21.14, the noise figure of the CS input stage is determined as:

$$NF = 1 + \frac{\overline{i_{nout2}^2}}{\overline{i_{nout1}^2}} = 1 + \Gamma\left(\frac{\omega_o^2 R_s C_{gs}^2}{g_m}\right) = 1 + \Gamma\left(\frac{L_s}{L_s + L_g}\right) \tag{21.15}$$

In practice, any inductor (especially a fully integrated inductor) has an associated resistance that will contribute thermal noise, degrading the noise figure in Eq. 21.15.

Voltage Amplifier with Inductive Load

Referring to Fig. 21.15, the small signal current output is given by:

$$i_{out} = \frac{g_m v_s}{[1 - \omega^2 C_{gs}(L_g + L_s)] + j\omega(g_m L_s + R_s C_{gs})} \tag{21.16}$$

For an inductive load (L_1) with a series internal resistance r_{L1}, the output voltage is thus:

$$v_{out} = -i_{out}(r_{L1} + j\omega L_1) = \frac{-(r_{L1} + j\omega L_1) g_m v_s}{[1 - \omega^2 C_{gs}(L_g + L_s)] + j\omega(g_m L_s + R_s C_{gs})} \tag{21.17}$$

Assuming that the input is impedance matched, the voltage gain at the output is given by:

$$\left|\frac{v_{out}}{v_s}\right| = \frac{\sqrt{(r_{L1})^2 + (\omega_o)^2 (L_1)^2}}{2\omega_o L_s} = \frac{r_{L1}}{2\omega_o L_s}\sqrt{1 + \left(\frac{\omega_o L_1}{r_{L1}}\right)^2} \cong \frac{1}{2}\omega_o \left(\frac{L_1}{L_s}\right)\left(\frac{L_1}{r_{L1}}\right) \tag{21.18}$$

CMOS Common-Source LNA: Effect of C_{gd}

In the analysis so far, the gate-drain capacitance (C_{gd}) has been assumed to be negligible. However, at very high frequencies, this component cannot be neglected. Figure 21.18 shows the modified input stage of a CS LNA including C_{gd} and an input ac-coupling capacitance C_{in}. Small signal analysis shows that the input impedance is now given by:

$$Z_{in} = \frac{g_m L_s}{C_{gs} + C_{gd}\left[j\omega L_s g_m + \dfrac{g_m(1-\omega^2 L_s C_{gd})}{\dfrac{1}{Z_L} + j\omega C_{gd}} \right]} \tag{21.19}$$

Equation 21.19 exhibits resonance frequencies that occur when:

$$1 - \omega^2 L_s C_{gs} = 0 \qquad \text{and} \qquad 1 - \omega^2 L_g C_{in} = 0 \tag{21.20}$$

Equation 21.19 indicates that the input impedance matching is degraded by the load Z_L when C_{gd} is included in the analysis.

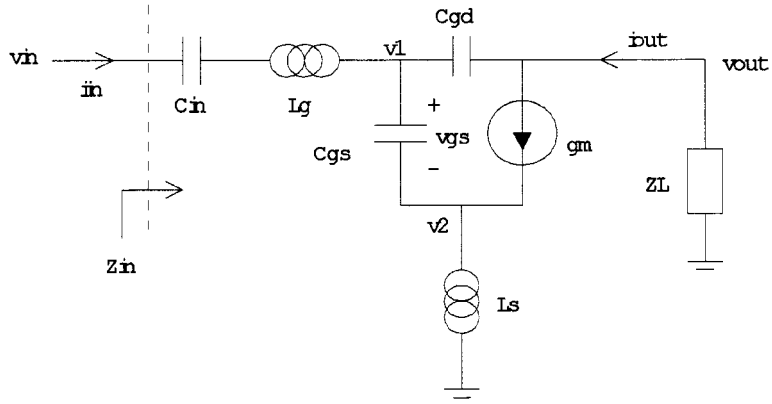

FIGURE 21.18 Noise equivalent circuit of the CS stage, including effects of C_{gd}.

Input Impedance with Capacitive Load

If the load Z_L is purely capacitive, that is,

$$Z_L = \frac{1}{j\omega C_L} \tag{21.21}$$

then the input impedance can be easily matched to the source resistor R_s. Substituting Eq. 21.21 for Z_L, the bracketed term in the denominator of Eq. 21.19 becomes:

$$d_1 = j\omega L_s g_m + \frac{g_m(1-\omega^2 L_s C_{gd})}{j\omega(C_{gd} + C_L)} = 0 \tag{21.22}$$

under the condition that

$$1 - \omega^2 L_s(2C_{gd} + C_L) = 0 \tag{21.23}$$

The three conditions in Eqs. 21.20 and 21.23 should be met to ensure input impedance matching. However, in practice, we are unlikely to be in the situation of using a load capacitor.

Input Impedance with Inductive Load

If $Z_L = j\omega L_L$, the CS LNA input impedance is given by:

$$Z_{in} = \frac{g_m L_s}{C_{gs} + j\omega C_{gd} g_m \left[L_s + L_L \left(\frac{1 - \omega^2 L_s C_{gd}}{1 - \omega^2 L_L C_{gd}} \right) \right]} \tag{21.24}$$

In order to match to a purely resistive input, the value of the reactive term in Eq. 21.24 must be negligible, which is difficult to achieve.

Cascode CS LNA

Input Matching

As outlined in the paragraph above, the gate-drain capacitance (C_{gd}) degrades the input impedance matching and therefore reduces the power transfer efficiency. In order to reduce the effect of C_{gd}, a cascoded structure can be used.[18–20] Figure 21.19 shows a cascode CS LNA. Since the voltage gain from the gate to the drain of M1 is unity, the gate-drain capacitance (C_{gd1}) no longer sees the full input-output voltage swing which greatly improves the input-output isolation. The input impedance can be approximated by Eq. 21.11, thus allowing a simple matching circuit to be employed.[18]

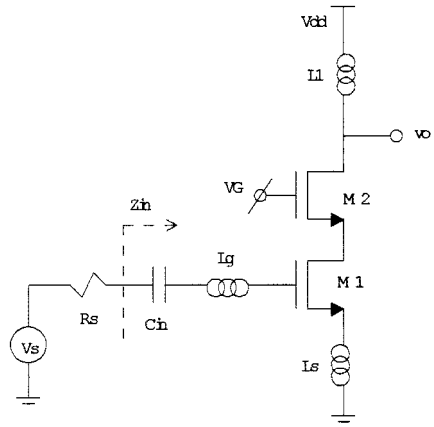

FIGURE 21.19 Cascode CS LNA.

Voltage Gain

Figure 21.20 shows the small-signal equivalent circuit of the cascode CS LNA. Assuming that input is fully matched to the source, the voltage gain of the amplifier is given by:

$$\frac{v_{out}}{v_s} = -\frac{1}{2}\left(\frac{j\omega L_1}{1 - \omega^2 L_1 C_{gd2}} \right)\left(\frac{g_{m2}}{g_{m2} + j\omega C_{gs2}} \right)\left[\frac{g_{m1}}{(1 - \omega^2 L_s C_{gs1}) + j\omega L_s g_{m1}} \right] \tag{21.25}$$

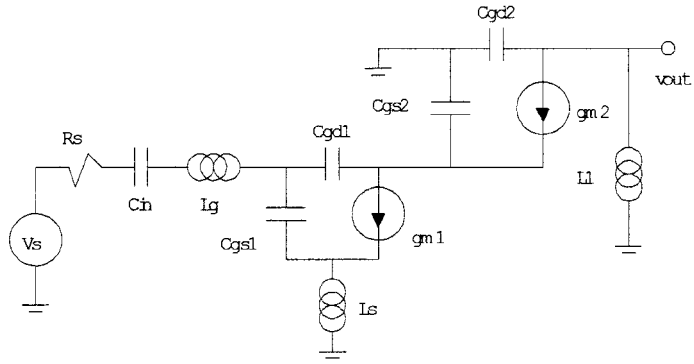

FIGURE 21.20 Equivalent circuit of cascode CS LNA.

At the resonant frequency, the voltage gain is given by:

$$\frac{v_{out}}{v_s}(\omega_o) = -\frac{1}{2}\left(\frac{L_1}{L_s}\right)\left(\frac{1}{1-\omega_o^2 L_1 C_{gd2}}\right)\times\frac{1}{1+j\omega_o\left(\frac{C_{gs1}}{g_{m2}}\right)} \approx -\frac{1}{2}\left(\frac{L_1}{L_s}\right)\times\frac{1}{1+j\left(\frac{\omega_o}{\omega_T}\right)} \quad (21.26)$$

From Eq. 21.26, the voltage gain is dependent on the ratio of the load and source inductance values. Therefore, high gain accuracy can be achieved since this ratio is largely process independent.

Noise Figure

Figure 21.21 shows an equivalent circuit of the cascode CS LNA for noise calculations. Three main noise sources can be identified: the thermal noise voltage from R_s, and the channel thermal noise currents from M1 and M2. Assuming that the input impedance is matched to the sources, the output noise current due to $\overline{v_{RS}^2}$ can be derived as:

$$\overline{i_{out1}} = \frac{1}{2j\omega_o L_s(1-\omega_o^2 L_1 C_{gd2})}\left(\frac{g_{m2}}{g_{m2}+j\omega_o C_{gs2}}\right)\overline{v_{RS}} \quad (21.27)$$

The output noise current contribution due to $\overline{i_{d1}^2}$ of M1 is given by:

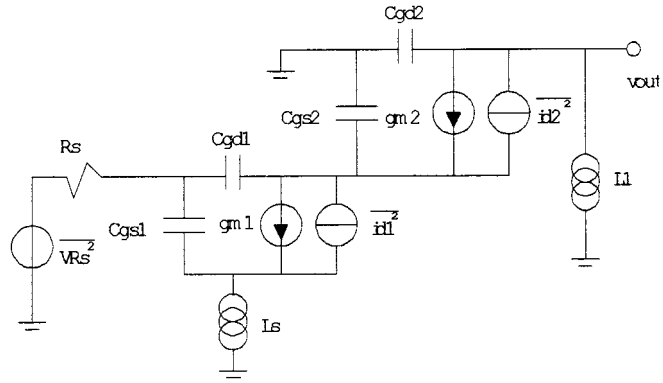

FIGURE 21.21 Noise equivalent circuit of cascode CS LNA.

$$\overline{i_{out2}} = \frac{1}{2(1-\omega_o^2 L_1 C_{gd2})}\left(\frac{g_{m2}}{g_{m2}+j\omega_o C_{ds2}}\right)\overline{i_{d1}} \tag{21.28}$$

The output noise current due to $\overline{i_{d2}^2}$ of M2 is given by:

$$\overline{i_{out3}} = \frac{j\omega_o C_{gs2}}{(1-\omega_o^2 L_1 C_{gd2})(g_{m2}+j\omega_o C_{gs2})}\overline{i_{d2}} \tag{21.29}$$

The noise figure of the cascode CS LNA can thus be derived as:

$$NF = 1 + \frac{\overline{i_{out2}^2}}{\overline{i_{out1}^2}} + \frac{\overline{i_{out3}^2}}{\overline{i_{out1}^2}} = 1 + \Gamma\left(1 + \frac{4\omega_o^2 C_{gs2}^2}{g_{m1}g_{m2}}\right) \tag{21.30}$$

In order to improve the noise figure, the transconductance values (g_m) of M1 and M2 should be increased. Since the gate-source capacitance (C_{gs2}) of M2 is directly proportional to the gate width, the gate width of M2 cannot be enlarged to increase the transconductance. Instead, this increase should be realized by increasing the gate bias voltage.

21.4 Optical Low-Noise Preamplifiers

Figure 21.22 shows a simple schematic diagram of an optical receiver, consisting of a photodetector, a preamplifier, a wide-band voltage amplifier, and a pre-detection filter. Since the front-end transimpedance preamplifier is critical in determining the overall receiver performance, it should possess a wide bandwidth so as not to distort the received signal, high gain to reject noise from subsequent stages, low noise to achieve high sensitivity, wide dynamic range, and low inter-symbol-interference (ISI).

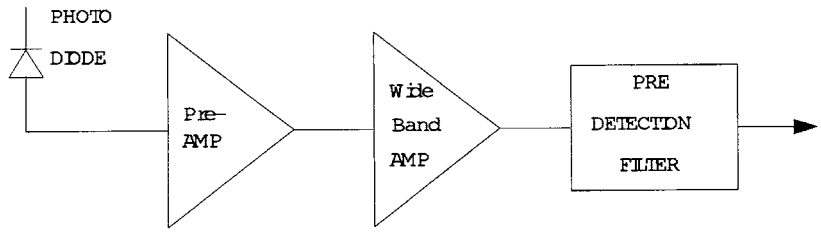

FIGURE 21.22 Front-end optical receiver.

Front-End Noise Sources

Receiver noise is dominated by two main noise sources: the detector (PIN photodiode) noise and the amplifier noise. Figure 21.23 illustrates the noise equivalent circuit of the optical receiver.

PIN Photodiode Noise

The noise generated by a PIN photodiode arises mainly from three shot noise contributions: quantum noise $S_q(f)$, thermally generated dark-current shot noise $S_D(f)$, and surface leakage-current shot noise $S_L(f)$. Other noise sources in a PIN photodiode, such as series resistor noise, are negligible in comparison. The quantum noise $S_q(f)$, also called signal-dependent shot noise, is produced by the light-generating nature of photonic detection and has a spectral density $S_q(f) = 2qI_{pd}\Delta f$, where I_{pd} is the mean signal current arising from the Poisson statistics. The dark-current shot noise $S_D(f)$ arises in the photodiode

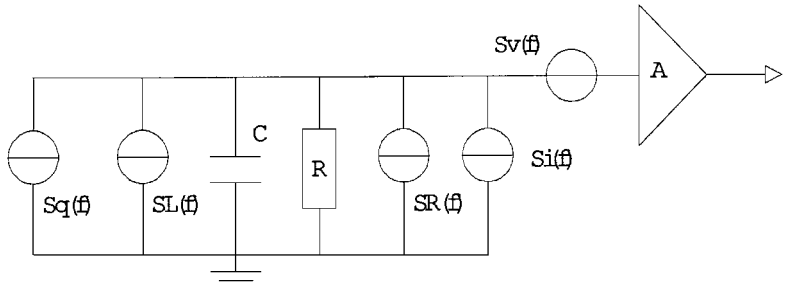

FIGURE 21.23 Noise equivalent circuit of the front-end optical receiver.

bulk material. Even when there is no incident optical power, a small reverse leakage current still flows, resulting in shot noise with a spectral density $S_D(f) = 2qI_{DB}\Delta f$, where I_{DB} is the mean thermally generated dark current. The leakage shot noise $S_L(f)$ occurs because of surface effects around the active region, and is described by $S_L(f) = 2qI_{SL}\Delta f$, where I_{SL} is the mean surface leakage current.

Amplifier Noise

For a simple noise analysis, the pre- and post-amplifiers in Fig. 21.22 are merged to a single amplifier with a transfer function of $A_v(\omega)$. The input impedance of the amplifier is modeled as a parallel combination of R_{in} and C_{in}.

If the photodiode noise is negligibly small, the amplifier noise will dominate the whole receiver noise performance, as can be inferred from Fig. 21.23. The equivalent noise current and voltage spectral densities of the amplifier are represented as $S_i(\text{A}^2/\text{Hz})$ and $S_v(\text{V}^2/\text{Hz})$, respectively.

Resistor Noise

The thermal noise generated by a resistor is directly proportional to the absolute temperature T and is represented by a series noise voltage generator or by a shunt noise current generator[21] of value:

$$\overline{v_R^2} = 4kTR\Delta f \qquad \text{or} \qquad \overline{i_R^2} = 4kT\frac{1}{R}\Delta f \tag{21.31}$$

where k is Boltzmann's constant and R is the resistance.

Receiver Performance Criteria

Equivalent Input Noise Current $\langle \overline{i_{eq}^2} \rangle$

The transfer function from the current input to the amplifier output voltage is given by:

$$Z_T(\omega) = \frac{V_{out}}{I_{pd}} = Z_{in}A_v(\omega) = \frac{R_{in}}{1j\omega R_{in}(C_{pd} + C_{in})}A_v(\omega) \tag{21.32}$$

where C_{pd} is the photodiode capacitance, and R_{in} and C_{in} are the input resistance and capacitance of the amplifier, respectively. Assuming that the photodiode noise contributions are negligible and that the amplifier noise sources are uncorrelated, the equivalent input noise current spectral density can be derived from Fig. 21.23 as:

$$S_{eq}(f) = S_i + \frac{S_v}{[Z_{in}]^2} = S_i + S_v\left[\frac{1}{R_{in}^2} + (2\pi f)^2(C_{pd} + C_{in})^2\right] \tag{21.33}$$

The total mean-square noise output voltage $\langle \overline{v_{no}^2} \rangle$ is calculated by combining Eqs. 21.32 and 21.33 as follows:

$$\langle \overline{v_{no}^2} \rangle = \int_0^\infty S_{eq}(f)|Z_T(f)|^2 df \tag{21.34}$$

This total noise voltage can be referred to the input of the amplifier by dividing it by the squared dc gain $|Z_T(0)|^2$ of the receiver, to give an equivalent input mean-square noise current:

$$\begin{aligned}\langle \overline{i_{eq}^2} \rangle &= \frac{\langle \overline{v_{no}^2} \rangle}{|Z_T(0)|^2} = \left(S_i + \frac{S_v}{R_{in}^2}\right)\int_0^\infty \frac{|Z_T(f)|^2}{|Z_T(0)|^2} df + S_v[2\pi(C_{pd} + C_{in})]^2 \int_0^\infty f^2 \frac{|Z_T(f)|^2}{|Z_T(0)|^2} df \\ &= \left(S_i + \frac{S_v}{R_{in}^2}\right) I_2 B + [2\pi(C_{pd} + C_{in})]^2 I_3 B^3 S_v\end{aligned} \tag{21.35}$$

where B is the operating bit-rate, and I_2(= 0.56) and I_3(= 0.083) are the Personick second and third integrals, respectively, as given in Ref. 22.

According to Morikoni et al.,[23] the Personick integral in Eq. 21.35 is correct only if a receiver produces a raised-cosine output response from a rectangular input signal at the cut-off bit rate above which the frequency response of the receiver is zero. However, the Personick integration method is generally preferred when comparing the noise (or sensitivity) performance of different amplifiers.

Optical Sensitivity

Optical sensitivity is defined as the minimum received optical power incident on a perfectly efficient photodiode connected to the amplifier, such that the presence of the amplifier noise corrupts on average only one bit per 10^9 bits of incoming data. Therefore, a detected power greater than the sensitivity level guarantees system operation at the desired performance. The optical sensitivity is predicted theoretically by calculating the equivalent input noise spectral density of the receiver, and is calculated[24] via Eq. 21.36:

$$S = 10\log_{10}\left(Q\frac{hc}{q\lambda}\sqrt{\langle \overline{i_{eq}^2} \rangle} \cdot \frac{1}{1\,mW}\right) \text{ (dBm)} \tag{21.36}$$

where h is Planck's constant, c is the speed of light, q is electronic charge, and λ (μm) is the wavelength of light in an optical fiber. $Q(= \sqrt{\text{SNR}})$, where SNR represents the required signal-to-noise ratio (SNR). The value of Q should be 6 for a bit error rate (BER) of 10^{-9}, and 7.04 for a BER of 10^{-12}. The relation between Q and BER is given by:

$$BER = \frac{\exp(-Q^2/2)}{\sqrt{2\pi}Q} \tag{21.37}$$

Since the number of photogenerated electrons in a single bit is very large (more than 10^4) for optoelectronic integrated receivers,[25] Gaussian statistics of the above BER equation can be used to describe the detection probability in PIN photodiodes.

SNR at the Photodiode Terminal[22]

Among the photodiode noise sources, quantum noise is generally dominant and can be estimated as:

$$\langle \overline{i_n^2} \rangle_q = 2qI_{pd}B_{eq} \tag{21.38}$$

where I_{pd} is the mean signal current and B_{eq} is the equivalent noise bandwidth. The signal-to-noise-ratio (SNR) referred to the photodiode terminal is thus given by:

$$\text{SNR} = \frac{{I_{pd}}^2}{\langle \overline{i_n^2} \rangle_{pd} + \frac{4kTB_{eq}}{R_B} + \langle \overline{i_{eq}^2} \rangle_{amp}} \tag{21.39}$$

where all noise contributions due to the amplifier are represented by the equivalent noise current where all noise contributions due to the amplifier are represented by the equivalent noise current $\langle \overline{i_{eq}^2} \rangle_{amp}$. It is often convenient to combine the noise contributions from the amplifier and the photodiode with the thermal noise from the bias resistor, by defining a noise figure NF:

$$\langle \overline{i_n^2} \rangle_{pd} + \frac{4kTB_{eq}}{R_B} + \langle \overline{i_{eq}^2} \rangle_{amp} = \frac{4kTB_{eq}\text{NF}}{R_B} \tag{21.40}$$

The SNR at the photodiode input is thus given by:

$$\text{SNR} \cong \frac{{I_{pd}}^2 R_B}{4kTB_{eq}\text{NF}} \tag{21.41}$$

Inter-Symbol Interference (ISI)

When a pulse passes through a band-limited channel, it gradually disperses. When the channel bandwidth is close to the signal bandwidth, the expanded rise and fall times of the pulse signal will cause successive pulses to overlap, deteriorating the system performance and giving higher error rates. This pulse overlapping is known as inter-symbol interference (ISI). Even with raised signal power levels, the error performance cannot be improved.[26]

In digital optical communication systems, sampling at the output must occur at the point of maximum signal in order to achieve the minimum error rate. The output pulse shape should therefore be chosen to maximize the pulse amplitude at the sampling instant and give a zero at other sampling points; that is, at multiples of $1/B$, where B is the data-rate. Although the best choice for this purpose is the sinc-function pulse, in practice a raised-cosine spectrum pulse is used instead. This is because the sinc-function pulse is very sensitive to changes in the input pulse shape and variations in component values, and because it is impossible to generate an ideal sinc-function.

Dynamic Range

The dynamic range of an optical receiver quantifies the range of detected power levels within which correct system operation is guaranteed. Dynamic range is conventionally defined as the difference between the minimum input power (which determines sensitivity) and the maximum input power (limited by overload level). Above the overload level, the bit-error-rate (BER) rises due to the distortion of the received signal.

Transimpedance (TZ) Amplifers

High-impedance (HZ) amplifiers are effectively open-loop architectures, and exhibit a high gain but a relatively low bandwidth. The frequency response is similar to that of an integrator, and thus HZ amplifiers require an output equalizer to extend their frequency capabilities. In contrast, the transimpedance (TZ) configuration exploits resistive negative feedback, providing an inherently wider bandwidth and eliminating the need for an output equalizer. In addition, the use of negative feedback provides a relatively low input resistance and thus the architecture is less sensitive to the photodiode parameters. In a TZ amplifier, the photodiode bias resistor R_B can be omitted, since bias current is now supplied through the feedback resistor.

In addition to wider bandwidth, TZ amplifiers offer a larger dynamic range because the transimpedance gain is determined by a linear feedback resistor, and not by a non-linear open-loop amplifier as is the case for HZ amplifiers. The dynamic range of TZ amplifiers is set by the maximum voltage swing available at the amplifier output, provided no integration of the received signal occurs at the front end. Since the TZ output stage is a voltage buffer, the voltage swing at the output can be increased with high current operation. The improvement in dynamic range in comparison to the HZ architecture is approximately equal to the ratio of open-loop to closed-loop gain.[27] Conclusively, the TZ configuration offers the better performance compromise compared to the HZ topology, and hence this architecture is preferred in optical receiver applications.

A schematic diagram of a TZ amplifier with PIN photodiode is shown in Fig. 21.24. With an open-loop, high-gain amplifier and a feedback resistor, the closed-loop transfer function of the TZ amplifier is given by:

$$Z_T(s) = \frac{-R_f}{\left(\frac{1+A}{A}\right) + sR_f\left[\frac{C_{in} + (1+A)C_f}{A}\right]} \cong \frac{R_f}{1 + sR_f\left(\frac{C_{in}}{A} + C_f\right)} \tag{21.42}$$

where A is the open-loop mid-band gain of the amplifier which is assumed to be greater than unity, R_f is the feedback resistance, C_{in} is the total input capacitance of the amplifier including the photodiode and the parasitic capacitance, and C_f represents the stray feedback capacitance. The –3 dB bandwidth of the TZ amplifier is approximately given by:

$$f_{-3d} = \frac{(1+A)}{2\pi R_f C_T} \tag{21.43}$$

where C_T is the total input capacitance including the photodiode capacitance. The TZ amplifier can thus have wider bandwidth by increasing the open-loop gain, although the open-loop gain cannot be increased indefinitely without stability problems.

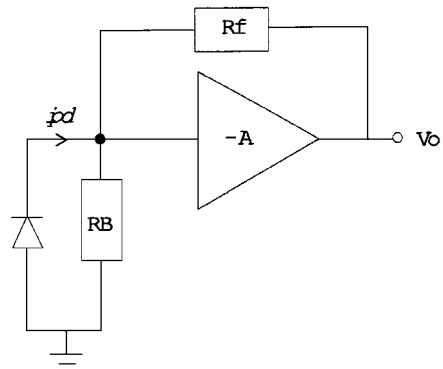

FIGURE 21.24 Schematic diagram of a transimpedance amplifier with photodiode.

However, a tradeoff between low noise and wide bandwidth exists, since the equivalent input noise current spectral density of TZ amplifier is given by:

$$S_{eq}(f) = \frac{4kT}{R_f} + \frac{4kT}{R_B} + S_i(f) + S_v(f)\left[\left(\frac{1}{R_f} + \frac{1}{R_B}\right)^2 + (2\pi f)^2(C_{pd} + C_{in})^2\right] \tag{21.44}$$

where C_{in} is the input capacitance of the input transistor. Increasing the value of R_f reduces the noise current in Eq. 21.44 but also shrinks the bandwidth in Eq. 21.43. This conflict can be mitigated by making A in Eq. 21.43 as large as the closed-loop stability allows.[28] However, the feedback resistance R_f cannot be increased indefinitely due to the dynamic range requirements of the amplifier, since too large a feedback resistance causes the amplifier to be overloaded at high signal levels. This overloading can be avoided by using automatic gain control (AGC) circuitry, which automatically reduces the transimpedance gain in discrete steps to keep the peak output signal constant.[27]

The upper limit of R_f is set by the peak amplitude of the input signal. Since the dc transimpedance gain is approximately equal to the feedback resistance R_f, the output voltage is given by $I_{pd} \times R_f$, where I_{pd} is the signal photocurrent. If this output voltage exceeds the maximum voltage swing at the output, the amplifier will be saturated and the output will be distorted, yielding bit errors. The minimum value of R_f is determined by the output signal level at which the performance of the receiver is degraded due to noise and offsets. For typical fiber-optic communication systems, the input signal power is unknown, and may vary from just above the noise floor to a large value enough to generate 0.5 mA at the detector diode.[29]

The TZ configuration has some disadvantages over HZ amplifiers. The power consumption is fairly high, partly due to the broadband operation provided by negative feedback. A propagation delay exists in the closed-loop of the feedback amplifier that may reduce the phase margin of the amplifier and cause peaking in the frequency response. Additionally, any stray feedback capacitance C_f will further deteriorate the ac performance.

Among three types of TZ configuration in CMOS technology (common-source, common-drain, and common-gate TZ amplifiers), the common-gate configuration has potentially the highest bandwidth due to its inherently lower input resistance. Using a common-gate input configuration, the resulting amplifier bandwidth can be made independent of the photodiode capacitance (which is usually the limiting factor in achieving GHz preamplifier designs). Recently, a novel common-gate TZ amplifier has been demonstrated, which shows superior performance compared to various other configurations.[30,31]

Layout for HF Operation

Wideband high-gain amplifiers have isolation problems irrespective of the choice of technology. Coupling from output to input, from the power supply rails, and from the substrate are all possible. Therefore, careful layout is necessary, and special attention must be given to stray capacitance, both on the integrated circuit and associated with the package.[32]

Input/Output Isolation

For stable operation, a high level of isolation between I/O is necessary. Three main factors degrade the I/O isolation[33,34]: (1) capacitive coupling between I/O signal paths through the air and through the substrate; (2) feedback through the dc power supply rails and ground-line inductance; and (3) the package cavity resonance since at the cavity resonant frequency, the coupling between I/O can become very large.

In order to reduce the unwanted coupling (or to provide good isolation, typically more than 60 dB) between I/O, the I/O pads should be laid out to be diagonally opposite each other on the chip with a thin 'left-to-right' geometry between I/O. The small input signal enters on the left-hand side of the chip, while the large output signal exits on the far right-hand side. This helps to isolate the sensitive input stages from the larger signal output stages.[35,36]

The use of fine line-widths and shielding are effective techniques to reduce coupling through the air. Substrate coupling can be reduced by shielding and by using a thin and low-dielectric substrate. Akazawa et al.[33] suggest a structure for effective isolation: a coaxial-like signal-line for high shielding, and a very thin dielectric dc feed-line structure for low characteristic impedance.

Reduction of Feedback Through the Power Supply Rails

Careful attention should be given to layout of power supply rails for stable operation and gain flatness. Power lines are generally inductive; thus, on-chip capacitive decoupling is necessary to reduce the

high-frequency power line impedance. However, a resonance between these inductive and capacitive components may occur at frequencies as low as several hundred MHz, causing a serious dip in the gain-frequency response and an upward peaking in the isolation-frequency characteristics. One way to reduce this resonance is to add a series damping resistor to the power supply line, making the Q factor of the LC resonance small. Additionally, the power supply line should be widened to reduce the characteristic impedance/inductance. In practice, if the characteristic impedance is as small as several ohms, the dip and peaking do not occur, even without resistive termination.[33]

Resonance also occurs between the IC pad capacitance (C_{pd}) and the bond-wire inductance (L_{bond}). This resonance frequency is typically above 2 GHz in miniature RF packages. Also in layout, the power supply rails of each IC chip stage should be split from the other stages in order to reduce the parasitic feedback (or coupling effect through wire-bonding inductance), which causes oscillation.[34] This helps to minimize crosstalk through power supply rail. The IC is powered through several pads and each pad is individually bonded to the power supply line.

I/O Pads

The bond pads on the critical signal path (e.g., input pad and output pads) should be made as small as possible to minimize the pad-to-substrate capacitance.[35] A floating n-well placed underneath the pad will further reduce the pad capacitance since the well capacitance will appear in series with the pad capacitance. This floating well also prevents the pad metal from spiking into the substrate.

High-Frequency (HF) Ground

The best possible HF grounds to the sources of the driver devices (and hence the minimization of interstage crosstalk) can be obtained by separate bonding of each source pad of the driver MOSFETs to the ground plane that is very close to the chip.[36] A typical bond-wire has a self-inductance of a few nH, which can cause serious peaking within the bandwidth of amplifiers or even instability. By using multiple bond-wires in parallel, the ground-line inductance can be reduced to less than 1 nH.

Flip-Chip Connection

In noisy environments, the noise-insensitive benefits of optical fibers may be lost at the receiver connection between the photodiode and the preamplifier. Therefore, proper shielding, or the integration of both components onto the same substrate, is necessary to prevent this problem. However, proper shielding is costly, while integration restricts the design to GaAs technologies.

As an alternative, the flip-chip interconnection technique using solder bumps has been used.[37,38] Small solder bumps minimize the parasitics due to the short interconnection lengths and avoid damages by mechanical stress. Also, it needs relatively low-temperature bonding and hence further reduces damage to the devices. Easy alignment and precise positioning of the bonding can be obtained by a self-alignment effect. Loose chip alignment is sufficient because the surface tension of the molten solder during re-flow produces precise self-alignment of the pads.[34] Solder bumps are fabricated onto the photodiode junction area to reduce parasitic inductance between the photodiode and the preamplifier.

21.5 Fundamentals of RF Power Amplifier Design

PA Requirements

An important functional block in wireless communication transceivers is the power amplifier (PA). The transceiver PA takes as input the modulated signal to be transmitted, and amplifies this to the power level required to drive the antenna. Because the levels of power required to transmit the signal reliably are often fairly high, the PA is one of the major sources of power consumption in the transceiver. In many systems, power consumption may not be a major concern, as long as the signal can be transmitted with adequate power. For battery-powered systems, however, the limited amount of available energy means that the power consumed by all devices must be minimized so as to extend the transmit time.

Therefore, power efficiency is one of the most important factors when evaluating the performance of a wireless system.

The basic requirement for a power amplifier is the ability to work at low supply voltages as well as high operating frequencies, and the design becomes especially difficult due to the tradeoffs between supply voltage, output power, distortion, and power efficiency that can be made. Moreover, since the PA deals with large signals, small-signal analysis methods cannot be applied directly. As a result, both the analysis and the design of PAs are challenging tasks.

This section will first present a study of various configurations employed in the design of state-of-the-art non-linear RF power amplifiers. Practical considerations toward achieving full integration of PAs in CMOS technology will also be highlighted.

Power Amplifier Classification

Power amplifiers currently employed for wireless communication applications can be classified into two categories: linear power amplifiers and non-linear power amplifiers. For linear power amplifiers, the output signal is controlled by the amplitude, frequency, and phase of the input signal. Conversely, for non-linear power amplifiers, the output signal is only controlled by the frequency of input signal.

Conventionally, linear power amplifiers can be classified as Class A, Class B, or Class AB. These PAs produce a magnified replica of the input signal voltage or current waveform, and are typically used where accurate reproduction of both the envelope and the phase of the signal is required. However, either poor power efficiency or large distortion prevents them from being extensively employed in wireless communications.

Many applications do not require linear RF amplification. Gaussian Minimum Shift Keying (GMSK),[39] the modulation scheme used in the European standard for mobile communications (GSM), is an example of constant envelope modulation. In this case, the system can make use of the greater efficiency and simplicity offered by non-linear PAs. The increased efficiency of non-linear PAs, such as Class C, Class D, and Class E, results from techniques that reduce the average collector voltage–current product (i.e., power dissipation) in the switching device. Theoretically, these switching-mode PAs have 100% power efficiency since, ideally, there is no power loss in the switching device.

Linear Power Amplifiers

Class A

The basic structure of the Class A power amplifier is shown in Fig. 21.25.[40] For Class A amplification, the conduction angle of the device is 360°, that is, the transistor is in its active region for the entire input

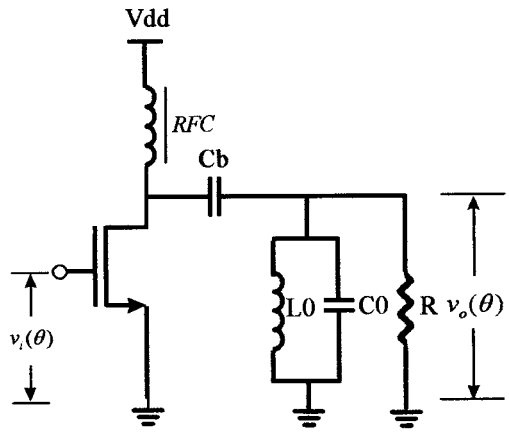

FIGURE 21.25 Single-ended Class A power amplifier.

cycle. The serious shortcoming with Class A PAs is their inherently poor power efficiency, since the transistor is always dissipating power. The efficiency of a single-ended Class A PA is ideally limited to 50%. However, in practice, few designs can reach this ideal efficiency due to additional power loss in the passive components. In an inductorless configuration, the efficiency is only about 25%.[41]

Class B

A PA is defined as Class B when the conduction angle for each transistor of a push-pull pair is 180° during any one cycle. Figure 21.26 shows an inductorless Class B power amplifier. Since each transistor only conducts for half of the cycle, the output suffers crossover distortion due to the finite threshold voltage of each transistor. When no signal is applied, there is no current flowing; as a result, any current through either device flows directly to the load, thereby maximizing the efficiency. The ideal efficiency can reach 78%,[41] allowing this architecture to be of use in applications where linearity is not the main concern.

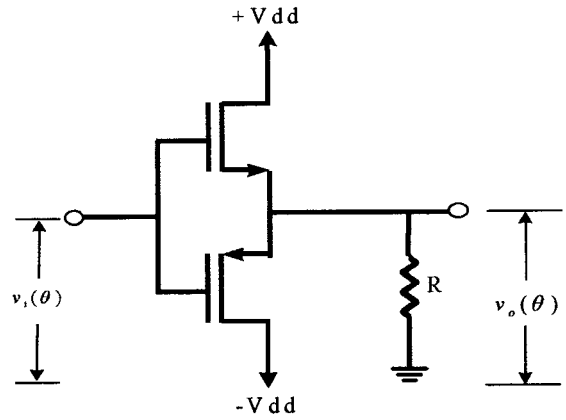

FIGURE 21.26 Inductorless Class B power amplifier.

Class AB

The basic idea of Class AB amplification is to preserve the Class B push-pull configuration while improving the linearity by biasing each device slightly above threshold. The implementation of Class AB PAs is similar to Class B configurations. By allowing the two devices to conduct current for a short period, the output voltage waveform during the crossover period can be smoothed, which thus reduces the crossover distortion of the output signal.

Nonlinear Power Amplifiers

Class C

A Class C power amplifier is the most popular non-linear power amplifier used in the RF band. The conduction angle is less than 180° since the switching transistor is biased on the verge of conduction. A portion of the input signal will make the transistor operate in the amplifying region, and thus the drain current of the transistor is a pulsed signal. Figures 21.27(a) and (b) show the basic configuration of a Class C power amplifier and its corresponding waveforms; clearly, the input and output voltages are not linearly related.

The efficiency of an ideal Class C amplifier is 100% since at any point in time, either the voltage or the current waveforms are zero. In practice, this ideal situation cannot be achieved, and the power efficiency should be maximized by reducing the power loss in the transistor. That is, minimize the current through the transistor when the voltage across the output is high, and minimize the voltage across the output when the current flows through the device.

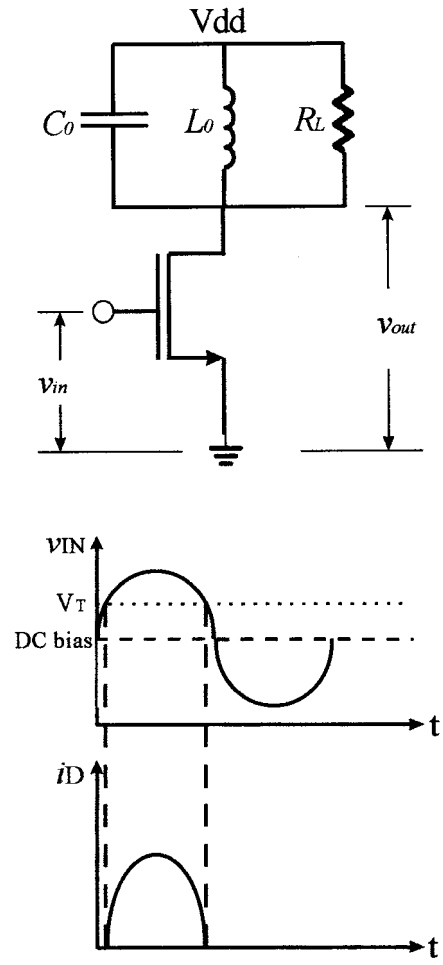

FIGURE 21.27 (a) Class C power amplifier, and (b) Class C waveforms.

Class D

A Class D amplifier employs a pair of transistors and a tuned output circuit, where the transistors are driven to act as a two-pole switch and the output circuit is tuned to the switching frequency. The theoretical power efficiency is 100%. Figure 21.28 shows the voltage-switching configuration of a Class D amplifier. The input signals of transistors Q_1 and Q_2 are out of phase, and consequently when Q_1 is on, Q_2 is off, and vice versa. Since the load network is a tuned circuit, we can assume that it provides little impedance to the operating frequency of the voltage v_d and high impedance to other harmonics. Since v_d is a square wave, its Fourier expansion is given by

$$v_d(\omega t) = V_{dc}\left[\frac{1}{2} + \frac{2}{\pi}\sin(\omega t) + \frac{2}{3\pi}\sin(3\omega t)\ldots\right] \tag{21.45}$$

The impedance of the RLC series load at resonance is equal to R_L, and thus the current is given by:

$$i_L(\omega t) = \frac{2V_{dc}}{\pi R_L}\sin(\omega t) \tag{21.46}$$

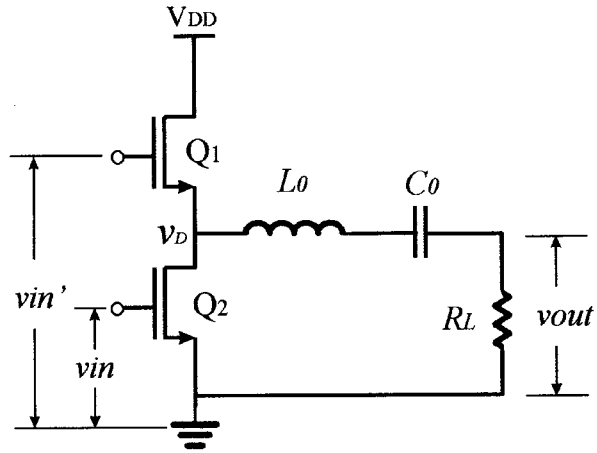

FIGURE 21.28 Class D power amplifier.

Each of the devices carries the current during one half of the switching cycle. Therefore, the output power is given by:

$$P_o = \frac{2}{\pi^2}\frac{V_{dc}^{\ 2}}{R_L} \tag{21.47}$$

Design efforts should focus on reducing the switching loss of both transistors as well as generating the input driving signals.

Class E

The idea behind the Class E PA is to employ non-overlapping output voltage and output current waveforms. Several criteria for optimizing the performance can be found in Ref. 42. Following these guidelines, Class E PAs have high power efficiency, simplicity, and relatively high tolerance to circuit variations.[43] Since there is no power loss in the transistor as well as in the other passive components, the ideal power efficiency is 100%. Figure 21.29 shows a class E PA, and the corresponding waveforms are given in Fig. 21.30.

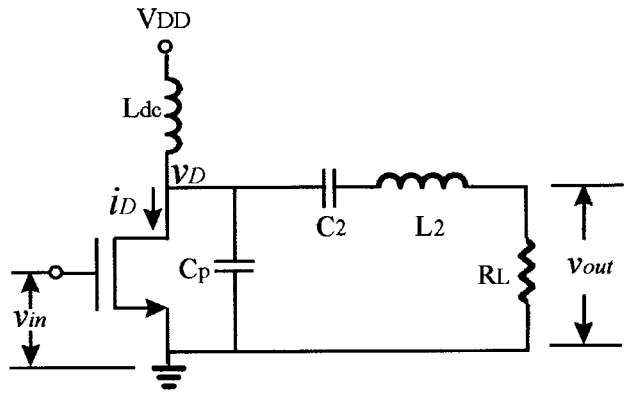

FIGURE 21.29 Class E power amplifier.

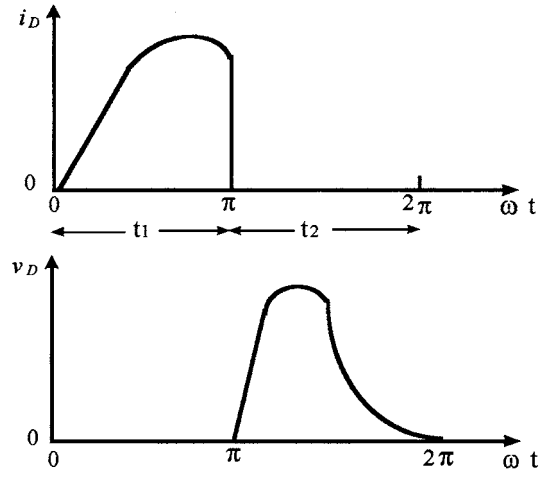

FIGURE 21.30 Waveforms of Class E operation.

The Class E waveforms indicate that the transistor should be completely off before the voltage across it changes, and that the device should be completely on before it starts to allow current to flow through it. Refs. 44 and 45 demonstrate practical Class E operation at RF frequencies using a GaAs process.

Practical Considerations for RF Power Amplifiers

More recently, single-chip solutions for RF transceivers have become a goal for modern wireless communications due to potential savings in power, size, and cost. CMOS must clearly be the technology of choice for a single-chip transceiver due to the large amount of digital baseband processing required. However, the power amplifier design presents a bottleneck toward full integration, since CMOS power amplifiers are still not available. The requirements of low supply voltage, gigahertz-band operation, and high output power make the implementation of CMOS PAs very demanding. The proposal of "microcell" communications may lead to a relaxed demand for output power levels that can be met by designs such as that described in Ref. 46, where a CMOS Class C PA has demonstrated up to 50% power efficiency with 20 mW output power.

Non-linear power amplifiers seem to be popular for modern wireless communications due to their inherent high power efficiency. Since significant power losses occur in the passive inductors as well as the switching devices, the availability of on-chip, low-loss passive inductors is important. The implementation of CMOS on-chip spiral inductors has therefore become an active research topic.[47]

Due to the poor spectral efficiency of a constant envelope modulation scheme, the high power efficiency benefit of non-linear power amplifiers is eliminated. A recently proposed linear transmitter using a non-linear power amplifier may prove to be an alternative solution.[48] The development of high mobility devices such as SiGe HBTs has led to the design of PAs demonstrating output power levels up to 23 dBm at 1.9 GHz with power-added efficiency of 37%.[49] Practical power amplifier designs require that much attention be paid to issues of package and harmonic terminations. Power losses in the matching networks must be absolutely minimized, and tradeoffs between power-added efficiency and linearity are usually achieved through impedance matching. Although GaAs processes provide low-loss impedance matching structures on the semi-insulating substrate, good shielding techniques for CMOS may prove to be another alternative.

Conclusions

Although linear power amplifiers provide conventional "easy-design" characteristics and linearity for modulation schemes such as π/4-DQPSK, modern wireless transceivers are more likely to employ

non-linear power amplifiers due to their much higher power efficiency. As the development of high-quality on-chip passive components makes progress, the trend toward full integration of the PA is becoming increasingly plausible.

The rapid development of CMOS technology seems to be the most promising choice for PA integration, and vast improvements in frequency performance have been gained through device scaling. These improvements are expected to continue as silicon CMOS technologies scale further, driven by the demand for high-performance microprocessors. The further development of high mobility devices such as SiGe HBTs may finally see GaAs MOSFETs being replaced by wireless communication applications, since SiGe technology is compatible with CMOS.

21.6 Applications of High-Q Resonators in IF-Sampling Receiver Architectures

Transconductance-C (gm-C) filters are currently the most popular design approach for realizing continuous-time filters in the intermediate frequency range in telecommunications systems. This section will consider the special application area of high-Q resonators for receiver architectures employing IF sampling.

IF Sampling

A design approach for contemporary receiver architectures that is currently gaining popularity is IF digitization, whereby low-frequency operations such as second mixing and filtering can be performed more efficiently in the digital domain. A typical architecture is shown in Fig. 21.31. The IF signal is digitized, multiplied with the quadrature phases of a digital sinusoid, and lowpass filtered to yield the quadrature baseband signals. Since processing takes place in the digital domain, I/Q mismatch problems are eliminated. The principal issue in this approach, however, is the performance required from the A/D converter (ADC). Noise referred to the input of the ADC must be very low so that selectivity remains high. At the same time, the linearity of the ADC must be high to minimize corruption of the wanted signal through intermodulation effects. Both the above requirements should be achieved at an input bandwidth commensurate with the value of the IF frequency, and at an acceptable power budget.

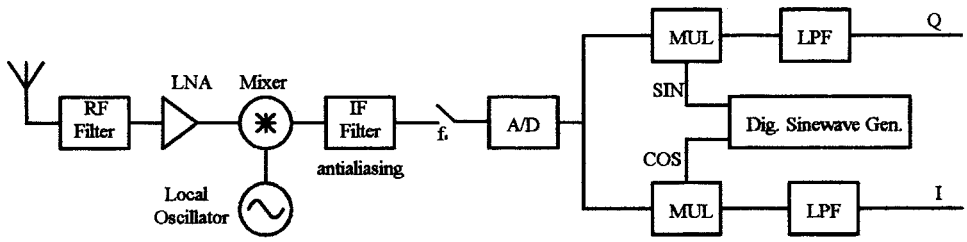

FIGURE 21.31 IF-sampling receiver.

Oversampling has become popular in recent years because it avoids many of the difficulties encountered with conventional methods for A/D and D/A conversion. Conventional converters are often difficult to implement in fine-line, very large-scale integration (VLSI) technology, because they require precise analog components and are very sensitive to noise and interference. In contrast, oversampling converters trade off resolution in time for resolution in amplitude, in such a way that the imprecise nature of the analog circuits can be tolerated. At the same time, they make extensive use of digital signal processing power, taking advantage of the fact that fine-line VLSI is better suited for providing fast digital circuits than for

providing precise analog circuits. Therefore, IF-digitization techniques utilizing oversampling Sigma-Delta modulators are very well suited to modern sub-micron CMOS technologies, and their potential has made them the subject of active research.

Most Delta-Sigma modulators are implemented with discrete-time circuits, switched-capacitor (SC) implementations being by far the most common. This is mainly due to the ease with which monolithic SC filters can be designed, as well as the high linearity which they offer. The demand for high-speed ΣΔ oversampling ADCs, especially for converting bandpass signals, makes it necessary to look for a technique that is faster than switched-capacitor. This demand has stimulated researchers to develop a method for designing continuous-time ΔΣ ADCs. Although continuous-time modulators are not easy to integrate, they possess a key advantage over their discrete-time counterparts. The sampling operation takes place inside the modulator loop, making it is possible to "noise-shape" the errors introduced by sampling, and provide a certain amount of anti-aliasing filtering at no cost. On the other hand, they are sensitive to memory effects in the DACs and are very sensitive to jitter. They must also process continuous-time signals with high linearity. In communications applications, meeting the latter requirement is complicated by the fact that the signals are located at very high frequencies.

As shown in Fig. 21.32, integrated bandpass implementations of continuous-time modulators require integrated continuous-time resonators to provide the noise shaping function. The gm-C approach of realizing continuous-time resonators offers advantages of complete system integration and total design freedom. However, the design of CMOS high-Q high-linearity resonators at the tens of MHz is very challenging. Since the linearity of the modulator is limited by the linearity of the resonators utilized, the continuous-time resonator is considered to be the most demanding analog sub-block of a bandpass continuous-time Sigma-Delta modulator. Typical specifications for a gm-C resonator used to provide the noise-shaping function in a ΣΔ modulator in a mobile receiver (see Fig. 21.32) are summarized in Table 21.4.

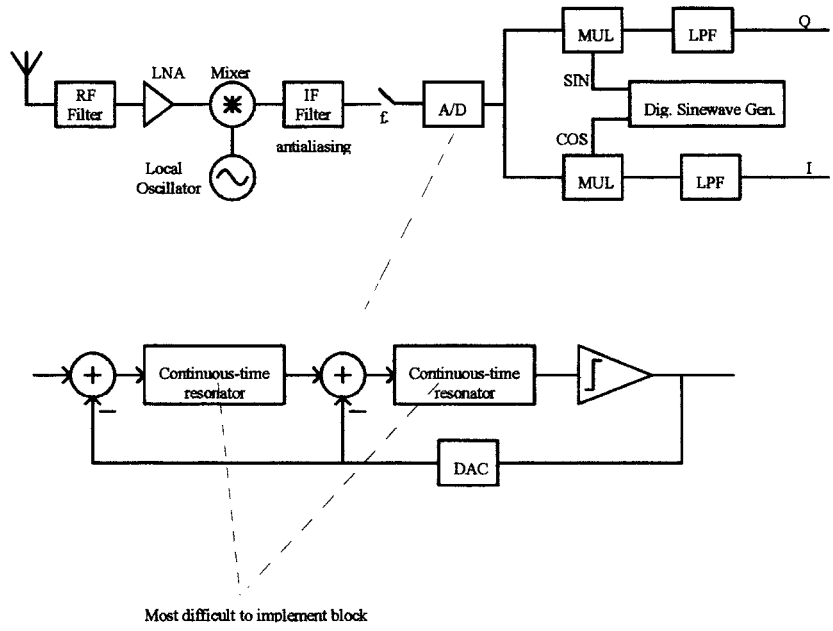

FIGURE 21.32 Continuous-time ΣΔ A/D in IF-sampling receiver.

Linear Region Transconductor Implementation

The implementation of fully integrated, high-selectivity filters operating at tens to hundreds of MHz provides benefits for wireless transceiver design, including chip area economy and cost reduction. The

TABLE 21.4 Fully Integrated Continuous-Time Resonator Specifications

Power dissipation	Minimal

main disadvantages of on-chip active filter implementations when compared to off-chip passives include increased power dissipation, deterioration in the available dynamic range with increasing Q, and Q and resonant frequency integrity (because of process variations, temperature drifts, and aging, automatic tuning is often unavoidable, especially in high-Q applications). The transconductor-capacitor (gm-C) technique is a popular technique for implementing high-speed continuous time filters and is widely used in many industrial applications.[52] Because gm-C filters are based on integrators built from an open-loop transconductance amplifier driving a capacitor, they are typically very fast but have limited linear dynamic range. Linearization techniques that reduce distortion levels can be used, but often lead to a compromise between speed, dynamic range, and power consumption.

As an example of the tradeoffs in design, consider the transconductor shown in Fig. 21.33. This design consists of a main transconductor cell (M1, M2, M3, M4, M10, M11, and M14) with a negative resistance load (M5, M6, M7, M8, M9 , M12, and M13). Transistors M1 and M2 are biased in the triode region of operation using cascode devices M3 and M4 and determine the transconductance gain of the cell. In the triode region of operation, the drain current versus terminal voltage relation can be approximated (for simple hand calculations) as $I_D = K[2(V_{GS} - V_T)V_{DS} - V_{DS}^2]$, where K and V_T are the transconductance parameter and the threshold voltage respectively. Assuming that V_{DS} is constant for both M1 and M2, both the differential mode and the common mode transconductance gains can be derived as $G_{DM} = G_{CM} = 2KV_{DS}$, which can thus be tuned by varying V_{DS}.

The high value of common-mode transconductance is undesirable since it may result in regenerative feedback loops in high-order filters. To improve the CMRR transistor and avoid the formation of such loops, M10 is used to bias the transconductor, thus transforming it from a pseudo-differential to a fully differential transconductor.[53] Transistors M11 and M14 constitute a floating voltage source, thus maintaining a constant drain-source voltage for M1 and M2.

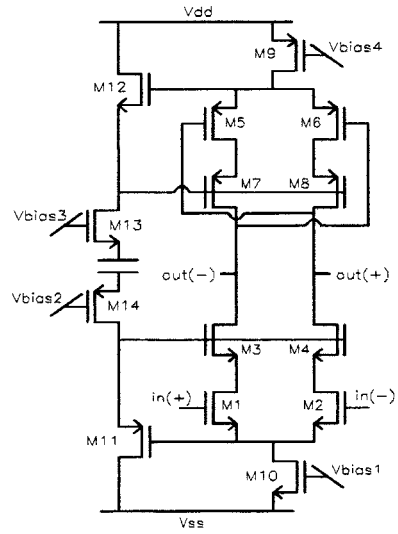

FIGURE 21.33 Triode region transconductor.

The non-linearities in the voltage-to-current transfer of this stage are mainly due to three effects. The first is the finite impedance levels at the sources of the cascode devices, which cause a signal-dependent variation of the corresponding drain-source voltages of M1 and M2. A fast floating voltage source and large cascode transistors therefore need to be used to minimize this non-linearity. The second cause of non-linearity is the variation of carrier mobility μ of the input devices M1 and M2 with $V_{GS} - V_T$, which becomes more apparent when short-channel devices are used ($K = \mu \cdot C_{ox} \cdot W/2 \cdot L$). A simple first-order model for transverse-field mobility degradation is given by $\mu = \mu_0/(1 + \theta \cdot (V_{GS} - V_T))$, where μ_0 and θ are the zero field mobility and the mobility reduction parameter, respectively. Using this model, the third-order distortion can be determined by a Maclaurin series expansion as $\theta^2/4(1 + \theta(V_{CM} - V_T))$.[54] This expression cannot be regarded as exact, although it is useful to obtain insight. Furthermore, it is valid only at low frequencies, where reactive effects can be ignored and the coefficients of the Maclaurin series expansion are frequency independent. At high frequencies or when very low values of distortion are predicted by the Maclaurin series method, a generalized power series method (Volterra series) must be employed.[55,56] Finally, a further cause of non-linearity is mismatch between M1 and M2, which can be minimized by good layout. A detailed linearity analysis of this transconductance stage is presented in Ref. 60.

To provide a load for the main transconductor cell, a similar cell implemented by p-devices is used. The gates of the linear devices M5 and M6 are now cross-coupled with the drains of the cascode devices M7 and M8. In this way, weak positive feedback is introduced. The differential-mode output resistance can now become negative and is tuned by the V_{DS} of M5 and M6 (M12 and M13 form a floating voltage source), while the common-mode output resistance attains a small value.

When connected to the output of the main transconductor cell as shown in Fig. 21.33, the cross-coupled p-cell forms a high-ohmic load for differential signals and a low-ohmic load for common-mode signals, resulting in a controlled common-mode voltage at the output.[54,57] CMRR can be increased even further using M10, as described previously. Transistor M9 is biased in the triode region of operation and is used to compensate the offset common-mode voltage at the output.

The key performance parameter of an integrator is the phase shift at its unity-gain frequency. Deviations from the ideal –90° phase include phase lead due to finite dc gain and phase lag due to high-frequency parasitic poles. In the transconductor design of Fig. 21.33, dc gain is traded for phase accuracy, thus compensating the phase lag introduced by the parasitic poles. The reduction in dc gain for increased phase accuracy is not a major problem for bandpass filter applications, since phase accuracy at the center frequency is extremely important while dc gain has to be adequate to ensure that attenuation specifications are met at frequencies below the passband.

From simulation results using parameters from a 0.8-μm CMOS process, with the transconductor unity gain frequency set at 50 MHz, third-order intermodulation components were observed at –78 dB with respect to the fundamental signals (two input signals at 49.9 MHz and 50.1 MHz were applied, each at 50 mVpp).

A gm-C Bandpass Biquad

Filter Implementation

The implementation of on-chip high-Q resonant circuits presents a difficult challenge. Integrated passive inductors have generally poor quality factors, which limits the Q of any resonant network in which they are employed. For applications in the hundreds of MHz to a few GHz, one approach is to implement the resonant circuit using low-Q passive on-chip inductors with additional Q-enhancing circuitry. However, for lower frequencies (tens of MHz), on-chip inductors occupy a huge area and this approach is not attractive.

As disscussed above, an alternative method is to use active circuitry to eliminate the need for inductors. gm-C-based implementations are attractive due to their high-speed potential and good tunability. A bandpass biquadratic section based upon the transconductor of Fig. 21.33 is shown in Fig. 21.34. The transfer function of Fig. 21.34 is given by:

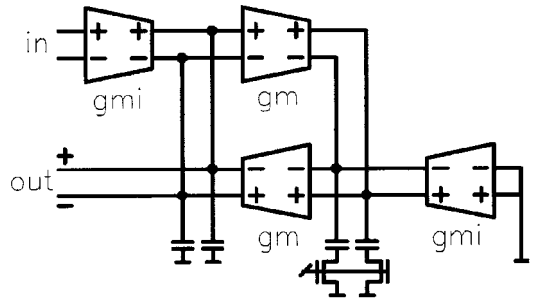

FIGURE 21.34 Biquad bandpass.

$$\frac{V_o}{V_i} = \frac{g_{mi} \cdot R_o}{(R_o \cdot C)^2} \cdot \frac{(1 + s \cdot R_o \cdot C)}{\left\{ s^2 + s\frac{2 \cdot R_o + g_m{}^2 \cdot R_o{}^2 \cdot R}{R_o{}^2 \cdot C} + \frac{1 + g_m{}^2 \cdot R_o{}^2}{R_o{}^2 \cdot C^2} \right\}} \tag{21.48}$$

R_o represents the total resistance at the nodes due to the finite output resistance of the transconductors. R represents the effective resistance of the linear region transistors in the transconductor (see Fig. 21.33), and is used here to introduce damping and control the Q. From Eq. 21.48, it can be shown that $\omega_o \approx g_m/C$, $Q \approx g_m \cdot R_o/(2 + R_o \cdot R \cdot g_m{}^2)$, $Q_{max} = Q|_{r=0} = (g_m \cdot R_o)/2$ and $A_o = g_{mi} \cdot Q$. Thus, g_m is used to set the central frequency, R is used to control the Q, and g_{mi} controls the bandpass gain A_o. A dummy g_{mi} is used to provide symmetry and thus better stability due to process variations, temperature, and aging.

One of the main problems when implementing high-Q high-frequency resonators is maintaining the stability of the center frequency ω_o and the quality factor Q. This problem calls for very careful layout and the implementation of an automatic tuning system. Another fundamental limitation regarding available dynamic range occurs: namely, that the dynamic range (DR) of high-Q gm-C filters has been found to be inversely proportional to the filter Q.[57] The maximum dynamic range is given by:

$$\text{DR} = \frac{V_{max}{}^2}{V_{noise}{}^2} = \frac{V_{max}{}^2 \cdot C}{4 \cdot k \cdot T \cdot \xi \cdot Q} \tag{21.49}$$

where V_{max} is the maximum rms voltage across the filter capacitors, C is the total capacitance, k is Boltzman's constant, T is the absolute temperature, and ξ is the noise factor of the active circuitry ($\xi = 1$ corresponds to output noise equal to the thermal noise of a resistor of value $R = 1/g_m$, where g_m is the transconductor value used in the filter).

In practice, the dynamic range achieved will be less than this maximum value due to the amplification of both noise and intermodulation components around the resonant frequency. This is a fundamental limitation, and the only solution is to design the transconductors for low noise and high linearity. The linearity performance in narrowband systems is characterized by the spurious-free dynamic range (SFDR). SFDR is defined as the signal-to-noise ratio when the power of the third-order intermodulation products equals the noise power. As shown in Ref. 60, the SFDR of the resonator in Fig. 21.34 is given by:

$$\text{SFDR} = \frac{1}{2(k \cdot T)^{2/3}} \left(\frac{3 \cdot V_{o,\,peak}{}^2 \cdot C}{4 \cdot \xi \cdot IM_{3,\,int}} \right)^{2/3} \frac{1}{Q^2} \tag{21.50}$$

where $IM_{3,\,int}$ is the third-order intermodulation point of the integrator used to implement the resonator. The spurious free dynamic range of the resonator thus deteriorates by 6 dB if the quality factor is doubled,

assuming that the output swing remains the same. In contrast, implementing a resonant circuit using low-Q passive on-chip inductors with additional Q-enhancing circuitry leads to a dynamic range amplified by a factor Q_o, where Q_o is the quality factor of the on-chip inductor itself.[59] However, as stated above, for frequencies in the tens of MHz, on-chip inductors occupy a huge area and thus the Q_o improvement in dynamic range is not high enough to justify the area increase.

Simulation Results

To confirm operation, the filter shown in Fig. 21.34 has been simulated in HSPICE using process parameters from a commercial 0.8-μm CMOS process. Figure 21.35 shows the simulated frequency and phase response of the filter for a center frequency of 50 MHz and a quality factor of 50. Figure 21.36 shows the simulated output of the filter when the input consists of two tones at 49.9 MHz and 50.1 MHz, respectively, each at 40 mVpp. At this level of input signal, the third-order intermodulation components were found to be at the same level as the noise. Thus, the predicted SFDR is about 34 dB with Q = 50. Table 21.5 summarizes the simulation results.

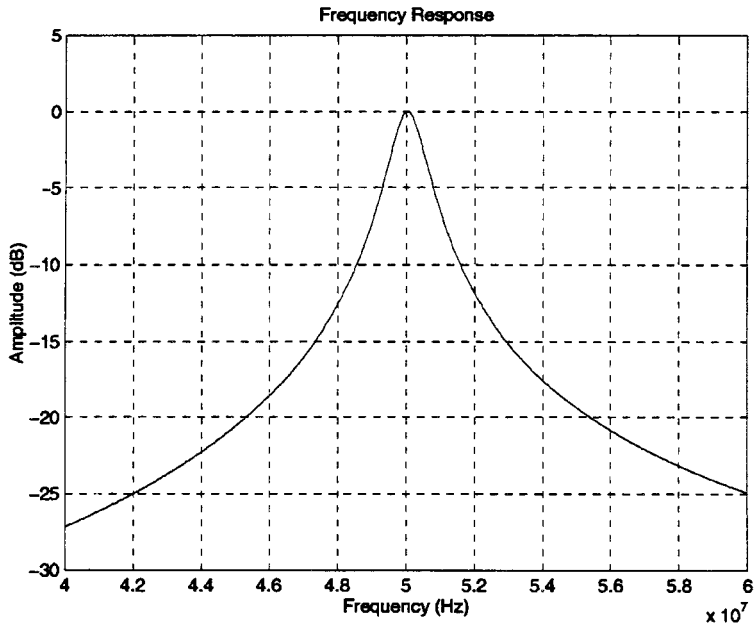

FIGURE 21.35 Simulated bandpass frequency response.

21.7 Log-Domain Processing

Instantaneous Companding

The concept of *instantaneous companding* is an emerging area of interest within the field of analog integrated circuit design. Currently, the main area of application for this technique is the implementation of continuous-time, fully integrated filters with wide dynamic range, high-frequency potential, and wide tunability.

With the drive toward lower supply voltages and higher operating frequencies, traditional analog integrated circuit design methodologies are proving inadequate. Conventional techniques to linearize inherently non-linear devices require an overhead in terms of increased power consumption or reduced operating speed. Recently, the use of companding, originally developed for audio transmission, has been

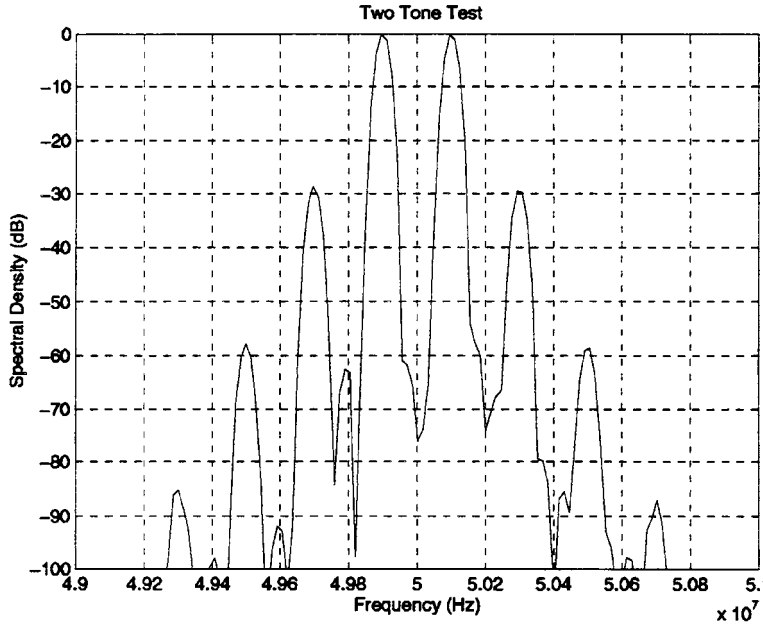

FIGURE 21.36 Simulated two-tone intermodulation test.

TABLE 21.5 Simulation Results

Power dissipation (Supply voltage = 5 V)	12.5 mW
Common-mode output offset	<1 mV
Center frequency	50 MHz
Quality factor	50
Output noise voltage (integrated over the band from 40 MHz to 60 MHz with Q = 50)	500 μV_{rms}
Output signal voltage (so that intermodulation components are at the same level as the noise, Q = 50)	25.2 mV_{rms}
Spurious free dynamic range (Q = 50)	34 dB

proposed as an elegant solution to the problem of maintaining dynamic range and high-frequency operation under low supply voltage.[50] In this approach, non-linear amplifiers are used to compress the dynamic range of the input signal to ensure, for example, that signal levels always remain above a certain noise threshold but below levels that may cause overload. The overall system must thus adapt its operation to ensure that input-output linearity is maintained as the instantaneous signal level alters. Although the system is input-output linear, signals internal to the system are inherently non-linear. Companding has traditionally been realized in two ways — syllabic and instantaneous — depending on how the system adapts in response to the changing input signal level. In *syllabic* companding, the level of compression (and expansion) is a non-linear function of a slowly varying property of the signal (e.g., envelope or power). In contrast, *instantaneous* companding adapts the compression and expansion ratios instantaneously with the changing input signal amplitude.

Perhaps the best-known recent example of this approach is the log-domain technique, where the exponential I–V characteristics of bipolar junction transistors (BJTs) are directly exploited to implement input-output linear filters. Since the large signal device equations are utilized, there is no need for small signal operation or local linearization techniques, and the resulting circuits have the potential for wide dynamic range and high-frequency operation under low power supply voltages. Log-domain circuits are generally implemented using BJTs and capacitors only and thus are inherently suitable for integration.

The filter parameters are easily tunable, which makes them robust. In addition, the design procedure is systematic, which suggests that these desirable features can be reproduced for different system implementations. The following section provides an introduction to the synthesis of log-domain filters and highlights various performance issues. Interested readers are advised to consult Refs. 62 through 77 for a more detailed treatment of the subject.

Log-Domain Filter Synthesis

The synthesis of log-domain filters using state-space transformations was originally proposed by Frey.[63] As an example of this methodology, consider a biquad filter with the following transfer function:

$$Y(s) = \frac{s\omega_o U_1(s) + \omega_o^{\,2} U_2(s)}{s^2 + (\omega_o/Q)s + \omega_o^{\,2}} \tag{21.51}$$

Thus, using u_1 as input gives a bandpass response at the output y, while using u_2 as input gives a lowpass response. This system can also be described by the following state space equations:

$$\begin{aligned} \dot{x}_1 &= -(\omega_o/Q)x_1 - \omega_o x_2 + \omega_o u_1 \\ \dot{x}_2 &= -\omega_o x_1 - \omega_o u_2 \\ y &= x_1 \end{aligned} \tag{21.52}$$

where a 'dot' denotes differentiation in time. To transform these linear state equations into non-linear nodal equations that can be directly implemented using bipolar transistors, the following exponential transformations are defined:

$$\begin{aligned} x_1 &= I_S \exp\left(\frac{V_1}{V_t}\right) \qquad & u_1 &= \left(\frac{I_S^{\,2}}{I_o}\right)\exp\left(\frac{V_{in1}}{V_t}\right) \\ x_2 &= I_o \exp\left(\frac{V_2}{V_t}\right) \qquad & u_2 &= I_S \exp\left(\frac{V_{in2}}{V_t}\right) \end{aligned} \tag{21.53}$$

These transformations map the linear state variables to currents flowing through bipolar transistors (BJTs) biased in the active region. I_S represents the BJT reverse saturation current, while V_t is the thermal voltage. Substituting these transformations into the state (Eq. 21.52) gives:

$$\begin{aligned} C\dot{V}_1 &= -\frac{I_o}{Q} - \frac{I_o^{\,2}}{I_S}\exp\left(\frac{V_2 - V_1}{V_t}\right) + I_S \exp\left(\frac{V_{o1} - V_1}{V_t}\right) \\ C\dot{V}_2 &= I_S \exp\left(\frac{V_1 - V_2}{V_t}\right) - I_S \exp\left(\frac{V_{o2} - V_2}{V_t}\right) \\ y &= I_S \exp\left(\frac{V_1}{V_t}\right) \end{aligned} \tag{21.54}$$

In Eq. 21.54, a tuning current $I_o = C\omega_o V_t$ is defined, where C is a scaling factor which represents a capacitance. The linear state space equations have thus been transformed into a set of non-linear nodal equations, and the task for the designer is now to realize a circuit architecture that will implement these non-linear equations. Considering the first two equations in Eq. 21.54, the terms on the LHS can be implemented as currents flowing through grounded capacitors of value C connected at nodes V_1 and V_2, respectively. The expressions on the RHS can be implemented by constant current sources in conjunction

with appropriately biased bipolar transistors to realize the exponential terms. The third equation in Eq. 21.54 indicates that the output y can be obtained as the collector current of a bipolar transistor biased with a base–emitter voltage V_1.

Figure 21.37 shows a possible circuit implementation, which is derived using Gilbert's translinear circuit principle.[64] The detailed circuit implementation is described in more detail in Ref. 63. The center frequency of this filter is given by $\omega_o = (I_o/CV_t)$ and can thus be tuned by varying the value of the bias current I_o.

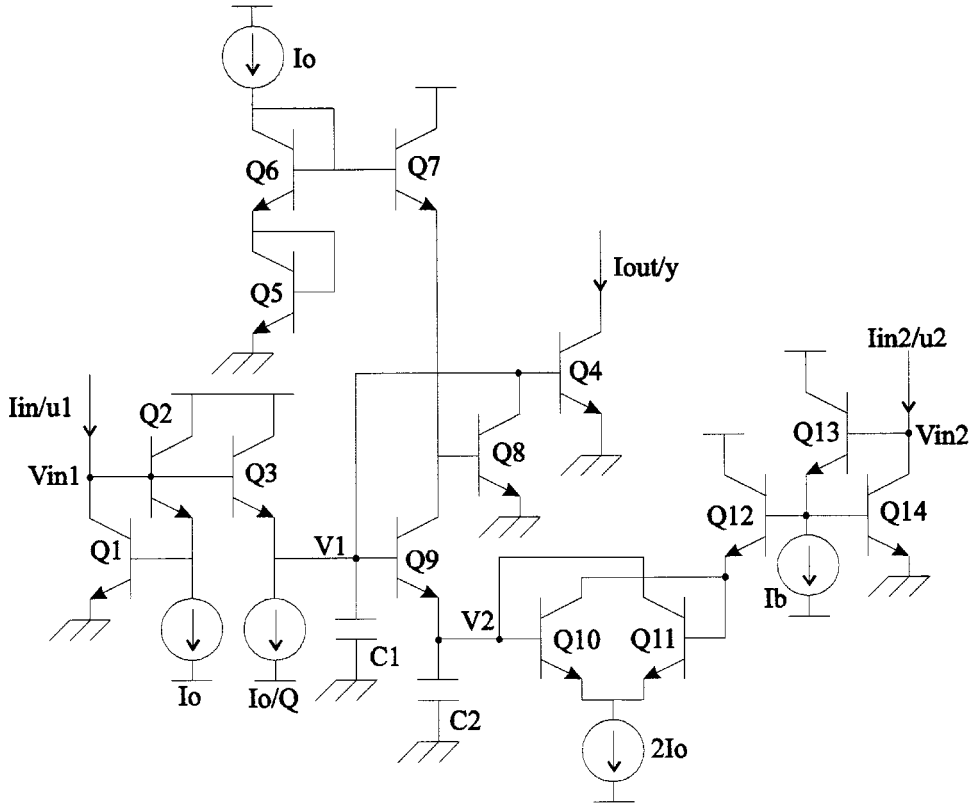

FIGURE 21.37 A log-domain biquadratic filter. A lowpass response is obtained by applying a signal at I_{u2} and keeping I_{u1} constant, while a bandpass response is obtained by applying a signal at I_{u1} and keeping I_{u2} constant.

Performance Aspects

Tuning Range

Both the quiescent bias current I_o and capacitance value C can be varied to alter the filter response. However, the allowable capacitor values are generally limited to within a certain range. On the lower side, C must not become smaller than the parasitic device capacitance. The base–emitter diffusion capacitance of the transistors is particularly important, since this is generally the largest device capacitance (up to the pF range) and is also non-linear. In addition, as the value of C decreases, it becomes more difficult to match capacitance values. The silicon area available limits the maximum value of C; for example, in a typical technology, a 50-pF poly-poly capacitor consumes 100 μm × 1000 μm of silicon area.

The range of allowable currents in a modern BJT is, in principle, fairly large (several decades); however, at very low and very high current levels, the current gain (β) is degraded. For high-frequency operation, particular attention must be paid to the actual f_t of the transistors, which is given by[6]:

$$f_t = \frac{g_m}{2\pi(C_\pi + C_\mu)} = \frac{g_m}{2\pi(C_d + C_{je} + C_{jc})} \tag{21.55}$$

C_{je} and C_{jc} represent the emitter and collector junction capacitance, respectively, and are only a weak function of the collector bias current. C_d represents the base–emitter diffusion capacitance and is proportional to the instantaneous collector current; $C_d = (\tau_f I_c/V_t)$, where τ_f is the effective base transit time. g_m represents the device transconductance, which is again dependent on the collector current; $g_m = (I_c/V_t)$. At high current levels, the diffusion capacitance is much larger than the junction capacitance, and thus:

$$f_t = \frac{g_m}{2\pi C_d} = \frac{1}{2\pi\tau_f} \tag{21.56}$$

At lower current levels, C_d and g_m decrease, whereas C_{je} and C_{jc} remain constant and f_t is reduced:

$$f_t = \frac{g_m}{2\pi(C_{je} + C_{jc})} \tag{21.57}$$

At very high current levels, f_t again reduces due to the effects of high-level injection.

Finite Current Gain

To verify the performance of the biquad filter, the circuit of Fig. 21.37 was simulated using HSPICE with transistor parameters from a typical bipolar process. Transient (large signal) simulations were carried out to confirm the circuit operation, and the lowpass characteristic (input at I_{u2}) is found to be very close to the ideal response. However, with an input signal applied at I_{u1} to obtain a bandpass response, the filter performance clearly deviates from the ideal characteristic as shown in Fig. 21.38. At low frequencies, the stop-band attenuation is only 25 dB. Re-simulating the circuit with ideal transistor models gives the required ideal bandpass characteristic as shown in Fig. 21.38; and by re-introducing the transistor parameters one at a time, the cause of the problem is found to be the finite current gain (β) of the bipolar transistors.

To increase the effective β, each transistor can be replaced by a Darlington pair, as shown in Fig. 21.39. This combination acts as a bipolar transistor with $\beta = \beta_a\beta_b + \beta_a + \beta_b \approx \beta^2$. Simulating the bandpass response of the circuit with Darlington pairs results in improved stopband attenuation as shown in Fig. 21.40, where the dc attenuation $H(0)$ is now approximately –50 dB. A disadvantage, however, is that a higher supply voltage is now required, since the effective base–emitter voltage V_{be} of the Darlington pair is double that of a single device. In addition, the current in device Q_a of Fig. 21.39 is now β times smaller than the design current I_o, resulting in a much lower f_t for this device.

An alternative method to improve the bandpass characteristic is described below. The (non-ideal) transfer function from the bandpass input I_{u1} is described by:

$$H_1(s) = \frac{I_{out}(s)}{I_{u1}(s)} = \frac{\omega_o(s + \omega_z)}{s^2 + (\omega_o/Q)s + \omega_o^2} \tag{21.58}$$

ω_z is a parasitic zero, which describes the low-frequency "flattening-out" of the bandpass characteristic. The transfer function from the second input I_{u2} is a lowpass response:

$$H_2(s) = \frac{I_{out}(s)}{I_{u2}(s)} = \frac{\omega_o^2}{s^2 + (\omega_o/Q)s + \omega_o^2} \tag{21.59}$$

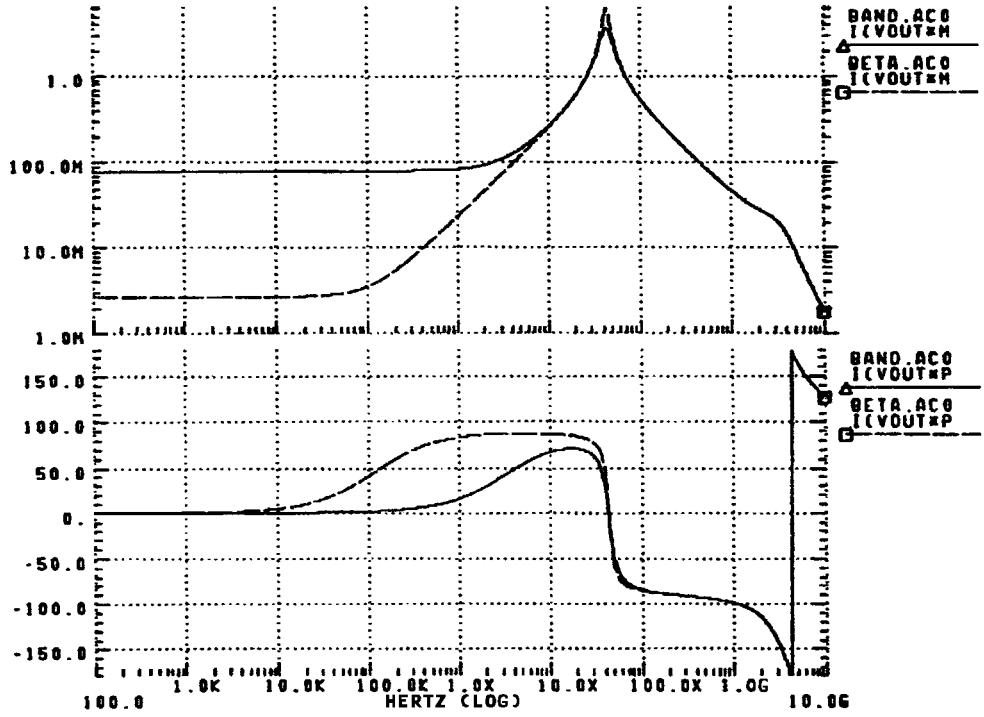

FIGURE 21.38 Bandpass response of the biquad of Fig. 21.37. Notice the poor low-frequency stop-band attenuation (approx. 25 dB) if real transistor models are used (solid line), versus the much better stop-band attenuation with β set to 1000 (dashed line).

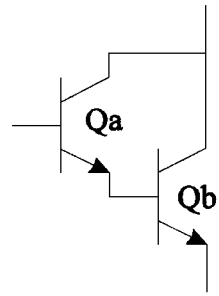

FIGURE 21.39 Darlington pair.

By applying a scaled version of the input signal I_{u1} to the lowpass input I_{u2}, the unwanted zero ω_z can thus be compensated. Setting $I_{u2} = -(\omega_z/\omega_o)\, I_{u1}$

$$I_{out}(s) = \frac{\omega_o(s+\omega_z)I_{u1}(s) + \omega_o^2\left(-\frac{\omega_z}{\omega_o}I_{u1}(s)\right)}{s^2 + (\omega_o/Q)s + \omega_o^2} = \frac{\omega_o s}{s^2 + (\omega_o/Q)s + \omega_o^2}I_{u1}(s) \tag{21.60}$$

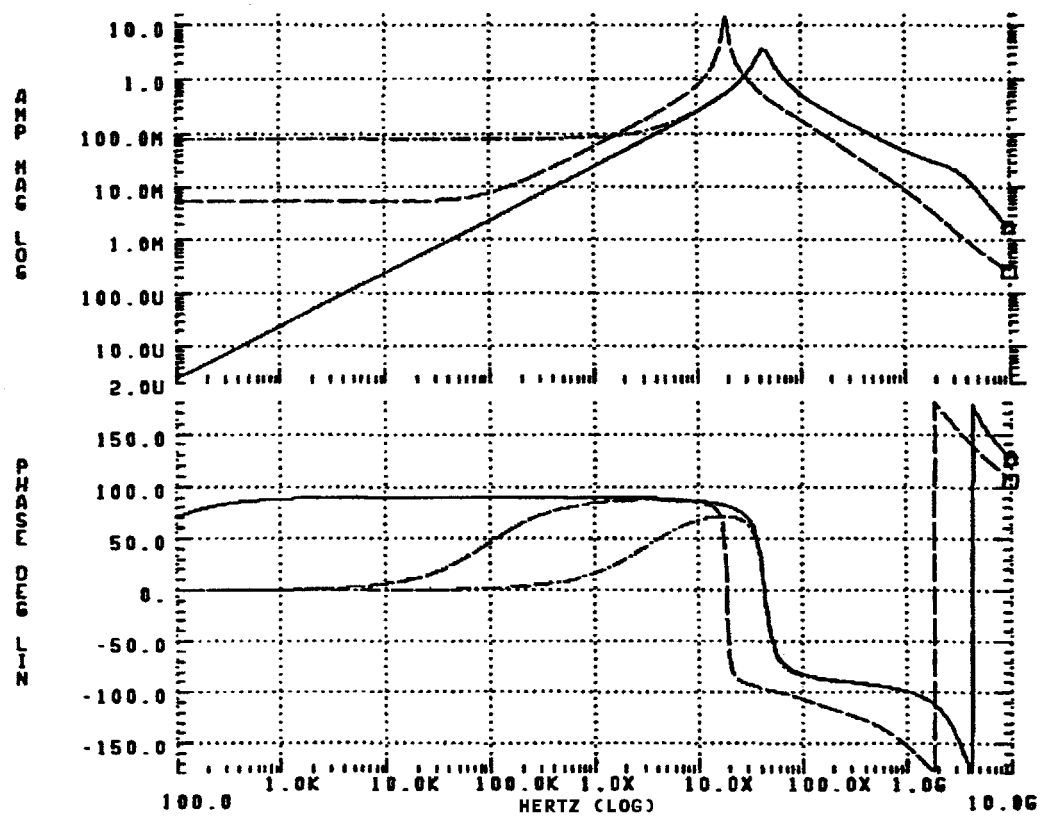

FIGURE 21.40 Possible solutions for the effect of finite β. The "dashed-dotted" line is the original response with a stopband attenuatin of only 25 dB. The dashed line (–50 dB) is the result of replacing all BJTs by Darlington pairs. The solid line is the result of feeding a fraction of the input signal to the second (i.e., lowpass) input.

This idea is confirmed by simulation as shown in Fig. 21.40. However, in practice, since this technique is very sensitive to the exact factor by which the input signal is scaled, active on-chip tuning would be required.

Frequency Performance

The log-domain filter operates in current mode, and all nodes within the circuit have an impedance of the order of $1/g_m$. Thus, any parasitic poles or zeros within the circuit are of the order of g_m/C_p, where C_p represents the parasitic capacitance at the given node. Typically, the parasitic capacitors are dominated by base–emitter diffusion capacitance Cπ, and the parasitic poles are situated close to the f_t of the technology. This underscores the potential of the log-domain technique for high-frequency operation. In practice, as with all high-frequency circuits, careful design and layout are required to achieve the maximum frequency potential.[76,77]

The Basic Log-Domain Integrator

The previous section has outlined some of the limitations of practical log-domain circuits that result from intrinsic device parasitics. This section analyzes these non-idealities in more detail by considering the simplest log-domain circuit, a first-order lowpass filter (lossy integrator).

A log-domain first-order lowpass filter is shown in Fig. 21.41. Referring to this circuit, and assuming an ideal exponential characteristic for each BJT, the following set of equations can be written (assuming matched components and neglecting the effect of base currents):

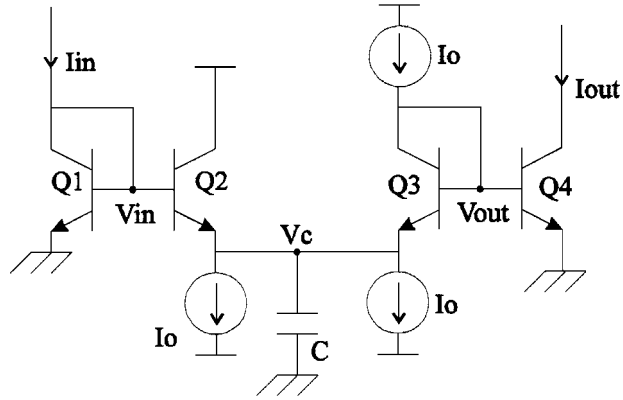

FIGURE 21.41 A first-order lowpass filter (lossy integrator).

$$\begin{aligned} I_{in} &= I_S \exp\left(\frac{V_{in}}{V_t}\right) & I_{out} &= I_S \exp\left(\frac{V_{out}}{V_t}\right) \\ V_{out} &= V_c + V_t \ln\left(\frac{I_o}{I_S}\right) & I_o + C\frac{dV_c}{dt} &= I_S \exp\left(\frac{V_{in} - V_c}{Vt}\right) \end{aligned} \tag{21.61}$$

Combining these equations results in the following linear first-order differential equation:

$$\left(\frac{CV_t}{I_o}\right)\frac{dI_{out}}{dt} + I_{out} = I_{in} \tag{21.62}$$

Taking the Laplace transform produces the following linear transfer function:

$$\frac{I_{out}(s)}{I_{in}(s)} = \frac{I_o}{I_o + sCV_t} \tag{21.63}$$

Equation 21.63 describes a first-order lowpass circuit with –3 dB frequency $f_c = I_o/2\pi CV_t$. This transfer function has been derived assuming an ideal exponential BJT characteristic; however, in practice, device non-idealities will introduce deviations from this ideal exponential characteristic, resulting in transfer function errors and distortion. This is similar to the case of "conventional" linear system design, where any deviation from the ideal linear building block response will contribute to output distortion. A brief discussion of the performance limitations of log-domain filters due to device non-idealities is given below; further discussion of distortion and performance limitations can be found in Refs. 66 and 67.

Effects of Finite Current Gain

Assuming all transistors have equal β, Eq. 21.62 is modified to the following non-linear differential equation (neglecting terms with β^2 or higher in the denominator):

$$\left(\frac{CV_t}{I_o}\right)\frac{dI_{out}}{dt}\left(1 + \frac{I_o}{I_{out}(1+\beta)}\right) + I_{out}\left(1 + \frac{I_{out}}{\beta I_o}\right) + \frac{2I_o}{1+\beta} = I_{in}\left(1 + \frac{I_{in}}{\beta}\right) \tag{21.64}$$

An analytical solution to Eq. 21.64 is difficult to obtain; thus, a qualitative discussion is given. At low frequencies, neglecting the differential terms, finite β causes a dc gain error and quadratic (even-order)

distortion. At high frequencies, the differential term is modified, depending on the values of I_{out} and β; therefore, scalar error and modulation of the 3 dB frequency are expected. In practice, the effects of finite β are further complicated due to its dependence on frequency and device collector current.

Component Mismatch

Emitter area mismatches cause variations in the saturation current I_S between transistors. Taking the emitter area into account, Eq. 21.62 can be rewritten as:

$$\left(\frac{CV_t}{I_o}\right)\frac{dI_{out}}{dt} + I_{out} = \lambda I_{in} \tag{21.65}$$

where $\lambda = (I_{S3}I_{S4}/I_{S1}I_{S2}) = (A_3A_4/A_1A_2)$. It is clear from Eq. 21.65 that area mismatches introduce only a change in the proportionality constant or dc gain of the integrator, and do not have any effect on the linearity or time constant of the integrator. The gain error can be compensated by easily adjusting one of the dc bias currents; thus, I_s mismatches do not seem to be a significant problem.

Ohmic Resistance

Ohmic resistances include the base and emitter diffusion resistance, and the resistance of interconnects and contact interfaces. For simplicity, all theses resistances can be referred to the base as an equivalent ohmic base resistance r_b. The device collector current can thus be defined as:

$$I_c = I_S\exp\left(\frac{V_{be} - I_b r_b}{V_t}\right) = I_S\exp\left(\frac{V_{be}}{V_t}\right)\exp(-\alpha I_c) \tag{21.66}$$

where V_{be} is the applied (extrinsic) base–emitter voltage and $\alpha = r_b/\beta V_t$. When the first-order filter of Fig. 21.41 is analyzed using the expression given in Eq. 21.66, a modified differential equation is obtained (assuming all base resistances are equal):

$$\left(\frac{CV_t}{I_o}\right)\frac{d[I_{out}e^{\alpha I_{out}}]}{dt} + I_{out}e^{\alpha I_{out}} = (e^{\partial\alpha I_o})I_{in}e^{\alpha I_{in}}e^{\left(-\alpha\frac{CV_t}{I_o}\frac{dI_{out}}{dt}\left(1+\alpha I_{out}\right)\right)} \tag{21.67}$$

The term $\partial\alpha$ represents the difference between two α values and will be close to zero if all base resistances are assumed equal, and thus can be neglected. At frequencies well below ω_o, the time derivative in the exponent can also be neglected to give:

$$\left(\frac{CV_t}{I_o}\right)\frac{d[I_{out}\exp(\alpha I_{out})]}{dt} + I_{out}\exp(\alpha I_{out}) = I_{in}\exp(\alpha I_{in}) \tag{21.68}$$

Expanding the differential term in Eq. 21.68:

$$I_{out}\exp(\alpha I_{out}) + \tau\frac{dI_{out}}{dt}\exp(\alpha I_{out}) + \tau\alpha I_{out}\frac{dI_{out}}{dt}\exp(\alpha I_{out}) = I_{in}\exp(\alpha I_{in}) \tag{21.69}$$

Equation 21.69 is clearly no longer linear; and thus, distortion products will be present at the output. To quantify this distortion, we apply as an input signal $I_{in} = A\exp(j\omega t)$, and expect as output:

$$I_{out} = B\exp j(\omega w + \theta) + c\exp j(2\omega t + \phi) + D\exp j(3\omega t + \psi) \tag{21.70}$$

Expanding the exponential terms in Eq. 21.69 by the first few terms of their series expansion:

$$\exp(x) = 1 + x + \frac{x^2}{2} + \frac{x^3}{6} \tag{21.71}$$

and identifying the terms in $\exp(j\omega t)$, $\exp(2j\omega t)$, etc. results in:

$$B\exp j\theta = \frac{A}{1+s\tau} \qquad C\exp j\phi = \alpha A^2 p(\tau) \qquad D\exp j\psi = \alpha^2 A^3 q(s\tau) \tag{21.72}$$

The expression for B is (as expected) the first-order transfer function of the system. The expressions for C and D give the second and third harmonic terms:

$$\mathrm{HD}_2 = \frac{|C\exp j\phi|}{|A|} \qquad \mathrm{HD}_3 = \frac{|D\exp j\psi|}{|A|} \tag{21.73}$$

$p(s\tau)$ and $q(s\tau)$ are rational functions in $s\tau$; thus, the output distortion is frequency dependent. Distortion is low at low frequencies, and peaks around the cut-off frequency ($s\tau = 1$), where $p = 0.25$ and $q = 2$. The maximum distortion levels can be approximated as:

$$\begin{aligned} \mathrm{HD}_{2(\max)} &= 0.25\alpha A = 0.25\frac{r_b}{\beta V_t} I_{in} \\ \mathrm{HD}_{3(\max)} &= 2(\alpha A)^2 = 2\left(\frac{r_b}{\beta V_t}\right)^2 I_{in}{}^2 \end{aligned} \tag{21.74}$$

These expressions demonstrate that when the voltage drop across the base resistance becomes comparable to V_t, there is significant distortion. This analysis also predicts that the distortion is larger at frequencies closer to the cut-off frequency, which is confirmed by circuit simulation.

In practice, the base resistance can be minimized by good layout (multiple base contacts), or by connecting several transistors in parallel. The latter, however, decreases the current through each transistor, which may lead to a decrease in f_t. It should be noted that, from a technological point of view, a high f_t and a low r_b are opposing goals. To achieve a high f_t, the base should be as shallow as possible, reducing base transit time. At the same time, however, a shallow base increases the silicon (intrinsic) base resistance.

Early Effect

The Early effect (base-width modulation) causes the collector current to vary with the collector–emitter and base–collector voltages. Considering the variation of collector–emitter voltage, the collector current can be written as $I_c = (1 + V_{ce}/V_A)\exp(V_{be}/V_t)$, where V_A is the forward-biased Early voltage. An analysis of the circuit of Fig. 21.41 shows that the Early effect introduces a scalar error to the dc gain as in the case of emitter area (I_S) mismatch. In practice, the base-width modulation of the devices also introduces distortion because V_{ce} and V_{bc} are signal dependent. However, since voltage swings in current-mode circuits are minimized, this is not believed to be a major source of distortion.

Frequency Limitations

Each bipolar transistor has various intrinsic capacitors, the most important being C_μ (base–collector junction capacitance), C_{cs} (collector–substrate junction capacitance), and C_π (the sum of the base–emitter junction capacitance and the base–emitter diffusion capacitance). The junction capacitors depend only slightly on the operating point, while the base–emitter diffusion capacitance is proportional to the bias current, as given by $C_d = \tau_f I_c/V_t$. To determine the position of the parasitic poles and zeros, Fig. 21.41 should be analyzed using large-signal device models. Unfortunately, the complexity of the resulting expressions renders this approach impractical even for the simplest log-domain circuits. To

gain an intuitive understanding of the high-frequency limitations of the circuit, a small-signal analysis can be performed. Although log-domain circuits are capable of large-signal operation, this small-signal approach is justified to some extent since small signals can be considered "special case" of large signals. If the circuit fails to operate correctly for small signals, then it will almost certainly fail in large-signal operation (unfortunately, the opposite does not hold; if a circuit operates correctly for small signals, it does not necessarily work well for large signals). Analyzing the circuit of Fig. 21.41, replacing each transistor by a small-signal (hybrid-π) equivalent model (comprising g_m, r_b, r_π, C_π, C_μ),[65] results in the following expression:

$$\frac{I_{out}}{I_{in}} = \left(\frac{g_{m4}}{g_{m1}}\right)\frac{1+\tau_z s}{(1+\tau_{p1}s)(1+\tau_{p2}s)} \tag{21.75}$$

τ_{p1} is the time constant of the first (dominant) pole, given by:

$$\tau_{p1} = \frac{C}{g_{m2}} + (C_{\mu4}+C_{\pi4})\left(r_{b4}+\frac{1}{g_{m2}}+\frac{1}{g_{m3}}\right)+\frac{C_{\pi1}}{g_{m1}}+\frac{C_{\pi2}}{g_{m2}} + \frac{C_{\pi3}}{g_{m3}} + C_{\mu1}r_{b1} + C_{\mu2}r_{b2} + C_{\mu3}r_{b3} \tag{21.76}$$

Ideally, this pole location should depend only on the design capacitance C, and not on the device parasitics. Therefore, $C_\mu r_b$, $C_\pi/g_m << C/g_{m2}$. Since $1/C_\mu r_b$ is typically much greater than f_t, this first constraint does not form a limit. The value of C_π/g_m depends on the operating point. For large currents, C_π is dominated by diffusion capacitance C_d so that $C_\pi/g_m = 1/f_t$. For smaller currents, g_m decreases while C_π becomes dominated by junction capacitance C_{je}, so that $C_\pi/g_m >> 1/f_t$. Thus, it would seem that the usable cut-off frequency of the basic log-domain first-order filter is limited by the actual f_t of the transistors. The second pole time constant τ_{p2} (assuming that $\tau_{p1} = C/g_{m2}$) is:

$$\tau_{p2} = (C_{\mu4}+C_{\pi4})\left(r_{b4}+\frac{1}{g_{m3}}\right)+(C_{\mu2}+C_{\pi2})\left(r_{b2}+\frac{1}{g_{m1}}\right)+\frac{C_{\pi1}+C_{cs1}}{g_{m1}} + \frac{C_{\pi13}+C_{cs3}}{g_{m3}} + C_{\mu1}r_{b1} + C_{\mu4}r_{b4} \tag{21.77}$$

This corresponds approximately to the f_t of the transistors, although Eq. 21.77 shows that the collector–substrate capacitance also contributes toward limiting the maximum operating frequency. The zero time constant τ_z is given by:

$$\tau_z = (C_{\pi1}+C_{\mu1})r_{b1} + \frac{C_{\pi2}}{g_{m2}} + \frac{C_{\pi4}}{g_{m4}} + C_{\mu4}r_{b4} \tag{21.78}$$

This is of the same order of magnitude as the second pole. This means that the first zero and the second pole will be close together, and will compensate to a certain degree. However, in reality, there are more poles and zeros than Eq. 21.75 would suggest, and it is likely that others will also occur around the actual f_t of the transistors.

Noise

Noise in companding and log-domain circuits is discussed in some detail in Refs. 69 to 71, and a complete treatment is beyond the scope of this discussion. For linear (non-companding) circuits, noise is generally assumed to be independent of signal level, and the signal-to-noise ratio (SNR) will increase with increasing input signal level. This is not true for log-domain systems. At small input signal levels, the noise value can be assumed approximately constant, and an increase in signal level will give an increase in

SNR. At high signal levels, the instantaneous value of noise will increase, and thus the SNR levels out at a constant value. This can be considered as an intermodulation of signal and noise power. For the Class A circuits discussed above, the peak signal level is limited by the dc bias current. In this case, the large-signal noise is found to be of the same order of magnitude as the quiescent noise level, and thus a linear approximation is generally acceptable (this is not the case for Class AB circuits).

Synthesis of Higher-Order Log-Domain Filters

The state-space synthesis technique outlined above proves difficult if implementation of high-order filters is required, since it becomes difficult to define and manipulate a large set of state equations. One solution is to use the signal flow graph (SFG) synthesis method proposed by Perry and Roberts[72] to simulate LC ladder filters using log-domain building blocks. The interested reader is also referred to Refs. 73 through 75, which present modular and transistor-level synthesis techniques that can be easily extended to higher-order filters.

22.1 Introduction

In many analog or mixed analog/digital VLSI applications, an operational amplifier may not be appropriate to use for an active element. For example, when designing integrated high-frequency active filter circuitry, a much simpler building block, called an operational transconductance amplifier (OTA), is often used.[1] This type of amplifier is characterized as a voltage-driven current source and in its simplest form is a combination of a differential input pair with a current mirror as shown in Fig. 22.1. It is a simple circuit with a relatively small chip area. Further, it has a high bandwidth and also a good common-mode rejection ratio up to very high frequencies. The small signal transconductance, $g_m = \partial I_{out}/\partial V_{in}$, can be controlled by the tail current. This chapter discusses CMOS OTA design for modern VLSI applications. We begin the chapter with a brief study of noise in OTAs, followed by OTA design techniques.

22.2 Noise Behavior of the OTA

The noise behavior of the OTA is discussed here. Attention will be paid to thermal and flicker noise and to the fact that, for minimal noise, some voltage gain, from the input of the differential pair to the input of the current mirror, is required. Then, only the noise of the input pair becomes dominant and the other noise sources can be neglected to first order. The noise behavior of a single MOS transistor is modeled by a single noise voltage source. This noise voltage source is placed in series with the input (gate) of a "noiseless" transistor. Fig. 22.2(a) shows the simple OTA, including the noise sources, while Fig. 22.2(b) shows the same circuit with all the noise referred to the input of the stage.

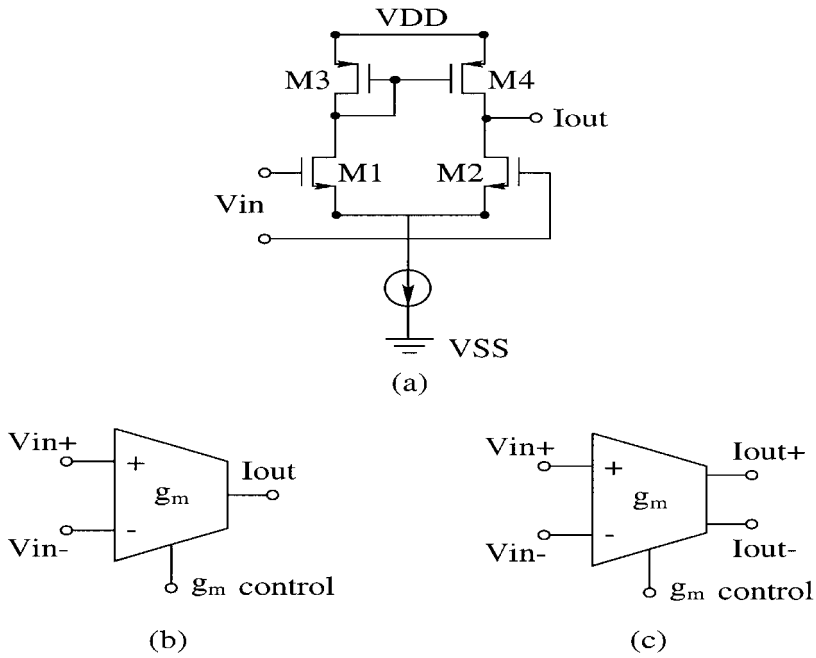

FIGURE 22.1 (a) A NMOS differential pair with a PMOS current mirror forming an OTA; (b) the symbol for a single-ended OTA; and (c) the symbol for a fully differential OTA.

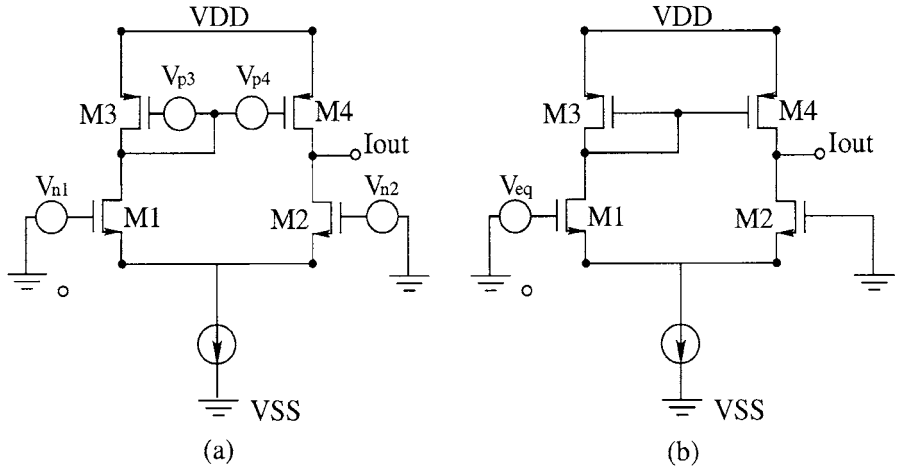

FIGURE 22.2 (a) The OTA with its noise voltage sources, and (b) the same circuit with the noise voltage sources referred to one of the input nodes.

All the noise sources indicated in Fig. 22.2(a) are converted to equivalent input noise voltags, which are then added to form a single noise source at the input (Fig. 22.2(b)). As a result, we obtain (assuming $g_{m1} = g_{m2}$ and $g_{m3} = g_{m4}$) the following mean-square input referred noise voltage

$$\overline{V_{eq}^2} = \overline{V_{n1}^2} + \overline{V_{n2}^2} + \left(\frac{g_{m3}}{g_{m1}}\right)^2 (\overline{V_{p3}^2} + \overline{V_{p4}^2}) \tag{22.1}$$

The thermal noise contribution of one transistor, over a band Δf, is written as:

$$\overline{V_{th}^2} = \frac{2}{3}4kT\frac{1}{g_m}\Delta f \tag{22.2}$$

where k is the Boltzman constant and T is the absolute temperature.

The equivalent noise voltage $\overline{V_{th_{eq}}^2}$ becomes:

$$\overline{V_{th_{eq}}^2} = \frac{2}{3}4kT\left(\frac{1}{g_{m1}} + \frac{1}{g_{m2}} + \left(\frac{g_{m3}}{g_{m1}}\right)^2\right)\left(\frac{1}{g_{m3}} + \frac{1}{g_{m4}}\right)\Delta f \tag{22.3}$$

and because $g_{m1} = g_{m2}$ and $g_{m3} = g_{m4}$, $\overline{V_{th_{eq}}^2}$ becomes:

$$\overline{V_{th_{eq}}^2} = \frac{16}{3}kT\left(\frac{1}{g_{m1}} + \left(\frac{g_{m3}}{g_{m1}}\right)^2\frac{1}{g_{m3}}\right)\Delta f \tag{22.4}$$

or

$$V_{th_{eq}}^2 = \frac{16}{3}\frac{kT}{g_{m1}}\left(1 + \frac{g_{m3}}{g_{m1}}\right)\Delta f \tag{22.5}$$

Expressing g_m in physical parameters results in:

$$\overline{V_{th_{eq}}^2} = \frac{16kT}{3\sqrt{\mu_n C_{ox}(W/L)_1 I_0}}\left(1 + \sqrt{\frac{\mu_p(W/L)_3}{\mu_n(W/L)_1}}\right)\Delta f \tag{22.6}$$

In this equation, I_0 represents the tail current of the differential pair. Note that the term between brackets represents the relative noise contribution of the current mirror. This term can be neglected if M_3 and M_4 are chosen relatively long and narrow in comparison to M_1 and M_2.

It should be mentioned that the thermal noise of an N-MOS transistor and a P-MOS transistor with equal transconductance is the same. In most standard IC processes, a three to ten times lower $1/f$ noise is observed for P-MOS transistors in comparison to N-MOS transistors of the same size. However, in modern processes, the $1/f$ noise contribution of N- and P-MOS transistors tends to be equal.

For the $1/f$ noise, it is usually assumed for standard IC processes that:

$$\overline{V_{1/f}^2} = \frac{K'}{WLC_{ox}f}\Delta f \tag{22.7}$$

where K' is the flicker noise coefficient in the range of 10^{-24} J for N-MOS transistors and in the range of 3×10^{-25} to 10^{-25} J for P-MOS transistors. The equivalent $1/f$ input noise source of the OTA in Fig. 22.2(b) yields:

$$\overline{V_{eq(1/f)}^2} = \frac{2K'_n\Delta f}{W_1L_1C_{ox}f}\left(1 + \frac{K'_p\mu_pL_1^2}{K'_n\mu_nL_3^2}\right) \tag{22.8}$$

Here, the noise contributions of the current mirror (M_3, M_4) will be negligible if L_3 is chosen much larger than L_1.

The offset voltage of a differential pair is lowest when the transistors are in the weak-inversion mode; but on the contrary, the mismatch in the current transfer of a current mirror is lowest when the transistors are deep in strong inversion. Hence, the conditions that have to be fulfilled for both minimal equivalent input noise and minimal offset are easy to combine.

22.3 An OTA with an Improved Output Swing

A CMOS OTA with an output swing much higher than that in Fig. 22.1(a) is shown in Fig. 22.3. This configuration needs two extra current mirrors and consumes more current, but the output voltage "window" is, in the case when common-mode input voltage is zero, about doubled. The rules discussed earlier for sizing the input transistors and current-mirror transistors to reduce noise and offset still apply. However, there is still a tradeoff. On the one hand, a high voltage gain from the input nodes to the current mirror is good for reducing noise and mismatch effects; on the other hand, too much gain also reduces the upper limit of the common-mode input voltage range and the phase margin needed to ensure stability (this will be discussed later).[2] A voltage gain on the order of 3 to 10 is advised. The frequency behavior of the OTA in Fig. 22.3 is rather complex since there are two different signal paths in parallel, as shown in Fig. 22.4. In this scheme, r_p represents the parallel value of the output resistance of the stage ($r_{o6} \| r_{o8}$) and the load resistance (R_L); therefore,

$$r_p = r_{o6} \| r_{o8} \| R_L \tag{22.9}$$

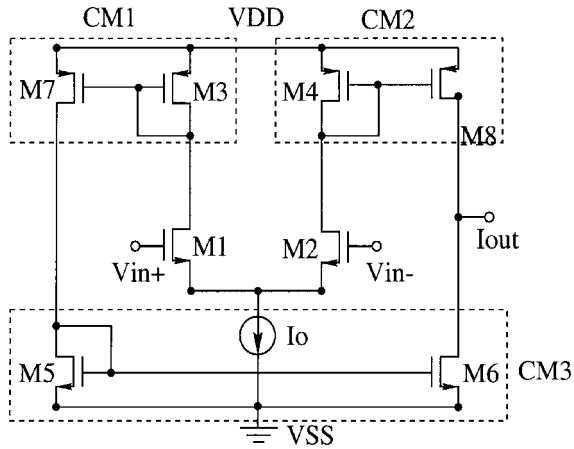

FIGURE 22.3 An OTA with an improved output window.

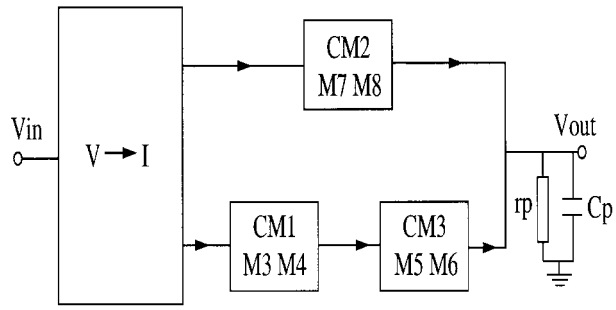

FIGURE 22.4 The signal paths of the OTA in Fig. 22.3.

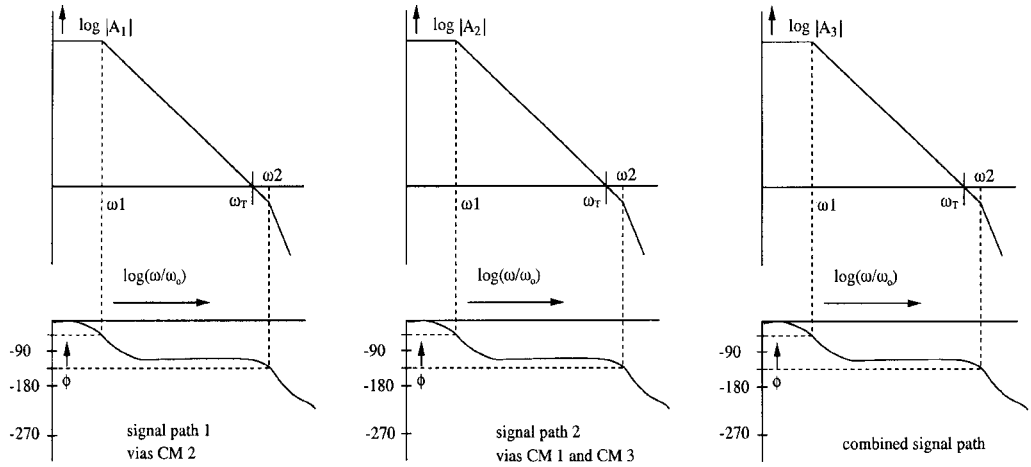

FIGURE 22.5 (a) The Bode plot belonging to signal path 1 in the OTA in Fig. 22.3 and 22.4, (b) signal path 2, and (c) to the combined signal path.

The capacitor C_p represents the sum of the parasitic output capacitance and the load capacitance $C_p = C_o + C_L$. Using the half-circuit principle for the differential pair, a fast signal path can be seen from M_2 via current mirror M_7, M_8 to the output. This signal path contributes an extra high-frequency pole. The other signal path leads from transistor M_1 via both current mirrors M_3, M_4 and M_5, M_6 to the output. In this path, two extra poles are added. The transfer of both signal paths and their combination are shown in the plots in Fig. 22.5, assuming equal pole positions of all three current mirrors. Note that the first (dominant) pole (ω_1) is determined by r_p and C_p.

$$\omega_1 = \frac{1}{r_p C_p} \tag{22.10}$$

The second pole (ω_2) is determined by the transconductance of M_3 and the sum of the gate-source capacitance of M_3 and M_4. If M_3 and M_4 are equal, the second pole is located at:

$$\omega_2 = \frac{g_{m3}}{2C_{gs3}} \tag{22.11}$$

The unity-gain corner frequency ω_T of the loaded OTA is at:

$$\omega_T = \frac{g_{m1}}{C_p} \tag{22.12}$$

Therefore, the ratio ω_2/ω_T is:

$$\frac{\omega_2}{\omega_T} = \frac{g_{m3}}{g_{m1}} \frac{C_p}{2C_{gs3}} \tag{22.13}$$

When the OTA is used for high-frequency filter design, an integrator behavior is required, that is, a constant 90° phase at least at frequencies around ω_T. Therefore, a high value of the ratio ω_2/ω_T is needed in order to have as little influence as possible from the second pole. It is obvious from Eq. 22.12 that the

low-frequency voltabe gain from the input nodes of the circuit to the input of the current mirrors (= g_{m1}/g_{m3}) must not be chosen too high. As mentioned, this is in contrast to the requirements for minimum noise and offset.

Sometimes, OTAs are used as unity gain voltage buffers; for example, in switched capacitor filters. In this case, the emphasis is put more on obtaining high open-loop voltage gain, improved output window, and good capability to drive capacitive loads efficiently (or small resistors); its integrator behavior is of less importance.

To increase the unloaded voltage gain, cascode transistors can be added in the output stage. This greatly increases the output impedance of the OTA and hardly decreases the phase margin. The penalty that has to be paid is an additional pole in the signal path and some reduction of the maximum possible output swing. This reduction can be very small if the cascode transistors are biased on the weak-inversion mode. The open-loop voltage gain can be in the order of 40 to 60 dB. A possible realization of such a configuration is shown in Fig. 22.6.[3]

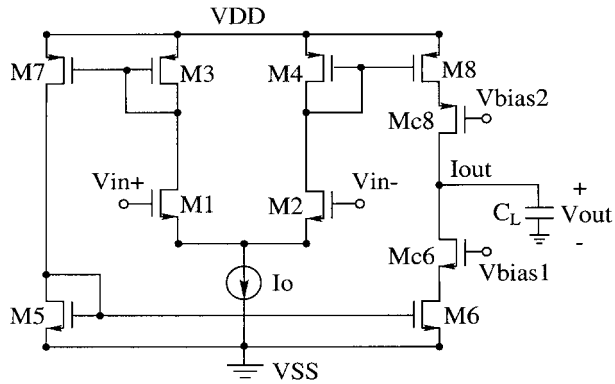

FIGURE 22.6 An OTA with improved output impedance.

22.4 OTAs with High Drive Capability

For driving capacitive loads (or small resistors), a large available output current is necessary. In the OTAs shown so far, the amount of output current available is equal to twice the quiescent current (i.e., the tail current I_0). In some situations, this current can be too small. There are several ways to increase the available current in an efficient way. To achieve this, four design principles will be discussed here:

1. Increasing the quiescent current by using current mirrors with a current transfer ratio greater than 1
2. Using a two-transistor level structure to drive the output transistors
3. Adaptive biasing techniques
4. Class AB techniques

OTAs with 1:B Current Mirrors

One way to increase available output current is to increase the transfer ratio of the current mirrors CM1 and CM2 by a factor B, as indicated in Fig. 22.7.[4] The amount of available output current and also the overall transconductance increase by the same factor. Unfortunately, the –3 dB frequency of the CM1-CM2 current mirrors will be reduced by a factor $(B + 1)/2$ due to the larger gate-source capacitance of the mirror output transistors. Moreover, ω_T will increase, ω_2 will decrease, and the ratio ω_2/ω_T will be

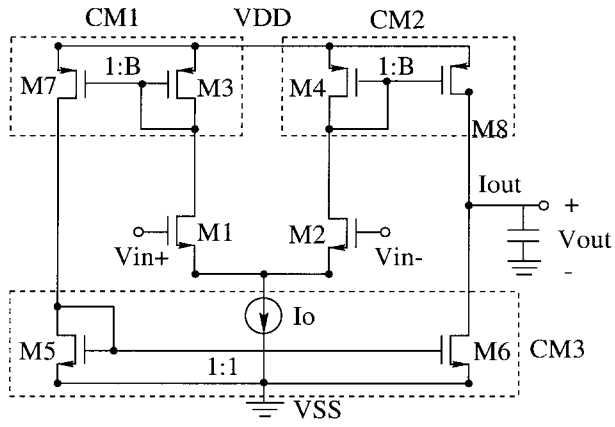

FIGURE 22.7 An OTA with improved load current using 1:B current mirrors.

strongly deteriorated. The amount of available output current though is B times the tail current. It is also possible to increase the current transfer ratio of current mirror CM3 instead of CM1. A better current efficiency then results, but at the expense of more asymmetry in the two signal paths. Although the amount of the maximum available output current is B times the tail current in both situations, the ratio between the maximum available current and quiescent current of the output stage remains equal to two, just as in the OTAs discussed previously.

OTA with Improved Output Stage

Another way of increasing the maximal available output current is illustrated in Fig. 22.8.[6] It improves upon the factor-two relationship between quiescent and maximal available current. Assuming equal K factors for all transistors shown in the circuit leads to the conclusion that the effective gate-source voltage of transistor M_{11} ($= V_{GS11} - V_{T11}$) equals that of transistor M_1 ($=V_{GS1} - V_{T1}$), since they carry the same current, assuming that transistors M_1, M_4, and M_6 are in saturation. Because the current drawn through transistor M_9 is equal to the current in transistor M_2, their effective source-gate voltages must also be equal assuming equal K factor for M_2 and M_9. Since the sum of the effective gate-source voltages transistors M_{11} and M_{12}, and also of M_9 and M_{10}, is fixed and equal to V_B, a situation exists which is equivalent to the two transistor level structure described in Ref. 5.

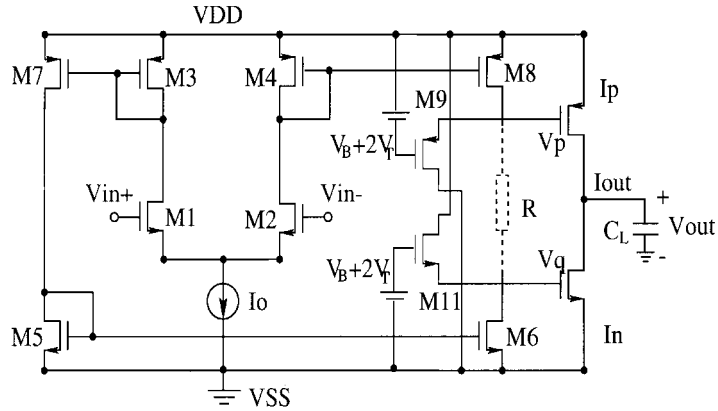

FIGURE 22.8 An OTA with an improved ratio between the maximum available current and the quiescent current of the output stage.

The ratio between the maximum available output current and the quiescent current of the output stage can be chosen by the designer. It is equal to: $(V_B/(V_B - V_{GS0}))^2$, where V_{GS0} is the quiescent gate-source voltage of transistor M_{11}.

If the OTA is used in an over-drive situation $|V_{in}| > \sqrt{(2I_0)/K}$, then either M_6 or M_5 will be cut off, while the other transistor carries its maximum current. As a result, one of the output transistors (M_{10} or M_{12}) carries its maximum current, while the other transistor is in a low-current stand-by situation. The maximum current that one of the output transistors carries is therefore proportional to V_B^2. With the high ohmic resistor R (indicated in Fig. 22.8 with dotted lines), this maximum current corresponds to either $(V_P - V_{SS} - V_{TN})^2$ or $(V_{DD} - V_Q - V_{TP})^2$, because in that situation no current flows through the resistor. Hence, with the extra resistor, it becomes possible to increase the maximum current in over-drive situations and therefore reduce the slewing time. Because resistor R is chosen to be high, it does not disturb the behavior of the circuit discussed previously. In practice, resistor R is replaced by transistor M_R working in the triode region, as shown in Fig. 22.9(a). Figure 22.9(b) shows the circuit which was used in Ref. 5 for biasing the gates of transistors M_0, M_9, and M_{11}. It is much like the so-called "replica biasing." The current in the circuit is strongly determined by the voltage across R (and its value) and is therefore very sensitive to variations in the supply voltage.

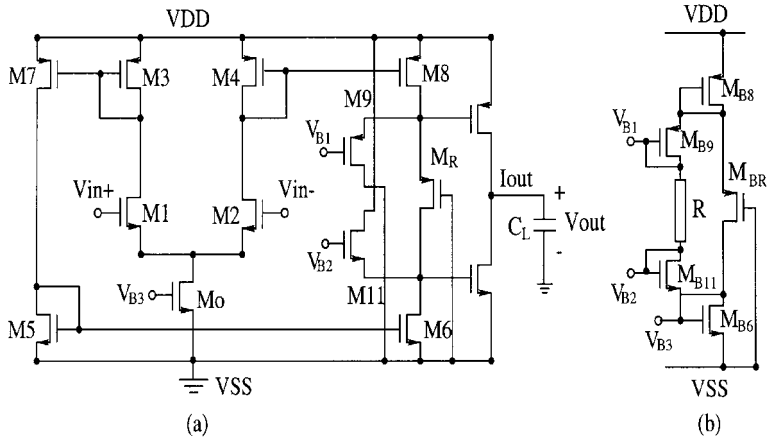

FIGURE 22.9 (a) The complete OTA, (b) and its bias stage.

Adaptively Biased OTAs

Another combination of high available output current with low standby current can be realized by making the tail current of the differential input pair signal dependent. Figure 22.10 shows the basic idea of such an OTA with adaptive biasing.[7] The tail current I_0 of the differential pair is the sum of a fixed value I_R and an additional current equal to the absolute value of the difference between the drain currents multiplied by the current feedback factor B ($I_0 = I_R + B|I_1 - I_2|$). Therefore, with zero differential input voltage, only a low bias current I_R flows through the input pair. A differential input voltage, V_{ind}, will cause a difference in the drain currents which will increase the tail current. This, in turn, again gives rise to a greater difference in the drain current, and so on. This is the kind of positive feedback that can bring the differential input pair from the weak-inversion mode into the strong-inversion mode, depending on the input voltage and the chosen current feedback factor B.

Normally, when $V_{ind} = V_{in+} - V_{in-}$ is small, the input transistors are in weak inversion. The differential output current $(I_1 - I_2)$ of a differential pair operating in weak inversion equals the tail current times $\tanh((qV_{ind})/(2AkT))$. This leads to the following equation:

$$(I_1 - I_2) = I_R + B|I_1 - I_2|\tanh\left(\frac{qV_{ind}}{2AkT}\right) \qquad (22.14)$$

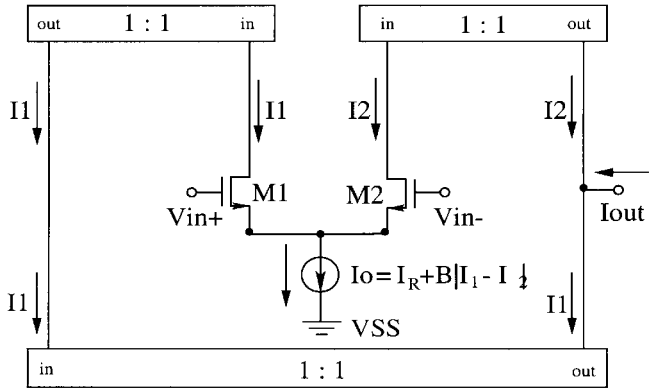

FIGURE 22.10 An OTA with an input dependent tail current.

or

$$(I_1 - I_2) = \frac{\tanh\left(\frac{qV_{ind}}{2AkT}\right)}{1 - B\left|\tanh\left(\frac{qV_{ind}}{2AkT}\right)\right|} I_R \tag{22.15}$$

and because $I_{out} = (I_1 - I_2)$:

$$I_{out} = \frac{\tanh\left(\frac{qV_{ind}}{2AkT}\right)}{1 - B\left|\tanh\left(\frac{qV_{ind}}{2AkT}\right)\right|} I_R \tag{22.16}$$

However, in the case of large currents, this expression will no longer be valid since $M_1 - M_2$ will leave the weak-inversion domain and enter the strong-inversion region. If that is the case, the output current becomes:

$$I_{out} = \begin{cases} \frac{k}{2} V_{ind} \sqrt{\frac{4I_R}{K} - (1 - B^2) V_{ind}^2} + B\frac{K}{2} V_{ind}^2 & \text{for } V_{ind} > 0 \\ \frac{k}{2} V_{ind} \sqrt{\frac{4I_R}{K} - (1 - B^2) V_{ind}^2} - B\frac{K}{2} V_{ind}^2 & \text{for } V_{ind} < 0 \end{cases} \tag{22.17}$$

In order to keep some control over the output current, a negative overall feedback must be applied, which is usually the case. For example, when an OTA is used as a unity-gain buffer with a load of C_L (see Fig. 22.11) and assuming a positive input step is applied, then the output current increases dramatically due to the positive feedback action described previously and, as a result, the output voltage will increase. This will lead to a decrease of the differential input voltage V_{ind} ($V_{ind} = V_s - V_{out}$). The result will be a very fast settling of the output voltage, and that is what we wanted to have. In order to realize current $|I_1 - I_2|$, two current-subtracter circuits can be combined (see Fig. 22.12). If the current I_2 is larger than current I_1, the output of current-subtracter circuit 1 (I_{out1}) will carry a current; otherwise, the output current will be zero. The opposite situation is found for the output current of subtracter circuit 2 because of the interchange of their input

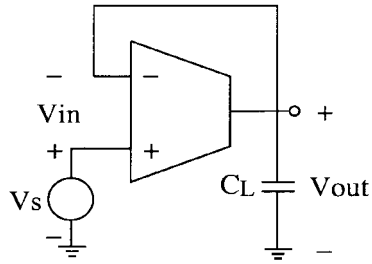

FIGURE 22.11 An OTA used as a unity gain buffer.

currents ($I_{out2} = B(I_1 - I_2)$). Consequently, either I_{out1} or I_{out2} will draw a current $B|I_1 - I_2|$ and the other current will be zero. It is for this reason that the upper current mirrors (in Fig. 22.13) have two extra outputs to support the currents for the circuit in Fig. 22.12. A practical realization of the adaptive biasing OTA is shown in Fig. 22.13. In order to avoid unwanted, relatively high stand-by currents due to transistors mismatches, the transfer ratio of the current mirrors (M_{12}, M_{13}) and (M_{19}, M_{18}) can be chosen somewhat larger than 1. This ensures an inactive region of the input voltage range whereby the feedback loop is deactivated.

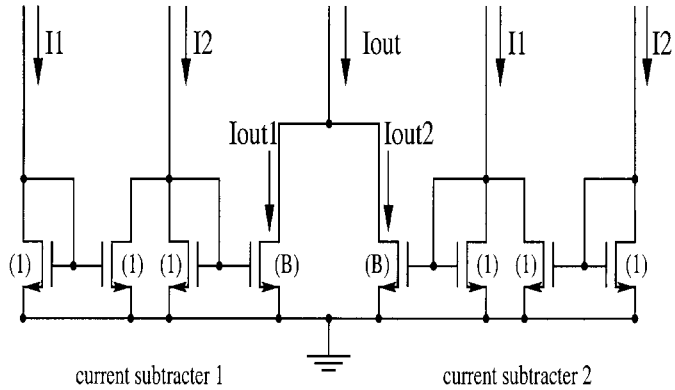

FIGURE 22.12 A combination of two current subtracters for realizing the adaptive biasing current for the circuit in Fig. 22.10.

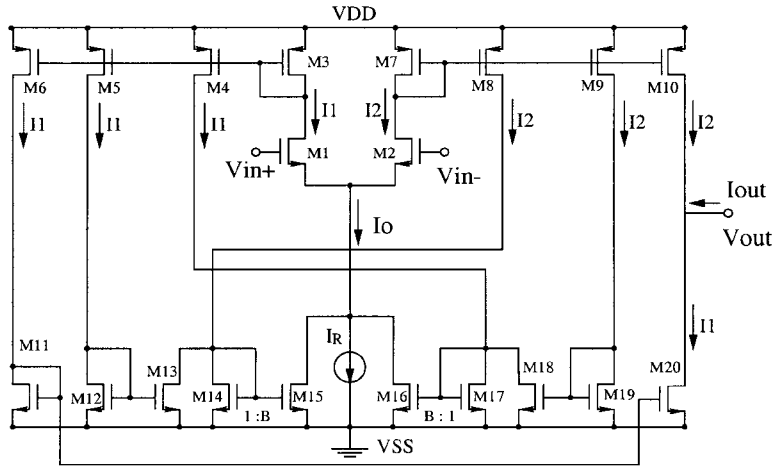

FIGURE 22.13 A practical realization of OTA with an adaptive biasing of its tail current.

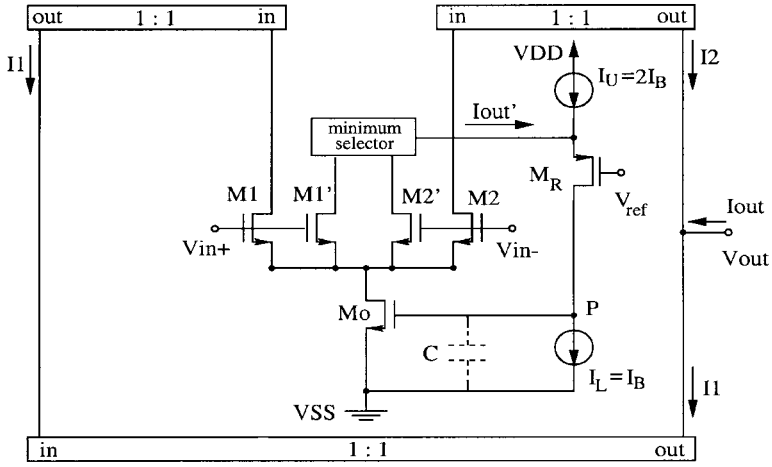

FIGURE 22.14 An OTA using a minimum selector for adapting the tail current.

Another example of an adaptive tail current circuit is shown in Fig. 22.14.[8] It has a normal OTA structure except that the input pair is realized in twofold, and the tail current transistor is used in a feedback loop. This feedback loop includes the inner differential pair and tail current transistor M_0 as well as a minimum current selector, the current source I_U, transistor M_R, and a current sink I_L. The minimum current selector[9] delivers an output current equal to the lowest value of its input currents ($I'_{out} = Min(I'_1, I'_2)$). The feedback loop ensures that the output current of the minimum current selector is equal to the difference in currents between the upper and lower current sources. Assume that the upper current carries a current $2I_B$ and the lower current source carries I_B, then the feedback loop will bias the tail current in such a way that either I'_1 or I'_2 becomes equal to I_B; for positive values of V_{ind}, that will be I'_2. It should be realized that at $V_{ind} = 0$, all four input transistors are biased at the same gate-source voltage (V_{GS0}), corresponding to a drain current I_B. In the case of positive input voltages, the gate-source voltage of M_2/M'_2 will not change.

Therefore, all the input voltage will be added to the bias voltage of M_1/M'_1, that is,

$$V_{GS1} = V_{GS0} + V_{ind} \tag{22.18}$$

Figure 22.15 shows the I_D vs. V_{GS} characteristic for both transistors M_1/M'_1 and M_2/M'_2. Accordingly, the relationship between $(I_1 - I_2)$ vs. V_{ind} (for $V_{ind} > 0$) follows the right side of the $I_D - V_{GS}$ curve of M_1,

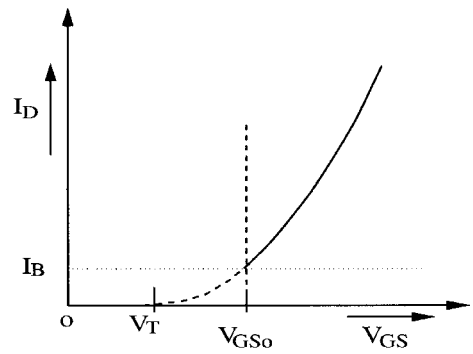

FIGURE 22.15 The I_D vs. V_{GS} characteristic for transistors M_1/M'_1 and $M_2/M(_2$, showing their standby point V_{GS0}, I_B.

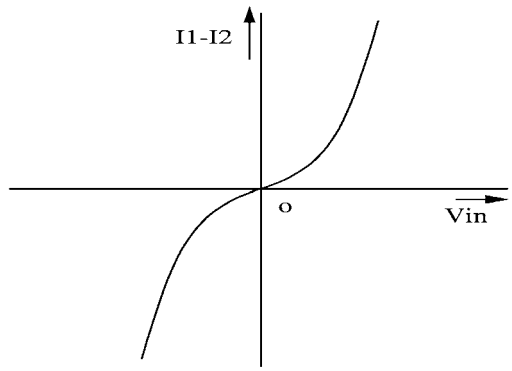

FIGURE 22.16 $I_1 - I_2$ vs. V_{ind}.

starting from the stand-by point (V_{GS0}, I_B) as indicated by the solid curve in Fig. 22.15. A similar view can be taken for negative values of the input voltage V_{ind}, resulting in an equal ($I_1 - I_2$) vs. V_{in} curve rotated 180°. The result is shown in Fig. 22.16.

Note that this input stage has a relationship between ($I_1 - I_2$) and V_{ind} that is different from that of a simple differential input stage. By increasing V_{ind}, the slope increases and, to a first-order approximation, there will not be a limit for the maximum value of ($I_1 - I_2$).

Note that there is an additional MOS transistor M_R in the circuit in Fig. 22.14 to fix the output voltage of the minimum current selector circuit. The lower current source I_L is necessary to be able to discharge the gate-source capacitor C of M_0 (indicated in Fig. 22.14 with dotted lines). The OTA in Fig. 22.14 is simpler than that in Fig. 22.13. However, its bandwidth is lower due to the high impedance of node P in the feedback loop.

Class AB OTAs

Another possibility to design an OTA with a good current efficiency is to use an input stage exhibiting a class AB characteristics.[11] The input stage in Fig. 22.17 contains two CMOS pairs[12] connected as Class AB input transistors. They are driven by four source-followers. By applying a differential input voltage,

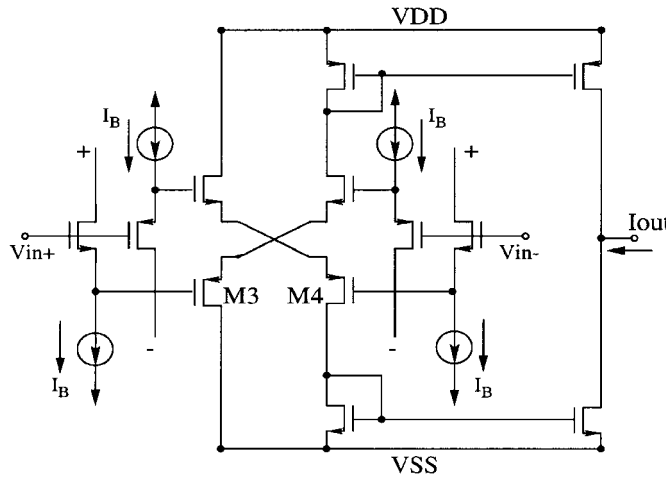

FIGURE 22.17 An OTA having a class AB input stage.

the current through one of the input pairs will increase while the current through the other will decrease. The maximum current that can flow through the CMOS pair is, to first order, unlimited. In practice, it is limited by the supply voltage, the K_{eq} factor, the mobility reduction factor, and the series resistance. The currents are delivered to the output with the help of two current mirrors. In the OTA shown in Fig. 22.17, only one of the two outputs of each CMOS pair is used. The other output currents flow directly to the supply rails. Instead of wasting the other output currents, they can be used to supply an extra output. So with the addition of two current mirrors, an OTA with complementary outputs as shown in Fig. 22.18 can be achieved.[10] An improvement of the output impedance and low-frequency voltage gain can be obtained by cascoding the output transistors of the current mirrors (Fig. 22.19). Usually, this reduces the output window. The function of transistors M_{41}-M_{44} is to control the dc output voltages. They form a part of a common-mode feedback system, which will be discussed next.

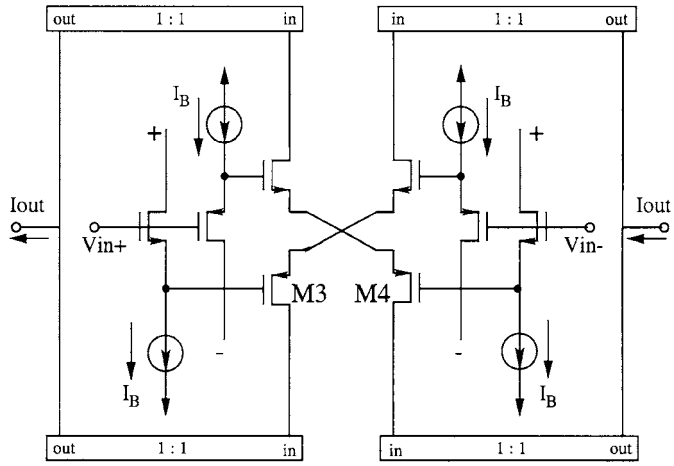

FIGURE 22.18 An OTA having a class AB input stage and two complementary outputs.

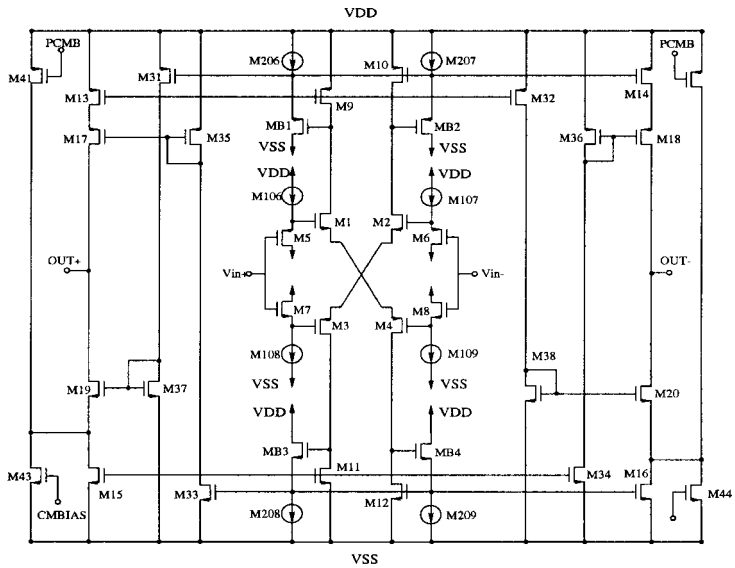

FIGURE 22.19 An improved fully differential OTA. (From Ref. 10. With permission.)

The relationship between the differential input voltage V_{in} and one of the output currents I_{out} is shown in Fig. 22.20. There is a linear relationship between V_{ind} and I_{out} for small to moderate values of V_{ind}. In the case of larger values of V_{ind}, one of the CMOS pairs becomes cut off, resulting in a quasi-quadratic relationship. At a further increase of V_{ind}, the output current will be somewhat saturated due to mobility reduction and to the fact that one of the transistors of the CMOS pair leaves saturation mode. The latter effect is, of course, also strongly dependent on the common input voltage.

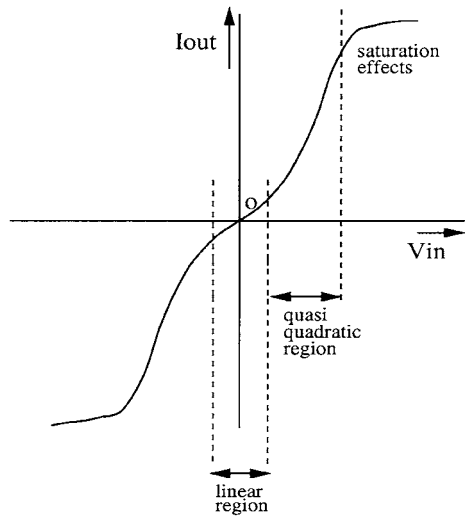

FIGURE 22.20 The $V_{in} \rightarrow I_{out}$ characteristic of the OTA in Fig. 5.19.

22.5 Common-Mode Feedback

A fully differential OTA circuit, as in Fig. 22.19, has many advantages compared with its single-ended counterpart. It is a basic building block in filter design. A fully differential approach, in general, leads to a more efficient current use, doubling of the maximum output-voltage swing, and an improvement of the power-supply rejection ratio (PSRR). It also leads to a significant reduction of the total harmonic distortion, since all even harmonics are canceled out due to the symmetrical structure. Even when there is a small imperfection in the symmetry, the reduction in distortion will be significant.

However, this type of symmetrical circuit needs an extra feedback loop. The feedback around a single-ended OTA usually only provides a differential-mode feedback and is ineffective for common-mode signals.

So, in the case of the fully differential OTA, a common-mode feedback (CMFB) circuit is needed to control the common output voltage. Without a CMFB, the common-mode output voltage of the OTA is not defined and it may drift out of its high-gain region. The general structure of a simple OTA circuit with a differential output and a CMFB circuit is shown in Fig. 22.21. The need for a CMFB circuit is a drawback since it counters many of the advantages of the fully differential approach. The CMFB circuit requires chip area and power, introduces noise, and limits the output-voltage swing.

Figure 22.22(b) shows a simple implementation of a CMFB circuit. A differential pair (M_1, M_2) is used to sense the common-mode output voltage. So, the voltage at the common source of this differential pair (V_s) is used. Its voltage provides, with a level shift of one V_{GS}, the common-mode output voltage of the OTA. The voltage at this node is the first order insensitive to the differential input voltage. The relationship between the differential input voltage V_{in} of the differential pair, superimposed on a common-mode input voltage V_{CM}, and its common-source voltage V_s is shown in Fig. 22.22(a). The common-mode output

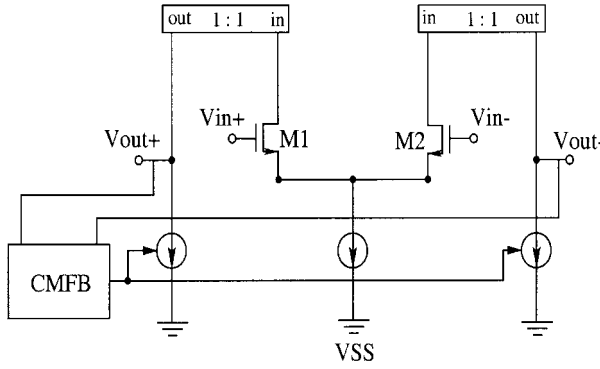

FIGURE 22.21 The general structure of a simple OTA circuit having a differential output and the required CMFB.

voltage of the OTA is determined by the V_{GS} of M_1/M_2 and M_9/M_{10} and can be controlled by the voltage source V_0. There might be an offset in the dc value of the two output voltages due to a mismatch in transistors M_9 and M_{10}.

If the amplitude of the differential output voltage increases, the common-mode voltage will not remain constant, but will be slightly modulated by the differential output voltage, with a modulation frequency that is twice the differential input signal frequency. This modulation is caused by the "non-flat" characteristic of the V_s vs. V_{in} characteristic of the differential pair (M_1, M_2) (see Fig. 22.22(a)).

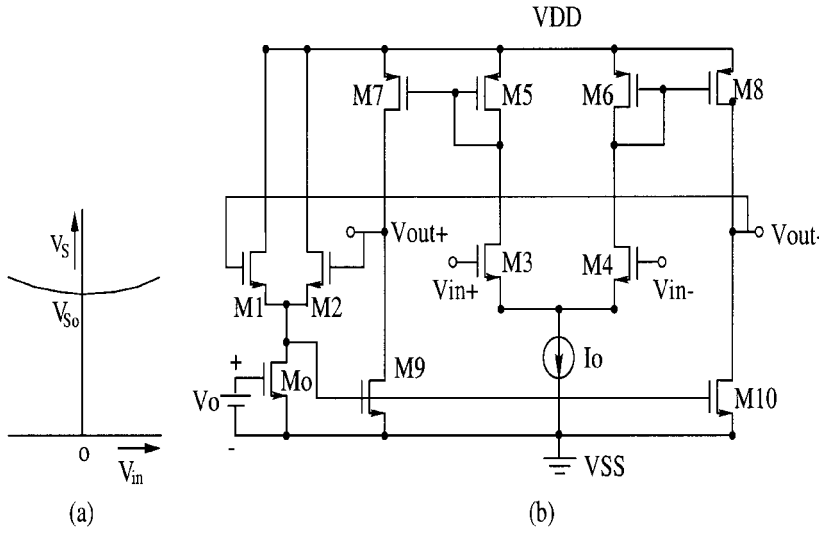

FIGURE 22.22 (a) The relationship between the differential input voltage, superimposed on a common-mode voltage V_{CM} of a differential pair (M_1, M_2) and its common-source voltage V_s; (b), a fully differential OTA with the differential pair (M_1, M_2) for providing a common-mode feedback.

Another commonly used CMFB circuit is shown in the fully-differential folded cascode OTA in Fig. 22.23.[13] In this circuit, a similar high-output resistance and high unloaded voltage gain can be achieved as in the normal cascode circuits. An advantage of the folded cascode technique, however, is a higher

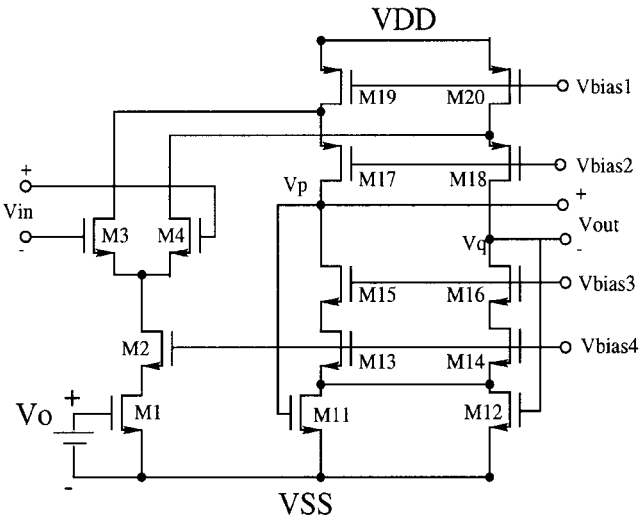

FIGURE 22.23 A fully differential folded cascode OTA with another commonly used CMFB circuit.

accuracy in the signal-current transfer because current mirrors are avoided. In Fig. 22.23, all transistors are in saturation, with the exception of M_1, M_{11}, and M_{12}, which are in the triode region. The CMFB is provided with the help of M_{11} and M_{12}. These two transistors sense the output voltages V_P and V_Q. Since they operate in the triode region, their sum-current is insensitive to the differential output voltage ($V_P - V_Q$) and depends only on the common output voltage ($(V_P+V_Q)/2$). Because the current that flows through M_{17} and M_{18} forces the value of the above-mentioned sum-current, they also determine, together with V_{bias4}, the common-mode output voltage. By choose V_{bias1} in such a way that I_{M19} is twice I_{M17}, and making the width of transistor M_1 twice that of M_{11} (= M_{12}), the nominal common-mode output voltage will be equal to the gate voltage of M_1.

22.6 Filter Applications with Low-Voltage OTAs

Usually, g_m-C filters are considered suitable candidates for high-speed and low-power applications. Compared with the SC op-amp and RC op-amp techniques, the applicability of the g_m-C filter is limited by the low dynamic range and medium, even poor, linearity. The strategy of both simplifying the architecture and designing an ultra-low-voltage OTA[16] are used to meet low-power and dynamic range requirements. The filter topology is derived from a passive ladder form of 5th-order elliptic filtering. Using element replacement and sharing multiple inputs for gyrators, a fully differential 5th-order elliptic filter is shown in Fig. 22.24.[14] This multi-input sharing in the filter design reduces the numbers of OTAs from 11 to 6. Especially for wide bandwidth design, the method saves almost half of the die area and power dissipation. This design uses balanced signals to reduce even harmonics and to relax parasitic matching requirements. The capacitors realizing the filter poles are connected between the outputs of the transconductors and signal ground. This helps the stability of the common-mode feedback circuit because of the loading to both common-mode and fully-differential signal paths> The inherent 6 dB loss at low frequency is compensated for by the first transconductor with $2g_m$ gain. Fig. 22.25 shows the frequency response and the passband of the filter. The filter has –3dB frequency tuning ranges of 1.2 MHz to 2.9 MHz and –60 dB stop band rejection. Obviously, the tuning range is limited by the low-power supply rail. This presents a problem for automatic tuning design at very low supply voltages. A possible application for this filter is for channel selection in wideband handy phones.[15]

Expressions of Logic Functions

Saburo Muroga
University of Illinois at Urbana-Champaign

23.1 Introduction to Basic Logic Operations

In a contemporary digital computer, logic operations for computational tasks are usually done with signals that take values of 0 or 1. These logic operations are performed by many logic networks which constitute the computer. Each logic network has input variables $x_1, x_2, \ldots, x_n$ and output functions $f_1, f_2, \ldots, f_m$. Each of the input variables and output functions take only binary value, 0 or 1. Now let us consider one of these output functions, f. Any **logic function** f can be expressed by a **combination table** (also called a **truth table**) exemplified in Table 23.1.

TABLE 23.1 Combination Table

x	y	z	f
0	0	0	0
0	0	1	0
0	1	0	1
0	1	1	1
1	0	0	0
1	0	1	0
1	1	0	0
1	1	1	1

Basic Logic Expressions

Any logic function can be expressed with three basic logic operations: OR, AND, and NOT. It can also be expressed with other logic operations, as explained in a later section.

The **OR operation** of n variables $x_1, x_2, \ldots, x_n$ yields the value 1 whenever at least one of the variables is 1, and 0 otherwise, where each of $x_1, x_2, \ldots, x_n$ assumes the value 0 or 1. This is denoted by $x_1 \vee x_2 \vee$

$\ldots \vee x_n$. The OR operation defined above is sometimes called **logical sum**, or **disjunction**. Also, some authors use "+", but throughout Section V, we use $\vee$, and + is used to mean an arithmetic addition.

The **AND operation** of n variables yields the value 1 if and only if all variables $x_1, x_2, \ldots, x_n$ are simultaneously 1. This is denoted by $x_1 \cdot x_2 \cdot x_3 \ldots x_n$. These dots are usually omitted: $x_1x_2x_3 \ldots x_n$. The AND operation is sometimes called **conjunction**, or **logical product**.

The **NOT operation** of a variable x yields the value 1 if $x = 0$, and 0 if $x = 1$. This is denoted by $\bar{x}$ or x'. The NOT operation is sometimes called **complement** or **inversion**.

Using these operations, AND, OR, and NOT, a logic function, such as the one shown in Table 23.1 can be expressed in the following formula:

$$f = \bar{x}y\bar{z} \vee \bar{x}yz \vee xyz \tag{23.1}$$

Logic Expressions

Expressions with logic operations with AND, OR, and NOT, such as Eq. 23.1, are called **switching expressions** or **logic expressions**. Variables x, y, and z are sometimes called **switching variables** or **logic variables**, and they assume only binary values 0 and 1. In logic expressions such as Eq. 23.1, each variable, x_i, appears with or without the NOT operation, that is, as $\bar{x}_i$ or x_i. Henceforth, $\bar{x}_i$ and x_i are called the **literals** of a variable x_i.

Logic Expressions with Cubes

Logic expressions such as $f = x\bar{y} \vee yz \vee \bar{x}y\bar{z}$ can be expressed alternatively as a set, {(10-), (-11), (010)}, using components in a vector expression such that the first, second, and third components of the vector represent x, y, and z, respectively, where the value "1" represents x_i, "0" represents $\bar{x}_i$, and "-" represents the lack of the variable. For example, (10-) represents $x\bar{y}$. These vectors are called **cubes**. Logic expressions with cubes are used often because of their convenience for processing by a computer.

23.2 Truth Tables

The value of a function f for different combinations of values of variables can be shown in a table, as exemplified in Tables 23.1 and 23.2. The table for n variables has 2^n rows. Thus the table size increases rapidly as n increases.

TABLE 23.2 Truth Table with Don't-Care Conditions

Decimal Number of Row	Variables			Function
	x	y	z	f
0	0	0	0	0
1	0	0	1	1
2	0	1	0	d
3	0	1	1	0
4	1	0	0	d
5	1	0	1	1
6	1	1	0	1
7	1	1	1	0

Under certain circumstances, some of the combinations of input variable values never occur, or even if they occur, we do not care what values f assumes. These combinations are called **don't-care conditions,** or simply **don't-cares,** and are denoted by "d" or "*", as shown in Table 23.2.

Decimal Specifications

A concise means of expressing the truth table is to list only rows with $f = 1$ and d, identifying these rows with their decimal numbers in the following **decimal specifications**. For example, the truth table of Table 23.2 can be expressed, using Σ, as

$$f(x, y, z) = \Sigma(1, 5, 6) + d(2, 4)$$

If only rows with $f = 0$ and d are considered, the truth table in Table 23.2 can be expressed, using Π, as

$$f(x, y, z) = \Pi(0, 3, 7) + d(2, 4)$$

23.3 Karnaugh Maps

Logic functions can be visually expressed using a Karnaugh map, which is simply a different way of representing a truth table, as exemplified for four variables in Fig. 23.1(a). For the case of four variables, for example, a Karnaugh map consists of 16 cells; that is, 16 small squares as shown in Fig. 23.1(a). Here, two-bit numbers along the horizontal line above the squares show the values of x_1 and x_2, and two-bit binary numbers along the vertical line on the left of the squares show the values of x_3 and x_4. The top left cell in Fig. 23.1(a) has 1 inside for $x_1 = x_2 = x_3 = x_4 = 0$. Also, the cell in the second row and the second column from the left has d inside. This means $f = d$ (i.e., don't-care) for $x_1 = 0$, $x_2 = 1$, $x_3 = 0$, and $x_4 = 1$. The binary numbers that express variables are arranged in such a way that binary numbers for any two cells that are horizontally or vertically adjacent differ in only one bit position. Also, the two numbers in each row in the first and last columns differ in only one bit position and are interpreted to be adjacent. Also, the two numbers in each column in the top and bottom rows are similarly interpreted to be adjacent. Thus, the four cells in the top row are interpreted to be adjacent to the four cells in the bottom row in each column. The four cells in the first column are interpreted to be adjacent to the four cells in the last column in each row. With this arrangement of cells and this interpretation, a Karnaugh map is more than a concise representation of a truth table; it can express many important algebraic concepts, as we will see later. A Karnaugh map is a two-dimensional representation of the 16 cells on the surface of a torus, as shown in Fig. 23.1(b), where the two ends of the map are connected vertically and horizontally.

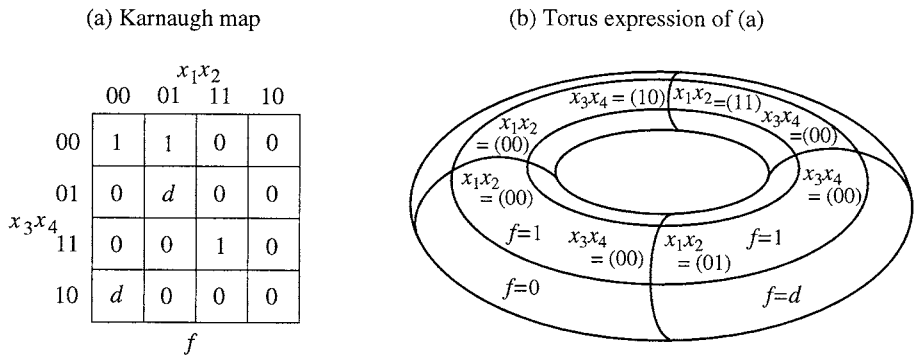

FIGURE 23.1 Karnaugh map for four variables.

Figure 23.2 shows the correspondence between the cells in the map in Fig. 23.2(a) and the rows in the truth table in Fig. 23.2(b). Notice that the rows in the truth table are not shown in consecutive order in the Karnaugh map. The Karnaugh map labeled with variable letters, instead of with binary numbers,

FIGURE 23.2 Correspondence between the cells in a Karanaugh map for four variables and the rows in a truth table.

shown in Fig. 23.2(c), is also often used. Although a 1 or 0 shows the function's value corresponding to a particular cell, 0 is often not shown in each cell. Cells that contain 1's are called **1-cells** (similarly, **0-cells**).

Patterns of Karnaugh maps for two and three variables are shown in Figs. 23.3(a) and (b), respectively. As we extend this treatment to the cases of 5 or more variables, the maps, which will be explained in a later subsection, become increasingly complicated.

(a) Two variables

x_2 \ x_1	0	1
0	f_0	f_2
1	f_1	f_3

f

(b) Three variables

x_3 \ x_1x_2	00	01	11	10
0	f_0	f_2	f_6	f_4
1	f_1	f_3	f_7	f_5

f

FIGURE 23.3 Karanaugh map for two and three variables.

A rectangular loop that consists of 2^i 1-cells without including any 0-cells expresses a product of literals for any i, where $i \geq 1$. For example, the square loop consisting four 1-cells in Fig. 23.4(a) represents the product $x_2\bar{x}_3$, as we can see it from the fact that $x_2\bar{x}_3$ takes value 1 only for these 1-cells, i.e., $x_1 = 0$, $x_2 = 1$, $x_3 = x_4 = 0$; $x_1 = x_2 = 1$, $x_3 = x_4 = 0$; $x_1 = 0$, $x_2 = 1$, $x_3 = 0$, $x_4 = 1$; and $x_1 = x_2 = 1$, $x_3 = 0$, $x_4 = 1$. A rectangular loop consisting of a single 1-cell, such as the one in Fig. 23.4(b), for example, represents the product of literals that the cube (0001) expresses, i.e., $\bar{x}_1\bar{x}_2\bar{x}_3x_4$. Thus, the map in Fig. 23.4(a) expresses the function $x_2\bar{x}_3 \vee x_1x_3\bar{x}_4$ and the map in Fig. 23.4(b) expresses the function $\bar{x}_1\bar{x}_2\bar{x}_3x_4 \vee x_1x_2\bar{x}_3 \vee x_2\bar{x}_4$.

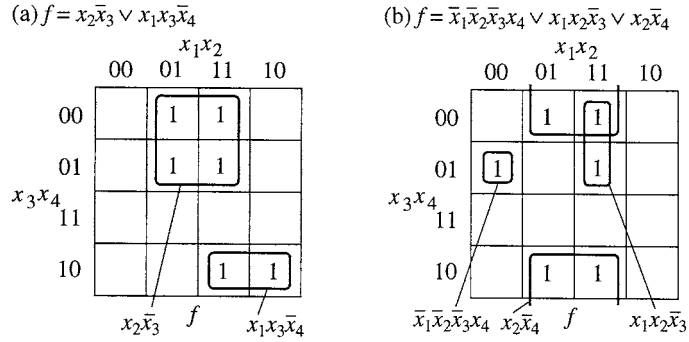

FIGURE 23.4 Products of literals expressed on Karnaugh maps.

Two Completely Specified Functions to Express an Incompletely Specified Function

Suppose we have an incompletely specified function f, as shown in Fig. 23.5(a), i.e., a function that has some don't-cares. This incompletely specified function f can be expressed alternatively with two completely specified functions, f^{ON} and f^{OFF}, shown in Fig. 23.5(b) and (c), respectively. f^{ON} is called **ON-set** of f and is the function whose value is 1 for $f = 1$and 0 for $f = 0$ and d. f^{OFF} is called **OFF-set** of f and is 1 for $f = 0$ and 0 for $f = 1$ and d. **Don't-care set** of f can be derived as

$$f^{DC} = \overline{f^{ON} \vee f^{OFF}}$$

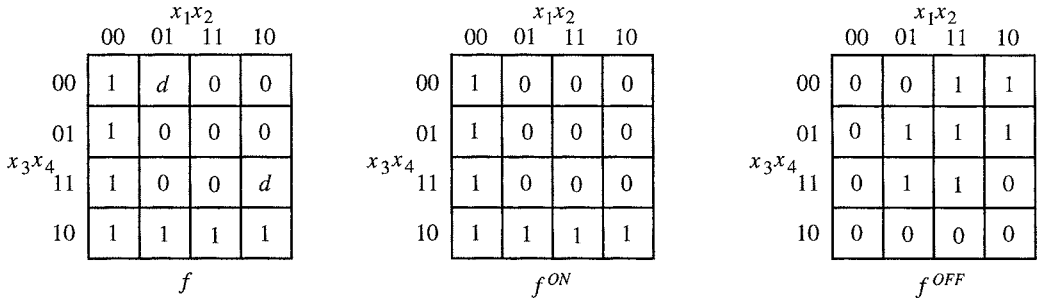

FIGURE 23.5 Expression of an incompletely specified function f with two completely specified functions.

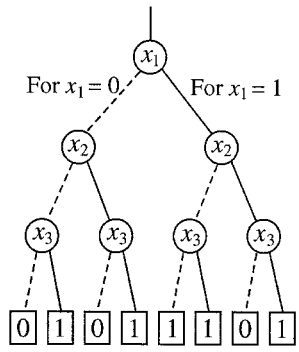
23.4 Binary Decision Diagrams

Truth tables or logic expressions can be expressed with **binary decision diagrams**, which are usually abbreviated as **BDDs**. Compared with logic expressions or truth tables, BDDs have unique features, such as unique concise representation, processing speed, and the memory space, as discussed in a later section.

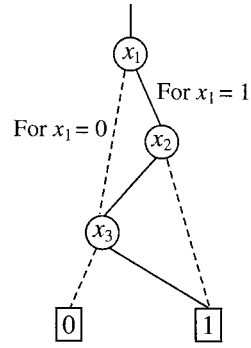
Let us consider a logic expression, $x_1\bar{x}_2 \vee x_3$, for example. This can be expressed as the truth table shown in Fig. 23.6(a). Then, this can be expressed as the BDD shown in Fig. 23.6(b). It is easy to see why Fig. 23.6(b) represents the truth table in Fig. 23.6(a). Let us consider the row, $(x_1x_2x_3) = (011)$, for example, in Fig. 23.6(a). In Fig. 23.6(b), starting from the top node which represents x_1, we go down to

x_1	x_2	x_3	f
0	0	0	0
0	0	1	1
0	1	0	0
0	1	1	1
1	0	0	1
1	0	1	1
1	1	0	0
1	1	1	1

(a) Truth table



(b) BDD equivalent to (a)



(c) Reduced BDD for (b)

FIGURE 23.6 Binary decision diagram.

the left node which represents x_2, following the dotted line corresponding to $x_1 = 0$. From this node, we go down to the second node from the left which represents x_3, following the solid line corresponding to $x_2 = 1$. From this node, we go down to the fourth rectangle from the left which represents, $f = 1$, following the solid line corresponding to $x_3 = 1$. Thus, we have the value of f that is shown for the row, $(x_1, x_2, x_3) = (011)$ in the truth table in Fig. 23.6(a). Similarly, for any row in the truth table, we reach the rectangle that shows the value of f identical to that in the truth table in Fig. 23.6(a), by following a solid or dotted line corresponding to 1 or 0 for each of x_1, x_2, x_3, respectively. BDD in Fig. 23.6(b) can be simplified to the BDD shown in Fig. 23.6(c), which is called the reduced BDD, by the reduction to be described in a later section.

When a function has don't-cares, *d*'s, we can treat it in the same manner by considering a rectangle for *d*'s, as shown in Fig. 23.7.

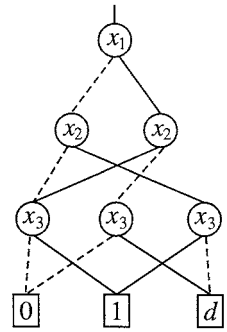


FIGURE 23.7 Reduced BDD with don't-cares.

Basic Theory of Logic Functions

Saburo Muroga
University of Illinois at Urbana-Champaign

24.1 Basic Theorems

Theory on logic functions where the values of variables and their functions are 0 or 1 only is called **switching theory**. Here, let us discuss the basics of switching theory.

Let us denote the set of input variables by the vector expression $(x_1, x_2, \ldots, x_n)$. There are 2^n different input vectors when each of these n variables assume the value 1 or 0. An input vector $(x_1, x_2, \ldots, x_n)$ such that $f(x_1, x_2, \ldots, x_n) = 1$ or 0 is called a **true (input) vector**, or a **false (input) vector** of f, respectively. Vectors with n components are often called ***n*-dimensional vectors** if we want to emphasize that there are n components. When the value of a logic function f is specified for each of the 2^n vectors (i.e., for every combination of the values of $x_1, x_2, \ldots, x_n$), f is said to be **completely specified**. Otherwise, f is said to be **incompletely specified**; that is, the value of f is specified for fewer than 2^n vectors. Input vectors for which the value of f is not specified are called **don't-care conditions** usually denoted by "d" or "*", as described in Chapter 23. These input vectors are never applied to a network whose output realizes f, or the values of f for these input vectors are not important. Thus, the corresponding values of f need not be considered.

If there exists a pair of input vectors $(x_1, \ldots, x_{i-1}, 0, x_{i+1}, \ldots, x_n)$ and $(x_1, \ldots, x_{i-1}, 1, x_{i+1}, \ldots, x_n)$ that differ only in a particular variable x_i, such that the values of f for these two vectors differ, the logic function $f(x_1, x_2, \ldots, x_n)$ is said to be **dependent on** x_i. Otherwise, it is said to be **independent of** x_i. In this case, f can be expressed without the x_i in the logic expression of f. If f is independent of x_i, x_i is called a **dummy variable**. If $f(x_1, x_2, \ldots, x_n)$ depends on all its variables, it is said to be **non-degenerate**; otherwise, **degenerate**. For example, $x_1 \vee x_2x_3 \vee x_2\bar{x}_3$ can be expressed as $x_1 \vee x_2$ without dummy variable x_3.

Logic Expressions and Expansions

Given variable x_i, x_i and $\bar{x}_i$ are called **literals** of x_i, as already explained.

Definition 24.1: (1) A conjunction (i.e., a logical product) of literals where a literal for each variable appears at most once is called a **term** (or a **product**). A term may consist of a single literal. A disjunction (i.e., logical sum) of terms is called a **disjunctive form** (or a sum of products). (2) Similarly, a disjunction (i.e., a logical sum) of literals where a literal for each variable appears at most

once is called an **alterm**. An alterm may consist of a single literal. A conjunction of alterms is called a **conjunctive form** (or a product of sums).

For example, $x_1\bar{x}_2x_3$ is a term, and $x_1 \vee x_2 \vee \bar{x}_3$ is an alterm. Also, $x_1x_2 \vee x_1 \vee x_2$ and $x_1 \vee \bar{x}_1x_2$ are disjunctive forms that are equivalent to the logic function $x_1 \vee x_2$, but $x_1 \vee x_2(\bar{x}_1 \vee \bar{x}_2)$ is not a disjunctive form, although it expresses the same function. A disjunctive form does not contain products of literals that are identically 0 (e.g., $x_1\bar{x}_2x_2$) from the first sentence of (1). Similarly, a conjunctive form does not contain disjunctions of literals that are identically 1 (e.g., $x_1 \vee \bar{x}_2 \vee x_2 \vee x_3$).

The following expressions of a logic function are important special cases of a disjunctive form and a conjunctive form.

Definition 24.2: Assume that n variables, $x_1, x_2, \ldots, x_n$, are under consideration. (1) A **minterm** is defined as the conjunction of exactly n literals, where exactly one literal for each variable (x_i and $\bar{x}_i$ are two literals of a variable x_i) appears. When a logic function f of n variables is expressed as a disjunction of minterms without repetition, it is called the **minterm expansion** of f. (2) A **maxterm** is defined as a disjunction of exactly n literals, where exactly one literal for each variable appears. When f is expressed as a conjunction of maxterms without repetition, it is called the **maxterm expansion** of f.

For example, when three variables, x_1, x_2, and x_3, are considered, there exist $2^3 = 8$ minterms: $\bar{x}_1\bar{x}_2\bar{x}_3$, $\bar{x}_1\bar{x}_2x_3$, $\bar{x}_1x_2\bar{x}_3$, $\bar{x}_1x_2x_3$, $x_1\bar{x}_2\bar{x}_3$, $x_1\bar{x}_2x_3$, $x_1x_2\bar{x}_3$, and $x_1x_2x_3$. For the given function $x_1 \vee x_2x_3$, the minterm expansion is $\bar{x}_1x_2x_3 \vee x_1\bar{x}_2\bar{x}_3 \vee x_1\bar{x}_2x_3 \vee x_1x_2\bar{x}_3 \vee x_1x_2x_3$ and the maxterm expansion is $(x_1 \vee x_2 \vee x_3)$ $(x_1 \vee x_2 \vee \bar{x}_3)$ $(x_1 \vee \bar{x}_2 \vee x_3)$, as explained in the following.

Also notice that the row for each true vector in a truth table and also its corresponding 1-cell in the Karnaugh map correspond to a minterm. If $f = 1$ for $x_1 = x_2 = 1$ and $x_3 = 0$, then this row in the truth table and its corresponding 1-cell in the Karnaugh map corresponds to a minterm $x_1x_2\bar{x}_3$. Also, as will be described in a later section, the row for each false vector in a truth table and also its corresponding 0-cell in the Karnaugh map corresponds to a maxterm. For example, if $f = 0$ for $x_1 = x_2 = 1$ and $x_3 = 0$, then this row in the truth table and its corresponding 0-cell in the Karnaugh map corresponds to a maxterm $(x_1 \vee x_2 \vee x_3)$.

Theorem 24.1: Any logic function can be uniquely expanded with minterms and also with maxterms.

For example, $f(x_1, x_2) = x_1 \vee x_2\bar{x}_3$ can be uniquely expanded with the minterms as

$$x_1 \vee x_2\bar{x}_3 = \bar{x}_1x_2\bar{x}_3 \vee x_1\bar{x}_2\bar{x}_3 \vee x_1\bar{x}_2x_3 \vee x_1x_2\bar{x}_3 \vee x_1x_2x_3$$

and also can be uniquely expressed with maxterms as

$$x_1 \vee x_2\bar{x}_3 = (x_1 \vee x_2 \vee x_3)(x_1 \vee x_2 \vee \bar{x}_3)(x_1 \vee \bar{x}_2 \vee \bar{x}_3) .$$

These expansions have different expressions but both express the same function $x_1 \vee x_2\bar{x}_3$.

The following expansions, called **Shannon's expansions,** are often useful.

Any function $f(x_1, x_2, \ldots, x_n)$ can be expanded into the following expression with respect x_1:

$$f(x_1, x_2, \ldots, x_n) = x_1 f(1, x_2, x_3, \ldots, x_n) \vee \bar{x}_1 f(0, x_2, x_3, \ldots, x_n)$$

where $f(1, x_2, x_3, \ldots, x_n)$ and $f(0, x_2, x_3, \ldots, x_n)$, which are $f(x_1, x_2, \ldots, x_n)$ with x_1 set to 1 and 0, respectively, are called **cofactors**. By further expanding each of $f(1, x_2, x_3, \ldots, x_n)$ and $f(0, x_2, x_3, \ldots, x_n)$ with respect to x_2, we have

$$\begin{aligned} f(x_1, x_2, \ldots, x_n) = {} & x_1x_2 f(1, x_2, x_3, \ldots, x_n) \vee x_1\bar{x}_2 f(1, 0, x_3, \ldots, x_n) \\ & \vee \bar{x}_1x_2 f(0, 1, x_3, \ldots, x_n) \vee \bar{x}_1\bar{x}_2 f(0, 0, x_3, \ldots, x_n) \end{aligned}$$

Then we can further expand with respect to x_3. And so on.

Also, similarly

$$f(x_1, x_2, \ldots, x_n) = (x_1 \vee f(0, x_2, x_3, \ldots, x_n))(\bar{x}_1 \vee f(1, x_2, x_3, \ldots, x_n))$$
$$f(x_1, x_2, \ldots, x_n) = (x_1 \vee x_2 \vee f(0, 0, x_3, \ldots, x_n))(x_1 \vee \bar{x}_2 \vee f(0, 1, x_3, \ldots, x_n))$$
$$(\bar{x}_1 \vee x_2 \vee f(1, 0, x_3, \ldots, x_n))(\bar{x}_1 \vee \bar{x}_2 \vee f(1, 1, x_3, \ldots, x_n))$$

And so on.

These expansions can be extended to the case with m variables factored out, where $m \leq n$, although the only expansions for $m = 1$ (i.e., x_1) and 2 (i.e., x_1 and x_2) are shown above. Of course, when $m = n$, the expansions become the minterm and maxterm expansions.

Theorem 24.2: De Morgan's Theorem —

$$\overline{(x_1 \vee x_2 \vee \ldots \vee x_n)} = \bar{x}_1\bar{x}_2\ldots\bar{x}_n \qquad \text{and} \qquad \overline{(x_1x_2\ldots x_n)} = \bar{x}_1 \vee \bar{x}_2 \vee \ldots \vee \bar{x}_n$$

A logic function is realized by a **logic network** that consists of **logic gates**, where logic gates are realized with hardware, such as transistor circuits.

De Morgan's Theorem 24.2 has many applications. For example, it asserts that a NOR gate, i.e., a logic gate whose output expresses the complement of the OR operation on its inputs, with noncomplemented variable input $x_1, x_2, \ldots, x_n$ is interchangeable with an AND gate, i.e., a logic gate whose output expresses the AND operation on its complemented variable inputs $\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n$, since the outputs of both gates express the same function. This is illustrated in Figure 24.1 for $n = 2$.

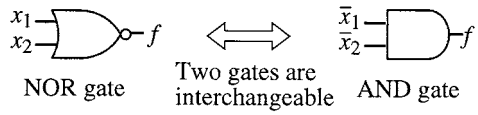

FIGURE 24.1 Application of De Morgan's theorem.

Definition 24.3: The **dual** of a logic function $f(x_1, x_2, \ldots, x_n)$ is defined as $\bar{f}(\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n)$ where $\bar{f}$ denotes the complement of the entire function $f(x_1, x_2, \ldots, x_n)$ [in order to denote the complement of a function $f(x_1, x_2, \ldots, x_n)$, the notation $\overline{f(x_1, x_2, \ldots, x_n)}$ might be used instead of $\bar{f}$]. Let it be denoted by $f^d(x_1, x_2, \ldots, x_n)$. In particular, if $f(x_1, x_2, \ldots, x_n) = f^d(x_1, x_2, \ldots, x_n)$, then $f(x_1, x_2, \ldots, x_n)$ is called a **self-dual function**.

For example, when $f(x_1, x_2) = x_1 \vee x_2$ is given, we have $f^d(x_1, x_2) = \bar{f}(\bar{x}_1, \bar{x}_2) = \overline{\bar{x}_1 \vee \bar{x}_2}$. This is equal to x_1x_2 by the first identity of Theorem 24.2. In other words, $f^d(x_1, x_2) = x_1x_2$. The function $x_1x_2 \vee x_2x_3 \vee x_1x_3$ is self-dual, as can be seen by applying the two identities of Theorem 24.2.

Notice that, if f^d is the dual of f, the dual of f^d is f.

The concept of a dual function has many important applications. For example, it is useful in the conversion of networks with different types of gates, as in Fig. 24.2, where the replacement of the AND and OR gates in Fig. 24.2(a) by OR and AND gates, respectively, yields the output function f^d in Fig. 24.2(b), which is dual to the output f of Fig. 24.2(a).

As will be explained in a later chapter, a logic gate in CMOS is another important application example of the concept of "dual," where **CMOS** stands for complementary MOS and is a **logic family**, i.e., a type of transistor circuit for realizing a logic gate. Duality is utilized for reducing the power consumption of a logic gate in CMOS.

The following theorem shows a more convenient method of computing the dual of a function than direct use of Definition 24.3.

(a)A network with AND and OR gates

(b)A network with AND and OR gates interchanged

FIGURE 24.2 Duality relation between two networks.

Theorem 24.3: Generalized De Morgan's Theorem — Let $f(x_1, x_2, \ldots, x_n)$ be a function expressed by "$\vee$" and "$\cdot$" (and possibly also by parentheses and the constants 0 and 1). Let $g(x_1, x_2, \ldots, x_n)$ be a function that is obtained by replacing every "$\vee$" and "$\cdot$" by "$\cdot$" and "$\vee$", respectively, throughout the logic expression of $f(x_1, x_2, \ldots, x_n)$ (and also, if 0 or 1 is contained in the original expression, by replacing 0 and 1 by 1 and 0, respectively). Then,

$$f^d(x_1, x_2, \ldots, x_n) = g(x_1, x_2, \ldots, x_n)$$

For example, when $f(x_1, x_2) = x_1 \vee x_2 \cdot \bar{x}_3$ is given, $f^d = x_1 \cdot (x_2 \vee \bar{x}_3)$ is obtained by this theorem. Here, notice that in f, the calculation of $\cdot$ precedes that of $\vee$; and in f^d, the $\vee$ must correspondingly be calculated first [thus, the parentheses are placed as $(x_2 \vee \bar{x}_3)$]. When $f = x_1 \vee 0 \cdot x_2 \cdot \bar{x}_3$ is given, $f^d = x_1 \cdot (1 \vee x_2 \vee \bar{x}_3)$ results by this theorem. When $f = x_1 \vee 1 \cdot x_2 \cdot \bar{x}_3$ is given, $f^d = x_1 \cdot (0 \vee x_2 \vee \bar{x}_3)$ results.

For example, the dual of $x_1 \vee x_2 x_3$ is $\overline{\bar{x}_1 \vee \bar{x}_2 \bar{x}_3}$ according to Definition 24.3, which is a somewhat complicated expression. But by using the generalized De Morgan's theorem, we can immediately obtain the expression without bars, $x_1 \cdot (x_2 \vee x_3) = x_1 x_2 \vee x_1 x_3$.

24.2 Implication Relations and Prime Implicants

In this section, we discuss the algebraic manipulation of logic expressions; that is, how to convert a given logic expression into others. This is very useful for simplification of logic expression. Although simplification of a logic expression based on a Karnaugh map, which will be discussed in Chapter 25, is convenient in many cases, algebraic manipulation is more convenient in many other situations.[3]

Definition 24.4: Let two logic functions be $f(x_1, x_2, \ldots, x_n)$ and $g(x_1, x_2, \ldots, x_n)$. If every vector $(x_1, x_2, \ldots, x_n)$ satisfying $f(x_1, x_2, \ldots, x_n) = 1$ satisfies also $g(x_1, x_2, \ldots, x_n) = 1$ but the converse does not necessarily hold, we write

$$f(x_1, x_2, \ldots, x_n) \subseteq g(x_1, x_2, \ldots, x_n) \tag{24.1}$$

and we say that f **implies** g. In addition, if there exists a certain vector $(x_1, x_2, \ldots, x_n)$ satisfying simultaneously $f(x_1, x_2, \ldots, x_n) = 0$ and $g(x_1, x_2, \ldots, x_n) = 1$, we write

$$f(x_1, x_2, \ldots, x_n) \subset g(x_1, x_2, \ldots, x_n) \tag{24.2}$$

and we say that f **strictly implies** g (some authors use different symbols instead of $\subset$). Therefore, Eq. 24.1 means $f(x_1, x_2, \ldots, x_n) \subset g(x_1, x_2, \ldots, x_n)$ or $f(x_1, x_2, \ldots, x_n) = g(x_1, x_2, \ldots, x_n)$. These relations are called **implication relations**. The left- and right-hand sides of Eq. (24.1) or (24.2) are called **antecedent** and **consequent**, respectively. If an implication relation holds between f and g. That is, if $f \subseteq g$ or $f \supseteq g$ holds, f and g are said to be **comparable** (more precisely, "$\subseteq$-comparable" or "implication-comparable"). Otherwise, they are **incomparable**.

When two functions, f and g, are given, we can find by the following methods at least whether or not there exists an implication relation between f and g; for example, using a truth table for f and g, directly based on Definition 24.4. If and only if there is no row in which $f = 1$ and $g = 0$, the implication relation $f \subseteq g$ holds. Furthermore, if there is at least one row in which $f = 0$ and $g = 1$, the relation is tightened to $f \subset g$. Table 24.1 shows the truth table for $f = x_1\bar{x}_3 \vee \bar{x}_1x_2x_3$ and $g = x_1 \vee x_2$. There is no row with $f = 1$ and $g = 0$, so $f \subseteq g$ holds. Furthermore, there is a row with $f = 0$ and $g = 1$, so the relation is actually $f \subset g$.

TABLE 24.1 Example for $f \subseteq g$

x_1	x_2	x_3	f	g
0	0	0	0	0
0	0	1	0	1
0	1	0	0	1
0	1	1	1	1
1	0	0	1	1
1	0	1	0	1
1	1	0	1	1
1	1	1	0	1

Although "g implies f" means "if $g = 1$, then $f = 1$," it is to be noticed that "g does not imply f" does not necessarily mean "f implies g" but does mean either "f implies g" or "g and f are incomparable." In other words, it does mean "if $g = 1$, then f becomes a function other than the constant function which is identically equal to 1." (As a special case, f could be identically equal to 0.) Notice that "g does not imply f" does not necessarily mean "if $g = 0$, then $f = 0$."

Definition 24.5: An **implicant** of a logic function f is a term that implies f.

For example, x_1, x_2, x_1x_2, , and $x_1x_3\bar{x}_2$ are examples of implicants of the function $x_1 \vee x_2$. But $\bar{x}_1\bar{x}_2$ is not. Notice that x_1x_3 is an implicant of $x_1 \vee x_2$ even though $x_1 \vee x_2$ is independent of x_3. (Notice that every product of an implicant of f with any dummy variables is also an implicant of f. Thus, f has an infinite number of implicants.) But x_1x_2 is not an implicant of $f = x_1x_3 \vee \bar{x}_2$ because x_1x_2 does not imply f. (When $x_1x_2 = 1$, we have $f = x_3$, which can be 0. Therefore, even if $x_1x_2 = 1$, f may become 0.) Some implicants are not obvious from a given expression of a function. For example, $x_1x_2 \vee \bar{x}_1x_2$ has implicants x_2x_3 and $x_2x_3x_4$. Also, $x_1\bar{x}_2 \vee x_2x_3 \vee \bar{x}_1x_3$ has an implicant x_3 because, if $x_3 = 1$, $x_1\bar{x}_2 \vee x_2x_3 \vee \bar{x}_1x_3$ becomes $x_1\bar{x}_2 \vee x_2 \vee \bar{x}_1 = x_1 \vee x_2 \vee \bar{x}_1 = (x_1 \vee \bar{x}_1) \vee x_2 = 1 \vee x_2$, which is equal to 1.

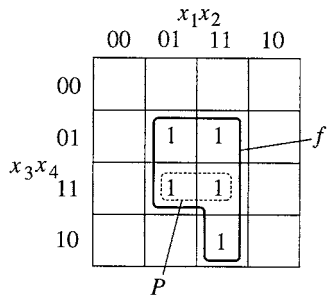
Definition 24.6: A term P is said to **subsume** another term Q if all the literals of Q are contained among those of P. If a term P which subsumes another term Q contains literals that Q does not have, P is said to **strictly subsume** Q.

For example, term $x_1\bar{x}_2x_3\bar{x}_4$ subsumes $x_1x_3\bar{x}_4$ and also itself. More precisely speaking, $x_1\bar{x}_2x_3\bar{x}_4$ strictly subsumes $x_1x_3\bar{x}_4$. Notice that Definition 24.6 can be equivalently stated as follows: "A term P is said to subsume another term Q if P implies Q; that is, $P \subseteq Q$. Term P strictly subsumes another term Q if $P \subset Q$."

Notice that when we have terms P and Q, we can say, "P implies Q" or, equivalently, "P subsumes Q." But the word "subsume" is ordinarily not used in other cases, except for comparing two alterms (as we will see in Section 25.4). For example, when we have functions f and g that are not in single terms, we usually do not say "f subsumes g."

On a Karnaugh map, if the loop representing a term P (always a single rectangular loop consisting of 2^i 1-cells because P is a product of literals) is part of the 1-cells representing function f, or is contained in the loop representing a term Q, P implies f or subsumes Q, respectively. Figure 24.3 illustrates this. Conversely, it is easy to see that, if a term P, which does not contain any dummy variables of f, implies f, the loop for P must consist of some 1-cells of f, and if a term P, which does not contain any dummy variables of another term Q, implies Q, the loop for P must be inside the loop for Q.

(a) Term P implies a function f.



(b) Term P subsumes a term Q.

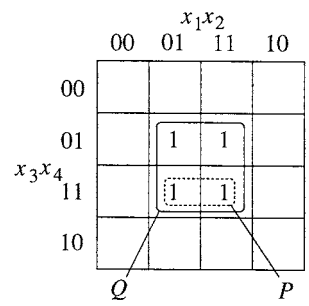


FIGURE 24.3 Comparison of "imply" and "subsume."

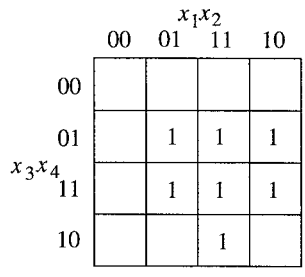
The following concept of "prime implicant" is useful for deriving a simplest disjunctive form for a given function f (recall that logic expressions for f are not unique) and consequently for deriving a simplest logic network realizing f.

Definition 24.7: A **prime implicant** of a given function f is defined as an implicant of f such that no other term subsumed by it is an implicant of f.

For example, when $f = x_1x_2 \vee \bar{x}_1x_3 \vee x_1x_2x_3 \vee \bar{x}_1x_2x_3$ is given, x_1x_2, $\bar{x}_1x_3$, and x_2x_3 are prime implicants. But $x_1x_2x_3$ and $\bar{x}_1x_2x_3$ are not prime implicants, although they are implicants (i.e., if any of them is 1, then $f = 1$). Prime implicants of a function f can be obtained from other implicants of f by stripping off unnecessary literals until further stripping makes the remainder no longer imply f. Thus, x_2x_3 is a prime implicant of $x_1x_2 \vee \bar{x}_1x_3$, and $x_2x_3x_4$ is an implicant of this function but not a prime implicant. As seen from this example, some implicants, such as x_2x_3, and accordingly some prime implicants are not obvious from a given expression of a function. Notice that, unlike implicants, **a prime implicant cannot contain a literal of any dummy variable of a function**.

On a Karnaugh map, all prime implicants of a given function f of at least up to four variables can be easily found. As is readily seen from Definition 24.7, each rectangular loop that consists of 2^i 1-cells, with i chosen as large as possible, is a prime implicant of f. If we find all such loops, we will have found all prime implicants of f. Suppose that a function f is given as shown in Fig. 24.4(a). Then, the prime implicants are shown in Fig. 24.4(b). In this figure, we cannot make the size of the rectangular loops any bigger. (If we increase the size of any one of these loops, the new rectangular loop will contain a number of 1-cells that is not 2^i for any i, or will include one or more 0-cells.)

(a) A function f



(b) Prime implicants

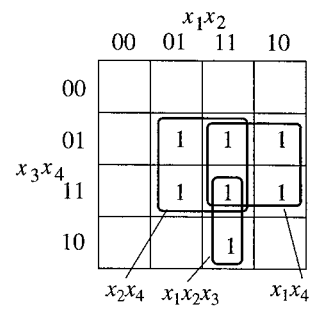


FIGURE 24.4 Expression of prime implicants on Karnaugh maps.

Consensus

Next, let us systematically find all prime implicants, including those not obvious, for a given logic function. To facilitate our discussion, let us define a consensus.

Definition 24.8: Assume that two terms, P and Q, are given. If there is exactly one variable, say x, appearing noncomplemented in one term and complemented in the other — in other words, if $P = xP'$ and $Q = \bar{x}\,Q'$ (no other variables appear complemented in either P' or Q', and noncomplemented in the other) — then the product of all literals except the literals of x, that is, $P'Q'$ with duplicates of literals deleted, is called the **consensus** of P and Q.

For example, if we have two terms, $x_1\bar{x}_2x_3$ and $\bar{x}_1\bar{x}_2x_4\bar{x}_5$, the consensus is $\bar{x}_2x_3x_4\bar{x}_5$. But $x_1\bar{x}_2x_3$ and $\bar{x}_1x_2x_4\bar{x}_5$ do not have a consensus because two variables, x_1 and x_2, appear noncomplemented and complemented in these two terms.

A consensus can easily be shown on a Karnaugh map. For example, Fig. 24.5 shows a function $f = x_1x_2 \vee \bar{x}_1x_4$. In addition to the two loops shown in Fig. 24.5(a), which corresponds to the two prime implicants, x_1x_2 and $\bar{x}_1x_4$, of f, this f can have another rectangular loop, which consists of 2^i 1-cells with i chosen as large as possible, as shown in Fig. 24.5(b). This third loop, which represents x_2x_4, the consensus of x_1x_2 and $\bar{x}_1x_4$, intersects the two loops in Fig. 24.5(a) and is contained within the 1-cells that represent x_1x_2 and $\bar{x}_1x_4$. This is an important characteristic of a loop representing a consensus. Notice that these three terms, x_2x_4, x_1x_2, and $\bar{x}_1x_4$, are prime implicants of f. **When rectangular loops of 2^i 1-cells are adjacent (not necessarily exactly in the same row or column), the consensus is a rectangular loop of 2^i 1-cells, with i chosen as large as possible, that intersects and is contained within these loops. Therefore, if we obtain all largest possible rectangular loops of 2^i 1-cells, we can obtain all prime implicants, including consensuses, which intersect and are contained within other pairs of loops.** Sometimes, a consensus term can be obtained from a pair consisting of another consensus and a term, or a pair of other consensuses that do not appear in a given expression. For example, $x_1\bar{x}_2$ and x_2x_3 of $x_1\bar{x}_2 \vee x_2x_3 \vee \bar{x}_1x_3$ yield consensus x_1x_3, which in turn yields consensus x_3 with $\bar{x}_1x_3$. Each such consensus is also obtained among the above largest possible rectangular loops.

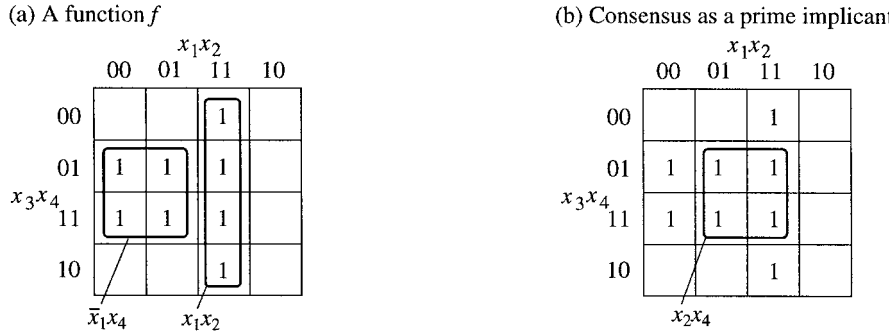

FIGURE 24.5 Expression of a consensus on Karnaugh maps.

As we can easily prove, **every consensus that is obtained from terms of a given function f implies f.** In other words, every consensus generated is an implicant of f, although not necessarily a prime implicant.

Derivation of All Prime Implicants from a Disjunctive Form

The derivation of all prime implicants of a given function f is easy, using a Karnaugh map. If, however, the function has five or more variables, the derivation becomes increasingly complicated on a Karnaugh

map. Therefore, let us discuss an algebraic method, which is convenient for implementation in a computer program, although for functions of many variables even algebraic methods are too time consuming and we need to resort to heuristic methods.

The following algebraic method to find all prime implicants of a given function, which Tison[4,5] devised, is more efficient than the previously known **iterated-consensus method**, which was proposed for the first time by Blake in 1937.[2]

Definition 24.9: Suppose that p products, $A_1, \ldots, A_p$, are given. A variable such that only one of its literals appears throughout $A_1, \ldots, A_p$ is called a **unate variable**. A variable such that both of its literals appear in $A_1, \ldots, A_p$ is called a **binate variable**.

For example, when $x_1\bar{x}_2$, $\bar{x}_1x_3$, $x_3\bar{x}_4$, and $\bar{x}_2x_4$ are given, x_1 and x_4 are binate variables, since x_1 and x_4 as well as their complements, $\bar{x}_1$ and $\bar{x}_4$ appear, and x_2 and x_3 are unate variables.

Procedure 24.1: The Tison Method — Derivation of All Prime Implicants of a Given Function

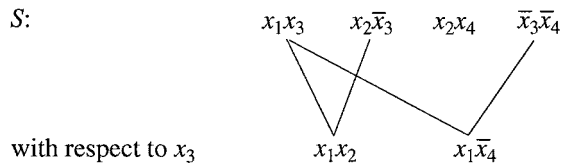
Assume that a function f is given in a disjunctive from $f = P \vee Q \vee \ldots \vee T$, where $P, Q, \ldots, T$ are terms, and that we want to find all prime implicants of f. Let S denote the set $\{P, Q, \ldots, T\}$.

1. Among $P, Q, \ldots, T$ in set S, first delete every term subsuming any other term. Among all binate variables, choose one of them.

For example, when $f = x_1x_2x_4 \vee x_1x_3 \vee x_2\bar{x}_3 \vee x_2x_4 \vee \bar{x}_3\bar{x}_4$ is given, delete $x_1x_2x_4$, which subsumes x_2x_4. The binate variables are x_3 and x_4. Let us choose x_3 first.

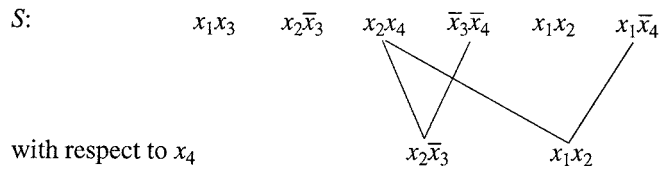
2. For each pair of terms, that is, one with the complemented literal of the chosen variable and the other with the noncomplemented literal of that variable, generate the consensus. Then add the generated consensus to S. From S, delete every term that subsumes another.

For our example, x_3 is chosen as the first binate variable. Thus we get consensus x_1x_2 from pair x_1x_3 and $x_2\bar{x}_3$, and consensus $x_1\bar{x}_4$ from pair x_1x_3 and $\bar{x}_3\bar{x}_4$. None subsumes another. Thus, S, the set of prime implicants, becomes x_1x_3, $x_2\bar{x}_3$, x_2x_4, $\bar{x}_3\bar{x}_4$, x_1x_2, and $x_1\bar{x}_4$.



3. Choose another binate variable in the current S. Then go to Step 2. If all binate variables are tried, go to Step 4.

For the above example, for the second iteration of Step 2, we choose x_4 as the second binate variable and generate two new consensuses as follows:



But when they are added to S, each one subsumes some term contained in S. Therefore, they are eliminated.

4. The procedure terminates because all binate variables are processed, and all the products in S are desired prime implicants.

The last expression is called the **complete sum** or **the all-prime-implicant disjunction**. The complete sum is the first important step in deriving the most concise expressions for a given function. □

Generation of prime implicants for an incompletely specified function, which is more general than the case of completely specified function described in Procedure 24.1, is significantly speeded up with the use of BDD (described in Chapters 24.1 and 24.4) by Coudert and Madre.[1]

Simplification of Logic Expressions

Saburo Muroga
University of Illinois at Urbana-Champaign

25.1 Minimal Sums

In this chapter, using only AND and OR gates, we will synthesize a two-level logic network. This is the fastest network, if we assume that every gate has the same delay, since the number of levels cannot be reduced further unless a given function can be realized with a single AND or OR gate. If there is more than one such network, we will derive the simplest network. Such a network has a close relation to important concepts in switching algebra, that is, irredundant disjunctive forms and minimal disjunctive forms (or minimal sums), as we discuss in the following.

Now let us explore basic properties of logic functions.

For many functions, some terms in their complete sums are redundant. In other words, even if we eliminate some terms from a complete sum, the remaining expression may still represent the original function for which the complete sum was obtained. Thus, we have the following concept.

Definition 25.1: An **irredundant disjunctive form** for f (sometimes called an irredundant sum-of-products expression or an irredundant sum) is a disjunction of prime implicants such that removal of any of the prime implicants makes the remaining expression not express the original f.

An irredundant disjunctive form for a function is not necessarily unique.

Definition 25.2: Prime implicants that appear in every irredundant disjunctive form for f are called **essential prime implicants** of f. Prime implicants that do not appear in any irredundant disjunctive form for f are called **absolutely eliminable prime implicants** of f. Prime implicants that appear in some irredundant disjunctive forms for f but not in all are called **conditionally eliminable prime implicants** of f.

Different types of prime implicants are shown in the Karnaugh map in Fig. 25.1 for a function $f = \bar{x}_1 x_3 \bar{x}_4 \vee \bar{x}_1 x_2 x_3 \vee \bar{x}_1 x_2 x_4 \vee x_2 x_3 x_4 \vee x_1 x_3 x_4 \vee x_1 \bar{x}_2 x_4$. Here, $\bar{x}_1 x_2 \bar{x}_4$, $\bar{x}_1 x_2 x_4$, and $x_1 \bar{x}_2 x_4$ are essential prime implicants, $x_2 x_3 x_4$ and $x_1 x_3 x_4$ are conditionally eliminable prime implicants and $\bar{x}_1 x_2 x_3$ is absolutely eliminable prime implicant.

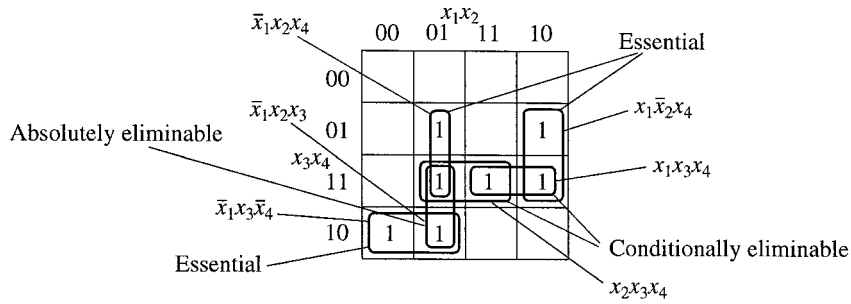

FIGURE 25.1 Different types of prime implicants.

The concepts defined in the following play an important role in switching theory.

Definition 25.3: Among all irredundant disjunctive forms of f, those with a minimum number of prime implicants are called **minimal sums** (some authors call them as "sloppy minimal sum"). Among minimal sums, those with a minimum number of literals are called **absolute minimal sums** for f.

Irredundant disjunctive forms for a given function f can be obtained by deleting prime implicants one by one from the complete sum in all possible ways, after obtaining the complete sum by the Tison method discussed in Chapter 24. Then the minimal sums can be found among the irredundant disjunctive forms. Usually, however, this approach is excessively time-consuming because a function has many prime implicants when the number of variables is very large. When the number of variables is too large, derivation of a minimal sum is practically impossible.

Later, we will discuss efficient methods to derive minimal sums within reasonable computation time when the number of variables is few.

25.2 Derivation of Minimal Sums by Karnaugh Map

Because of its pictorial nature, a Karnaugh map is a very powerful tool for deriving manually all prime implicants, irredundant disjunctive forms, minimal sums, and also absolute minimal sums. Algebraic concepts such as prime implicants and consensuses can be better understood on a map.

One can derive all prime implicants, irredundant disjunctive forms, and minimal sums by the following procedures on Karnaugh maps, when the number of variables is small enough for the map to be manageable.

Procedure 25.1: Derivation of Minimal Sums on a Karnaugh Map

This procedure consists of three steps:

1. On a Karnaugh map, encircle all the 1-cells with rectangles (also squares as a special case), each of which consists of 2^i 1-cells, choosing i as large as possible, where i is a non-negative integer. Let us call these loops **prime implicant loops**, since they correspond to prime implicants in the case of the Karnaugh map for four or fewer variables. (In the case of a five- or six-variable map, the correspondence is more complex, as will be explained later.) Examples are shown in Fig. 25.2(a).
2. Cover all the 1-cells with prime-implicant loops so that removal of any loops leaves some 1-cells uncovered. These sets of loops represent **irredundant disjunctive forms**. Figs. 25.2(b) through 25.2(e) represent four irredundant disjunctive forms, obtained by choosing the loops in Fig. 25.2(a) in four different ways. For example, if the prime-implicant loop $x_1\bar{x}_3x_4$ is omitted in Fig. 25.2(b), the 1-cells for $(x_1, x_2, x_3, x_4) = (1\ 1\ 0\ 1)$ and $(1\ 0\ 0\ 1)$ are not covered by any loops.
3. From the sets of prime implicant loops formed in Step 2 for irredundant disjunctive forms, choose the sets with a minimum number of loops. Among these sets, the sets that contain as many of the largest loops as possible (a larger loop represents a product of fewer literals) represent minimal sums. Figure 25.2(c) expresses the unique minimal sum for this function, since it contains one less loop than Fig. 25.2(b), (d), or (e).

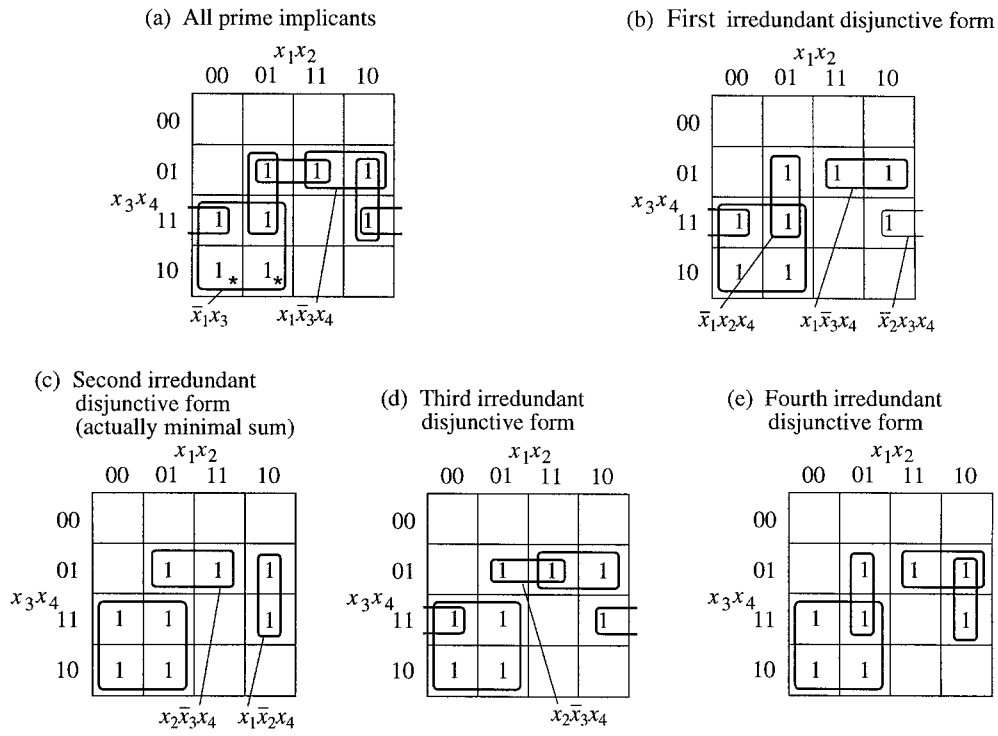

FIGURE 25.2 Irredundunt disjunctive forms and a minimal sum.

It is easy to see, from the definitions of prime implicants, irredundant disjunctive forms, and minimal sums, why Procedure 25.1 works.

When we derive irredundant disjunctive forms or minimal sums by Procedure 25.1, the following property is useful. When we find all prime-implicant loops by Step 1, some 1-cells may be contained in only one loop. Such 1-cells are called **distinguished 1-cells** and are labeled with asterisks. (The 1-cells shown with asterisks in Fig. 25.2(a) are distinguished 1-cells.) A prime implicant loop that contains distinguished 1-cells is called an **essential prime implicant loop**. The corresponding prime implicant is an essential prime implicant, as already defined. In every irredundant disjunctive form and every minimal sum to be found in Step 2 and 3, respectively, essential prime implicants must be included, since each 1-cell on the map must be contained in at least one prime implicant loop and distinguished 1-cells can be contained only in essential prime implicant loops. Hence, if essential prime implicant loops are first identified and chosen, Procedure 25.1 is quickly processed.

Even if the don't-care condition d is contained in some cells, prime implicants can be formed in the same manner, by simply regarding d as being 1 or 0 whenever necessary to draw a greater prime implicant loop. For example, in Fig. 25.3, we can draw a greater rectangular loop by regarding two d's as being 1. One d is left outside and is regarded as being 0. We need not consider loops consisting of d's only.

Maps for Five and Six Variables

The Karnaugh map is most useful for functions of four or fewer variables, but it is often useful also for functions of five or six variables. A map for five variables consists of two four-variable maps, as shown in Fig. 25.4, one for each value of the first variable. A map for six variables consists of four four-variable maps, as shown in Fig. 25.5, one for each combination of values of the first two variables. Note that **the four maps in Fig. 25.5 are arranged so that binary numbers represented by x_1 and x_2 differ in only one bit horizontally and vertically** (the map for $x_1 = x_2 = 1$ goes to the bottom right-hand side).

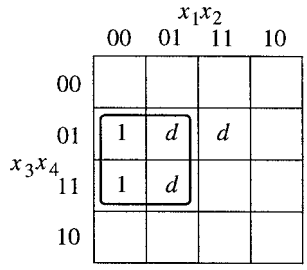

FIGURE 25.3 A map with don't-care conditions.

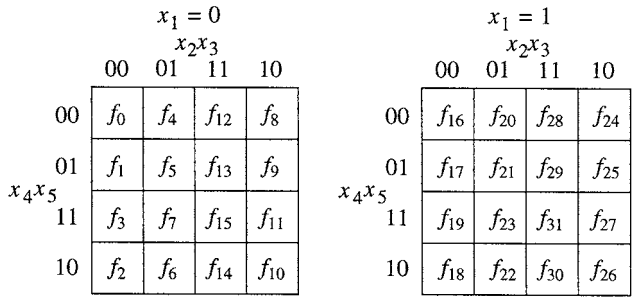

FIGURE 25.4 Karnaugh map for five variables.

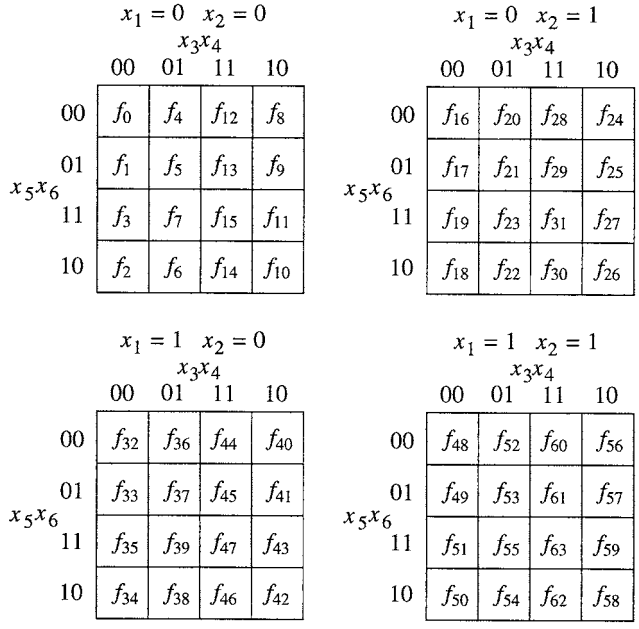

FIGURE 25.5 Karnaugh map for six variables.

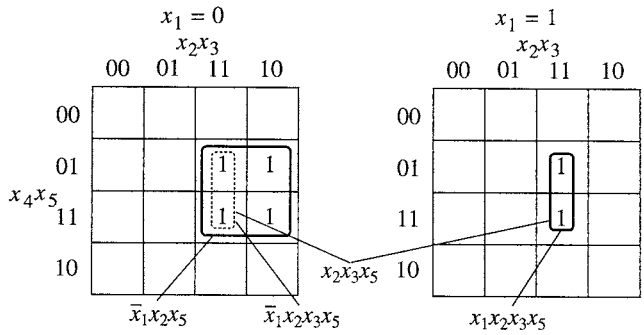
In a five-variable map, 1-cells are combined in the same way as in the four-variable case, with the additional feature that rectangular loops of 2^i 1-cells that are on different four-variable maps can be combined to form a greater loop replacing the two original loops only if they occupy the same relative position on their respective four-variable maps. Notice that these loops may be inside other loops in each four-variable map. For example, if f_{15} and f_{31} are 1, they can be combined; but even if $f_{15} = f_{29} = 1$, f_{15} and f_{29} cannot. In a six-variable map, only 1-cells in two maps that are horizontally or vertically adjacent can be combined if they are in the same relative positions. In Fig. 25.5, for example, if f_5 and f_{37} are 1, they can be combined; but even if f_5 and f_{53} are 1, f_5 and f_{53} cannot. Also, four 1-cells that occupy the same relative positions in all four-variable maps can be combined as representing a single product. For example, f_5, f_{21}, f_{37}, and f_{53} can be combined if they are 1.

In the case of a five-variable map, we can find prime implicant loops as follows.

Procedure 25.2: Derivation of Minimal Sums on a Five-Variable Map

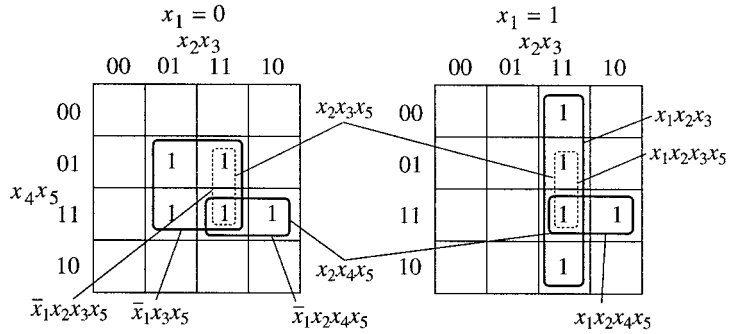
1. Unlike Step 1 of Procedure 25.1 for a function of four variables, this step requires the following two substeps to form prime implicant loops:
   a. On each four-variable map, encircle all the 1-cells with rectangles, each of which consists of 2^i 1-cells, choosing the number of 1-cells contained in each rectangle as large as possible. Unlike the case of Procedure 25.1, **these loops are not necessarily prime implicant loops** because they may not represent prime implicant, depending on the outcome of substep b.

In Figs. 25.6 and 25.7, for example, loops formed in this manner are shown with solid lines.



The prime implicants of this function are $\bar{x}_1x_2x_5$ and $x_2x_3x_5$.

FIGURE 25.6 Prime implicant loops on a map for five variables.



The prime implicants of this function are $\bar{x}_1x_3x_5$, $x_2x_3x_5$, $x_2x_4x_5$, and $x_1x_2x_3$.

FIGURE 25.7 Prime implicant loops on a map for five variables.

b. On each four-variable map, encircle all the 1-cells with rectangles, each of which consists of 2^i 1-cells in exactly the same relative position on the two maps, choosing i as great as possible. Then connect each pair of the corresponding loops with an arc. On each four-variable map, some of these loops may be inside some loops formed in substep a.

In Fig. 25.6, one pair of loops that is in the same relative position is newly formed. One member of the pair, shown in a dotted line, is contained inside a loop formed in substep a. The pair is connected with an arc. The other loop coincides with a loop formed in substep a. In Fig. 25.7, two pairs of loops are formed: one pair is newly formed, as shown in dotted lines, and the second pair is the connection of loops formed in substep a.

The loops formed in substep b and also those formed in substep a but not contained in any loop formed in substep b are **prime implicant loops,** since they correspond to prime implicants.

In Fig. 25.6, the loop formed in substep a, which represents $\bar{x}_1 x_2 x_3 x_5$, is contained in the prime implicant loop formed in substep b, which represents $x_2 x_3 x_5$. Thus, the former loop is not a prime implicant loop, and consequently $\bar{x}_1 x_2 x_3 x_5$ is not a prime implicant.

2. Processes for deriving irredundant disjunctive forms and minimal sums are the same as Steps 2 and 3 of Procedure 25.1. □

In the case of six-variable map, the derivation of prime implicant loops requires more comparisons of four-variable maps, as follows.

Procedure 25.3: Derivation of Minimal Sums on a Six-Variable Map

1. Derivation of all prime-implicant loops requires the following three substeps:
   a. On each four-variable map, encircle all the 1-cells with rectangles, each of which consists of 2^i 1-cells, choosing i as great as possible.
   b. Find the rectangles (each of which consists of 2^i 1-cells) occupying the same relative position on every two adjacent four-variable maps, choosing i as great as possible. (Two maps in diagonal positions are not adjacent.) Thus, we need four comparisons of two maps (i.e., upper two maps, lower two maps, left two maps, and right two maps).
   c. Then find the rectangles (each of which consists of 2^i 1-cells) occupying the same relative position on all four-variable maps, choosing i as great as possible. **Prime implicant loops** are loops formed at substeps c, loops formed at b but not contained inside those at c, and loops formed at a but not contained inside those formed at b or c.
2. Processes for deriving irredundant disjunctive forms and minimal sums are the same as Steps 2 and 3 of Procedure 25.1. □

An example is shown in Fig. 25.8.

Irredundant disjunctive forms and minimal sums are derived in the same manner as in the case of four variables.

Procedures 25.1, 25.2, and 25.3 can be extended to the cases of seven or more variables with increasing complexity. It is usually hard to find a minimal sum, however, because each prime implicant loop consists of 1-cells scattered in many maps.

25.3 Derivation of Minimal Sums for a Single Function by Other Means

Derivation of a minimal sum for a single function by Karnaugh maps is convenient for manual processing because designers can know the nature of logic networks better than automated minimization, to be described in Chapter 27, but its usefulness is limited to functions of four or five variables.

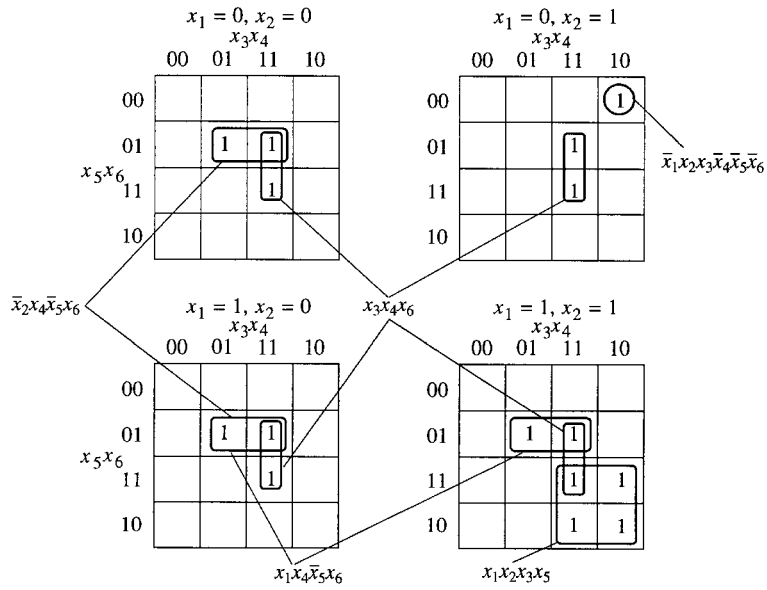


FIGURE 25.8 Prime-implicant loops on a map for six variables.

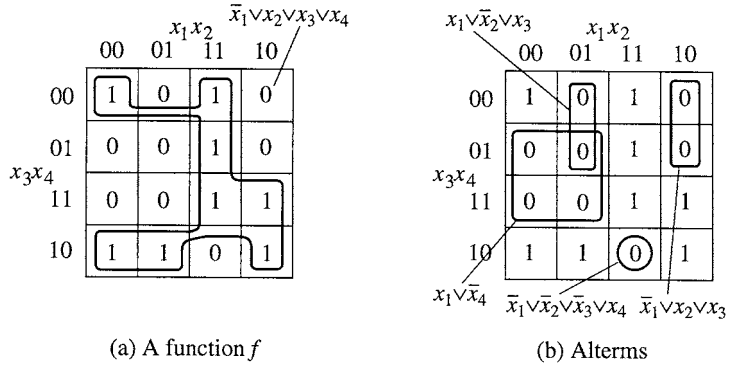
There are several methods for derivation of a minimal sum for a single function. A minimal sum can be found by forming a so-called a covering table where the minterms of a given function *f* are listed on the horizontal coordinate and all the prime implicants of *f* are listed on the vertical coordinate. A minimal sum can be described as a solution, that is, a minimal set of prime implicants that covers all the minterms.[2] The feasibility of this approach based on the covering table is limited by the number of minterms and prime implicants rather than the number of variables, which is the limiting factor for the feasibility of the derivation of minimal sums based on Karnaugh maps. This approach based on the table can be converted to an algebraic method, with prime implicants derived by the Tison method, as described by Procedure 4.6.1 in Ref. 3. This is much faster than the approach based on the table. Another approach is generation of irredundant disjunctive forms and then derive a minimal sum among them.[4,5] The feasibility of this approach is limited by the number of consensuses rather than the number of variables, minterms, or prime implicants.

As the number of variables, minterms, or prime implicants increases, the derivation of absolute minimal sums or even prime sums becomes too time-consuming, although the enhancement of the feasibility has been explored.[1] When too time-consuming, we need to resort to heuristic minimization, as will be described in Chapter 27 and Chapter 42, Section 42.3.

25.4 Prime Implicates, Irredundant Conjunctive Forms, and Minimal Products

The "implicates," "irredundant conjunctive forms," and "minimal products," which can be defined all based on the concept of conjunctive form, will be useful for deriving a minimal network that has OR gates in the first level and one AND gate in the second level.

First, let us represent the maxterm expansion of a given function *f* on a Karnaugh map. Unlike the map representation of the minterm expansion of *f*, where each minterm contained in the expansion is represented by a 1-cell on a Karnaugh map, each maxterm is represented by a 0-cell. Suppose that a function *f* is given as shown by the 1-cells in Fig. 25.9(a). This function can be expressed in the maxterm expansion:



(a) A function f (b) Alterms

FIGURE 25.9 Representation of a function f on a map with alterms.

$$f = (\bar{x}_1 \vee x_2 \vee x_3 \vee x_4)(\bar{x}_1 \vee x_2 \vee x_3 \vee \bar{x}_4)(\bar{x}_1 \vee \bar{x}_2 \vee \bar{x}_3 \vee x_4)(x_1 \vee \bar{x}_2 \vee x_3 \vee x_4)$$
$$(x_1 \vee \bar{x}_2 \vee x_3 \vee \bar{x}_4)(x_1 \vee \bar{x}_2 \vee \bar{x}_3 \vee \bar{x}_4)(x_1 \vee x_2 \vee x_3 \vee \bar{x}_4)(x_1 \vee x_2 \vee \bar{x}_3 \vee \bar{x}_4)$$

The first maxterm, $(\bar{x}_1 \vee x_2 \vee x_3 \vee x_4)$, for example, is represented by the 0-cell that has components $(x_1, x_2, x_3, x_4) = (1\ 0\ 0\ 0)$ in the Karnaugh map in Fig. 25.9(a) (i.e., $(\bar{x}_1 \vee x_2 \vee x_3 \vee x_4)$ becomes 0 for $x_1 = 1$, $x_2 = x_3 = x_4 = 0$). Notice that each literal in the maxterm is complemented or noncomplemented, corresponding to 1 or 0 in the corresponding component, respectively, instead of corresponding to 0 or 1 in the case of minterm. All other maxterms are similarly represented by 0-cells. It may look somewhat strange that these 0-cells represent the f expressed by 1-cell on the Karnaugh map in Fig. 25.9(a). But the first maxterm, $(\bar{x}_1 \vee x_2 \vee x_3 \vee x_4)$, for example, assumes the value 0 only for $(x_1, x_2, x_3, x_4) = (1\ 0\ 0\ 0)$ and assumes the value 1 for all other combinations of the components. The situation is similar with other maxterms. Therefore, the conjunction of these maxterms becomes 0 only when any of the maxterms becomes 0. Thus, these 0-cells represent f through its maxterms. This is what we discussed earlier about the maxterm expansion or the Π-decimal specification of f, based on the false vectors of f.

Like the representation of a product on a Karnaugh map, any alterm can be represented by a rectangular loop of 2^i 0-cells by repeatedly combining a pair of 0-cell loops that are horizontally or vertically adjacent in the same rows or columns, where i is a non-negative integer. For example, the two adjacent 0-calls in the same column representing maxterms $(\bar{x}_1 \vee x_2 \vee x_3 \vee x_4)$ and $(\bar{x}_1 \vee x_2 \vee x_3 \vee \bar{x}_4)$ can be combined to form alterm $\bar{x}_1 \vee x_2 \vee x_3$, by deleting literals x_4 and $\bar{x}_4$, as shown in a solid-line loop in Fig. 25.9(b).

The function f in Fig. 25.9 can be expressed in the conjunctive form $f = (\bar{x}_1 \vee x_2 \vee x_3)(x_1 \vee \bar{x}_2 \vee x_3)(x_1 \vee \bar{x}_4)(\bar{x}_1 \vee \bar{x}_2 \vee \bar{x}_3 \vee x_4)$, using a minimum number of such loops. The alterms in this expansion are represented by the loops shown in Fig. 25.9(b).

Definition 25.4: An implicate of f is an alterm implied by a function f.

Notice that an implicate's relationship with f is opposite to that of an implicant that implies f.

For example, $(x_1 \vee x_2 \vee x_3)$ and $(x_1 \vee x_2 \vee \bar{x}_3)$ are implicates of function $f = x_1 \vee x_2$, since whenever $f = 1$, both $(x_1 \vee x_2 \vee x_3)$ and $(x_1 \vee x_2 \vee \bar{x}_3)$ become 1. The implication relationship between an alterm P and a function f can sometimes be more conveniently found, however, by using the property "f implies P if $f = 0$ whenever $P = 0$," which is a restatement of the property "f implies P if $P = 1$ whenever $f = 1$" defined earlier (we can easily see this by writing a truth table for f and P). Thus, $(x_1 \vee x_3)$, $(x_1 \vee \bar{x}_2)$, and $(x_1 \vee x_2 \vee x_3)$ are implicates of $f = (x_1 \vee \bar{x}_2)(\bar{x}_2 \vee x_3)$, because when $(x_1 \vee x_3)$, $(x_1 \vee \bar{x}_2)$, or $(x_1 \vee x_2 \vee x_3)$ is 0, f is 0. [For example, when $(x_1 \vee x_3)$ is 0, $x_1 = x_3 = 0$ must hold. Thus, $f = (\bar{x}_2)(x_2) = 0$. Consequently, $(x_1 \vee x_3)$ is an alterm implied by f, although this is not obvious from the given expressions of f and $(x_1 \vee x_3)$.] Also, $(x_1 \vee \bar{x}_2 \vee x_4)$ and $(x_1 \vee x_2 \vee x_3 \vee x_4)$, which contain the literals of a dummy variable x_4 of this f, are implicates of f.

Definition 25.5: An alterm P is said to **subsume** another alterm Q if all the literals in Q are among the literals of P.

The alterm $(x_1 \vee \bar{x}_2 \vee x_3 \vee x_4)$ subsumes $(\bar{x}_2 \vee x_3)$. Summarizing the two definitions of "subsume" for "alterms" in Definition 25.5 and "terms" in Definition 24.6, we have that **"*P* subsumes *Q*" simply means "*P* contains all the literals in *Q*," regardless of whether *P* and *Q* are terms or alterms**. But the relationships between "subsume" and "imply" in the two cases are opposite. If an alterm P subsumes another alterm Q, then $Q \subseteq P$ holds; whereas if a term P subsumes another term Q, then $P \subseteq Q$ holds.

Definition 25.6: A **prime implicate** of a function f is defined as an implicate of f such that no other alterm subsumed by it is an implicate of f.

In other words, if deletion of any literal from an implicate of f makes the remainder not an implicate of f, the implicate is a prime implicate. For example, $(x_2 \vee x_3)$ and $(x_1 \vee x_3)$ are prime implicates of $f = (x_1 \vee \bar{x}_2)(x_2 \vee x_3)(\bar{x}_1 \vee x_2 \vee x_3)$, but $x_1 \vee x_3 \vee x_4$ is not a prime implicate of f, although it is still an implicate of this f. As seen from these examples, some implicates are not obvious from a given conjunctive form of f. Such an example is $x_1 \vee x_3$ in the above example. As a matter of fact, $x_1 \vee x_3$ can be obtained as the consensus by the following Definition 25.7 of two alterms, $(x_1 \vee \bar{x}_2)$ and $(x_2 \vee x_3)$, of f. Also notice that, unlike implicates, prime implicates cannot contain a literal of any dummy variable of f.

On a Karnaugh map, **a loop for an alterm *P* that subsumes another alterm *Q* is contained in the loop for *Q***. For example, in Fig. 25.10, the loop for alterm $(x_1 \vee \bar{x}_3 \vee x_4)$, which subsumes alterm $(x_1 \vee \bar{x}_3)$, is contained in the loop for $x_1 \vee \bar{x}_3$. Thus, **a rectangular loop that consists of 2^i 0-cells, with *i* as large as possible, represents a prime implicate of *f*.**

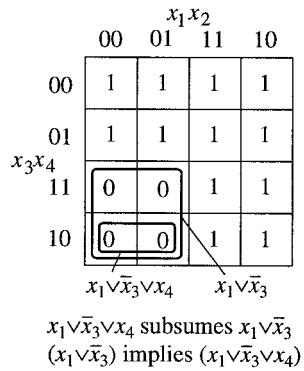


FIGURE 25.10 An alterm that subsumes another alterm.

The consensus of two **alterms**, V and W, is defined in a manner similar to the consensus of two terms.

Definition 25.7: If there is exactly one variable, say x, appearing noncomplemented in one alterm and complemented in the other (i.e., if two alterms, V and W, can be written as $V = x \vee V'$ and $W = \bar{x} \vee W'$, where V' and W' are alterms free of literals of x), the disjunction of all literals except those of x (i.e., $V' \vee W'$ with duplicate literals deleted) is called the **consensus** of the two alterms V and W.

For example, when $V = x \vee y \vee \bar{z} \vee u$ and $W = \bar{x} \vee y \vee u \vee \bar{v}$ are given, their consensus is $y \vee \bar{z} \vee u \vee \bar{v}$.

On a Karnaugh map, a consensus is represented by the largest rectangular loop of 2^i 0-cells that intersects, and is contained within, two adjacent loops of 0-cells that represent two alterms. For example, in Fig. 25.11 the dotted-line loop represents the consensus of two alterms, $(\bar{x}_2 \vee \bar{x}_4)$ and $(\bar{x}_1 \vee x_2 \vee \bar{x}_3)$, which are represented by the two adjacent loops.

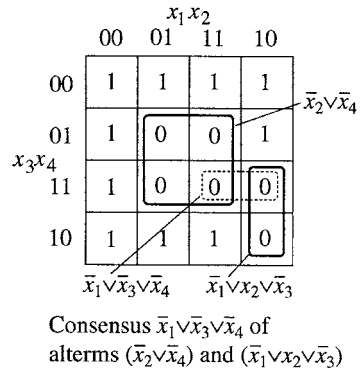

FIGURE 25.11 Consensus of two adjacent alterms.

All prime implicates of a function f can be algebraically obtained from a conjunctive form for f by modifying the Tison method discussed in Procedure 24.1; that is, by using dual operations in the method.

We can define the following concepts, which are dual to irredundant disjunctive forms, minimal sums, absolute minimal sums, essential prime implicants, complete sums, and others.

Definition 25.8: An **irredundant conjunctive form** for a function f is a conjunction of prime implicates such that removal of any of them makes the remainder not express f. The **minimal products** are irredundant conjunctive forms for f with a minimum number of prime implicates. The **absolute minimal products** are minimal products with a minimum number of literals. Prime implicates that appear in every irredundant conjunctive form for f are called **essential prime implicates** of f. **Conditionally eliminable prime implicates** are prime implicates that appear in some irredundant conjunctive forms for f, but not in others. **Absolutely eliminable prime implicates** are prime implicates that do not appear in any irredundant conjunctive form for f. The **complete product** for a function f is the product of all prime implicates of f.

25.5 Derivation of Minimal Products by Karnaugh Map

Minimal products can be derived by the following procedure, based on a Karnaugh map.

Procedure 25.4: Derivation of Minimal Products on a Karnaugh Map

Consider the case of a map for four or fewer variables (cases for five or more variables are similar, using more than one four-variable map).

1. Encircle **0-cells**, instead of 1-cells, with rectangular loops, each of which consists of 2^i 0-cells, choosing i as large as possible. These loops are called **prime implicate loops** because they represent prime implicates (not prime implicants). Examples of prime implicate loops are shown in Fig. 25.12 (including the dotted-line loop). The **prime implicate** corresponding to a loop is formed by making a **disjunction** of literals, instead of a conjunction, **using a noncomplemented variable corresponding to 0 of a coordinate of the map and a complemented variable corresponding to 1.** (Recall that, in forming a prime implicant, variables corresponding to 0's were complemented and those corresponding to 1's were noncomplemented.) Thus, corresponding to the loops of Fig. 25.12, we get the prime implicates, $(x_1 \vee \bar{x}_4)$, $(\bar{x}_1 \vee \bar{x}_2 \vee \bar{x}_3)$ and $(\bar{x}_2 \vee \bar{x}_3 \vee \bar{x}_4)$.
2. Each **irredundant conjunctive form** is derived by the conjunction of prime implicates corresponding to a set of loops, so that removal of any loop leaves some 0-cells uncovered by loops. An example is the set of two solid-line loops in Fig. 25.12, from which the irredundant conjunctive form $(x_1 \vee \bar{x}_4)(\bar{x}_1 \vee \bar{x}_2 \vee \bar{x}_3)$ is derived.

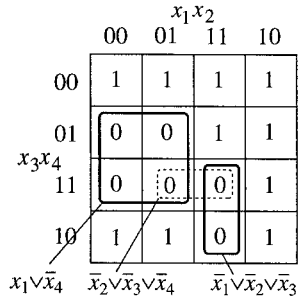

FIGURE 25.12 Prime-implicate loops and the corresponding prime implicates.

3. Among sets of a minimum number of prime implicate loops, the sets that contain as many of the largest loops as possible yield **minimal products**.

The don't-care conditions are dealt with in the same manner as in case of minimal sums. In other words, whenever possible, we can form a larger prime implicate loop by interpreting some *d*'s as 0-cells. Any prime-implicate loops consisting of only *d*-cells need not be formed. □

Procedure 25.4 can be extended to five or more variables in the same manner as Procedures 25.2 and 25.3, although the procedure will be increasingly complex.

University of Illinois at Urbana-Champaign

26.1 Basic Concepts

Binary decision diagrams (BDDs), which were introduced in Chapter 23, Section 23.1, are a powerful means for computer processing of logic functions because in many cases, with BDDs, smaller memory space is required for storing logic functions and values of functions can be calculated faster than with truth tables or logic expressions. As logic design has been done in recent years with computers, BDDs are extensively used because of these features. BDDs are used in computer programs for automation of logic design, verification (i.e., identifying whether two logic networks represent the identical logic functions), diagnosis of logic networks, simplification of transistor circuits (such as ECL and MOSFET circuits, as explained in Chapters 35, 36, and 37), and other areas, including those not related to logic design.

In this chapter, we discuss the basic data structures and algorithms for manipulating BDDs. Then we describe the variable ordering problem, which is important for the effective use of BDDs. The concept of BDD was devised by Lee in 1959.[15] Binary decision programs that Lee discussed are essentially binary decision diagrams. Then, in 1978, its usefulness for expressing logic functions was shown by Akers.[3,4] But since Bryant[6] developed a reduction method in 1986, it has been extensively used for design automation for logic design and related areas.

From a truth table, we can easily derive the corresponding binary decision diagram. For example, the truth table shown in Fig. 26.1(a) can be converted into the BDD in Fig. 26.1(b). But there are generally many BDDs for a given truth table, that is, the logic function expressed by this truth table. For example, all BDDs shown in Fig. 26.1(c) through (e) represent the logic function that the truth table in Fig. 26.1(a) expresses. Here, note that in each of Figs. 26.1 (b), (c), and (d), the variables appear in the same order and none of them appears more than once in every path from the top node. But in (e), they appear in different orders in different paths. BDDs in Figs. 26.1(b), (c), and (d) are called **ordered BDD**s (or **OBDD**s). But the BDD in Fig. 26.1(e) is called an **unordered BDD**. These BDDs can be reduced into a simple BDD by the following procedure.

In a BDD, the top node is called the **root** that represents the given function $f(x_1, x_2, \ldots, x_n)$. Rectangles that have 1 or 0 inside are called **terminal nodes**. They are also called **1-terminal** and **0-terminal**.

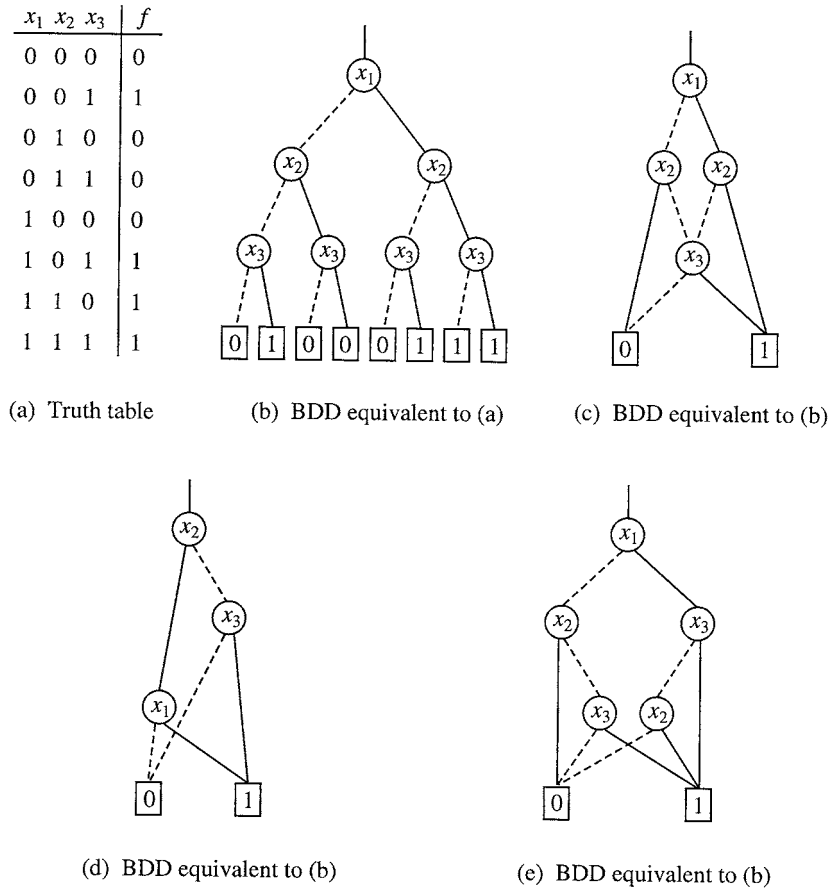

FIGURE 26.1 Truth table and BDDs for $x_1x_2 \vee \bar{x}_2x_3$.

Other nodes are called **non-terminal nodes** denoted by circles with variables inside. They are also called simply **nodes**, differentiating themselves from the 0- and 1-terminals. From a node with x_i inside, two lines go down. The solid line is called **1-edge**, representing $x_i = 1$; and the dotted line is called **0-edge**, representing $x_i = 0$.

In an OBDD, the value of the function f can be evaluated by following a path of edges from the root node to one of the terminal nodes. If the nodes in every path from the root node to a terminal node are assigned with variables, x_1, x_2, x_3, …, and x_n, in this order, then f can be expressed as follows, according to the Shannon expansion (described in Chapter 24). By branching with respect to x_1 from the root node, $f(x_1, x_2, \ldots, x_n)$ can be expanded as follows, where $f(0, x_2, \ldots, x_n)$ and $f(1, x_2, \ldots, x_n)$ are functions that the nodes at the low ends of 0-edge and 1-edge from the root represent, respectively:

$$f(x_1, x_2, \ldots, x_n) = \bar{x}_1 f(0, x_2, \ldots, x_n) \vee x_1 f(1, x_2, \ldots, x_n)$$

Then, by branching with respect to x_2 from each of these two nodes that $f(0, x_2, \ldots, x_n)$ and $f(1, x_2, \ldots, x_n)$ represent, each $f(0, x_2, \ldots, x_n)$ and $f(1, x_2, \ldots, x_n)$ can be expanded as follows:

$$f(0, x_2, \ldots x_n) = \bar{x}_2 f(0, 0, x_3, \ldots, x_n) \vee x_2 f(0, 1, x_3, \ldots, x_n)$$

and

$$f(1, x_2, \ldots, x_n) = \bar{x}_2 f(1, 0, x_3, \ldots, x_n) \vee x_2 f(1, 1, x_3, \ldots, x_n)$$

And so on. As we go down from the root node toward the 0- or 1-terminal, more variables of f are set to 0 or 1. Each term excluding x_i or $\bar{x}_i$ in each of these expansions [i.e., $f(0, x_2, \ldots, x_n)$ and $f(1, x_2, \ldots, x_n)$ in the first expansion, $f(0, 0, \ldots, x_n)$ and $f(0, 1, \ldots, x_n)$ in the second expansion, ect.], are called **cofactors**. Each node at the low ends of 0-edge and 1-edge from a node in an OBDD represents cofactors of the **Shannon expansion** of the logic function at the node, from which these 0-edge and 1-edge come down.

Procedure 26.1: Reduction of a BDD

1. For the given BDD, apply the following steps in any order.
   a. If two nodes, v_a and v_b, that represent the same variable x_i, branch to the same nodes in a lower level for each of $x_i = 0$ and $x_i = 1$, then combine them into one node that still represents variable x_i.

In Fig. 26.2(a), two nodes, v_a and v_b, that represent variable x_i, go to the same node v_u for $x_i = 0$ and the same node v_v for $x_i = 1$. Then, according to Step a, two nodes, v_a and v_b, are merged into one node v_{ab}, as shown in Fig. 26.2(b). The node v_{ab} represents variable x_i.

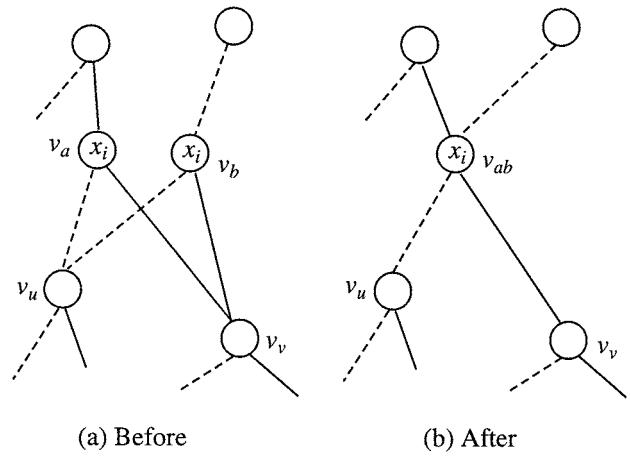

FIGURE 26.2 Step 1(a) of Procedure 26.1.

   b. If a node that represents a variable x_i branches to the same node in a lower level for both $x_i = 0$ and $x_i = 1$, then that node is deleted, and the 0- and 1-edges that come down to the former are extended to the latter.

In Fig. 26.3(a), node v_a that represents variable x_i branches to the same node v_b for both $x_i = 0$ and $x_i = 1$. Then, according to Step b, node v_a is deleted, as shown in Fig. 26.3(b), where the node v_a is a don't-care for x_i, and the edges that come down to v_a are extended to v_u.

   c. Terminals nodes with the same value, 0 or 1, are merged into the terminal node with the same original value.

All the 0-terminals in Fig. 26.1(b) are combined into one 0-terminal in each of Figs. 26.1(c), (d), and (e). All the 1-terminals are similarly combined.

2. When we cannot apply any step after repeatedly applying these steps (a), (b), and (c), the **reduced ordered BDD** (i.e., **ROBDD**) or simply called the **reduced BDD** (i.e., **RBDD**), is obtained for the given function.

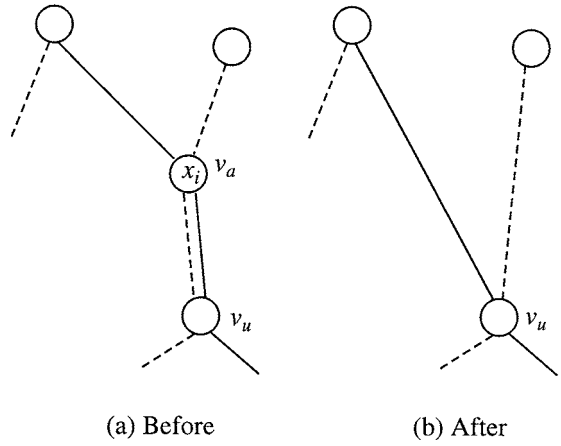

FIGURE 26.3 Step 1(b) of Procedure 26.1.

The following process is faster than the repeated application of Step 1(a) of Procedure 26.1. Suppose a BDD contains two nodes, v_a and v_b, both of which represent x_i, such that a sub-BDD, B_1, that stretches downward from v_a is completely identical to another sub-BDD, B_2, that stretches downward from v_b. In this case, each sub-BDD is said to be **isomorphic** to the other. Then the two sub-BDDs can be merged. For example, the two sub-BDDs, B_1 and B_2, shown in the two dotted rectangles in Fig. 26.4(a), both representing x_4, can be merged into one, B_3, as shown in Fig. 26.4(b).

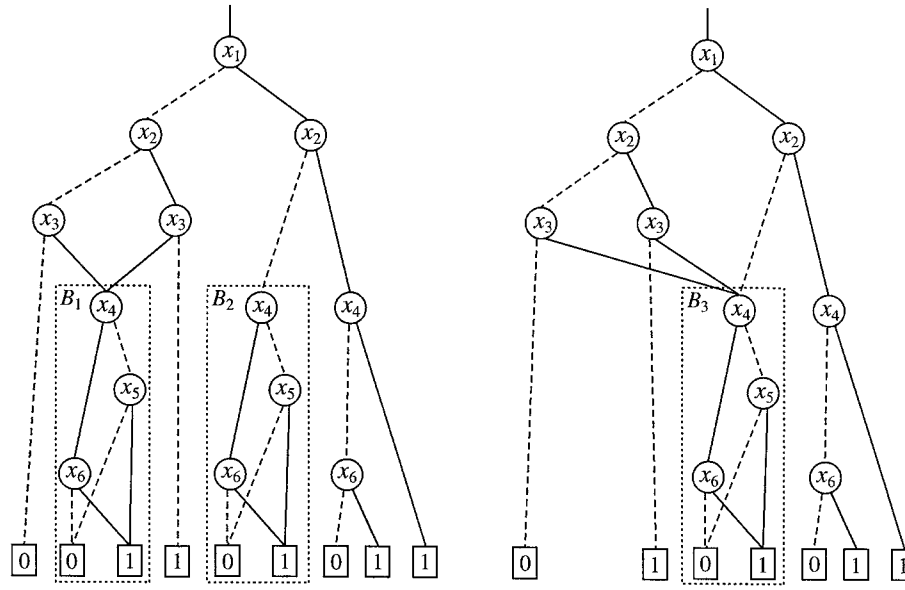

FIGURE 26.4 Merger of two isomorphic sub-BDDs.

Theorem 26.1: Any completely or incompletely specified function has a unique reduced ordered BDD and any other ordered BDD for the function in the same order of variables (i.e., not reduced) has more nodes.

According to this theorem, the ROBDD is unique for a given logic function when the order of the variables is fixed. (A BDD that has don't-cares can be expressed with addition of the *d*-terminal or two BDDs for the ON-set and OFF-set completely specified functions, as explained with Fig. 23.5. For details, see Ref. 24.) Thus, ROBDDs give canonical forms for logic functions. This property is very important to practical applications, as we can easily check the equivalence of two logic functions by only checking the isomorphism of their ROBDDs. **Henceforth in this chapter, ROBDDs will be referred to as BDDs for the sake of simplicity.**

It is known that a BDD for an *n*-variable function requires an exponentially increasing memory space in the worst case, as *n* increases.[16] However, the size of memory space for the BDD varies with the types of functions, unlike truth tables which always require memory space proportional to 2^n. But many logic functions that we encounter in design practice can be shown with BDDs without large memory space.[14] This is an attractive feature of BDDs. Fig. 26.5 shows the BDDs representing typical functions, AND, OR, and the parity function with three and *n* input variables. The parity function for *n* variables, $x_1 \oplus x_2 \oplus \ \ldots \oplus x_n$, can be shown with the BDD of $2(n-1)+1$ nodes and 2 terminals; whereas, if a truth table or a logic expression is used, the size increases exponentially as *n* increases.

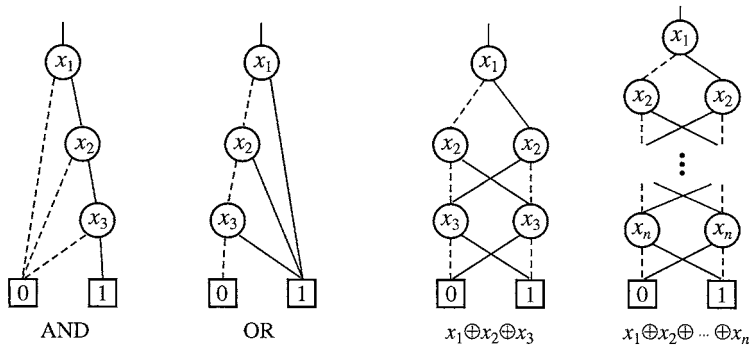

FIGURE 26.5 BDDs for typical logic functions.

A set of BDDs representing many functions can be combined into a graph that consists of BDDs sharing sub-graphs among them, as shown in Fig. 26.6. This idea saves time and space for duplicating isomorphic BDDs. By sharing all the isomorphic sub-graphs completely, no two nodes that express the same function coexist in the graph. We call it **shared BDDs** (**SBDDs**),[25] or **multi-rooted BDDs**. In a shared BDD, no two root nodes express the same function.

Shared BDDs are now widely used and those algorithms are more concise than ordinary BDDs. In the remainder of this chapter, we deal with shared BDD only.

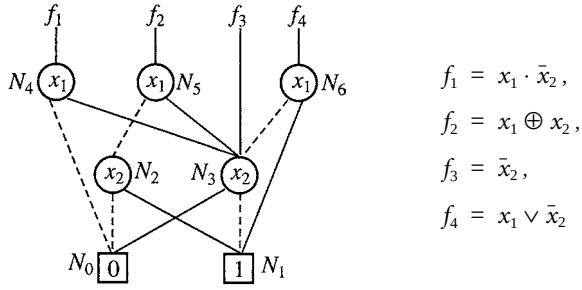

FIGURE 26.6 A shared BDD.

26.2 Construction of BDD Based on a Logic Expression

Procedure 26.1 shows a way of constructing compact BDDs from the truth table for a function f of n variables. This procedure, however, is not efficient because the size of its initial BDD is always of the order of 2^n, even for a very simple function. To avoid this problem, Bryant[6] presented a method to construct BDDs by applying a sequence of logic operations in a logic expression. Figure 26.7 shows a simple example of constructing a BDD for $f = (x_2 \cdot x_3) \vee x_1$. First, trivial BDDs for $x_2 \cdot x_3$, and x_3 are created in Fig. 26.7(a). Next, applying the *AND* operation between x_2 and x_3, the BDD for $x_2 \cdot x_3$ is then generated. Then, the BDD for the entire expression is obtained as the result of the *OR* operation between $(x_2 \cdot x_3)$ and x_1. After deleting the nodes that are not on the paths from the root node for f toward the 0- or 1-terminal, the final BDD is shown in Fig. 26.7(b).

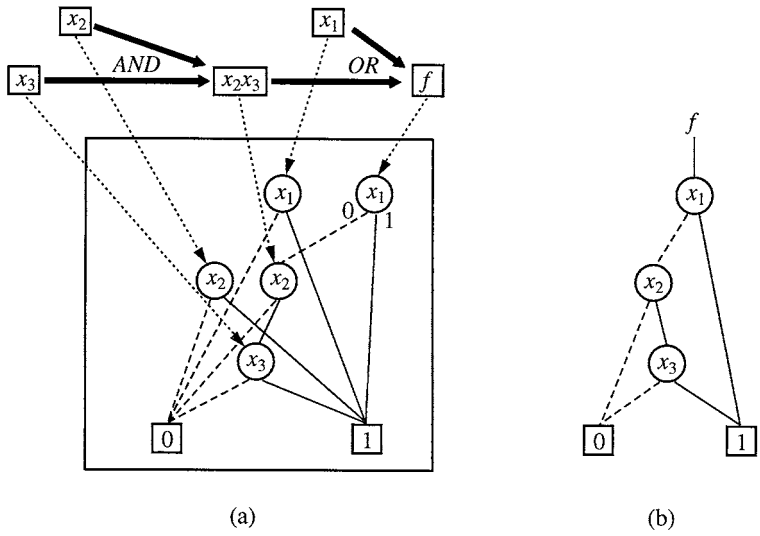

FIGURE 26.7 Generation of BDDs for $f = (x_2 \cdot x_3) \vee x_1$.

In the following, we show a formal algorithm for constructing BDDs for an arbitrary logic expression. This algorithm is generally far more efficient than that based on a truth table.

Binary logic operation

Suppose we perform a binary operation between two functions, g and h, and this operation is denoted by $g \circ h$, where "$\circ$" is one of *OR*, *AND*, *Exclusive-OR*, and others. Then by the Shannon expansion of a function explained previously, $g \circ h$ can be expanded as follows:

$$g \circ h = \bar{x}_i \cdot \left(g_{(x_i = 0)} \circ h_{(x_i = 0)} \right) \vee x_i \cdot \left(g_{(x_i = 1)} \circ h_{(x_i = 1)} \right)$$

with respect to variable x_i, which is the variable of the node that is in the highest level among all the nodes in g and h. This expansion creates the 0- and 1-edges which go to the next two nodes from the node for the variable x_i, by operations $\left(g_{(x_i = 0)} \circ h_{(x_i = 0)} \right)$ and $\left(g_{(x_i = 1)} \circ h_{(x_i = 1)} \right)$. The two subgraphs whose roots are these two nodes represent the cofactors derived by the Shannon expansion, $\left(g_{(x_i = 0)} \circ h_{(x_i = 0)} \right)$ and $\left(g_{(x_i = 1)} \circ h_{(x_i = 1)} \right)$. Repeating this expansion for all the variables, as we go down ontually trivial operations, such as $g \cdot 1 = g$, $g \oplus g = 0$, and $h \vee 0 = h$, finishing the construction of a BDD for $g \circ h$.

When BDDs for functions g and h are given, we can derive a new BDD for function $f = g \circ h$ by the following procedure.

Procedure 26.2: Construction of a BDD for Function $f = g \circ h$, Given BDDs for g and h.

Given BDDs for functions g and h (e.g., Fig. 26.8(a)), let us construct a new BDD (e.g., Fig. 26.8(b)) with respect to the specified logic operation $g \circ h$ and then reduce it by the previous Procedure 26.1 (e.g., Fig. 26.8(d)).

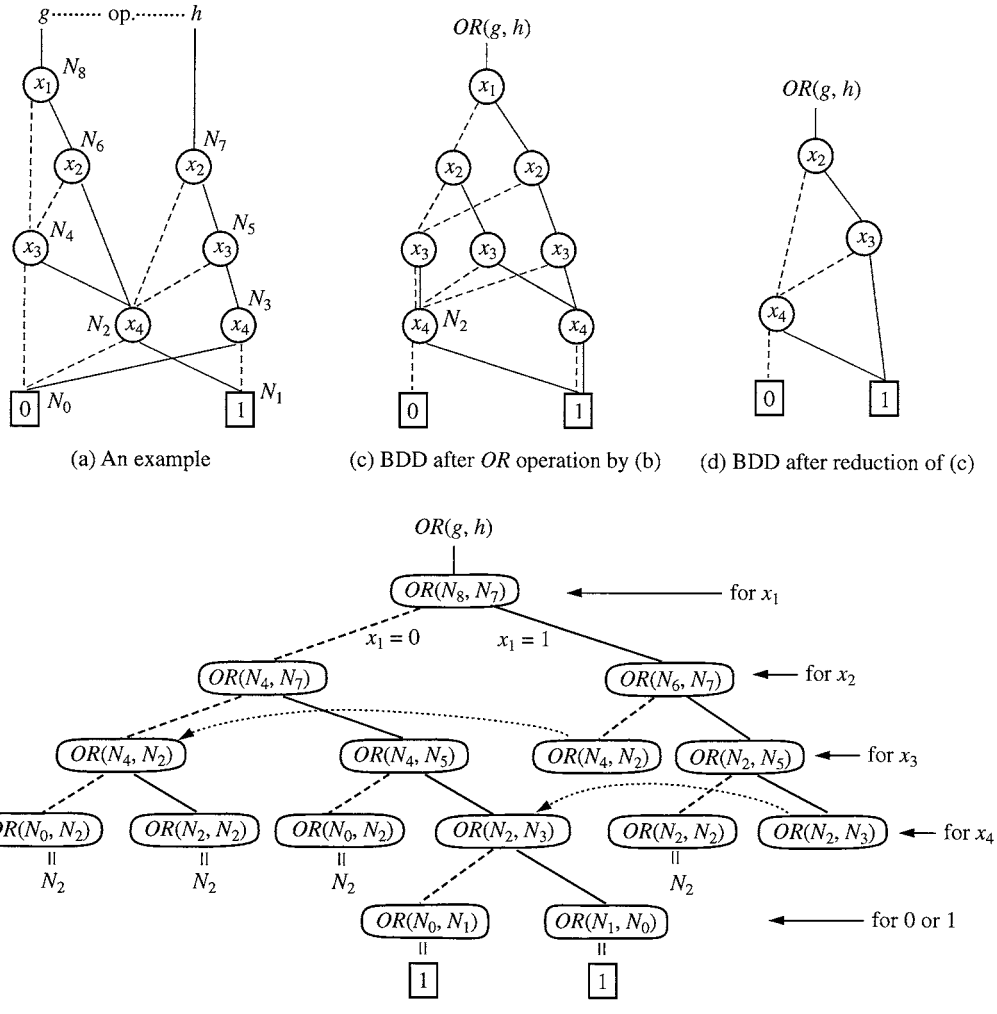

FIGURE 26.8 Procedure of binary operation.

1. Starting with the root nodes for g and h and going down toward to the 0- or 1-terminal, apply repeatedly steps a and b in the following, considering steps c and d.
   a. When the node under consideration, say N_a, in one of the two BDDs for g and h is in a higher level than the other node, N_b:
   If N_a and N_b are for variables x_a and x_b, respectively, and

if the 0-edge from N_a for $x_a = 0$ goes to node N_{a0} and the 1-edge from N_a for $x_a = 1$ goes to node N_{a1},

then we create the following two new nodes, to which the 0- and 1-edges go down from the corresponding node N'_a for the variable x_a in the new BDD (i.e., N'_a corresponds to this combination of N_a and N_b), as a part of the new BDD:

One new node for the operation ○ between N_{a0} and N_b for $x_a = 0$, and
the other new node for the operation ○ between N_{a1} and N_b for $x_a = 1$.

The variable for the first node, i.e., the node for N_{a0} ○ N_b will be the one in the higher level of the two nodes, N_{a0} and N_b, in the BDDs for g and h; and the variable for the second node (i.e., the node for N_{a1} ○ N_b) will be the one in the higher level of the two nodes, N_{a1} and N_b, in the BDDs for g and h.

In this case, creation of edges is not considered with respect to N_b in the original BDDs.

For example, suppose binary operation g ○ h is to be performed on the functions g and h in the BDD shown in Fig. 26.8(a) and furthermore, "○" is *OR* in this case. We need to start the *OR* operation with the root nodes for g and h (i.e., N_8 and N_7 respectively). N_8 is in a higher level than N_7. So, in Fig. 26.8(b) which explains how to construct the new BDD according to this procedure, we create two new nodes; one for $OR(N_4, N_7)$ for the 0-edge for $x_1 = 0$ from the node for $OR(N_8, N_7)$ and the other for $OR(N_6, N_7)$ for the 1-edge for $x_1 = 1$ from the node for $OR(N_8, N_7)$, corresponding to this step (a). Thus, we need next to form the *OR* between N_4 and N_7 and also the *OR* between N_6 and N_7 at these nodes in the second level in Fig. 26.8(b). These two nodes are both for variable x_2.

For $OR(N_4, N_7)$, N_7 is now in a higher level than N_4. So, corresponding to this step (a), we create the new nodes for $OR(N_4, N_2)$ and also for $OR(N_4, N_5)$ for 0- and 1-edge, respectively, in the third level in Fig. 26.8(b).

b. When the node under consideration, say N_a, in one of the BDDs for g and h is in the same level as the other node, N_b. (If N_a is for a variables x_a, these two nodes are for the same variable x_a because both g and h have this variable.):
If the 0-edge from N_a for $x_a = 0$ goes to node N_{a0} and the 1-edge from N_a for $x_a = 1$ goes to node N_{a1}, and
if the 0-edge from N_b for $x_b = 0$ goes to node N_{b0} and the 1-edge from N_b for $x_b = 1$ goes to node N_{b1},

then we create the following two new nodes, to which the 0- and 1-edges come down from the corresponding node N'_a for the variable x_a in the new BDD (i.e., N'_a corresponds to this combination of N_a and N_b), as a part of the new BDD:

one new node for the operation ○ between N_{a0} and N_{b0} for $x_a = 0$, and
the other new node for the operation ○ between N_{a1} and N_{b1} for $x_a = 1$.

The variable for the first node, i.e., the node for N_{a0} ○ N_{b0} will be the one in the higher level of the two nodes, N_{a0} and N_{b0}, in the BDDs for g and h; and the variable for the second node, i.e., the node for N_{a1} ○ N_{b1} will be the one in the higher level of the two nodes, N_{a1} and N_{b1}, in the BDDs for g and h.

For the example in Fig. 26.8(b), we need to create two new nodes for the operations, $OR(N_4, N_2)$ and $OR(N_2, N_5)$ to which the 0- and 1-edges go for $x_2 = 0$ and $x_2 = 1$, respectively, from the node $OR(N_6, N_7)$ because N_6 and N_7 are in the same level for variable x_2 in Fig. 26.8(a). These two nodes are both for variable x_3.

c. In the new BDD for the operation g ○ h, we need not have more than one subgraph that represent the same logic function. So, during the construction of the new BDD, whenever a new node (i.e., a root node of a subgraph) is for the same operation as an existing node, we need not continue creation of succeeding nodes from that new node.

For the example, in Fig. 26.8(b), the node for operation $OR(N_4, N_2)$ appears twice, as shown with a dotted arc, and we do not need to continue the creation of new nodes from the second and succeeding nodes for $OR(N_4, N_2)$. $OR(N_2, N_3)$ also appears twice, as shown with a dotted arc.

d. In the new BDD for the operation $g \circ h$, if one of N_a and N_b is the 0- or 1-terminal, or N_a and N_b are the same, i.e., $N_a = N_b$, then we can apply the logic operation that $g \circ h$ defines. If $g \circ h$ is for *AND* operation, for example, the node for $AND(N_1, N_a)$ represents N_a because N_1 is the 1-terminal in Fig. 26.8(a), and furthermore, if N_a represents function g, this node represents g.

Also, it is important to notice that only this step (d) is relevant to the logic operation defined by $g \circ h$, whereas all other steps from (a) through (c) are irrelevant of the logic operation $g \circ h$.

For the example in Fig. 26.8(b), the node for operation $OR(N_0, N_2)$ represents N_2, which is for variable x_4. Also, the node for operation $OR(N_0, N_1)$ represents constant value 1 because N_0 and N_1 are the 0- and 1-terminals, respectively, and consequently, $0 \vee 1$.

By using binary operation $f \oplus 1$, $\bar{f}$ can be performed and its processing time is linearly proportional to the size of a BDD. However, it is improved to a constant time by using the **complement edge**, which is discussed in the following. This technique is now commonly used.

2. Convert each node in the new BDD that is constructed in Step 1 to a node with the corresponding variable inside. Then derive the reduced BDD by Procedure 26.1.

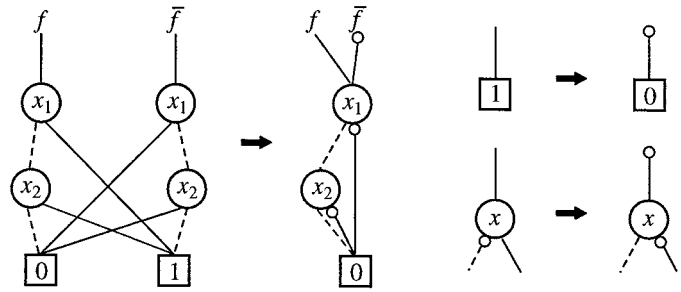
For the example, each node for operation $OR(N_a, N_b)$ in Fig. 26.8(b) is converted to a node with the corresponding variable inside in Fig. 26.8(c), which is reduced to the BDD in Fig. 26.8(d).

Complement Edges

Complement edge is a technique to reduce computation time and memory requirement of BDDs by using edges that indicates to complement the function of the subgraph pointed to by the edge, as shown in Fig. 26.9(a). This idea was first shown by Akers[3] and later discussed by Madre and Billon.[18] The use of complement edges brings the following outstanding merits.

- The BDD size is reduced by up to a half
- Negation can be performed in constant time
- Logic operations are sped by applying the rules, such as $f \cdot \bar{f} = 0$, $f \vee \bar{f} = 1$, and $f \oplus \bar{f} = 1$

Use of complement edges may break the uniqueness of BDDs. Therefore, we have to adopt the two rules, as illustrated in Fig. 26.9(b):



(a) Effect of complement edges (b) Rules for usage

FIGURE 26.9 Complement edges.

1. Using the 0-terminal only.
2. Not using a complement edge as the 0-edge of any node (i.e., use it on 1-edge only). If necessary, the complement edges can be carried over to higher nodes.

Derivation of a Logic Expression from a BDD

A logic expression for f can be easily derived from a BDD for f. A path from the root node for f to the 1-terminal in a BDD is called **1-path**, where the values of the variables on the edges on this path make f equal 1. For each 1-path, a product of literals is formed by choosing x_i for $x_i = 1$ or its complement, $\bar{x}_i$ for $x_i = 0$. The disjunction of such products for all 1-paths yields a logic expression for f. For example, in Fig. 26.8(a), the sequence of nodes, N_8-N_6-N_4-N_2-N_1, is a 1-path and the values of variables on this path, $x_1 = 1$, $x_2 = 0$, $x_3 = 1$, and $x_4 = 1$, make the value of f (g for this example) equal 1. Finding all 1-paths, a logic expression for f is derived as $f = x_1\bar{x}_2x_3x_4 \vee x_1x_2x_4 \vee \bar{x}_1x_3x_4$. It is important to notice that logic expressions that are derived from all 1-paths are usually not minimum sums for the given functions.

26.3 Data Structure

In a typical realization of a BDD manipulator, all the nodes are stored in a single table in the main memory of the computer. Figure 26.10 is a simple example of realization for the BDD shown in Fig. 26.6. Each node has three basic attributes: input variable and the next nodes accessed by the 0- and 1-edges. Also, 0- and 1-terminals are first allocated in the table as special nodes. The other non-terminal nodes are created one by one during the execution of logic operations.

Current node	Variable	0-edge	1-edge	
N_0	-	-	-	← 0-terminal
N_1	-	-	-	← 1-terminal
N_2	x_2	N_0	N_1	
N_3	x_2	N_1	N_0	← f_3 ($= \bar{x}_2$)
N_4	x_1	N_0	N_3	← f_1 ($= x_1 \cdot \bar{x}_2$)
N_5	x_1	N_2	N_3	← f_2 ($= x_1 \oplus x_2$)
N_6	x_1	N_3	N_1	← f_4 ($= x_1 \vee \bar{x}_2$)

FIGURE 26.10 Table-based realization of a shared BDD.

Before creating a new node, we check the reduction rules of Procedure 26.1. If the 0- and 1-edges go to the same next node (Step 1(b) of Procedure 26.1) or if an equivalent node already exists (Step 1(a)), then we do not create a new node but simply copy that node as the next node. To find an equivalent node, we check a table which displays all the existing nodes. The hash table technique is very effective to accelerate this checking. (It can be done in a constant time for any large-scale BDDs, unless the table overflows in main memories.)

When generating BDDs for logic expressions, such as Procedure 26.2, many intermediate BDDs are temporarily generated. It is important for memory efficiency to delete such unnecessary BDDs. In order to determine the necessity of the nodes, a **reference counter** is attached to each node, which shows the number of incoming edges to the node.

In a typical implementation, the BDD manipulator consumes 20 to 30 bytes of memory for each node. Today, there are personal computers and workstations with more than 100 Mbytes of memory, and those facilitate us to generate BDDs containing as many as millions of nodes. However, the BDDs still grow beyond the memory capacity in some practical applications.

26.4 Ordering of Variables for Compact BDDs

BDDs are a canonical representation of logic functions under a fixed order of input variables. A change of the order of variable, however, may yield different BDDs of significantly different sizes for the same function. The effect of variable ordering depends on logic functions, changing sometimes dramatically the size of BDDs. Variable ordering is an important problem in using BDDs.

It is generally very time consuming to find the best order.[30] Currently known algorithms are limited to run on the small size of BDDs with up to about 17 variables.[13] It is difficult to find the best order for larger problems in reasonably short processing time. However, if we can find a fairly good order, it is useful for practical applications. There are many research works on heuristic methods of variable ordering.

Empirically, the following properties are known on the variable ordering.

1. Closely-related variables:
   Variables that are in close relationship in a logic expression should be close in variable order (e.g., x_1 in $x_1 \cdot x_2 \vee x_3 \cdot x_4$ is in closer relationship with x_2 than x_3). The logic network of AND-OR gates with $2n$ inputs in 2-level shown in Fig. 26.11(a) has $2n$ nodes in the best order with the expression $(x_1 \cdot x_2) \vee (x_3 \cdot x_4) \vee \ldots \vee (x_{2n-1} \cdot x_{2n})$, as shown for $n = 2$ in Fig. 26.11(b), while it needs $(2^{n+1} - 2)$ nodes in the worst order, as shown in Fig. 26.11(c). If the same order of variables as the one in Fig. 26.11(b) is kept on the BDD, Fig. 26.11(c) represents the function $(x_1 \cdot x_{n+1}) \vee (x_2 \cdot x_{n+2}) \vee \ldots \vee (x_n \cdot x_{2n})$.

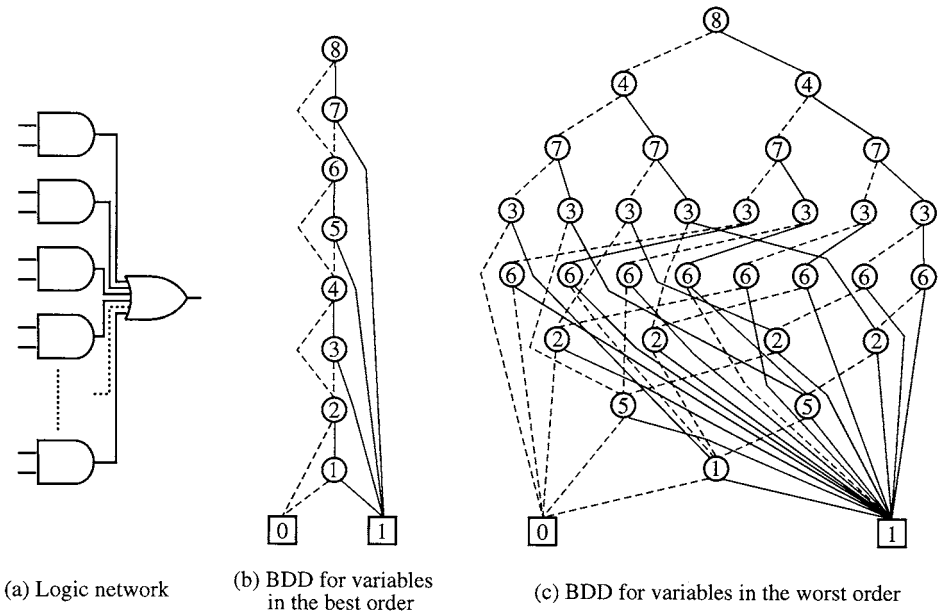


FIGURE 26.11 BDDs for 2-level logic network with AND/OR gates.

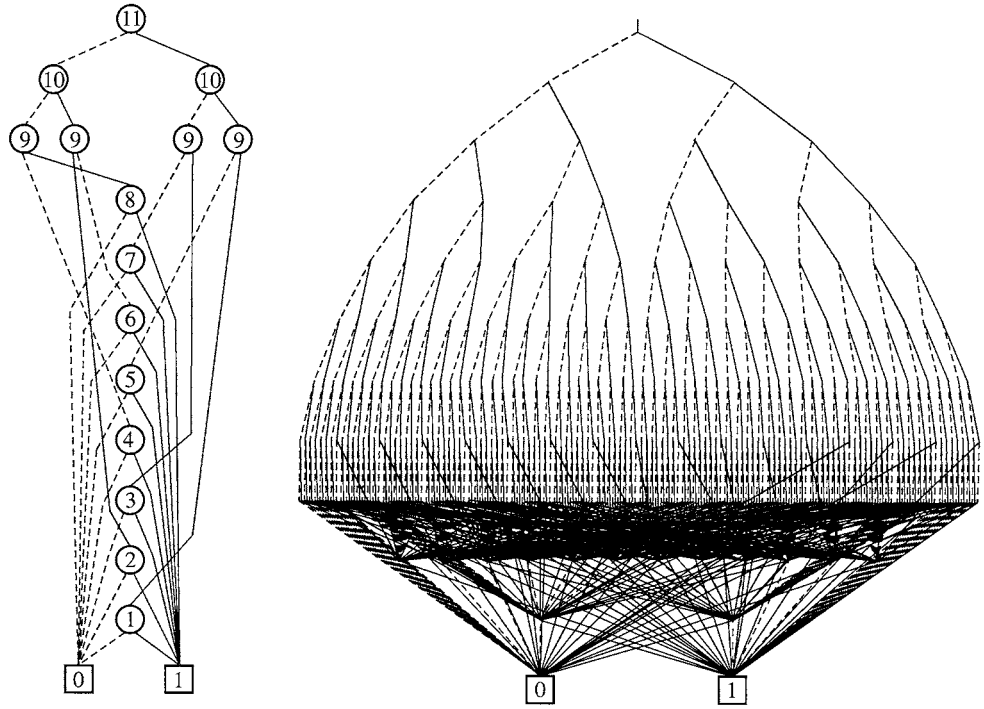
2. Influential variables:
   The variables that greatly influence the nature of a function should be at higher position. For example, the **8-to-1 selector** shown in Fig. 26.12(a) can be represented by a linear size of BDD when the three control inputs are ordered high, but when the order is reversed, it becomes of exponentially increasing size as the number of variables (i.e., the total number of data inputs and control inputs) increases, as shown in Fig. 26.12(b).



(a) Best order (b) Worst order

FIGURE 26.12 BDDs for 8-to-1 selector.

Based on empirical rules like this, Fujita et al.[9] and Malik et al.[20] presented methods; in these methods, an output of the given logic networks is reached, traversing in a depth-first manner, then an input variable that can be reached by going back toward the inputs of the network is placed at highest position in variable ordering. Minato[25] devised another heuristic method in which each output function of the given logic networks is weighted and then input variables are ordered by the weight of each input variable determined by how each input can be reached from an output of the network. Butler et al.[8] proposed another heuristic based on a measure which uses not only the connection configuration of the network, but also the output functions of the network. These methods probably find a good order before generating BDDs. They find good orders in many cases, but there is no method that is always effective to a given network.

Another approach reduces the size of BDDs by reordering input variables. A greedy local exchange (swapping adjacent variables) method was developed by Fujita et al.[10] Minato[22] presented another reordering method which measures the width of BDDs as a cost function. In many cases, these methods find a fairly good order using no additional information. A drawback of the approach of these methods is that they cannot start if an initial BDD is too large.

One remarkable work is **dynamic variable ordering,** presented by Rudell.[27] In this technique, the BDD package itself determines and maintains the variable order. Every time the BDDs grow to a certain size, the reordering process is invoked automatically. This method is very effective in terms of the reduction of BDD size, although it sometimes takes a long computation time.

Table 26.1 shows experimental results on the effect of variable ordering. The logic network "sel8" is an 8-bit data selector, and "enc8" is an 8-bit encoder. "add8" and "mult6" are an 8-bit adder and a 6-bit multiplier. The rest is chosen from the benchmark networks in MCNC'90.[1] Table 26.1 compares four different orders: the original order, a random order, and two heuristic orders. The results show that the heuristic ordering methods are very effective except for a few cases which are insensitive to the order.

TABLE 26.1 Effect of Variable Ordering

	Network Feature			BDD Size (with complement edges)			
Name	No. of Inputs	No. of Outputs	No. of Inputs to All Gates	Original	Random	Heur-1	Heur-2
sel8	12	2	29	16	88	23	19

Note: Heuristic-1: Heuristic order based on connection configuration.[5]
Heuristic-2: BDD reduction by exchanging variables.[14]

Unfortunately, there are some hard examples where variable ordering is powerless. For example, Bryant[6] proved that an *n*-bit multiplier function requires an exponentially increasing number of BDD nodes for any variable order, as *n* increases. However, for many other practical functions, the variable ordering methods are useful for generating compact BDDs in a reasonably short time.

26.5 Remarks

Several groups developed BDD packages, and some of them are open to the public. For example, the CUDD package[12] is well-known to BDD researchers in the U.S. Many other BDD packages may be found on the Internet. BDD packages, in general, are based on the quick search of hash tables and linked-list data structures. They greatly benefit from the property of the **random access machine model**,[2] where any data in main memory can be accessed in constant time.

Presently, considerable research is in progress. Detection of total or partial symmetry of a logic function with respect to variables has been a very time-consuming problem, but now it can be done in a short time by BDDs.[26,29] Also, decomposition of a logic function, which used to be very difficult, can be quickly solved with BDD.[5,21] A number of new types of BDDs have been proposed in recent years. For example, the Zero-Suppressed BDD (ZBDD)[23] is useful for solving covering problems, which are used in deriving a minimal sum and other combinatorial problems. The Binary Moment Diagram (BMD)[7] is another type of BDD that is used for representing logic functions for arithmetic operations. For those who are interested in more detailed techniques related to BDDs, several good surveys[11,24,28] are available.

Logic Synthesis With AND and OR Gates in Two Levels

Saburo Muroga
University of Illinois at Urbana-Champaign

27.1 Introduction

When logic networks are realized in transistor circuits on an integrated circuit chip, each gate in logic networks usually realizes more complex functions than AND or OR gates. But handy design methods are not available for designing logic networks with such complex gates under very diversified complex constraints such as delay time and layout rules. Thus, designers often design logic networks with AND, OR, and NOT gates as a starting point for design with more complex gates under complex constraints. AND, OR, and NOT gates are much easier for human minds to deal with. Logic networks with AND, OR, and NOT gates, after designing such networks, are often converted into transistor circuits. This conversion process illustrated in Fig. 27.1 (the transistor circuit in this figure will be explained in later chapters) is called **technology mapping**. As can be seen, technology mapping is complex because logic gates and the corresponding transistor logic gates usually do not correspond one to one before and after technology mapping and layout has to be considered for speed and area.

Also, logic gates are realized by different types of transistor circuits, depending on design objectives. They are called **logic families**. There are several logic families, such as ECL, nMOS circuits, static CMOS, and dynamic CMOS, as discussed in Chapters 30, 35, and 36. Technology mapping is different for different logic families.

First, let us describe the design of logic networks with AND and OR gates in two levels, because handy methods are not available for designing logic networks with AND and OR gates in more than two levels. Although logic networks with AND and OR gates in two levels may not be directly useful for designing transistor circuits to be laid out on an integrated circuit chip, there are some cases where they are directly usable, such as programmable logic arrays to be described in a later chapter.

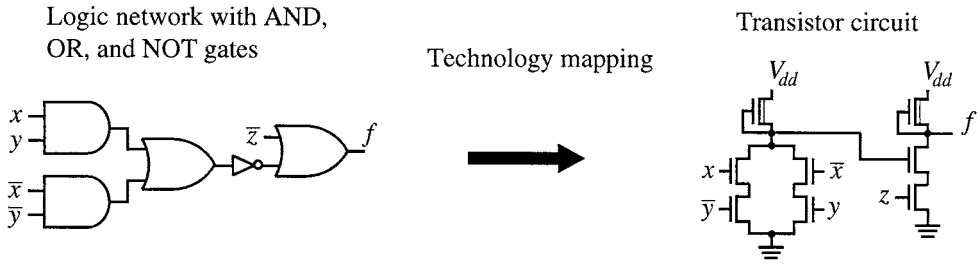

FIGURE 27.1 Conversion of a logic network with simple gates by technology mapping.

27.2 Design of Single-Output Minimal Networks with AND and OR Gates in Two Levels

Suppose that we want to obtain a two-level network with a minimum number of gates and, then, as a secondary objective, a minimum number of connections under Assumptions 27.1 in the following, regardless of whether we have AND or OR gates, respectively, in the first and second levels, or in the second and first levels. In this case, we have to design a network based on the minimal sum and another based on the minimal product, and then choose the better network. Suppose that we want to design a two-level AND/OR network for the function shown in Fig. 27.2(a). This function has only one minimal sum, as shown with loops in Fig. 27.2(a). Also, it has only one minimal product, as shown in Fig 27.3(a). The network in Fig. 27.3(b), based on this minimal product, requires one less gate, despite more loops, than the network based on the minimal sum in Fig. 27.2(b), and consequently the network in Fig. 27.3(b) is preferable.

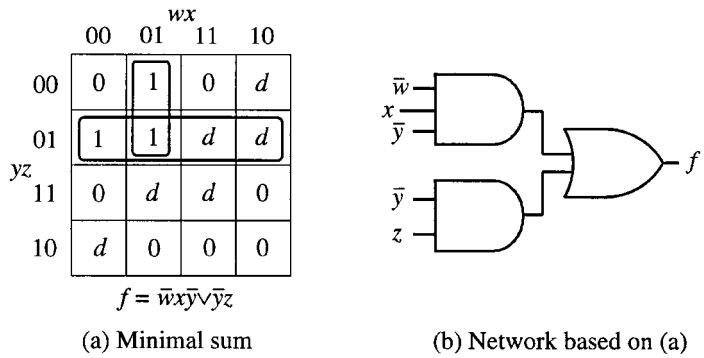

FIGURE 27.2 Minimal sum and the corresponding network.

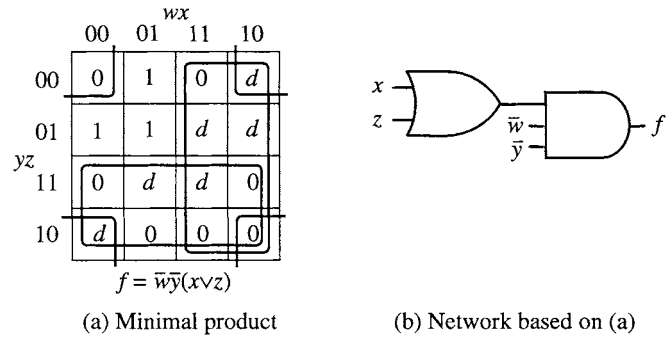

FIGURE 27.3 Minimal product and the corresponding network.

The above design procedure of a minimal network based on a minimal sum is meaningful under the following assumptions.

Assumptions 27.1: (1) The number of levels is at most two; (2) Only AND gates and OR gates are used in one level and second the other level; (3) Complemented variables $\bar{x}_i$'s as well as noncomplemented x_i's for each i are available as the network inputs; (4) No maximum fan-in restriction is imposed on any gate in a network to be designed; (5) Among networks realizable in two levels, we will choose networks that have a minimum number of gates. Then, from those with the minimum number of gates, we will choose a network that has a minimum number of connections.

If any of these is violated, the number of logic gates as the primary objective and the number of connections as the secondary objective are not minimized. If we do not have the restriction "at most two levels," we can generally have a network of fewer gates.

Karnaugh maps have been widely used because of convenience when the number of variables is small. But when the number of variables is many, maps are increasingly complex and processing with them become tedious, as discussed in Chapter 25. Furthermore, the corresponding logic networks with AND and OR gates in two levels are not useful because of excessive fan-ins and fan-outs.

27.3 Design of Multiple-Output Networks with AND and OR Gates in Two Levels

So far, we have discussed the synthesis of a two-level network with a single output. In many cases in practice, however, we need a two-level network with multiple outputs; so here let us discuss the synthesis of such a network, which is more complex than a network with a single output.

An obvious approach is to design a network for each output function separately. But this approach usually will not yield a more compact network than will synthesis of the functions collectively, because, for example, in Fig. 27.4, the AND gate h, which can be shared by two output gates for f_i and f_j, must be repeated in separate networks for f_i and f_j by this approach.

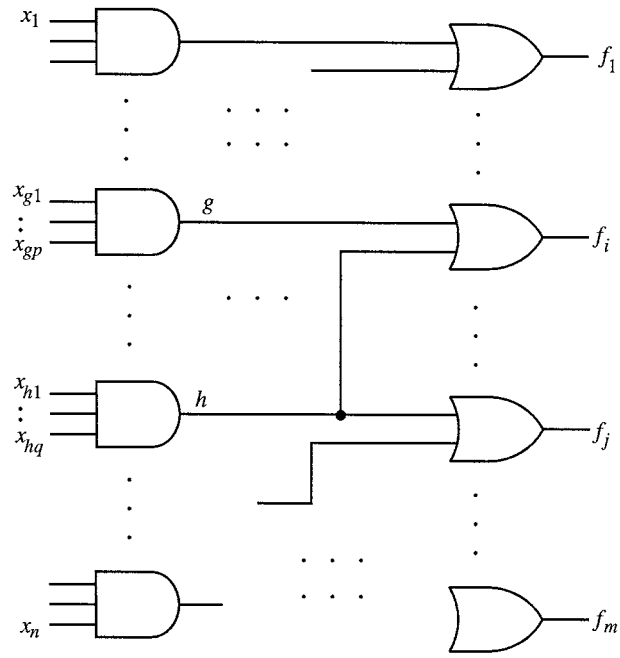

FIGURE 27.4 A two-level network with multiple outputs.

Before discussing a design procedure, let us study the properties of a minimal two-level network that has only AND gates in the first level and only OR gates for given output functions $f_1, f_2, \ldots, f_m$ in the second level, as shown in Fig. 27.4, where "a minimal network" means that the network has a minimum number of gates as the primary objective and a minimum number of connections as the secondary objective. The number of OR gates required for this network is at most m. Actually, when some functions are expressed as single products of literals, the number of OR gates can be less than m because these functions can be realized directly at the outputs of the AND gates without the use of OR gates. Also, when a function f_i has a prime implicant consisting of a single literal, that literal can be directly connected to the OR gate for f_i without the use of an AND gate. (These special cases can be treated easily by modifying the synthesis under the following assumption.) However, for simplicity, let us **assume that every variable input is connected only to AND gates in the first level and every function f_i, $1 \le i \le m$, is realized at the outputs of OR gates in the second level.** This is actually required with some electronic realizations of a network (e.g., when every variable input needs to have the same delay to the network outputs, or when PLAs which will be described in Chapter 42 are used to realize two-level networks).

Multiple-Output Prime Implicants

Suppose that we have a two-level, multiple-output network that has AND gates in the first level, and m OR gates in the second (i.e., output) level for functions $f_1, f_2, \ldots, f_m$ (as an example, f_1, f_2, and f_3 are given as shown in the Karnaugh maps in Fig. 27.5). The network has a minimum number of gates as the primary objective, and a minimum number of connections as the secondary objective. Let us explore the basic properties of such a minimal network.

Property 27.1: First consider an AND gate, g, that is connected to only one output gate, say for f_i, in Fig. 27.4. If gate g has inputs $x_{g1}, x_{g2}, \ldots, x_{gp}$, its output represents the product $x_{g1}x_{g2}\ldots x_{gp}$. Then, if the product assumes the value 1, f_i becomes 1. Thus, the product $x_{g1}x_{g2}\ldots x_{gp}$ is an implicant of f_i. Since the network is minimal, gate g has no unnecessary inputs, and the removal of any input from gate g will make the OR gate for f_i express a different function (i.e., in Fig. 27.5, the loop that the product represents becomes larger, containing some 0-cells, by deleting any variables from the product and then the new product is not an implicant of f_i). Thus, $x_{g1}, x_{g2}, \ldots, x_{gp}$ is a prime implicant of f_i.

Property 27.2: Next consider an AND gate, h, that is connected to two output gates for f_i and f_j in Fig. 27.4. This time, the situation is more complicated. If the product $x_{h1}x_{h2}\ldots x_{hq}$ realized at the output of gate h assumes the value 1, both f_i and f_j become 1 and, consequently, the product f_if_j of the two functions also becomes 1 (thus, if a Karnaugh map is drawn for f_if_j as shown in Fig. 27.5, the map has a loop consisting of only 1-cells for $x_{h1}x_{h2}\ldots x_{hq}$). Thus $x_{h1}x_{h2}\ldots x_{hq}$ is an implicant of product f_if_j. The network is minimal in realizing each of functions $f_1, f_2, \ldots, f_m$; so, if any input is removed from AND gate h, at least one of f_i and f_j will be a different function and $x_{h1}x_{h2}\ldots x_{hq}$ will no longer be an implicant of f_if_j. (That is, if any input is removed from AND gate h, a loop in the map for at least one of f_i and f_j will become larger. For example, if x_1 is deleted from M: $x_1\bar{x}_2x_3$ for f_1f_2, the loop for $\bar{x}_2x_3$, product of the remaining literals, appears in the maps for f_1 and also for f_2 in Fig. 27.5. The loop in the map for f_2 contains 0-cell. Thus, if a loop is formed in the map for f_1f_2 as a product of these loops in the maps for f_1 and f_2, the new loop contains 0-cell in the map for f_1f_2. This means that if any variable is removed from $x_{h1}x_{h2}\ldots x_{hq}$, the remainder is not an implicant of f_1f_2.) Thus, $x_{h1}x_{h2}\ldots x_{hq}$ is a prime implicant of the product f_if_j. (But notice that the product $x_{h1}x_{h2}\ldots x_{hq}$ is not necessarily a prime implicant of each single function f_i or f_j, as can be seen in Fig. 27.5. For example, M: $x_1\bar{x}_2x_3$ is a prime implicant of f_1f_2 in Fig. 27.5. Although this product, $x_1\bar{x}_2x_3$, is a prime implicant of f_2, it is not a prime implicant of f_1 in Fig. 27.5.)

Generalizing this, we obtain the following conclusion. Suppose that the output of an AND gate is connected to r OR gates for functions $f_{i1}, \ldots, f_{ir}$. Since the network is minimal, this gate has no unnecessary inputs. Then the product of input variables realized at the output of this AND gate is a prime implicant of the product $f_{i1}\ldots f_{ir}$ (but is not necessarily a prime implicant of any product of $r-1$ or fewer, of these $f_{i1}, \ldots, f_{ir}$).

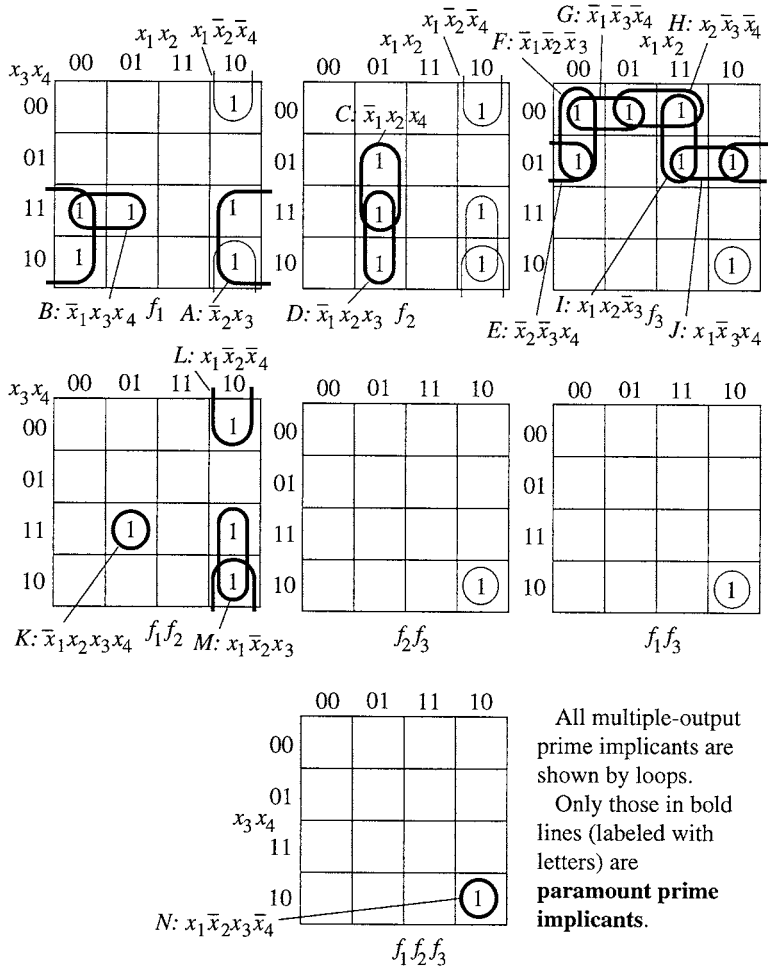

FIGURE 27.5 Multiple-output prime implicants on Karnaugh maps.

As in the synthesis of a single-output network, we need to find all prime implicants and then develop disjunctive forms by choosing an appropriate set of prime implicants. (Notice that each of these disjunctive forms is not necessarily a minimal sum for one of functions, f_i.) But, unlike the synthesis of a single-output network, in this case we must consider all prime implicants not only for each of the given functions $f_1, \ldots, f_m$, but also for all possible products of them, f_1f_2, f_1f_3, …, $f_{m-1}f_m$; $f_1f_2f_3$, $f_1f_2f_4$, …; …; …; $f_1f_2 \ldots f_{m-1}f_m$.

Definition 27.1: Suppose that m functions $f_1, \ldots, f_m$ are given. All prime implicants for each of these m functions, and also all prime implicants for every possible product of these functions, that is,

$$
\begin{aligned}
&f_1, f_2, \ldots, f_m \\
&f_1f_2, f_1f_3, \ldots, f_{m-1}f_m, \\
&f_1f_2f_3, f_1f_2f_4, \ldots, f_{m-2}f_{m-1}f_m \\
&\ldots, \ldots, \ldots, \\
&\ldots, \ldots, \ldots, \\
&f_1f_2 \ldots f_{m-1}, f_1f_2 \ldots f_{m-2}f_m, \ldots, f_2f_3 \ldots f_m \\
&f_1f_2f_3 \ldots f_{m-1}f_m
\end{aligned}
$$

are called the **multiple-output prime implicants** of $f_1, \ldots, f_m$.

When the number of variables is small, we can find all multiple-output prime implicants on Karnaugh maps, as illustrated in Fig. 27.5 for the case of three functions of four variables. In addition to the maps for given functions f_1, f_2, and f_3, we draw the maps for all possible products of these functions; that is, f_1f_2, f_2f_3, f_1f_3, and $f_1f_2f_3$. Then, prime-implicant loops are formed on each of these maps. These loops represent all the multiple-output prime implicants of given functions f_1, f_2, and f_3.

Paramount Prime Implicants

Suppose we find all multiple-output prime implicants for the given functions. Then, if a prime implicant P appears more than once as prime implicants for different products of functions, P for the product of the largest number of functions among these products of functions is called a **paramount prime implicant for *P*** in order to differentiate this P from other multiple-output prime implicants. As a special case, if P appears only once, it is the paramount prime implicant for P.

For example, among all multiple-output prime implicants for f_1, f_2, and f_3 (i.e., among all prime implicants for f_1f_2, f_2f_3, f_1f_3, and $f_1f_2f_3$ shown as loops in Fig. 27.5), the prime implicant $x_1\bar{x}_2\bar{x}_4$ appears three times in Fig. 27.5. In other words, $x_1\bar{x}_2\bar{x}_4$ appears as a prime implicant for the function f_1 (see the map for f_1 in Fig. 27.5), as a prime implicant for f_2, and also as a prime implicant for the product f_1f_2 (in the map for f_1f_2, this appears as L: $x_1\bar{x}_2\bar{x}_4$). Then, the prime implicant $x_1\bar{x}_2\bar{x}_4$ for f_1f_2 is the paramount prime implicant for $x_1\bar{x}_2\bar{x}_4$ because it is a prime implicant for the product of two functions, f_1 and f_2, but the prime implicant $x_1\bar{x}_2\bar{x}_4$ for f_1 or f_2 is a prime implicant for a single function f_1 or f_2 alone. In the two-level network, $x_1\bar{x}_2\bar{x}_4$ for the product f_1f_2 realizes the AND gate with output connections to the OR gates for f_1 and f_2, whereas $x_1\bar{x}_2\bar{x}_4$ for f_1 or f_2 realizes the AND gate with output connection to only the OR gate for f_1 or f_2, respectively. Thus, if we use $x_1\bar{x}_2\bar{x}_4$ for the product f_1f_2 instead of $x_1\bar{x}_2\bar{x}_4$ for f_1 or f_2 (in other words, if we use AND gates with more output connections) then the network will be realized with no more gates. In this sense, $x_1\bar{x}_2\bar{x}_4$ for the product f_1f_2 is more desirable than $x_1\bar{x}_2\bar{x}_4$ for the function f_1 or f_2. Prime implicant $x_1\bar{x}_2\bar{x}_4$ for the product f_1f_2 is called a paramount prime implicant, as formally defined in the following, and is shown with label L in a bold line in the map for f_1f_2 in Fig. 27.5; whereas $x_1\bar{x}_2\bar{x}_4$ for f_1 or f_2 alone is not labeled and is also not in a bold line in the map for f_1 or f_2. Thus, **when we provide an AND gate whose output realizes the prime implicant $x_1\bar{x}_2\bar{x}_4$, we can connect its output connection in three different ways, i.e., to f_1, f_2, or both f_1 and f_2, realizing the same output functions, f_1, f_2, and f_3. In this case, the paramount prime implicant means that we can connect the largest number of OR gates from this AND gate; in other words, this AND gate has the largest coverage, although some connections may turn out to be redundant later.**

Definition 27.2: Suppose that when all the multiple-output prime implicants of $f_1, \ldots, f_m$ are considered, a product of some literals, P, is a prime implicant for the product of k functions $f_{p1}, f_{p2}, \ldots, f_{pk}$ (possibly also prime implicants for products of $k-1$or fewer of these functions), but is not a prime implicant for any product of more functions that includes all these functions $f_{p1}, f_{p2}, \ldots, f_{pk}$. (For the above example, $x_1\bar{x}_2\bar{x}_4$ is a prime implicant for the product of two functions, f_1 and f_2, and also a prime implicant for a single function, f_1 or f_2. But $x_1\bar{x}_2\bar{x}_4$ is not a prime implicant for the product of more functions, including f_1 and f_2, that is, for the product $f_1f_2f_3$.) Then, P for the product of $f_{p1}, f_{p2}, \ldots, f_{pk}$ is called the **paramount prime implicant** for this prime implicant ($x_1\bar{x}_2\bar{x}_4$ for f_1f_2 is a paramount prime implicant, but $x_1\bar{x}_2\bar{x}_4$ for f_1 or f_2 is not). As a special case, if P is a prime implicant for only one function but not a prime implicant for any product of more than one function, it is a paramount prime implicant (B: $\bar{x}_1x_3x_4$ for f_1 is such an example in Fig. 27.5).

In Fig. 27.5, only labeled loops shown in bold lines represent paramount prime implicants.

If a two-level network is first designed only with the AND gates that correspond to the paramount prime implicants, we can minimize the number of gates. This does not necessarily minimize the number of connections as the secondary objective. But in some important electronic realizations of two-level networks, such as PLAs (which will be explained later) this is not important. Thus, let us consider only the minimization of the number of gates in the following for the sake of simplicity.

Design of a Two-Level Network with a Minimum Number of AND and OR Gates

In the following procedure, we will derive a two-level network with a minimum number of gates (but without minimizing the number of connections as the secondary objective) by finding a minimal number of paramount prime implicants to represent the given functions.

Procedure 27.1: Design of a Multiple-Output Two-Level Network That Has a Minimum Number of Gates Without Minimizing the Number of Connections

We want to design a two-level network that has AND gates in the first level and OR gates in the second level. We shall assume that variable inputs can be connected to AND gates only (not to OR gates), and that the given output functions $f_1, f_2, \ldots, f_m$ are to be realized only at the outputs of OR gates.

Suppose we have already found all the paramount prime implicants for the given functions and their products.

1. Find a set of a smallest number of paramount prime implicant loops that covers all 1-cells in Karnaugh maps for the given functions $f_1, f_2, \ldots, f_m$. In this case, maps for their products, such as f_1f_2, need not be considered. If there is more than one such set, choose a set that has as large loops as possible (i.e., choose a set of loops such that the total number of inputs to the AND gates that correspond to these loops is the smallest).

For example, suppose that the three functions of four variables, f_1, f_2, f_3, shown in the Karnaugh maps in Fig. 27.5 are given. Then, using only the bold-lined loops labeled with letters (i.e., paramount prime implicants), try to cover all 1-cells in the maps for f_1, f_2, and f_3 only (i.e., using the only top three maps in Fig. 27.5). Then, we find that more than one set of loops have the same number of loops with the same sizes. *AKLCDMNFHJ*, one of these sets, covers all functions f_1, f_2, and f_3, as illustrated in Fig. 27.6.

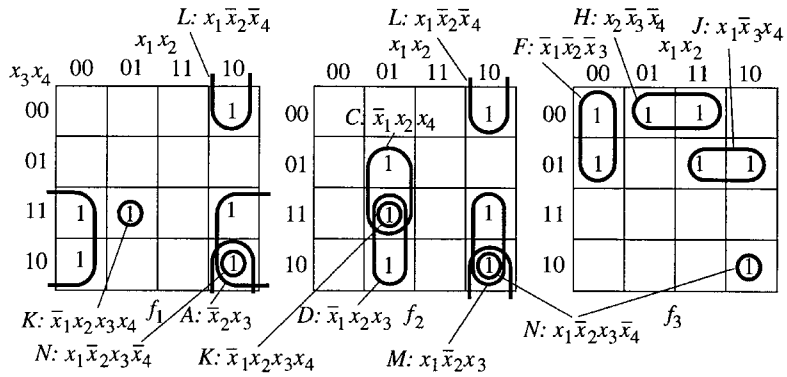

FIGURE 27.6 Covering f_1, f_2, and f_3 with the minimum number of paramount prime implicants.

2. Construct a network corresponding to the chosen set of paramount prime implicant loops.

Then, the network of 13 gates shown in Fig. 27.7 has been uniquely obtained. Letter *N* (i.e., $x_1\bar{x}_2x_3\bar{x}_4$), for example, is a paramount prime implicant for the product $f_1f_2f_3$, so the output of an AND gate with inputs, x_1, $\bar{x}_2$, x_3, and $\bar{x}_4$, is connected to the OR gates for f_1, f_2, and f_3.

3. Then delete unnecessary connections, or replace some logic gates by new ones, by the following steps from the logic networks derived in Step 2, by considering whether some Karnaugh maps have a paramount prime implicant loop that is inside another one, or adjacent to another one.

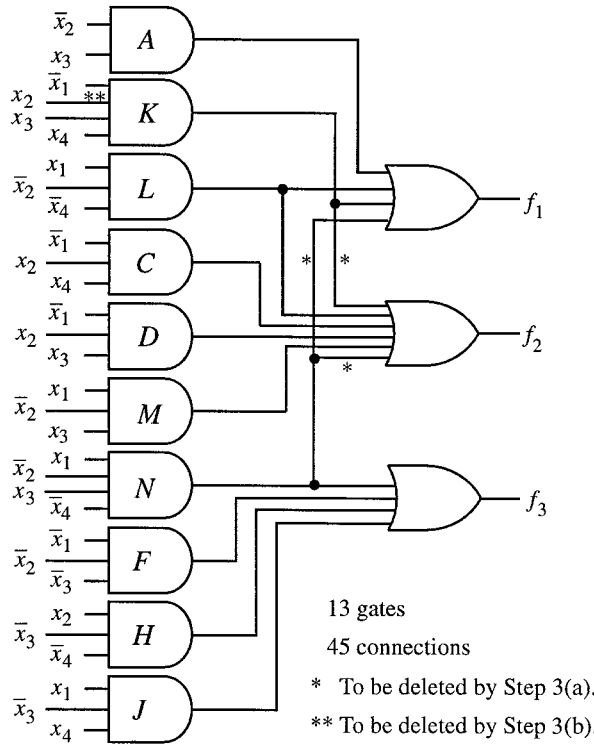

FIGURE 27.7 The network corresponding to *AKLCDMNFHJ*.

a. If, in a Karnaugh map for a function f_i, there is a paramount prime implicant loop that is inside another one, then the former is not necessary, because the 1-cells contained in this loop are covered by the latter loop. Thus, we can delete the connection from the AND gate corresponding to the former loop to the OR gate for f_i, without changing the output functions of the logic network.

For example, loop K in the map for f_2 is inside the loop C in Fig. 27.6. Thus, we can delete K from the map for f_2, because the 1-cell in K is covered by the loop C. This means that we can delete the connection (shown with * in Fig. 27.7) from the AND gate labeled K in Fig. 27.7. Similarly we can delete the loops N from the maps for f_1 and f_2, and accordingly, the connections (shown with * in Fig. 27.7) from the AND gates labeled N to the OR gates for f_1 and f_2.

b. If, in a Karnaugh map for a function f_i, there is a paramount prime implicant loop that is adjacent to another one, we may be able to expand the former by incorporating some 1-cells of the latter without having any 0-cells and at the same time replace the loop by the expanded loop (i.e., the number of logic gates unchanged). If we can do so, replace the former loop by the expanded loop. The expanded loop represents a product of fewer literals. Thus, we can delete the connection to the AND gate corresponding to the expanded loop without changing the output functions of the logic network.

For example, loop K in the map for f_1 has an adjacent loop A. Then we can replace the loop K by a larger loop (i.e., loop B in Fig. 27.5) by incorporating the 1-cell on its left, which represents the product $\bar{x}_1 x_3 x_4$. Also, K appears only in the map for f_2, beside K in the map for f_1. K in the map for f_2 is concluded to be eliminable, so the AND gate for K in Fig. 27.7 can be replaced by the new gate for B, keeping the number of logic gates unchanged. This means that we can delete the connection of input

x_2 (shown with ** in Fig. 27.7) to the AND gate labeled K in Fig. 27.7 (i.e., this is essentially replacement of K by B). Thus we can delete in totally, 4 connections from the logic network shown in Fig. 27.7, ending up with a simpler network with 13 gates and 41 connections.

When the number of paramount prime implicants is very small, we can find, directly on the maps, a minimum number of paramount prime implicants that cover all 1-cells in the maps for $f_1, f_2, \ldots, f_m$ (not their products) and derive a network with a minimum number of gates, using Procedure 27.1. But when the number of paramount prime implicants is many, the algebraic procedure of Section 4.6 in Ref. 5 is more efficient.

Procedure 27.1 with the deletion of unnecessary connections, however, may not necessarily yield a minimum number of connections as the secondary objective, although the number of gates is minimized as the primary objective. If we want to have a network with a minimum number of connections as the secondary objective, although the network has the same minimum number of gates as the primary objective, then we need to modify Procedure 27.1 and then delete unnecessary connections, as described as Procedure 5.2.1 in Ref. 5. But this procedure is more tedious and time-consuming.

Networks That Cannot be Designed by the Preceding Procedure

Notice that the design procedures in this section yield only a network that has all AND gates in the first level and all OR gates in the second level. (If 0-cells on Karnaugh maps are worked on instead of 1-cells in Procedure 27.1, we have a network with all OR gates in the first level and all AND gates in the second level.) If AND and OR gates are mixed in each level, or the network need not be in two levels, Procedure 27.1 does not guarantee the minimality of the number of logic gates.[6]

These two problems can be solved by the integer programming logical design method (to be mentioned in Chapter 31, Section 31.5), which is complex and can be applied to only networks of a small number of gates.

Applications of Procedure 27.1

Procedure 27.1 has important applications, such as PLAs, it but cannot be applied for designing large PLAs. For multiple-output functions with many variables, absolute minimization is increasingly time-consuming. Using BDD (described in Chapter 26), Coudert, Madre, and Lin extended the feasibility of absolute minimization.[2,3] But as it is becoming too time-consuming, we have to give up absolute minimization, resorting to heuristic minimization, such as a powerful method which is called MINI[4] and was later improved as ESPRESSO.[1]

Sequential Networks

Saburo Muroga
University of Illinois at Urbana-Champaign

28.1 Introduction

A logic network is called a **sequential network** when the values of its outputs depend not only on the current values of inputs but also on some of the past values, whereas a logic network is called a **combinational network** when the values of its outputs depend only on the current values of inputs but not on any past values. Analysis and synthesis of sequential networks are far more complex than combinational networks. When reliable operation of the networks is very important, the operations of logic gates are often synchronized by clocks. Such clocked networks, whether they are combinational or sequential networks, are called **synchronous networks**, and networks without clock are called **asynchronous networks**.

28.2 Flip-Flops and Latches

Because in a sequential network the outputs assume values depending not only on the current values but also on some past values of the inputs, a sequential network must remember information about the past values of its inputs. Simple networks called **flip-flops** that are realized with logic gates are usually used as memories for this purpose. Semiconductor memories can also serve as memories for sequential networks, but flip-flops are used if higher speed is necessary to match the speed of logic gates. Let us explain the simplest flip-flops, which are called **latches**.

S-R Latches

The network in Fig. 28.1(a) which is called an ***S-R* latch**, consists of two NOR gates. Assume that the values at terminals S and R are 0, and the value at terminal Q is 0 (i.e., $S = R = 0$ and $Q = 0$). Since gate 1 has inputs of 0 and 0, the value at terminal $\overline{Q}$ is 1 (i.e., $\overline{Q} = 1$). Since gate 2 in the network has two inputs, 0 and 1, its output is $Q = 0$. Thus, signals 0 and 1 are maintained at terminals Q and $\overline{Q}$, respectively, as long as S and R remain 0. Now let us change the value at S to 1. Then, $\overline{Q}$ is changed to 0, and Q becomes 1 after a short time delay. Even if $Q = 1$ and $\overline{Q} = 0$ were their original values, the change of the value at S to 1 still yields $Q = 1$ and $\overline{Q} = 0$. In other words, Q is set to 1 by supplying 1 to S, no matter whether we originally had $Q = 0$, $\overline{Q} = 1$, or $Q = 1$, $\overline{Q} = 0$. Similarly, when 1 is supplied to R with S remaining at 0, Q and $\overline{Q}$ are set to 0 and 1, respectively, after a short time delay, no matter what values they had before. Thus, we get the first three combinations of the values of S and R shown in the table in Fig. 28.1(b). In other words, as long as $S = R = 0$, the values of Q and $\overline{Q}$ are not changed. If $S = 1$, Q is set to 1. If $R = 1$, Q is set to 0. Thus, S and R are called **set** and **reset terminals**, respectively. In order to let the latch work properly, the value 1 at S or R must be maintained until new values of Q and $\overline{Q}$ are established. The *S-R* latch is usually denoted as in Fig. 28.1(c). An *S-R* latch can also be realized with NAND gates, as shown in Fig. 28.1 (d). Latches and flip-flops have a direct reset-input terminal and a direct set-input terminal, although these input terminals are omitted in Fig. 28.1 and in the figures for other flip-flops for the sake of simplicity. These input terminals are convenient for initial setting to $Q = 1$, or resetting to $Q = 0$.

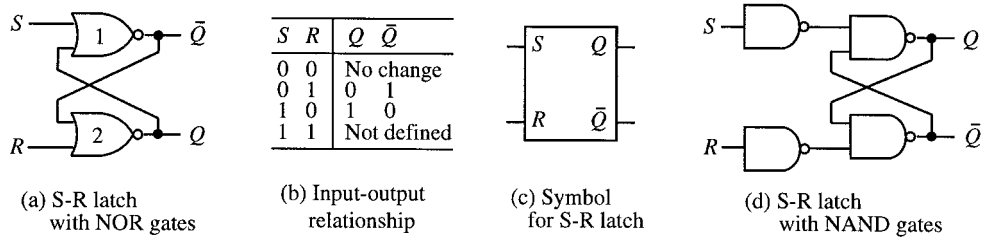

FIGURE 28.1 S-R latches.

When $S = R = 1$ occurs, the outputs Q and $\overline{Q}$ are both 0. If S and R simultaneously return to 0, these two outputs cannot maintain 0. Actually, a simultaneous change of S and R to 0 or 1 is physically impossible, often causing the network to malfunction, unless we make the network more sophisticated, such as synchronization of logic gates by a clock, as will be explained later. If S returns to 0 from 1 before R does, we have $Q = 0$ and $\overline{Q} = 1$. If R returns to 0 from 1 before S does, we have $Q = 1$ and $\overline{Q} = 0$. Thus, it is not possible to predict what values we will have at the outputs after having $S = R = 1$. The output of this network is not defined for $S = R = 1$, as this combination is not used. **For simplicity, let us assume that only one of the inputs to any network changes at a time, unless otherwise noted. This is a reasonable and important assumption.**

Flip-Flops

Usually, *S-R* latches are used in designing asynchronous sequential networks, although sequential networks can be designed without them. For example, the memory function can be realized with longer loops of gates than the loop in the latch, and also more sophisticated flip-flops than *S-R* latches can be used. For example, a loop consisting of a pair of inverters and a special gate called a transmission gate is used in CMOS networks, as we will see in Chapter 36, Section 36.2. But for synchronous networks, **raceless flip-flops** (described later in this chapter) are particularly important.

28.3 Sequential Networks in Fundamental Mode

In a sequential network, the value of the network output depends on both the current input values and some of past input values stored in the network. We can find what value the output has for each individual combination of input values, depending on what signal values are stored in the network. This essentially means interpreting the signals stored inside the network as new input variables called **internal variables** and then interpreting the entire network as a combinational network of the new input variables, plus the original inputs, which are **external input variables**.

Let us consider the sequential network in Fig. 28.2. Assume that the inputs are never changed unless the network is in a stable condition, that is, unless none of the internal variables is changing. Also assume that, whenever the inputs change, only one input changes at a time. Let y_1, $\bar{y}_1$, y_2, and $\bar{y}_2$ denote the outputs of the two *S-R* latches.

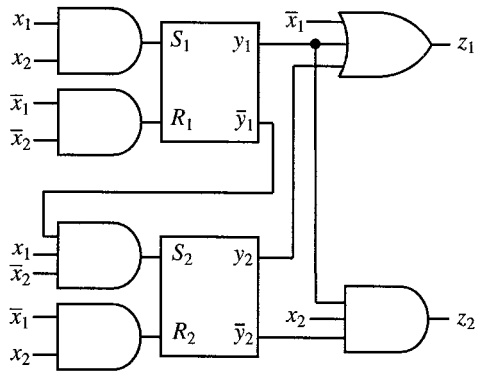

FIGURE 28.2 A sequential network with S-R latches.

Let us assume that $y_1 = y_2 = 0$ (accordingly, $\bar{y}_1 = \bar{y}_2 = 1$). $x_1 = 0$, and $x_2 = 1$. Then, as can be easily found, we have $z_1 = 1$ and $z_2 = 0$ for this combination of values. Because of $x_1 = 0$ and $x_2 = 1$, the inputs of the latches have values $R_2 = 1$ (accordingly, $y_2 = 0$) and $S_1 = S_2 = R_1 = 0$. Then y_1 and y_2 remain 0. As long as x_1, y_1, and y_2 remain 0 and x_2 remains 1, none of the signal values in this network changes and, consequently, this combination of values of x_1, x_2, y_1, and y_2 is called a **stable state**.

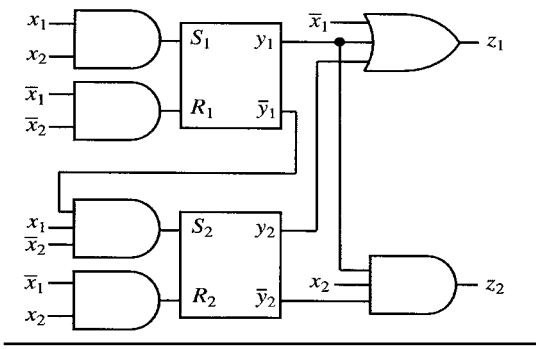
Next let us assume that x_1 is changed to 1, keeping $x_2 = 1$ and $y_1 = y_2 = 0$. For this new combination of input values, we get $z_1 = 0$ and $z_2 = 0$ after a time delay of τ, where τ is the switching time (delay time) of each gate, assuming for the sake of simplicity that each gate has the same τ (this is not necessarily true in practice). The two latches have new inputs $S_1 = 1$ and $S_2 = R_1 = R_2 = 0$ after a time delay of τ. Then, they have new output values $y_1 = 1$ (previously 0), $\bar{y}_1 = 0$, $y_2 = 0$, and $\bar{y}_2 = 1$ after a delay due to the response time of the latches. Outputs z_1 and z_2 both change from 0 to 1. After this change, the network does not change any further. Summarizing the above, we can say that, when the network has the combination $x_1 = x_2 = 1$, $z_1 = z_2 = y_1 = y_2 = 0$, the network does not remain in this combination, but changes into the new combination $x_1 = x_2 = z_1 = z_2 = y_1 = 1$, $y_2 = 0$. Also, outputs z_1 and z_2 change into $z_1 = z_2 = 1$, after assuming the values $z_1 = z_2 = 0$ temporarily. After the network changes into the combination $x_1 = x_2 = y_1 = 1$, $y_2 = 0$, and $z_1 = z_2 = 1$, it remains there. The combination $x_1 = x_2 = 1$ and $z_1 = z_2 = y_1 = y_2 = 0$ is called an **unstable state**. The transition from an unstable to a stable state, such as the above transition to the stable state, is the key to the analysis of a sequential network.

Transition Tables

This and other transitions for other combinations of values of x_1, x_2, y_1, y_2, z_1, and z_2 can be shown on the map in Table 28.1, which is called a **transition-output table,** showing the next values of y_1 and

y_2 as Y_1 and Y_2, respectively. The entry in each cell in Table 28.1 is next states Y_1, Y_2 and outputs z_1 and z_2. The above transition from $x_1 = 0$, $x_2 = 1$, $y_1 = y_2 = 0$ to $x_1 = x_2 = y_1 = 1$, $y_2 = 0$ is shown by the line with an arrow in Table 28.1. For this transition, the network is initially in the cell labeled with $*$ in Table 28.1; and when x_1 changes to 1, the network moves to the next cell labeled with the dot with this cell's entry, $Y_1 = 1$, $Y_2 = 0$, and $z_1 = z_2 = 0$, during the transient period. Here, it is important to notice that in this cell, next values of internal variables y_1 and y_2, i.e., Y_1 and Y_2 are shown but the network actually has current values of y_1 and y_2, that is, $y_1 = y_2 = 0$ during this transition period corresponding to this cell. Y_1 and Y_2 in this cell, which is in an unstable state, indicates what values y_1 and y_2 should take after the transition. Then, the network moves to the bottom cell where the values of y_1 and y_2 are identical to Y_1 and Y_2, respectively, as indicated by the line with an arrow, because Y_1 and Y_2 will be current y_1 and y_2 after the transition. The present values of the internal variables are shown with y_1 and y_2 in small letters and their next values are with Y_1 and Y_2 in capital letters. More specifically, variables y_1 and y_2 are called **present-state (internal) variables**, and Y_1 and Y_2 are called **next-state (internal) variables**. As can easily be seen, when the values of Y_1 and Y_2 shown inside a cell are identical to those of y_1 and y_2 shown on the left of the table, respectively, a state containing these values of Y_1, Y_2, y_1, and y_2 is stable, because there is no transition of y_1 and y_2 into a new, different state. Next-state variables in stable states are encircled in Table 28.1. Each column in this table corresponds to a combination of values of network inputs x_1 and x_2, that is, an **input state**. Each row corresponds to a combination of values of internal variables y_1 and y_2, that is, a present **internal state**. Thus, each cell corresponds to a **total state**, or simply a **state**; that is, a combination of values of x_1, x_2, y_1, and y_2.

TABLE 28.1 Transition-Output Table in Fundamental Mode



When only next states Y_1 and Y_2 are shown, instead of showing all next states Y_1, Y_2, and outputs z_1 and z_2 in each cell of a transition-output table, the table is called a **transition table**, and when only outputs z_1 and z_2 are shown, the table is called an **output table**.

Fundamental Mode

A sequential network is said to be operating in **fundamental mode** when the transition occurs horizontally in the transition table corresponding to each network input change and, then, unless the new state in the same row is stable, the transition continues vertically (not diagonally), settling in a new stable state, such as the transition shown with the line with an arrow in Table 28.1. The transitions of the network take place under the assumption that only one of the network inputs changes at a time, only when the network is not in transition; that is, only when the network is settled in a stable state.

By using a transition-output table, the output sequence [i.e., the sequence of output values corresponding to any input sequence, (i.e., the sequence of input values)] can be easily obtained. In other words, the output sequence can be obtained by choosing columns corresponding to the input sequence and then moving to stable states whenever states.

28.4 Malfunctions of Asynchronous Sequential Networks

An asynchronous sequential network does not work reliably unless appropriate binary numbers are assigned to internal variables for each input change.

Racing Problem of Sequential Networks

A difference in time delays of signal propagation along different paths may cause a malfunction of an asynchronous sequential network that is called a **race**. This is caused by a difference in the delay times of gates.

Let us consider the transition-output table of a certain asynchronous sequential network shown in Table 28.2.

TABLE 28.2 Transition-Output Table in Fundamental Mode

y_1y_2 \ x_1x_2	00	01	11	10
00	(00), 0	(00), 0	11, 0**	01, 0
01	(01), 0	00, 0	11, 1	(01), 1
11	(11), 0	10, 0	10, 1	(11), 1
10	—	00, 0	(10), 0	01, 0*

Y_1Y_2, z

Suppose that the network is in the stable state $(x_1, x_2, y_1, y_2) = (1110)$. If the inputs change from $(x_1, x_2) = (11)$ to (10), the network changes into the unstable state $(x_1, x_2, y_1, y_2) = (1010)$, marked with $*$ in Table 28.2. Because of $y_1 = 1$, $y_2 = 0$, $Y_1 = 0$ and $Y_2 = 1$, two logic gates whose outputs represent y_1 and y_2 in the network must change their output values simultaneously. However, it is extremely difficult for the two gates to finish their changes at exactly the same time, because no two paths that reach these gates have identical time delays. Actually, one of these two logic gates finishes its change before the other does. In other words, we have one of the following two cases:

1. y_2 changes first, making the transition of (y_1, y_2) from (10) to (11) and leading the network into stable state $(x_1, x_2, y_1, y_2) = (1011)$.
2. y_1 changes first, making the transition of (y_1, y_2) from (10) to (00) and reaching the unstable state $(x_1, x_2, y_1, y_2) = (1000)$, and then y_2 changes, making the further transition of (y_1, y_2) from (00) to (01), settling in the stable state $(x_1, x_2, y_1, y_2) = (1001)$.

Thus, the network will go to either state $(y_1, y_2) = (11)$, in case 1, or state $(y_1, y_2) = (00)$, in case 2, instead of going directly to $(y_1, y_2) = (01)$. If $(y_1, y_2) = (11)$ is reached, state (11) is stable, and the network stops here. If (00) is reached, this is an unstable state, and another transition to the next stable state, (01), occurs. State (01) is the **destination stable state** (i.e., desired stable state), but (11) is not. Thus, depending on which path of gates works faster, the network may malfunction. This situation is called a **race**. The network may or may not malfunction, depending on which case actually occurs.

Next, suppose that the network is in the stable state $(x_1, x_2, y_1, y_2) = (0100)$ and that inputs $(x_1, x_2) = (01)$ change to (11). The cell labeled with ** in Table 28.2 has $(Y_1\ Y_2) = (11)$. Thus, y_1 and y_2 must have simultaneous changes. Depending on which one of the two logic gates whose outputs represent y_1 and y_2 changes its output faster, there are two possible transitions. But in this case, both end up in the same stable state, $(y_1, y_2) = (10)$. This is another race, but the network does not have a malfunction depending on the order of change of internal variables. Hence, this is called a **noncritical race**, whereas the previous race for cases 1 and 2 is termed a **critical race** because the performance is unpredictable (it is hard to predict which path of gates will have the signal change faster), possibly causing the network to malfunction. We may have more complex critical racing. In other words, if we have a network such that the output of the gate whose output represents y_1 feeds back to the input of a gate on a path that reaches the gate whose output represents y_1, the y_1 may continue to change its value from 0 to 1 (or from 1 to 0), then change back to 0 by feedback of new value 1, and so on. This **oscillatory race** may continue for a long time.

Remedies for the Racing Problem

Whenever a network has critical races, we must eliminate them for reliable operation. One approach is to make the paths of gates have definitely different time delays. This approach, however, may not be most desirable for the following reasons. First, the speed may be sacrificed by adding gates for delay. Second, there are cases where this approach is impossible if a network contains more than one critical race. By eliminating a critical race in one column in the transition table by using a path of different time delay, a critical race in another column may occur or may be aggravated.

A better approach is to choose some entries in the transition table so that no critical races occur. Then, on the basis of this new table, we synthesize a network with the desired performance, according to the synthesis method to be described later. A change of entries in some unstable states without changing destination stable states, such that only one internal variable changes its value at a time, is one method for eliminating critical races. The critical race discussed above can be eliminated from Table 28.2 by replacing the entry marked with * by (00), as shown in Table 28.3, where only Y_1 and Y_2 are shown without the network output z. If every entry that causes the network to malfunction can be changed in this manner, a reliable network with the performance desired in the original is produced, because every destination stable state to which the network should go is not changed, and the output value for the destination stable state is also not changed. (We need not worry about noncritical races, since they cause no malfunctions.) However, sometimes, there are entries for some unstable states that cannot be changed in this manner. For example, consider Table 28.4 (some states are not shown, for the sake of simplicity). The entry (01) for $(x_1, x_2, y_1, y_2) = (0010)$ is such an entry

TABLE 28.3 Transition Table in Fundamental Mode, Derived by Modifying Table 28.2

and causes a critical race. [State $(x_1, x_2, y_1, y_2) = (0010)$ in Table 28.2 may have the same property, but actually, the network never enters this state because of the assumption that inputs x_1 and x_2 do not change simultaneously.] Since this entry requires simultaneous transitions of two internal variables, y_1 and y_2, we need to change it to (00) or (11). Both lead the network to stable states different from the destination stable state (01).

When a change of entries in unstable states does not work, we need to redesign the network completely by adding more states (e.g., 8 states with 3 internal variables, y_1, y_2, and y_3, instead of 4 states with 2 internal variables, y_1 and y_2, for Table 28.4) without changing transitions among stable states, as we will see later in this chapter. This redesign may include the reassignment of binary numbers to states, or the addition of intermediate unstable states through which the network goes from one stable state to another. The addition of more states, reassignment of binary numbers to states, and addition of intermediate unstable states for this redesign, however, is usually cumbersome. So, designers usually prefer the use of synchronous sequential networks because design procedures are simpler and the racing problem, including oscillatory races due to the existence of feedback loops in a sequential network, is completely eliminated.

28.5 Different Tables for the Description of Transitions of Sequential Networks

When we look at a given sequential network from the outside, we usually cannot observe the values (i.e., binary numbers) of the internal variables; that is, the inside of the network (e.g., if the network is implemented in an IC package, no internal variables may appear at its pins). Also, binary numbers are not very convenient to use. Therefore, binary numbers for the internal states of the network may be replaced in a transition-output table by arbitrary letters or decimal numbers. The table that results is called a **state-output table**. For example, Table 28.5 is the state-output table obtained from the transition-output table in Table 28.2, where y_1y_2 is replaced by s and Y_1Y_2 is replaced by S. A present state of the internal state is denoted by s and its next state by S.

In some state tables, networks go from one stable state to another through more than one unstable state, instead of exactly one unstable state. For example, in the state-output table in Table 28.5, when inputs (x_1, x_2) change from (00) to (01), the network goes from stable state $(x_1, x_2, s) = (00C)$ to another stable state, $(01A)$, by first going to unstable state $(01C)$, then to intermediate unstable state $(01D)$, and finally to stable state $(01A)$. Here, $(x_1, x_2, s) = (01D)$ is called an **intermediate unstable state**. Such a multiple transition from one stable state to another in a state-output table cannot be observed well from outside the network, and is not important as far as the external performance of the network is concerned. Even if each intermediate unstable state occurring during multiple transitions is replaced by the corresponding ultimate stable state, it does not make any difference if the

TABLE 28.5 State-Output Table Derived from Table 28.2

network performance is observed from outside. Such a table is called a **flow-output table**. The flow-output table corresponding to the state-output table in Table 28.5 is shown in Table 28.6, where D in the intermediate unstable state $(x_1, x_2, s) = (01C)$, for example, in Table 28.5 is replaced by A in Table 28.6.

28.6 Steps for the Synthesis of Sequential Networks

Let us first introduce the general model for sequential networks and then describe a sequence of steps for designing a sequential network.

General Model of Sequential Networks

A sequential network may be generally expressed in the schematic form shown in Fig. 28.3. A large block represents a loopless network of logic gates only (without any flip-flops). All loops with and without flip-flops (i.e., both loops that do not contain flip-flops and loops that contain flip-flops) are drawn outside the large block.

This loopless network has external input variables $x_1, \ldots, x_n$, and internal variables $y_1, \ldots, y_p$, as its inputs. It also has external output variables $z_1, \ldots, z_m$, and **excitation variables** $e_1, \ldots, e_q$, as its outputs. Some of the excitation variables $e_1, \ldots, e_q$ are inputs to the flip-flops, serving to excite the flip-flops. The remainder of the excitation variables are starting points of the loops without flip-flops, which end up at some of the internal variables. For loops without flip-flops, $e_i = Y_i$ holds for each i. For example, the network in Fig. 28.2 can be redrawn in the format of Fig. 28.3, placing the latches outside the loopless network.

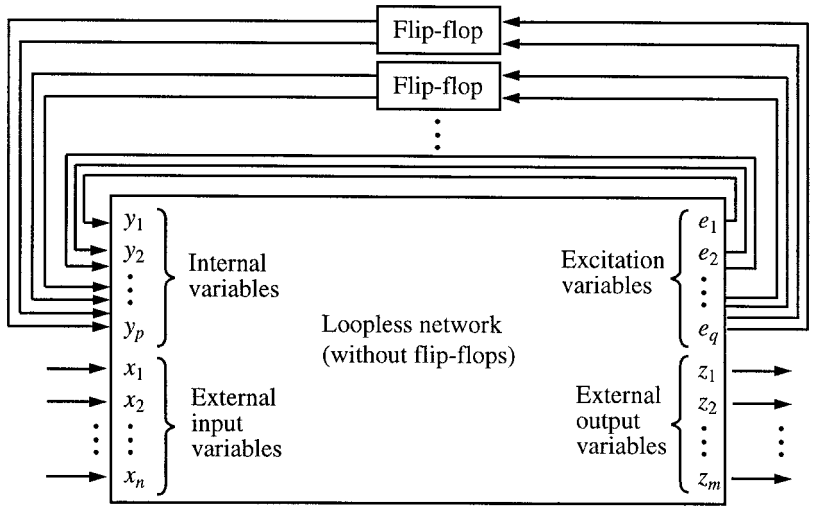

FIGURE 28.3 A general model of a sequential network.

Synthesis as a Reversal of Network Analysis

The outputs $e_1, \ldots, e_q, z_1, \ldots, z_m$ of the combinational network inside the sequential network in Fig. 28.3 express logic functions that have $y_1, \ldots, y_p, x_1, \ldots, x_n$ as their variables. Thus, if these logic functions are given, the loopless network can be designed by the methods discussed in earlier chapters. This means that we have designed the sequential network, since the rest of the general model in Fig. 28.3 is simply loops with or without flip-flops to be placed outside this combinational network. But we cannot derive these logic functions $e_1, \ldots, e_q, z_1, \ldots, z_m$ directly from the given design problem, so let us find, in the following, what gap to fill in.

When loops have no flip-flops, $e_i = Y_i$ holds for each i, where Y is the next value of y, and the binary-value relationship between the inputs $y_1, \ldots, y_p, x_1, \ldots, x_n$ and the outputs $Y_1, \ldots, Y_q, z_1, \ldots, z_m$ of the combinational network inside the sequential network in Fig. 28.3 is expressed by a transition-output table. But when loops have flip-flops, we need the relationship between $e_1, \ldots, e_q, z_1, \ldots, z_m$ and $y_1, \ldots, y_p, x_1, \ldots, x_n$, where $e_1, \ldots, e_q$ are the inputs $S_1, R_1, S_2, R_2 \ldots$ of the latches. A table that shows this relationship is called an **excitation-output table**. For this purpose, we need to derive the output-input relation of the S-R latch, as shown in Table 28.8, by reversing the input-output relationship in Table 28.7, which shows the output y of a latch and its next value Y for every feasible combination of the values of S and R.

TABLE 28.7 Input-Output Relationship of a S-R Latch

S	R	y	Y
0	0	0	0
		1	1
0	1	0	0
		1	0
1	0	0	1
		1	1

In Table 28.8, d's mean don't-care conditions. For example, $y = Y = 0$ in Table 28.8 results from $S = R = 0$ and also from $S = 0$, $R = 1$ in Table 28.7. Therefore, the first row in Table 28.8, $y = Y = 0$,

TABLE 28.8 Output-Input Relationship of a *S-R* Latch

y	Y	S	R
0	0	0	d
0	1	1	0
1	0	0	1
1	1	d	0

$S = 0$, $R = d$, is obtained, because $y = Y = 0$ results from $S = 0$ only, but R can be 0 or 1; that is, don't-care, d. By using Table 28.8, the transition-output table in Table 28.1, for example, is converted into the excitation-output table in Table 28.9. For example, corresponding to $y_1 = Y_1 = 0$ in the first row and the first column in Table 28.1, $S_1 = 0$, $R_1 = d$ is obtained as the first $0d$ in the cell in the first row and the first column of Table 28.9, because the first row in Table 28.8 corresponds to this case. Of course, when a network, for example, Fig. 28.2 is given, we can derive the excitation-output table directly from the network in Fig. 28.2 rather than the transition-output table in Table 28.1 (which was derived for Fig. 28.2). But when we are going to synthesize a sequential network from a transition-output table, we do not have the network yet and we need to construct an excitation-output table from a transition-output table, using Table 28.8.

Design Steps for Synthesis of Sequential Networks

A sequential network can be designed in the sequence of steps shown in Fig. 28.4. The required performance of a network to be designed for the given problem is first converted into a flow-output table. Then this table is converted into a state-output table, and next into a transition-output table, by choosing an appropriate assignment of binary numbers to all states. Then, the transition-output table is converted into an excitation-output table if the loops contain flip-flops. If the loops contain no flip-flops, the excitation-output table need not be prepared, since it is identical to the transition-output table. Finally, a network is designed, using the logic design procedures discussed in the preceding chapters.

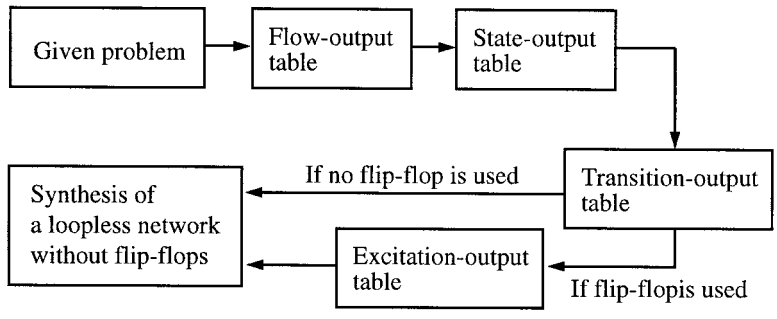

FIGURE 28.4 Steps for designing a sequential network.

28.7 Synthesis of Sequential Networks

Since the use of clocks has many advantages, synchronous sequential networks with clocks are in many cases preferred to asynchronous sequential networks. In addition to the ease of design and elimination of hazards including racing problems, the speed of logic networks can sometimes (e.g., Domino CMOS) be improved by synchronizing the operations of logic gates by clocks, and waveforms of signals can be reshaped into clean ones.

For synchronous sequential networks, more sophisticated flip-flops than latches are usually used, along with clocks. With these flip-flops, which are called raceless flip-flops, network malfunctioning due to hazards can be completely eliminated. Design of sequential networks with raceless flip-flops and clocks is much simpler than that of networks in fundamental mode, since we can use simpler flow-output and state-output tables, which are said to be in skew mode, and multiple changes of internal variables need not be avoided in assigning binary numbers to states.

Raceless Flip-Flops

Raceless flip-flops are flip-flops that have complex structures but eliminate network malfunctions due to races. Most widely used raceless flip-flops are master-slave flip-flops and edge-triggered flip-flops. A **master-slave flip-flop** (or simply, an MS flip-flop) consists of a pair of flip-flops called a master flip-flop and a slave flip-flop. Let us explain the features of master-slave flip-flops based on the ***J-K* master-slave flip-flop** shown in Fig. 28.5. For the sake of simplicity, all the gates in these flip-flops are assumed to have equal delay times, although in actual electronic implementations, this may not be true. Its symbol is shown in Fig. 28.6, where the letters *MS* are shown inside the rectangle. Each action of the master-slave flip-flop is controlled by the leading and trailing edges of a clock pulse, as explained in the following.

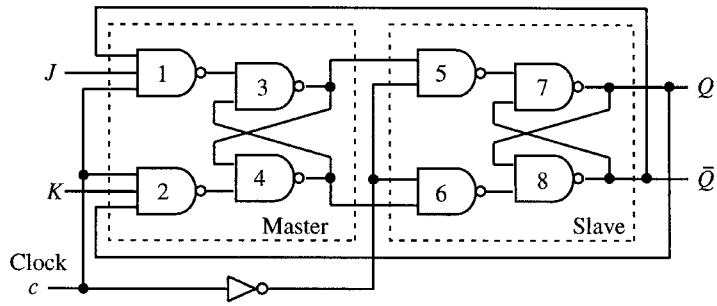

FIGURE 28.5 *J-K* master-slave flip-flop.

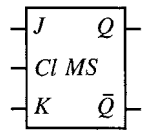

FIGURE 28.6 Symbol for *J-K* master-slave flip-flop.

The *J-K* master-slave flip-flop in Fig. 28.5 works with the clock pulse, as illustrated in Fig. 28.7, where the rise and fall of the pulse are exaggerated for illustration. When the clock has the value 0 (i.e., $c = 0$) NAND gates 1 and 2 in Fig. 28.5 have output values 1, and then the flip-flop consisting of gates 3 and 4 does not change its state. As long as the clock stays at 0, gates 5 and 6 force the flip-flop consisting of

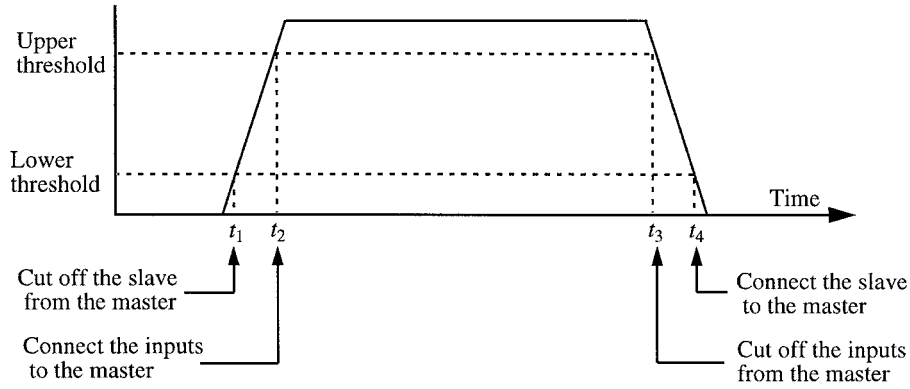

FIGURE 28.7 Clock pulse waveform.

gates 7 and 8 to assume the same output values as those of the flip-flop consisting of gates 3 and 4 (i.e., the former is slaved to the latter, which is the master). Each of the master and slave is a slight modification of the latch in Fig. 28.1(d).

When the clock pulse starts to rise to the lower threshold at time t_1 in Fig. 28.7, gates 5 and 6 are disabled: in other words, the slave is cut off from the master. (The lower threshold value of the clock pulse still presents the logic value 0 to gates 1 and 2. The clock waveform is inverted to gates 5 and 6 through the inverter. The inputs to gates 5 and 6 from the inverter present the logic value 0 also to gates 5 and 6, because the inverted waveform is still close to logic value 1 but is not large enough to let gates 5 and 6 work. The inverter is actually implemented by a diode which is forward-biased, so that the network works in this manner.) When the clock pulse reaches the upper threshold at t_2, (i.e., $c = 1$), gates 1 and 2 are enabled, and the information at J or K is read into the master flip-flop through gate 1 or 2. Since the slave is cut off from the master by disabled gates 5 and 6, the slave does not change its state, maintaining the previous output values of Q and $\overline{Q}$. When the clock pulse falls to the upper threshold at t_3 after its peak, gates 1 and 2 are disabled, cutting off J and K from the master. In other words, the outputs of 1 and 2 become 1, and the master maintains the current output values. When the clock pulse falls further to the lower threshold at t_4, gates 5 and 6 are enabled and the information stored at the master is transferred to the slave, gates 7 and 8.

The important feature of the master-slave flip-flop is that the reading of information into the flip-flop and the establishment of new output values are done at different times; in other words, the outputs of the flip-flop can be completely prevented from feeding back to the inputs, possibly going through some gates outside the master-slave flip-flop, while the network that contains the flip-flop is still in transition. The master-slave flip-flop does not respond to its input until the leading edge of the next clock pulse. Thus, we can avoid oscillatory races. Now we have a *J-K* flip-flop that works reliably, regardless of how long a clock pulse or signal 1 at terminal J or K lasts, since input gates 1 and 2 in Fig. 28.5 are gated by output gates 7 and 8, which do not assume new values before gates 1 and 2 are disconnected from J and K. As we will see later, sequential networks that work reliably can be constructed compactly with master-slave flip-flops, without worrying about hazards.

Other types of master-slave flip-flops are also used. The ***T* (type) master-slave flip-flop** (this is also called toggle flip-flop, trigger flip-flop, or T flip-flop) has only a single input, labeled T, as shown in Fig. 28.8(a), which is the *J-K* master-slave flip-flop with J and K tied together as T. Whenever we have $T = 1$ during the clock pulse, the outputs of the flip-flop change, as shown in Fig. 28.8(b). The T-type flip-flop, denoted as Fig. 28.8(c), is often used in counters. The ***D* (type) master-slave flip-flop** (D implies "delay") has only a single input D, and is realized, as shown in Fig. 28.9(a). As shown in Fig. 28.9(b), no matter what value Q has, Q is set to the value of D that is present during the clock pulse. The D-type flip-flop is used for delay of a signal or data storage and is denoted by the symbol shown in Fig. 28.9(c).

FIGURE 28.9 *D*-type master-slave flip-flop.

Edge triggered flip-flops are another type of raceless flip-flop. Either the leading or the trailing edge of a clock pulse (not both) causes a flip-flop to respond to an input, and then the input is immediately disengaged from the flip-flop. Edge-triggered flip-flops are mostly used in the same manner as master-slave flip-flops.

Example of Design of a Synchronous Sequential Network

Let us now explain synthesis of a synchronous sequential network with an example.

Specification for the Design Example

Suppose we want to synthesize a clocked network with two inputs, x_1 and x_2, and single output z under the following specifications:

1. Inputs do not change during the presence of clock pulses, as illustrated in Fig. 28.10. Inputs x_1 and x_2 cannot assume value 1 simultaneously during the presence of clock pulses. During clock pulses, an input signal of value 1 appears at exactly one of two inputs, x_1 and x_2, of the network, or does not appear at all.
2. The value of z changes as follows.
   a. The value of z becomes 1 when the value 1 appears during the clock pulse at the same input at which the last value 1 appeared. Once z becomes 1, z remains 1 regardless of the presence or absence of clock pulses, until signal 1 starts to appear at the other input during clock pulses. (This includes the following case. Suppose that we have $z = 0$, when signal 1 appears at one of the inputs during a clock pulse. Then, signal 0 follows at both x_1 and x_2 during the succeeding clock pulses. If signal 1 comes back to the same input, z becomes 1.) As illustrated in Fig. 28.10, z becomes 1 at time t_1 at the leading edge of the second pulse because signal 1 is repeated at input x_1. Then z continues to remain 1 even though signal 1 appears at neither input at the third pulse starting t_2.
   b. The value of z becomes 0 when the value 1 appears at the other input during the clock pulse. Once z becomes 0, z remains 0 regardless of the presence or absence of clock pulses, until signal 1 starts to appear at the same input during clock pulses. In Fig. 28.10, z continues to be 1 until the leading edge of the pulse starting at time t_3. Then z continues to remain 0 until the time t_4.

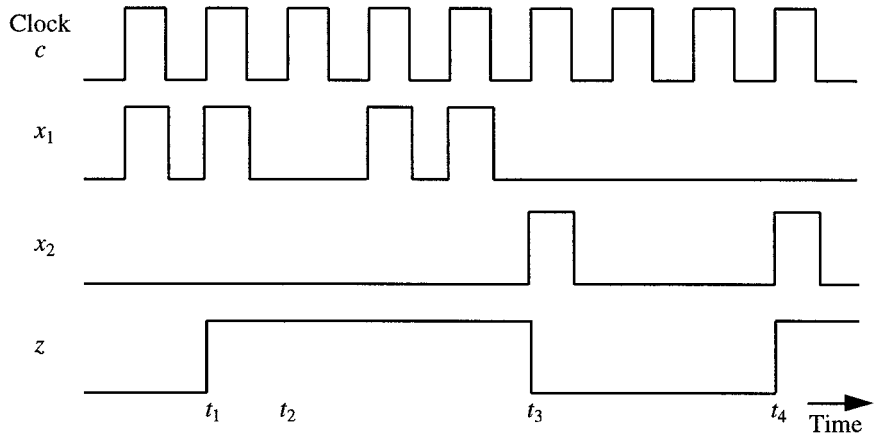

FIGURE 28.10 Waveform for the design example.

Let us prepare a flow-output table for this design problem in the following steps.

1. An output value of z must depend on an internal state only, because z has to maintain its value until next change. Let us assume that there are exactly two states, A and B, such that $z = 0$ when the network is in state A and $z = 1$ when the network is in state B. (We will try more than two states if two are found insufficient.)
2. Assume that during the absence of a clock pulse, the network is in state A. Let c denote the clock. Since the network must stay in this state as long as $c = 0$, the next state, S, in the column for $c = 0$ must be A, as shown in Table 28.10(a). Similarly, the next state for the second row in the column $c = 0$ must be B. It is to be noted that during $c = 0$, there are four combinations of values of x_1 and x_2 (i.e., $x_1 = x_2 = 0$; $x_1 = 1$ and $x_2 = 0$; $x_1 = 0$ and $x_2 = 1$; and $x_1 = x_2 = 1$). But the states of the network to be synthesized is irrelevant of the values of x_1 and x_2. Thus, in Table 28.10, we have only one column corresponding to $c = 0$, instead of four columns.

TABLE 28.10 Two States Are Not Enough

		$c = 1$				
		x_1, x_2				
z	s	$c = 0$	00	01	11	10
0	A	A, 0			—	A
1	B	B, 1			—	
		S, z				

(a) Entering A is not correct.

		$c = 1$				
		x_1, x_2				
z	s	$c = 0$	00	01	11	10
0	A	A, 0			—	B
1	B	B, 1			—	
		S, z				

(b) Entering B is not correct.

3. When the network is in state A during $c = 0$, suppose that we have $x_1 = 1$ at the next clock pulse. Let us choose A as the next state, S, as shown in the last column in Table 28.10(a). But this choice means that, if we apply value 1 repeatedly at x_1, the network goes back and forth between the two states in the first and last columns in the first row in Table 28.10(a). Then $z = 1$ must result from the specification of the network performance; but since the network stays in the first row, we must have $z = 0$. This is a contradiction. Thus, the next state for $(x_1, x_2, s) = (10A)$ cannot be A.
4. Next assume that the next state for $(x_1, x_2, s) = (10A)$ is B, as shown in Table 28.10(b). Suppose that the value 1 has been alternating between x_1 and x_2. If we had the last 1 at x_2, the network must be currently in A because of $z = 0$ for alternating 1's. When the next 1 appears at x_1, $z = 0$ must still hold because the value 1 is still alternating. But the network will produce $z = 1$ for state $(10A)$, because B is assumed to correspond to $z = 1$. This is a contradiction, and the choice of B is also wrong.

5. In conclusion, two states are not sufficient, so we try again with more states. For this example, considering only two states corresponding to $z = 0$ and 1 is not appropriate.
6. In the above, we had contradictions by assuming only two states, A and B, corresponding to $z = 0$ and 1; we did not know which input's 1 led to each state. Thus, in addition to the values of z, let us consider which input had the last 1. In other words, we have four states corresponding to the combinations of z and the last 1, as shown in Table 28.11. At this stage, we do not know whether or not three states are sufficient. But let us assume four states for the moment. As a matter of fact, both three states and four states require two internal variables. Hence, in terms of the number of internal variables, it does not matter whether we have three or four states, although the two cases may lead to different networks.

TABLE 28.11 Flow-Output Table in Skew-Mode

Last 1 at	z	s	$c = 0$	$c = 1$ x_1, x_2 00	01	11	10
x_1	0	A	$A, 0$	$A, 0$	$C, 0$	—	$B, 1$
x_1	1	B	$B, 1$	$B, 1$	$C, 0$	—	$B, 1$
x_2	0	C	$C, 0$	$C, 0$	$D, 1$	—	$A, 0$
x_2	1	D	$D, 1$	$D, 1$	$D, 1$	—	$A, 0$
					S, z		

7. **Derivation of a flow-output table in skew mode**: Let us form a flow-output table, assuming the use of J-K master-slave flip-flops. In the column of $c = 0$ in Table 28.11, the network must stay in each state during the absence of a clock pulse. Thus, all the next states S in all the cells in the column of $c = 0$ must be identical to s in each row. Suppose that the network is in state $(c, x_1, x_2, s) = (000A)$ with output $z = 0$ after having the last 1 at x_1. When the value 1 appears at x_1 and c becomes 1, the next state S must be B for the following reason. When the current clock pulse disappears, this 1 at x_1 will be "the last 1" at x_1 (so S must be A or B) and z will have to be 1 because of the repeated occurrence of 1's at x_1. (This contradicts $z = 0$, which we will have if A is entered as S.) Hence, the possibility of S being A is ruled out, and S must be B. Since value 1 is repeated at x_1, we have $z = 1$. The next states and the values of output z in all other cells in Table 28.11 can be found in a similar manner.

   Let us analyze how a transition among stable states occurs in this table. According to the problem specification, inputs x_1 and x_2 can change only during the absence of clock pulses.

   Suppose that during the absence of a clock pulse, the network is in state $(c, x_1, x_2, s) = (000A)$ in Table 28.11. Suppose that inputs (x_1, x_2) change from (00) to (10) sometime during the absence of a clock pulse and $(x_1, x_2) = (10)$ lasts at least until the trailing edge of the clock pulse. If this transition is interpreted on Table 28.11, the network moves from $(c, x_1, x_2, s) = (000A)$ to $(110A)$, as shown by the dotted-line with an arrow, at the leading edge of the clock pulse. Then the network must stay in this state, $(110A)$, until the trailing edge of the clock pulse, because the outputs of the J-K master-slave flip-flops keep the current values during the clock pulse, changing to its new values only at the trailing edge of the clock pulse and thus the internal state s does not change yet to its new state S. (This is different from the fundamental mode, in which the network does not stay in this state unless the state is a stable one, and vertically moves to a stable state in a different row in the same column.) Then the network moves from $(c, x_1, x_2, s) = (110A)$ to $(010B)$, as shown by the solid-line with an arrow in Table 28.11, when s assumes the new state S at the trailing edge of the clock pulse. Thus, the transition occurs horizontally and then **diagonally** in Table 28.11. This type of transition is called **skew mode**, in order to differentiate it from the fundamental mode.

Notice, however, that in the new state (110*A*) at the leading edge of the clock pulse in the above transition from (c, x_1, x_2, s) = (000*A*), the network z assumes the new output value. Consequently, in this new stable state during $c = 1$ in Table 28.11, the new current value of the network output, z, is shown, while the value of the internal state in this new stable state shows the next state S, though the network is actually in s. In the fundamental mode, when the network moves horizontally to a new unstable state in the same row in the state-output table, the current value of the network output is shown and the internal state represents the next state, S (in this sense the situation is not different), but the network output lasts only during a short, transient period, unless the new state is stable. In contrast, in skew mode, the output value for the new state is not transient (because the network stays in this state during the clock pulse) and is essential in the description of the network performance.

Let us synthesize a network for this flow-output table in skew mode later.

8. **Derivation of a flow-output table in fundamental mode**: Next let us try to interpret this table in fundamental mode. Table 28.11 shows that, when the network placed in state (c, x_1, x_2, s) = (000*A*) receives $x_2 = 1$ before the appearance of the next pulse, the next state will be *C* at the leading edge of the next pulse. But the network goes to unstable state (c, x_1, x_2, s) = (101*C*) that has entry *D*, since if we assume fundamental mode, it must move vertically, instead of the diagonal transition in skew mode. Hence, the network must go further to stable state (101*D*), without settling in the desired stable state, *C*, if the network still keeps $x_2 = 1$ and $c = 1$. Therefore, the network cannot be in fundamental mode. (Recall that the next state entries in a flow-output table, unlike a state-output table, do not show intermediate unstable states but do show the destination stable states.) The above difficulty can be avoided by adding two new rows, *E* and *F*, as shown in Table 28.12. When the network placed in state (c, x_1, x_2, s) = (000*A*) receives $x_2 = 1$, the network goes to the new stable state *F* in column (x_1, x_2) = (01) and in row *F*. For this state *F*, $z = 0$, without causing contradiction. When the clock pulse disappears, the network goes to stable state (000*C*) after passing through unstable state (000*F*). The problem with the other states is similarly eliminated. All stable states are encircled as stable states.

TABLE 28.12 Flow-Output Table in Fundamental Mode

				$c = 1$			
				x_1, x_2			
Last 1 at	z	s	$c = 0$	00	01	11	10
x_1	0	*A*	(*A*), 0	(*A*), 0	*F*, 0	—	*B*, *d*
x_1	0	*E*	*A*, 0	—	—	—	(*E*), 0
x_1	1	*B*	(*B*), 1	(*B*), 1	*F*, *d*	—	(*B*), 1
x_2	0	*C*	(*C*), 0	(*C*), 0	*D*, *d*	—	*E*, 0
x_2	0	*F*	*C*, 0	—	(*F*), 0	—	—
x_2	1	*D*	(*D*), 1	(*D*), 1	(*D*), 1	—	*E*, *d*
					S, z		

The values of z for stable states are easily entered. The values of z for unstable states can be entered with certain freedom. For example, suppose that the network placed in state (c, x_1, x_2, s) = (000*A*) receives $x_1 = 1$. Then the next state S is *B*. In this case, we may enter 0 or 1 as z for (110*A*) for the following reason. We have $z = 0$ for the initial stable state *A* during $c = 0$ and $z = 1$ for the destination stable state *B* during $c = 1$ and correspondingly $z = 0$ or 1. This does not make much difference as far as the external behavior of the network is concerned, because the network stays

in this unstable state (110*A*) for the short transient period and it simply means that $z = 1$ appears a little bit earlier or later. The network that results, however, may be different. Accordingly, $z = d$ (d denotes "don't-care") would be the best assignment, since this gives flexibility in designing the network later.

Design of Synchronous Sequential Networks in Skew Mode

Now let us design a synchronous sequential network based on a flow-output table in skew mode, using *J-K* master-slave flip-flops.

As pointed out previously, when master-slave flip-flops are used, the network does not have racing hazards even if internal variables make multiple changes, because the flip-flops do not respond to any input changes during clock pulses. Thus, we need not worry about hazards due to multiple changes of internal variables and consequently appropriate assignment of binary numbers to states in forming a transition-output table from a state-output table or a flow-output table in the design steps in Fig. 28.4. But the number of gates, connections, or levels in a network to be designed can differ, depending on how binary numbers are assigned to states (it is of secondary importance compared with the hazard problem, which makes networks useless if they malfunction). Making state assignments without considering multiple changes of internal variables is much easier than having to take these changes into account.

Let us derive the transition-output table shown in Table 28.13 from Table 28.11, using a state assignment as shown.

TABLE 28.13 Transition-Output Table in Skew Mode

			$c = 1$			
			x_1, x_2			
s	y_1y_2	$c = 0$	00	01	11	10
A	00	00, 0	00, 0	11, 0	*dd, d*	01, 0
B	01	01, 1	01,1	11, 0	*dd, d*	01, 1
C	11	11, 0	11, 0	10, 1	*dd, d*	00, 0

				Y_1Y_2, z		

Reversing the inputs and outputs relationship of *J-K* master-slave flip-flops shown in Table 28.14(a), we have the output-input relationship shown in Table 28.14(b) (other master-slave flip-flop types can be treated in a similar manner). Table 28.14(b) shows what values inputs J and K must take for each change of internal variable y to its next value Y. (In order to have $y = Y = 0$, $J = K = 0$ or $J = 0$ and $K = 1$ must hold, as we can see in Table 28.14(a) and thus we have $S = 0$ and $R = d$ in Table 28.14(b).) Using Table 28.14(b), we form the excitation table in Table 28.15. Decomposing Table 28.15 into five Karnaugh maps for J_1, K_1, J_2, K_2 and z, we can find a minimal sum for each of J_1, K_1, J_2, K_2, and z. On the basis of these logic expressions, we design the loopless network inside the general model of sequential networks in Fig. 28.3. Then, placing two *J-K* master-slave flip-flops outside this loopless network, we have designed the sequential network shown in Fig. 28.11.

Master-slave flip-flops do not respond to changes in their inputs when and after their outputs change until the leading edges of next clock pulses. Thus, no network malfunction due to races occurs, and no post-analysis of whether or not the designed networks malfunction due to this is necessary. This is the advantage of clocked networks with raceless flip-flops.

Design of Asynchronous Sequential Networks in Fundamental Mode

Now let us design an asynchronous sequential network based on a flow-output table in fundamental mode.

According to the design steps of Fig. 28.4, we have to derive a transition-output table from the flow-output table shown in Table 28.12, by deriving a state-output table by assigning appropriate binary

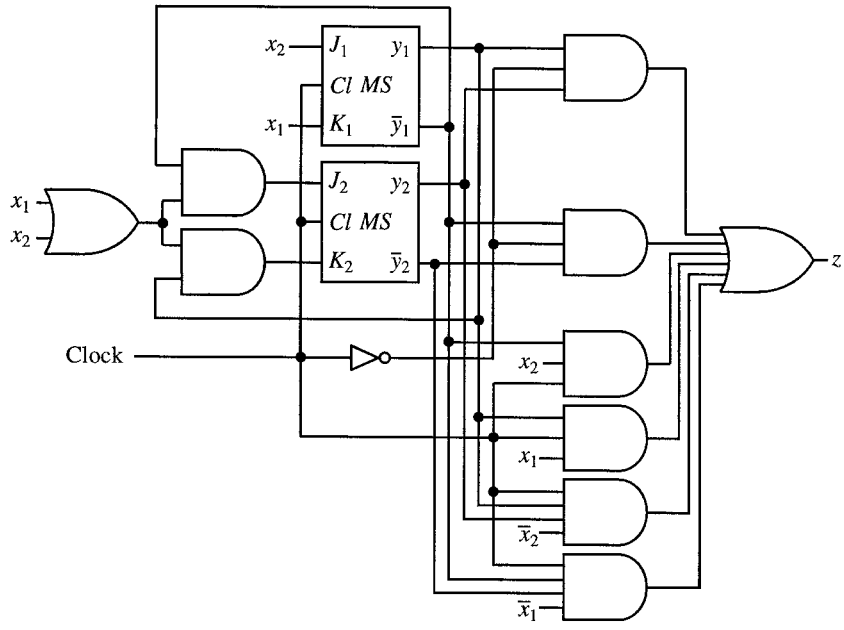

FIGURE 28.11 Synthesized network based on Table 28.15.

numbers to states such that multiple changes do not occur for every transition from one binary number to another, possibly changing some intermediate unstable states to others. Then, if the designers want to use *S-R* latches, we can derive an excitation table by finding the output-input relationship of the *S-R* latch, as illustrated with Tables 28.7, 28.8, and 28.9. Then, we can design the loopless network inside the general model of Fig. 28.3 by deriving minimal sums from the Karnaugh maps decomposed from the excitation-output table. If the designers do not want to use *S-R* latches, we can design the loopless network inside the general model of Fig. 28.3 by deriving minimal sums from the Karnaugh maps decomposed from the transition-output table without deriving an excitation-output table.

In the case of an asynchronous sequential network, we need post-analysis of whether the designed network works reliably.

Advantages of Skew Mode

The advantages of skew-mode operation with raceless flip-flops, such as master-slave or edge-triggered flip-flops, can be summarized as follows:

1. We can use no more complex and often simpler flow-output tables (or state-output tables) in skew mode than are required in fundamental mode, making design easier (because we need not consider both unstable and stable states for each input change, and need not consider adding extra states, or changing intermediate unstable states, which are to avoid multiple changes of internal variables).
2. State assignments are greatly simplified because we need not worry about hazard due to multiple changes of internal variables. (If we want to minimize the number of gates, connections, or levels, we need to try different state assignments. This is less important than the reliable operations of the networks to be synthesized.)
3. Networks synthesized in skew mode usually require fewer internal variables than those in fundamental mode.
4. After the network synthesis, we do not need to check whether the networks contain racing hazards or not. This is probably the greatest of all the advantages of skew mode, since checking hazards and finding remedies is usually very cumbersome and time-consuming.

29.1 Logic Networks with AND and OR Gates in Multi-levels

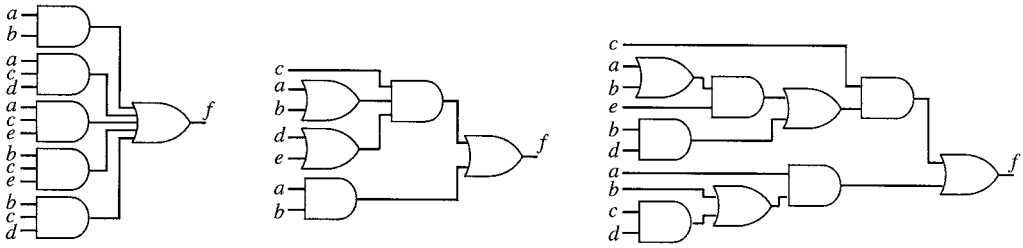
In logic networks, the number of levels is defined as the number of gates in the longest path from external inputs to external outputs. When we design logic networks with AND and OR gates, those in multi-levels can be designed with no more gates than those in two levels. Logic networks in multi-levels have more levels than those in two levels, but this does not necessarily mean that those in multi-levels have greater delay time than those in two levels because a logic gate that has many fan-out connections generally has greater delay time than gates that have fewer fan-out connections (Remark 29.1). Also, a logic gate that has many fan-in connections from other logic gates tends to have larger area in the chip and longer delay time than other gates that have fewer fan-in connections. Thus, if we want to design a logic network with a small delay time and small area, we need to design a logic network in many levels, keeping maximum fan-out and fan-in of each gate under a reasonably small limit.

Remark 29.1: When the line width in an IC chip is large, the delay time of logic gates is larger than those over connections and, once a logic network is designed, it can be laid out on the chip usually without further modifications. But when the line width becomes very short, under 0.25 μm, long connections add more delay due to parasitic capacitance and resistance than the delay of gates. But length of connections cannot be known until making layout on an IC chip after finishing logic design. So at the time of logic design, prior to layout, designers know only the number of fan-out connections from each gate, and this is only partial information on delay estimation. Thus, when the line width becomes very short, it is difficult to estimate precisely the delay of a logic network at the time of logic design. We need to modify a logic network interactively, as we lay it out on the chip.

Such a multi-level logic network can be derived by rewriting a logic expression with parentheses. For example, a logic expression

$$f = ab \vee acd \vee ace \vee bce \vee bcd \tag{29.1}$$

can be realized with five AND gates and one OR gate in two levels, as illustrated in Fig. 29.1(a). However,



(a) Two-level network (b) Network for divisor $a \vee b$ (c) Network for divisor $b \vee cd$

FIGURE 29.1 Networks for $f = ab \vee acd \vee ace \vee bce \vee bcd$.

$$f = c(a \vee b)(d \vee e) \vee ab \tag{29.2}$$

can be obtained by rewriting the expression with parentheses, as explained in the following. This logic expression can be realized with three OR gates and two AND gates in three levels, as illustrated in Fig. 29.1(b). The network in Fig. 29.1(b) would have a smaller area and smaller delay than the one in Fig. 29.1(a) because of fewer logic gates and a smaller maximum fan-in (a logic gate with five fan-ins, for example, has more than twice the area and delay of a gate with two fan-ins).

A logic network in two levels with the fewest gates can be derived by minimal sums or minimal products, which can be derived by reasonably simple algorithms (described in Chapter 27). But if we try to derive multi-level logic networks, only few reasonable algorithms are known. One of them is the weak division described in the following, although the minimality is not guaranteed and its execution is not straightforward. Another algorithm is the special case (i.e., AND and OR gates) of the map-factoring method (described in Chapter 31).

29.2 General Division

Rewriting of a logic expression using parentheses can be done by the following division. The division is based on the use of sub-expressions that can be found in the given logic expression. The given logic expression in a sum-of-products can be rewritten with parentheses if it has common sub-expressions. For example, the logic expression in Eq. 29.1 can be converted to the following expression, using a sub-expression $(a \vee b)$:

$$f = cd(a \vee b) \vee ce(a \vee b) \vee ab$$

This can be further rewritten into the following, by sharing the common sub-expression $(a \vee b)$:

$$f = c(a \vee b)(d \vee e) \vee ab \tag{29.3}$$

This rewriting can be regarded symbolically as division. Rewriting of the expression in Eq. 29.1 into the one in Eq. 29.3 may be regarded as division with the divisor $x = a \vee b$, the quotient $q = cd \vee ce$ and the remainder $r = ab$. Then, the expression f can be represented as follows:

$$f = xq \vee ab, \text{ with divisor } x = a \vee b, \text{ quotient } q = cd \vee ce = c(d \vee e), \text{ and remainder } r = ab.$$

The division is symbolically denoted as f/x. Generally, the quotient should not be 0, but the remainder may be 0.

The division, however, may yield many different results because there are many possibilities in choosing a divisor and also the given logic function can be written in many different logic expressions, as explained in the following.

Division can be repeated on one given logic expression. Suppose $f = \bar{a}b \vee \bar{a}c \vee \bar{b}a \vee \bar{b}c \vee \bar{c}a \vee \bar{c}b$ is given. Repeating division three times, choosing successively $b \vee c$, $a \vee c$, and $a \vee b$ as divisors, the following result is derived:

$$f = x_1\bar{a} \vee x_2\bar{b} \vee x_3\bar{c} \text{ with divisors } x_1 = \text{b} \vee c,\ x_2 = a \vee c, \text{ and } x_3 = a \vee b.$$

29.3 Selection of Divisors

Among the divisions, those with a certain type of divisor to be described in the following are called **weak divisions**. The objective of the weak division is the derivation of a logic network with a logic expression having a minimal total number of literals, repeatedly applying the weak division to the given logic expression until the division cannot apply to the logic expression any further. In this case, the total number of literals is intended to be an approximation of the total number of inputs to all the logic gates, although not exactly, as explained later. Thus, we should start with a logic expression in a minimal sum of products by using two-level logic minimization[1,2] before weak division in order to obtain a good result.

In the weak division, the divisor selection is the most important problem to produce a compact network because there are many divisor candidates to be found in the given logic expression and the result of the weak division depends on divisor selection. For example, the expression $f = ab \vee acd \vee ace \vee bce \vee bcd$ in Eq. 29.1 with 14 literals has many divisor candidates, a, b, c, $a \vee b$, $b \vee cd$, and others. When $a \vee b$ is first selected as the divisor, the resultant network illustrated in Fig. 29.1(b) for $f = c(a \vee b)(d \vee e) \vee ab$ with 7 literals is obtained. On the other hand, if $b \vee cd$ is first selected as the divisor, the resultant network for $f = c(e(a \vee b) \vee bd) \vee a(b \vee cd)$ with 10 literals illustrated in Fig. 29.1(c) is obtained, which is larger than the network illustrated in Fig. 29.1(b).

Divisors can be derived by finding sub-expressions called kernels. All the kernels for the given logic expression can be found as follows.

First, all the subsets of products in the given logic expression are enumerated. Next, for each subset of products, the product of the largest number of literals that is common with all the products in this subset is found. This product of the largest number of literals is called a **co-kernel**. Then the sum of products, from each of which this co-kernel (i.e., the product of the largest number of literals) is eliminated is obtained as a **kernel**. For example, the sum of products $abc \vee abd$ has the co-kernel ab as the product of the largest number of literals that is common to all the products, abc and abd. The kernel of $abc \vee abd$ is $c \vee d$. However, $ab \vee ac \vee d$ has no kernels, because it has no common literals for all products. The kernel $b \vee c$ with co-kernel a is found when the subset of products, $ab \vee ac$, is considered.

Certainly, by trying all divisor candidates and selecting the best one, we can derive a network as small as possible by the weak division. However, such an exhaustive search is too time-consuming, requiring a huge memory space. The branch-and-bound method is generally more efficient than the exhaustive search.[3]

Thus, the heuristic method that the type of divisor candidates is restricted to sum of products with specific feature is proposed.[2] This method is called **kernel decomposition,** reducing the number of divisor candidates.

A kernel of an expression for f is the sum with at least two products such that all the products in the sum contain no common literals (e.g., $ab \vee c$ is a kernel, but $ab \vee ac$ and abc are not kernels, because all products, ab and ac, in $ab \vee ac$ contain a, and abc is a single product), especially, a kernel whose subsets contain no other kernels is called a **level-0 kernel** (e.g., $a \vee b$ is a level-0 kernel, but $ab \vee ac \vee d$ is not a level-0 kernel because sub-expression $ab \vee ac$ contains kernel $b \vee c$). The level of kernels is defined recursively as a **level-K kernel** contains at the next lower level-$(K-1)$ kernel (e.g., $ab \vee ac \vee d$ is a level-1 kernel because it contains level-0 kernel $b \vee c$).

Usually, a level-K kernel with $K \geq 1$ is not used as a divisor to save processing time, because the results obtained by all level kernels as divisors are the almost same as those obtained by using only the level-0 kernels. Thus, all the kernels that are not level-0 kernels are excluded from divisor candidates.

For example, the logic expression illustrated in Fig. 29.1, $f = ab \vee acd \vee ace \vee bce \vee bcd$, has 16 kernels as shown in Table 29.1. By eliminating all the level-1 kernels, $ad \vee ae \vee bd \vee be$, $ea \vee eb \vee bd$ and others from Table 29.1, we have the divisor candidates in Table 29.2.

TABLE 29.1 Kernals for $f = ab \vee acd \vee ace \vee bce \vee bcd$

Kernel	Co-kernel	Level
$ad \vee ae \vee bd \vee be$	c	1
$ea \vee eb \vee bd$	c	1
$eb \vee ed \vee cd$	c	1
$ab \vee ae \vee bd$	c	1
$ad \vee ae \vee be$	c	1
$a \vee ce \vee cd$	b	1
$b \vee cd$	a	0
$b \vee ce$	a	0
$a \vee be$	b	0
$a \vee cd$	b	0
$d \vee e$	ac	0
$ad \vee be$	c	0
$a \vee b$	cd	0
$ae \vee bd$	c	0
$a \vee b$	ce	0
$d \vee e$	bc	0

TABLE 29.2 0-level Kernals and Co-kernels Derived from Table 29.1

Kernel	Co-kernel	Weight of Kernels
$b \vee cd$	a	1
$b \vee ce$	a	1
$a \vee be$	b	1
$a \vee cd$	b	1
$ad \vee be$	c	1
$ae \vee bd$	c	1
$a \vee b$	ce, cd	6
$d \vee e$	ac, bc	6

The next step is the selection of one divisor from all candidates. A candidate that decreases the largest number of literals in the expression by the weak division is selected as a divisor. If there is a tie, choose one of them. The difference in the number of literals before and after the weak division by the kernel is called the **weight of the kernel**. In the above example, the result of the weak division by the kernel $b \vee cd$ is $f = a(b \vee cd) \vee ace \vee bce \vee bcd$. The weight of the kernel $b \vee cd$ is 1, because the number of literals is reduced from 14 to 13 by this division. The weight of the kernels can be easily calculated by the number of literals in kernels and co-kernels without execution of weak division, because the quotient of the division by a kernel is a product of a co-kernel and other sub-expressions. The weight of the kernels for this example is shown in Table 29.2.

Then the kernel $a \vee b$ is selected as a divisor with the largest weight. The expression $f = ab \vee acd \vee ace \vee bce \vee bcd$ is divided by $a \vee b$. In the next division, $d \vee e$ is selected and divides the expression after division by $a \vee b$. Finally, the network $f = c(a \vee b)(d \vee e) \vee ab$ illustrated in Fig. 29.1(b) is obtained.

These operations, enumeration of all the kernels, calculation of the weights of all kernels, selection of the largest one, and division are applied repeatedly until no kernel can be found. In this case, we can choose a different sequence of divisors, deriving a different result. But often we do not have a different result, so it may not be worthwhile to try many different sequences of divisors.

Instead of the kernel decomposition method, a faster method is proposed.[4] In this method, the divisor candidates are restricted to only 0-level kernels with two products, along with introduction of complement-sharing that when both $\bar{a}b \vee a\bar{b}$ and $\bar{a}\bar{b} \vee ab$ are among divisor candidates, one is realized with a logic gate while realizing the other by complementing it by an inverter ($\overline{\bar{a}b \vee a\bar{b}} = (a \vee \bar{b})(\bar{a} \vee b) = \bar{a}\bar{b} \vee ab$ for this example). Although the restriction is stronger than the kernel decomposition method, the method produces smaller networks and can run faster than the kernel decomposition in many cases.

29.4 Limitation of Weak Division

Although simpler networks can be easily derived by the weak division, the weak division cannot derive certain types of logic networks because of its restrictions in its rewriting of logic expressions with parentheses. Rewriting of logic expressions without such restrictions is called **strong division**. For example, complements of sub-expressions, such as $f = \overline{(a\bar{b} \vee a\bar{c})} \vee b\bar{a} \vee c$, is not used in the weak division. Also, the two literals, x and $\bar{x}$, for each variable x are regarded as different variables without using identities such as $ab \vee a = a$, $a\bar{a} = 0$, and $a \vee \bar{a} = 1$ in the weak division.

Suppose the sum-of-products $f = a\bar{b} \vee a\bar{c} \vee b\bar{a} \vee b\bar{c} \vee c\bar{a} \vee c\bar{b}$ is given. This can be rewritten in the following two different logic expressions:

$$f_1 = a\bar{b} \vee a\bar{c} \vee b\bar{a} \vee b\bar{c} \vee c\bar{a} \vee c\bar{b}$$

and

$$f_2 = a\bar{a} \vee a\bar{b} \vee a\bar{c} \vee b\bar{a} \vee b\bar{b} \vee b\bar{c} \vee c\bar{a} \vee c\bar{b} \vee c\bar{c},$$

using the identities $a\bar{a} = 0$, $b\bar{b} = 0$, and $c\bar{c} = 0$

They can be further rewritten as follows:

$$f_1 = a(\bar{b} \vee \bar{c}) \vee b(\bar{a} \vee \bar{c}) \vee c(\bar{a} \vee \bar{c})$$

and

$$f_2 = (\bar{a} \vee \bar{b} \vee \bar{c})(a \vee b \vee c)$$

Both of these expressions can be written in the following expressions, using the divisors, quotients, and remainders, which are 0 in this particular example:

$$f_1 = x_{11}q_{11} \vee x_{12}q_{12} \vee x_{13}q_{13} \vee r_1$$

with divisors $x_{11} = \bar{b} \vee \bar{c}$, $x_{12} = \bar{a} \vee \bar{c}$, $x_{13} = \bar{a} \vee \bar{b}$, quotients $q_{11} = a$, $q_{12} = b$, $q_{13} = c$, and remainder $r_1 = 0$

$$f_2 = x_{21}q_{21} \vee r_2$$

with divisor $x_{21} = a \vee b \vee c$, quotient $q_{21} = \bar{a} \vee \bar{b} \vee \bar{c}$, and remainder $r_2 = 0$.

Corresponding to these expressions, we have two different logic networks, as shown in Fig. 29.2. The function f_2 is derived by division by a divisor above but actually cannot be obtained by the weak division. Thus, the logic network for f_2 is labeled as the result by strong division in Fig. 29.2. Strong division is rewriting of logic expressions using any form, including the complement of a sub-expression and accordingly has far greater possibilities than the division explained so far.

The results of division are evaluated by the number of literals contained in each of the obtained expressions. This number is an approximation of the total number of fan-ins of gates in networks in the

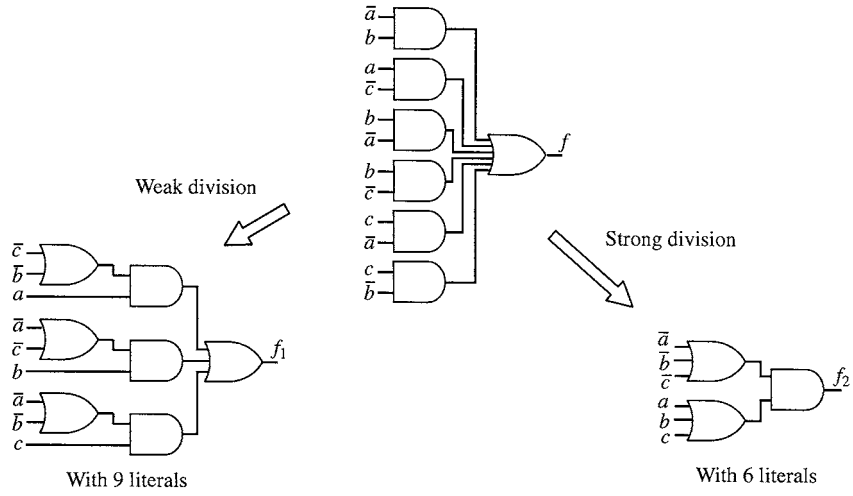


FIGURE 29.2 Strong and weak divisions.

following sense: inputs to a logic gate from other gates are not counted as literals. In Fig. 29.2, the number of literals of f_1 is 9, and the number of literals of f_2 is 6. But in the logic network for f_1, an input to each of three AND gates in Fig. 29.2, for example, is not counted as a literal. Counting them, the total number of fan-ins of all logic gates in the logic network for f_1, which is 15 in Fig. 29.2, is larger than the total number of fan-ins of all gates in the logic network for f_2, 8.

Logic Properties of Transistor Circuits

Saburo Muroga
University of Illinois at Urbana-Champaign

30.1 Basic Properties of Connecting Relays

Relays are probably the oldest means to realize logic operations. Relays, which are electromechanical devices, and their solid-state equivalents (i.e., transistors) are extensively used in many industrial products, such as computers. Relays are conceptually simple and appropriate for introducing physical realization of logic operations. More importantly, the connection configuration of a relay contact network is the same as that of transistors inside a logic gate realized with transistors, in particular MOSFETs (which stands for metal-oxide semiconductor field effect transistors).

A **relay** consists of an armature, a magnet, and a metal contact. An armature is a metal spring made of magnetic material with a metal contact on it. There are two different types of relays: a make-contact relay and a break-contact relay.

A **make-contact relay** is a relay such that, when there is no current through the magnet winding, the contact is open. When a direct current is supplied through the magnet winding, the armature is attracted to the magnet and, after a short time delay, the contact is closed. This type of relay contact is called a "make-contact" and is usually denoted by a lower-case x. The current through the magnet is denoted by a capital letter X, as shown in Fig. 30.1.

A **break-contact relay** is a relay such that when there is no current through the magnet winding, the contact closes. When a direct current is supplied, the armature is attracted to the magnet and, after a short time delay, the contact opens. This type of relay contact is called a "break-contact" and is usually denoted by $\bar{x}$. The current through the magnet is again denoted by X, as shown in Fig. 30.2.

In either case of a make-contact relay or a break-contact relay, no current in a magnet is represented by $X = 0$, and the flow of a current is represented by $X = 1$. Then $x = X$, no matter whether $X = 0$ or 1. But the contact of a make-contact relay is open or closed according as $X = 0$ or 1, because the contact is expressed by x, whereas the contact of a break-contact relay is closed or open according as $X = 0$ or 1, because the contact is expressed by $\bar{x}$.

Let us connect two make-contacts x and y in series, as shown in Fig. 30.3. Since X and x assume identical values at any time, the magnet, along with its symbol X, will henceforth be omitted in figures unless it is needed for some reason. Then we have the combinations of states shown in Table 30.1(a),

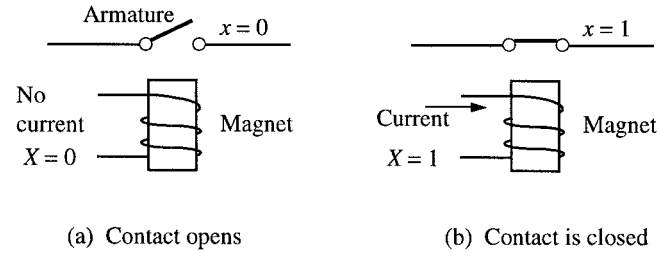

FIGURE 30.1 A make-contact relay.

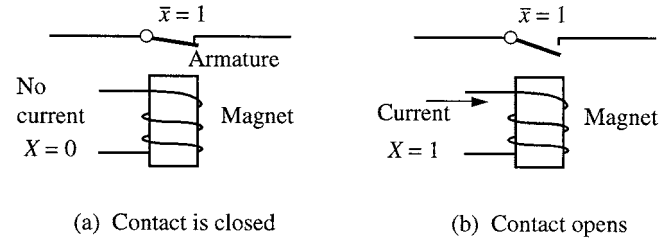

FIGURE 30.2 A break-contact relay.

FIGURE 30.3 Series connection of relay contacts.

TABLE 30.1 Combinations of States for the Series Connection in Fig. 30.3

(a)			(b)		
x	y	Entire Path Between a and b	x	y	f
Open	Open	Open	0	0	0
Open	Closed	Open	0	1	0
Closed	Open	Open	1	0	0
Closed	Closed	Closed	1	1	1

which has only two states, "open" and "closed." Let f denote the state of the entire path between terminals a and b, where f is called the **transmission** of the network. Since "open" and "closed" of a make-contact are represented by $x = 0$ and $x = 1$, respectively, Table 30.1(a) may be rewritten as shown in Table 30.1(b). This table shows the AND of x and y, defined in Chapter 23 and denoted by $f = xy$. Thus the network of a series connection of make-contacts realizes the AND operation of x and y.

Let us connect two make-contacts x and y in parallel as shown in Fig. 30.4. Then we have the combinations of states shown in Table 30.2(a). Replacing "open" and "closed" by 0 and 1, respectively, we may rewrite Table 30.2(a) as shown in Table 30.2(b). This table shows the OR of x and y, defined in Chapter 24 and denoted by $f = x \vee y$.

30.2 Analysis of Relay-Contact Networks

Let us analyze a relay contact network. "Analysis of a network" means the description of the logic performance of the network in terms of a logic expression.[1]

Transmission of Relay-Contact Networks

We now discuss general procedures to calculate the transmission of a network in which relay contacts are connected in a more complex manner. The first general procedure is based on the concept of tie sets, defined as follows.

Definition 30.1: Consider a path that connects two external terminals, a and b, and no part of which forms a loop. Then the literals that represent the contacts on this path are called a **tie set** of this network.

An example of a tie set is the contacts x_1, x_6, $\bar{x}_2$, and x_5 on the path numbered 1 in Fig. 30.5.

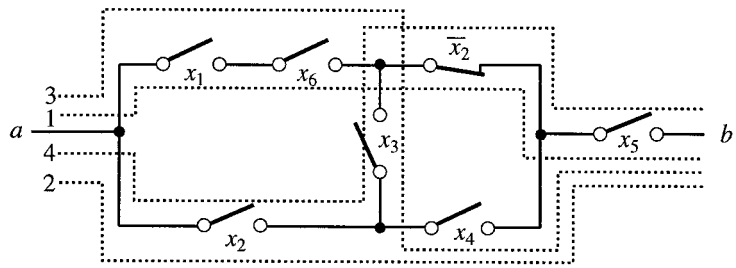

FIGURE 30.5 Tie sets of non-series-parallel network.

Procedure 30.1: Derivation of the Transmission of a Relay-Contact Network by Tie Sets

Find all the tie sets of the network. Form the product of all literals in each tie set. Then the disjunction of all these products yields the transmission of the given network. □

These tie sets represent all the shortest paths that connect terminals a and b. As an example, the network of Fig. 30.5 has the following tie sets:

For path 1: $x_1, x_6, \bar{x}_2, x_5$
For path 2: x_2, x_4, x_5
For Path 3: x_1, x_6, x_3, x_4, x_5
For path 4: $x_2, x_3, \bar{x}_2, x_5$

Then, we get the transmission of the network:

$$f = x_1x_6\bar{x}_2x_5 \vee x_2x_4x_5 \vee x_1x_6x_3x_4x_5 \vee x_2\bar{x}_2x_3x_5 \tag{30.1}$$

where the last term, $x_2\bar{x}_2x_3x_5$, may be eliminated, since it is identically equal to 0 for any value of x_2.

Procedure 30.1 yields the transmission of the given network because all the tie sets correspond to all the possibilities for making f equal 1. For example, the first term, $x_1x_6\bar{x}_2x_5$, in Eq. 30.1 becomes 1 for the combination of variables $x_1 = x_6 = x_5 = 1$ and $x_2 = 0$. Correspondingly, the two terminals a and b of the network in Fig. 30.5 are connected for this combination.

The second general procedure is given after the following definition.

Definition 30.2: Consider a set of contacts that satisfy the following conditions:

1. If all of the contacts in this set are opened simultaneously (ignoring functional relationship among contacts; in other words, even if two contacts, x and $\bar{x}$, are included in this set, it is assumed that contacts x and $\bar{x}$ can be opened simultaneously), the entire network is split into exactly two isolated subnetworks, one containing terminal a and the other containing b.

2. If any of the contacts are closed, the two subnetworks can be connected.

Then, the literals that represent these contacts are called a **cut set** of this network. □

As an example, let us find all the cut sets of the network in Fig. 30.5, which is reproduced in Fig. 30.6. First, let us open contacts x_1 and x_2 simultaneously, as shown in Fig. 30.6(a). Then terminals a and b are completely disconnected (thus condition 1 of Definition 30.2 is satisfied). If either of contacts x_1 and x_2 is closed, the two terminals a and b can be connected by closing the remaining contacts (thus, condition 2 of Definition 30.2 is satisfied). We have all the cut sets shown in the following list and also in Fig. 30.6(b):

For cut 1: x_1, x_2
For cut 2: x_6, x_2
For cut 3: x_1, x_3, x_4
For cut 4: x_6, x_3, x_4
For cut 5: $\bar{x}_2$, x_3, x_2
For cut 6: $\bar{x}_2$, x_4
For cut 7: x_5

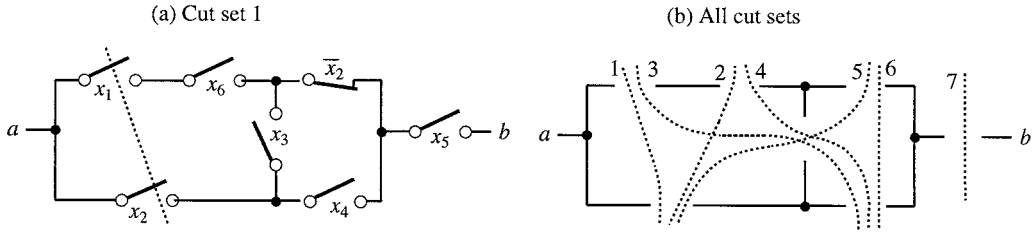

FIGURE 30.6 Cut sets of the network in Fig. 30.5.

Procedure 30.2: Derivation of the Transmission of Relay-Contact Network by Cut Sets

Find all the cut sets of a network. Form the disjunction of all literals in each cut set. Then the product of all these disjunctions yields the transmission of the given network. □

On the basis of the cut sets in the network of Fig. 30.5 derived above, we get

$$f = (x_1 \vee x_2)(x_6 \vee x_2)(x_1 \vee x_3 \vee x_4)(x_6 \vee x_3 \vee x_4)(\bar{x}_2 \vee x_3 \vee x_2)(\bar{x}_2 \vee x_4)(x_5) \tag{30.2}$$

This expression looks different from Eq. 30.1, but they are equivalent, since we can get identical truth tables for both expressions.

Procedure 30.2 yields the transmission of a relay contact network because all the cut sets correspond to all possible ways to disconnect two terminals, *a* and *b*, of a network; that is, all possibilities of making *f* equal 0. Any way to disconnect *a* and *b* which is not a cut set constitutes some cut set plus additional unnecessary open contacts, as can easily be seen.

The disjunction inside each pair of parentheses in Eq. 30.2 corresponds to a different cut set. A disjunction that contains the two different literals of any variable (e.g., $(\bar{x}_2 \vee x_3 \vee x_2)$ in Eq. 30.2 contains two literals, $\bar{x}_2$ and x_2, of the variable x_2) is identically equal to 1 and is insignificant in multiplying out *f*. Therefore, every cut set that contains the two literals of some variable need not be considered in Procedure 30.2.

30.3 Transistor Circuits

Bipolar transistor and MOSFET are currently the two most important types of transistors for integrated circuit chips, although MOSFET is becoming increasingly popular.[2] A transistor is made of pure silicon that contains a trace of impurities (i.e., n-type silicon or p-type silicon). When a larger amount of impurity than standard is added, we have n^+- and p^+-type silicon. When less, we have n^-- and p^--type silicon. A bipolar transistor has a structure of **n-type region** (or simply n-region) consisting of n-type silicon and **p-type region** (or simply p-region) consisting of p-type silicon, as illustrated in Fig. 30.7, different from that of MOSFET illustrated in Fig. 30.10.

Bipolar Transistors

An implementation example of an n-p-n bipolar transistor, which has three electrodes (i.e., an emitter, a base, and a collector) is shown in Fig. 30.7(a) along with its symbol in Fig. 30.7(b). A p-n-p transistor has the same structure except p-type regions and n-type regions exchanged (n^+- and p^+-type regions also exchanged).

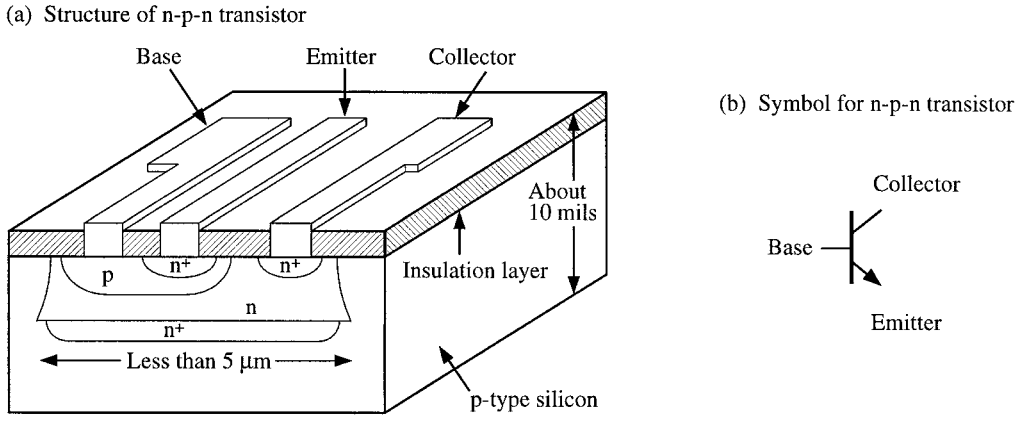

FIGURE 30.7 n-p-n transistor.

Suppose that an n-p-n transistor is connected to a power supply with a resistor and to the ground, as shown in Fig. 30.8(a). When the input voltage v_i increases, the collector current i_c gradually increases, as shown in Fig. 30.8(b). (Actually, i_c is 0 until v_i reaches about 0.6 V. Then i_c gradually increases and then starts to saturate.) As i_c increases, the output voltage v_o decreases from 5 V to 0.3 V or less because of the voltage difference across the resistor *R*, as shown in Fig. 30.8(c). Therefore, when the input v_i is a high

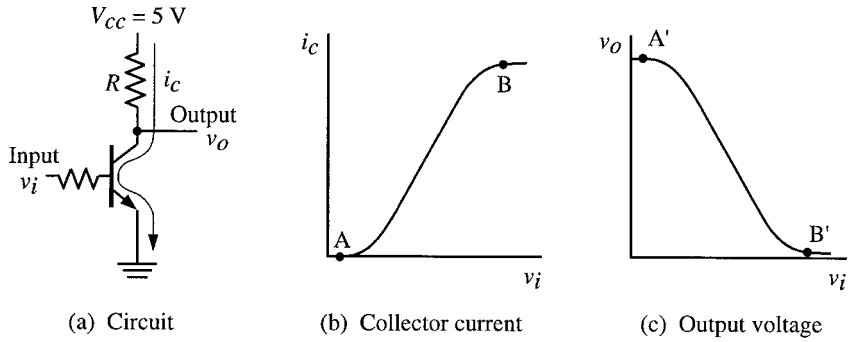

FIGURE 30.8 Inverter circuit.

voltage (about 5 V), the output v_o is a low voltage (about 0.3 V), and when v_i is a low voltage (about 0.3 V), v_o is a high voltage (about 5 V). This is illustrated in Table 30.3(a). Thus, if binary logic values 0 and 1 are represented by low and high voltages, respectively, we have the truth table in Table 30.3(b). This means that the circuit in Fig. 30.8(a) works as an **inverter**. In other words, if v_i represents a logic variable x, then v_o represents the logic function $\bar{x}$.

TABLE 30.3 Input-Output Relations of the Inverter in Fig. 30.8(a)

(a) Voltage Required

Input v_i	Output v_o
Low voltage	High voltage
High voltage	Low voltage

(b) Truth Table

v_i	v_o
0	1
1	0

Since we are concerned with binary logic values in designing logic networks, we will henceforth consider only the on-off states of currents or the corresponding voltages in electronic circuits (e.g., A and B in Fig. 30.8(b), or A′ and B′ in Fig. 30.8(c)), without considering their voltage magnitudes.

As we will see later, the transistor circuit in Fig. 30.8(a) is often used as part of more complex transistor circuits that constitute logic gates. Here, notice that if resistor R' is added between the emitter and the ground, and the output terminal v_o is connected to the emitter, instead of to the collector, as shown in Fig. 30.9, then the new circuit does not work as an inverter. In this case, when v_i is a high voltage, v_o is also a high voltage, because the current that flows through the transistor produces the voltage difference across resistor R'. When v_i is a low voltage, v_o is also a low voltage, because no current flows and

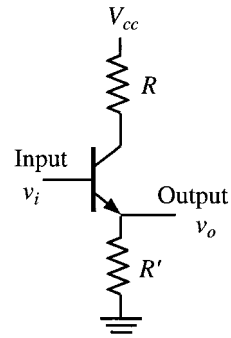

FIGURE 30.9 Emitter follower.

consequently no voltage difference develops across R'. So if v_i represents a variable x, v_o represents the logic function x, and no logic operation is performed. The transistor circuit in Fig. 30.9, which is often called an **emitter follower**, works as a current amplifier. This circuit is used often as part of other circuits to supply a large output current by connecting the collector of the transistor directly to the V_{cc} without R.

A logic gate based on bipolar transistors generally consists of many transistors which are connected in a more complex manner than Fig. 30.8 or 30.9, and realizes a more complex logic function than $\bar{x}$. (See Chapter 35 on ECL.)

MOSFET (Metal-Oxide Semiconductor Field Effect Transistor)

In integrated circuit chips, two types of MOSFETs are usually used; that is, **n-channel enhancement-mode MOSFET** (or abbreviated as n-channel enhancement MOS, or enhancement nMOS) and **p-channel enhancement-mode MOSFET** (or abbreviated as p-channel enhancement MOS, or enhancement pMOS). The structure of the former is illustrated in Fig. 30.10(a). They are expressed by the symbols shown in Fig. 30.10 (b) and (c), respectively. Each of them has three terminals: **gate**, **source,** and **drain**. In Fig. 30.10(a), the gate realized with metal is shown for the sake of simplicity, but a more complex structure, called **silicon-gate MOSFET**, is now far more widely used. **The "gate" in Fig. 30.10 should not be confused with "logic gates."** The thin area underneath the gate between the source and drain regions in Fig. 30.10(a) is called a **channel**, where a current flows whenever conductive.

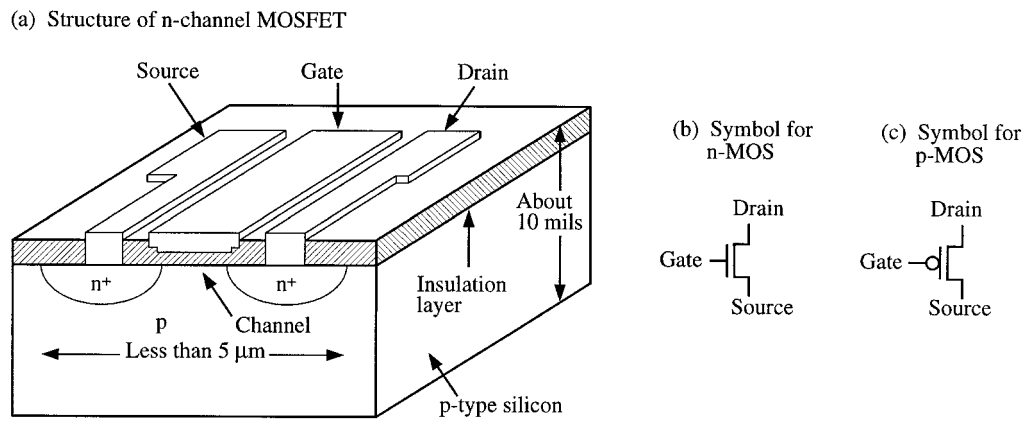

FIGURE 30.10 MOSFET.

Suppose that the source of an n-channel enhancement-mode MOSFET is grounded and the drain is connected to the power supply of 3.3 V through resistor R, as illustrated in Fig. 30.11(a). When the input voltage v_i increases from 0 V, the current i, which flows from the power supply to the ground through R and the MOSFET, increases as shown in Fig. 30.11(b), but for v_i smaller than the threshold voltage V_T, essentially no current flows. Then because of the voltage drop across R, the output voltage v_o, decreases, as shown in Fig. 30.11(c). Since we use binary logic, we need to use only two different voltage values, say 0.2 and 3.3 V. If v_i is 0.2 V, no current flows from the power supply to the ground through the MOSFET and v_o is 3.3 V. If v_i is 3.3 V, the MOSFET becomes conductive and a current flows. V_o is 0.2 V because of the voltage drop across R. Thus, if v_i is a low voltage (0.2 V), v_o is a high voltage (3.3 V); and if v_i is a high voltage, v_o is a low voltage, as shown in Table 30.4(a). If low and high voltages represent logic values 0 and 1, respectively, in other words, if we use **positive logic**, Table 30.4(a) is converted to the truth table in Table 30.4(b). (When low and high voltages represent 1 and 0, respectively, this is said to be in **negative logic**.) Thus, if v_i represents logic variable x, output v_o represents function $\bar{x}$. This means that the electronic circuit in Fig. 30.11(a) works as an **inverter**.

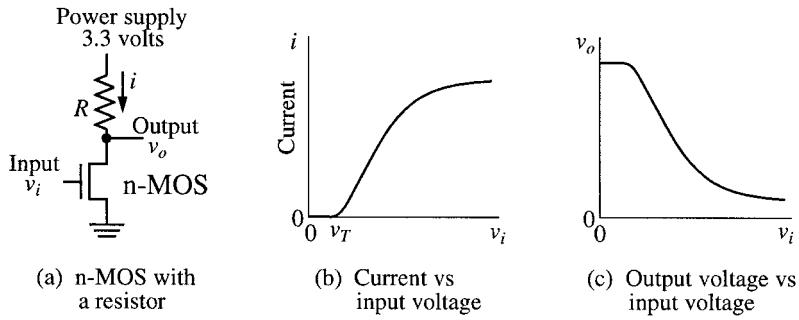

FIGURE 30.11 Inverter.

Resistor R shown in Fig. 30.11 occupies a large area, so it is usually replaced by a MOSFET, called an n-channel depletion-mode MOSFET, as illustrated in Fig. 30.12, where the depletion-mode MOSFET is denoted by the MOSFET symbol with double lines. Notice that **the gate of this depletion-mode MOSFET is connected to the output terminal instead of the power supply**, the logic gate with depletion-mode MOSFET replacing the resistor work in the same manner as before. Logic gates with depletion-mode MOSFETs work faster and are more immune to noise.

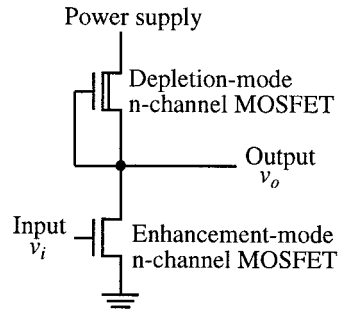

FIGURE 30.12 A logic gate with depletion-mode MOSFET.

The n-channel **depletion-mode MOSFET** is different from the n-channel enhancement-mode MOSFET in having a thin n-type silicon layer embedded underneath the gate, as illustrated in Fig. 30.13. When a positive voltage is applied at the drain against the source, a current flows through this thin n-type silicon layer even if the voltage at the gate is 0 V (against the source). As the gate voltage becomes more positive, a greater current flows. Or, as the gate voltage becomes more negative, a smaller current flows. If the gate voltage decreases beyond threshold voltage V_T, no current flows. This relationship, called a **transfer curve**, between the gate voltage V_{GS} (against the source) and the current i is shown in Fig. 30.14(a), as compared with that for the n-channel enhancement-mode MOSFET shown in Fig. 30.14(b).

By connecting many n-channel enhancement MOSFETs, we can realize any **negative function**, i.e., the complement of a sum-of-products where only non-complemented literals are used ($\overline{x \vee yz}$ is an example of negative function). For example, if we connect three MOSFETs in series, including the one

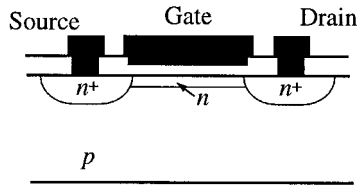

FIGURE 30.13 *n*-Channel depletion-mode MOSFET.

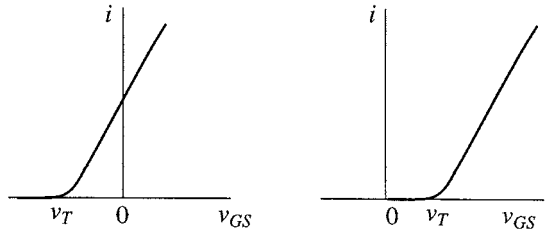

FIGURE 30.14 Shift of threshold voltage V_T (V_{GS} is a voltabe between gate and source).

for resistor replacement, as shown in Fig. 30.15, the output f realizes the NAND function of variables x and y. Only when both inputs x and y have high voltages, two MOSFETs for x and y become conductive and a current flows through them. Then the output voltage is low. Otherwise, at least one of them is non-conductive and no current flows. Then the output voltage is high. This relationship is shown in Table 30.5(a). In positive logic, this is converted to the truth table 30.5(b), concluding that the circuit represents $\overline{xy}$ which is called the NAND function. Figure 30.16 shows a logic circuit for $\overline{x \vee y}$ (called the NOR function) by connecting MOSFETs in parallel. A more complex example is shown in Fig. 30.17.

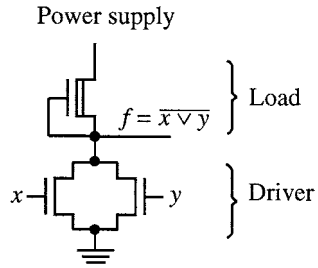

FIGURE 30.16 Logic gate for the NOR function.

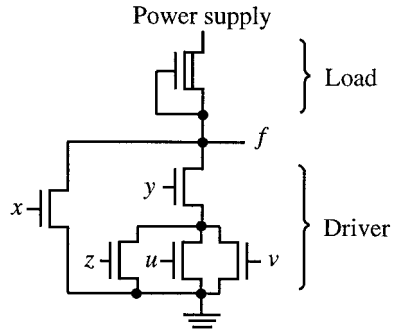

FIGURE 30.17 A logic gate with many MOSFETs.

The MOSFET that is connected between the power supply and the output terminal is called a **load** or **load MOSFET** in each of Figs. 30.15 through 30.17. Other MOSFETs that are directly involved in logic operations are called a **driver** or **driver MOSFETs** in each of these circuits.

Procedure 8.3: Calculation of the Logic Function of a MOS Logic Gate

The logic function f for the output of each of these MOS logic gates can be obtained as follows.

1. Calculate the transmission of the driver, regarding each n-channel MOSFET as a make-contact of relay, as illustrated in Fig. 30.18. When $x = 1$, a current flows through the magnet in the make-contact relay in Fig. 30.18 and the contact x is closed and becomes conductive, whereas n-MOS becomes conductive when $x = 1$, i.e., input x of nMOS is a high voltage.
2. Complement it. □

For example, the transmission of the driver in Fig. 30.16 is $x \vee y$. Then by complementing it, we have the output function $f = \overline{x \vee y}$. The output function of a more complex logic gate, such as Fig. 30.18, can be calculated in the same manner. Thus, **a MOS circuit expresses a negative function with respect to input variables connected to driver MOSFETs**.

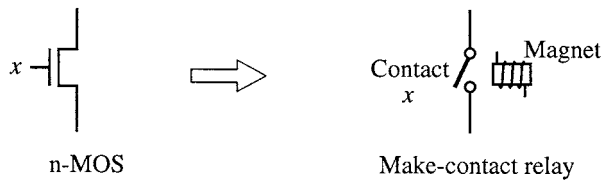

FIGURE 30.18 Analogy between n-MOS and a make-contact relay.

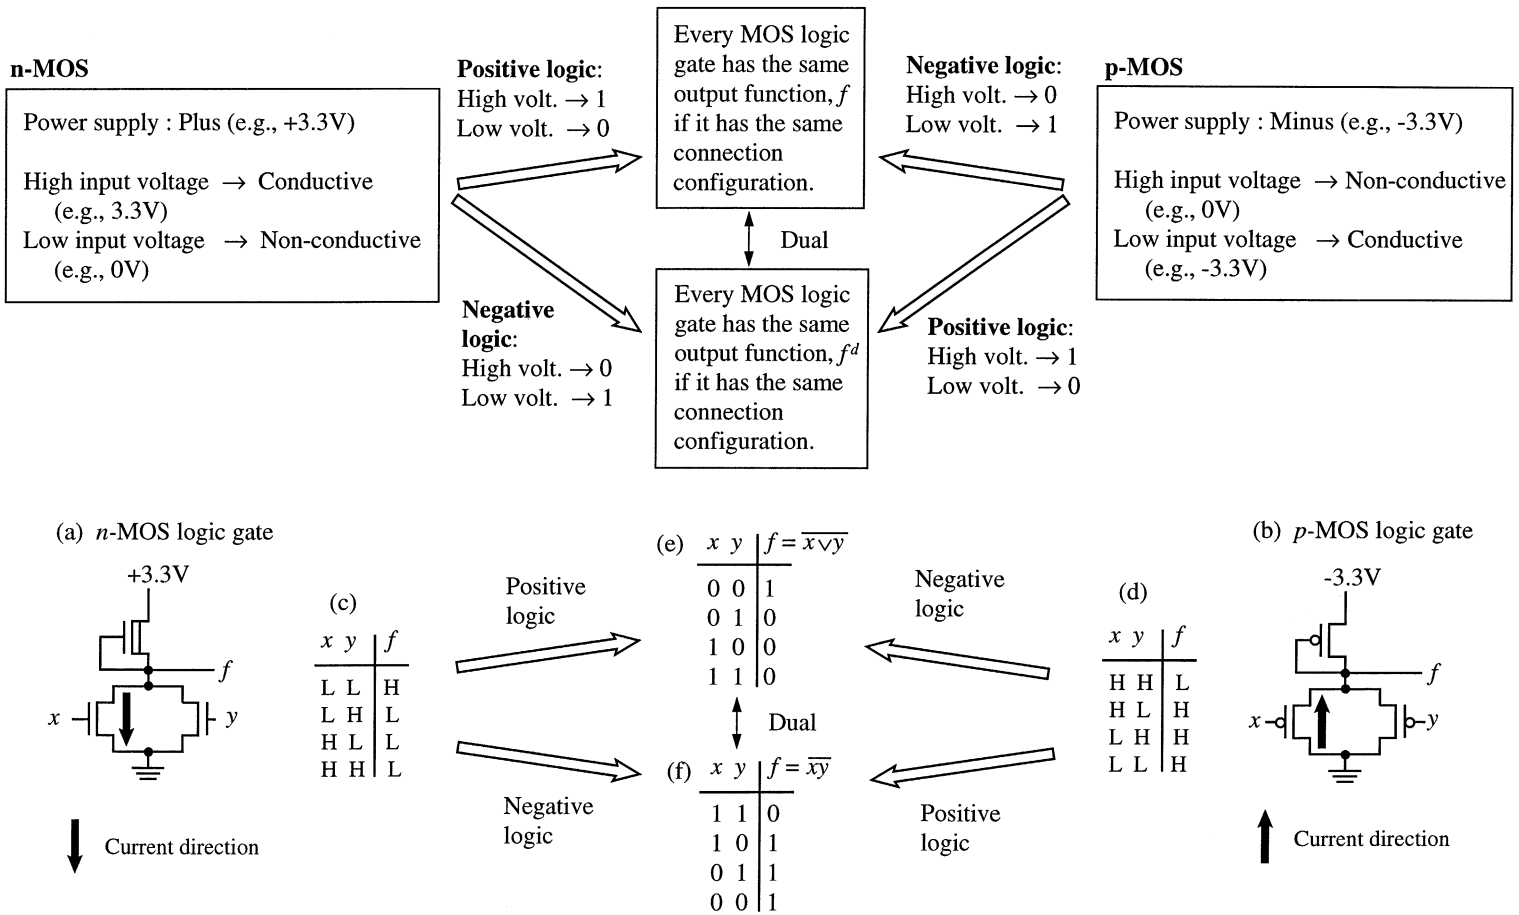

FIGURE 30.19 Behavior of logic gates with n-MOS and p-MOS.

Difference in the Behavior of n-MOS and p-MOS Logic Gates

As illustrated in Fig. 30.19, an n-MOS logic gate behaves differently from a p-MOS logic gate. In the case of an n-MOS logic gate which consists of all nMOSFETs, illustrated in Fig. 30.19(a), the power supply of the n-MOS logic gate must be positive voltage, say +3.3 V, whereas the power supply of the p-MOS logic gate which consists of all pMOSFETs, illustrated in Fig. 30.19(b), must be a negative voltage. Otherwise, these logic gates do not work. Each n-MOS in the driver in Fig. 30.19(a) becomes conductive when a high voltage (e.g., +3.3 V) is applied to its MOSFET gate, and becomes non-conductive when a low voltage (e.g., 0 V) is applied to its MOSFET gate. A direct current flows to the ground from the power supply, as shown by the bold arrow when the driver becomes conductive. In contrast, each p-MOS in the driver in Fig. 30.19(b) becomes non-conductive when a high voltage (e.g., 0 V) is applied to its MOSFET gate, and becomes conductive when a low voltage (e.g., – 3.3 V) is applied to its MOSFET gate. A direct current flows to the power supply from the ground (i.e., in the opposite direction to the case of n-MOS logic gate in (a)), as shown by the bold arrow when the driver becomes conductive. The relationship among voltages at the inputs and outputs for these logic gates are shown in Figs. 30.19(c) and (d). In positive logic, i.e., interpretation of a positive and negative voltages as 1 and 0, respectively, the table in Fig. 30.19(c) yields the truth table for NOR, i.e., $\overline{x \vee y}$, shown in (e), and in negative logic, i.e., interpretation of a positive and negative voltages as 0 and 1 respectively, the table in (d) also yields the truth table for NOR in (e). Similarly, in negative logic, the table in Fig. 30.19(c) yields the truth table for NAND, i.e., $\overline{xy}$, shown in (f), and in positive logic, the table in (d) also yields the truth table for NAND in (f). The two functions in (e) and (f) are dual. The relationships in these examples are extended into the general statements, as shown in the upper part of Fig. 30.19. Whether we use n-MOSFETs or p-MOSFETs in a logic gate, the output of the gate represents the same function by using positive or negative logic, respectively, or negative or positive logic, respectively. Thus, if we have a logic gate, realizing a function f, that consists of all n-MOS or all p-MOS, then the logic gate that is derived by exchanging n-MOS and p-MOS realizes its dual f^d, no matter whether positive logic or negative logic is used.

The output function of a logic gate that consists of all p-MOS can be calculated by Procedure 30.3, regarding each p-MOS as a make-contact relay. But each p-MOS is conductive (instead of being non-conductive) when its gate voltage is low, and is non-conductive (instead of being conductive) when its gate voltage is high. Also the output of the p-MOS logic gate is high when its driver is conductive (in the case of the n-MOS logic gate, the output of the gate is low when its driver is conductive) and is low when its driver is non-conductive (in the case of the n-MOS logic gate, the output of the gate is high when its driver is non-conductive). In other words, the polarity of voltages at the inputs and output of a p-MOS logic gate is opposite to that of an n-MOS logic gate. Thus, by using negative logic, a p-MOS logic gate has the same output function as the n-MOS logic gate in the same connection configuration in positive logic, as illustrated in Fig. 30.19.

Logic Synthesis With NAND (or NOR) Gates in Multi-levels

Saburo Muroga
University of Illinois at Urbana-Champaign

31.1 Logic Synthesis with NAND (or NOR) Gates

In the previous sections, we have discussed the design of a two-level network with AND and OR gates in **double-rail input logic** (i.e., both x_i and $\bar{x}_i$ for each x_i are available as network inputs) that has a minimum number of gates as the primary objective and a minimum number of connections as the secondary objective. If a network need not be in two levels, we may be able to further reduce the number of gates or connections, but there is no known simple systematic design procedure for this purpose, whether tabular, algebraic, or graphical, that guarantees the minimality of the network. (The integer programming logic design method[4,6] can do this but is complex, requiring long processing time.) But when multi-level minimal networks with NAND gates only (or NOR gates only) are to be designed, there is a method called the **map-factoring method** to design a logic network based on a Karnaugh map.

In designing a logic network in **single-rail input logic** (i.e., only one of x_i and $\bar{x}_i$ for each x_i is available as a network input) with the map-factoring method, it is less easy to see the minimality of the number of gates, although when two-level minimal networks with NAND gates in double-rail input logic are to be designed, it is as easy to see the minimality as two-level minimal networks with AND and OR gates in double-rail input logic on Karnaugh maps. By using designer's intuition based on the pictorial nature of a Karnaugh map, at least reasonably good networks in multi-levels can be derived after trial-and-error efforts. As a matter of fact, minimal networks can sometimes be obtained, although the method does not enable us to prove their minimality. However, if we are satisfied with reasonably good networks, the map-factoring method is useful for manual design. It is actually an extension of the Karnaugh map method for minimal two-level networks with AND and OR gates discussed so far, with far greater

flexibility: by the map-factoring method, we can design not only in two-levels but also in multi-levels in single-rail or double-rail input logic, and also two-level minimal networks with NAND gates in double-rail input logic that can be designed by the map-factoring method are essentially two-level minimal networks with AND and OR gates, as will be discussed later. The map-factoring method, which was first described in Chapter 6 of Ref. 3 for single-rail input logic as discussed later in this chapter, is extended here with minor modification.[5]

Logic networks with NOR gates only or NAND gates only are useful in some cases, such as gate arrays (to be described in Chapter 43) because the simple connection configuration of MOSFETs in each of these gates makes the area small with high speed.

In designing a logic network in multi-levels, we usually minimize the number of logic gates as the primary objective and then the number of connections as the secondary objective. This is because the design with the minimization of the number of logic gates as the primary objective and then the number of connections as the secondary objective is easier than the minimization of the number of connections as the primary objective and then the number of logic gates as the secondary objective, although the minimization of the number of connections, or the lengths of connections (which is far more difficult to minimize), is important because connections occupy significantly large areas on an integrated circuit chip. But judging the results by an experiment by the integer programming logic design method in limited scale, we have the same or nearly same minimal logic networks by either approach.[7]

31.2 Design of NAND (or NOR) Networks in Double-Rail Input Logic by the Map-Factoring Method

NAND gates and NOR gates, which are realized with MOSFETs, are often used in realizing integrated circuit chips, although logic gates that express negative functions which are more complex than NAND or NOR are generally used. (A "negative function" is the complement of a disjunctive form of non-complemented variables. An example is $\overline{xy \vee z}$.) NAND gates are probably more often used than other types of logic gates realizing negative functions because a NAND gate in CMOS has a simple connection configuration of MOSFETs and is fast.

Let us consider representing a NAND gate on a Karnaugh map. The output of the NAND gate with inputs x, $\bar{y}$, and z shown in Fig. 31.1(a) can be expressed as the loop for $x\bar{y}z$ consisting of only 0-cells on the map in Fig. 31.1(b). (Recall that this loop represents product $x\bar{y}z$ on an ordinary Karnaugh map in the previous chapters.) In this case, it is important to note that only 0-cells are contained inside the loop and all the 1-cells are outside. This is because the output of this NAND gate is the complement of the AND operation of inputs, x, $\bar{y}$, and z (i.e., $\overline{x\bar{y}z}$). Thus, if all the 0-cells in the map can be encircled by a single rectangular loop representing a product of some literals (i.e., the number of 0-cells constituting this loop is 2^i where i is a non-negative integer), the map represents the output of a NAND gate whose

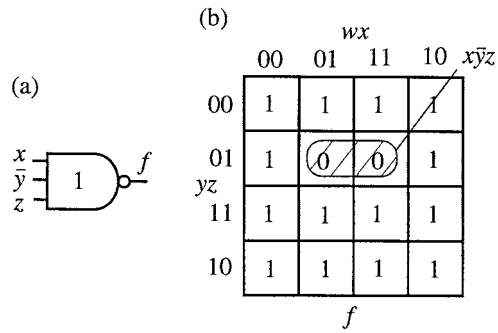

FIGURE 31.1 Representation of a NAND gate on a map.

inputs are the literals in the product represented by the loop. The value of f is 0 for $x = \bar{y} = z = 1$ (i.e., $x = z = 1$ and $y = 0$) in both Figs. 31.1(a) and (b). The value of f is 1 if at least one of x, $\bar{y}$, and z is 0.

Next, connect a new NAND gate (numbered gate 2) to the output of the above NAND gate (i.e., gate 1) and also connect inputs w and z to the new gate, as shown in Fig. 31.2(a). Unlike the case of gate 1 explained in Fig. 31.1, the output f of this new NAND gate is not expressed by the entire loop for wz in Fig. 31.2(b), but is expressed by the portion of the loop (i.e., only 0-cells inside the loop for wz) because the input of gate 2 from gate 1 becomes 0 for the combination, $w = x = z = 1$ and $y = 0$, and consequently f becomes 1 for this combination (if there were no connection from gate 1, the rectangular loop representing wz contains only 0-cells, like gate 1 explained in Fig. 31.1). This may be interpreted as the rectangular loop representing wz for gate 2 being **inhibited** by the loop for gate 1, as shown in Fig. 31.2(b). The remainder of the loop (i.e., all 0-cells, which is actually all the 0-cells throughout the map) is encircled by a loop and is shaded. This shaded loop represents the output of gate 2 and is said to be **associated** with the output of gate 2. In other words, the loop (labeled wz) which represents wz denotes NAND gate 2, whereas the shaded loop (labeled 2) inside this loop in Fig. 31.2(b) denotes the output function of gate 2. Notice that the entire loop for gate 1 is shaded to represent the output function of gate 1, because gate 1 has no inputs from other gates (i.e., gate 1 is inhibited by no other shaded loops) and consequently the loop representing gate 1 coincides with the shaded loop representing the output of gate 1 (i.e., the shaded loop associated with the output of gate 1).

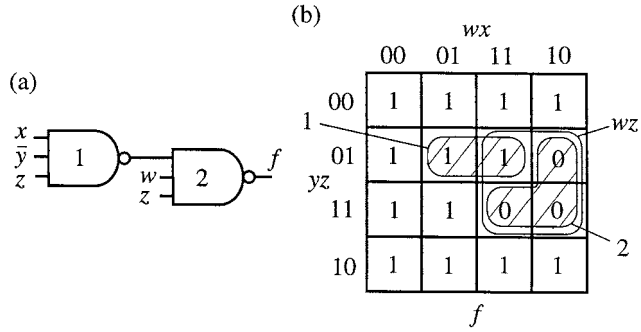

FIGURE 31.2 Representation of a network of two NAND gates.

Now let us state a formal procedure to design a NAND network on a Karnaugh map.

Procedure 31.1: The Map-Factoring Method: Design of a Network in Double-Rail Input Logic with as few NAND Gates as Possible

1. Make the first rectangular loop of 2^i cells. This loop may contain 1-cells, 0-cells, d-cells, or a mixture. Draw a NAND gate corresponding to this loop. As inputs to this gate, connect all the literals in the product that this loop represents. Shade the entirety of this loop.

For example, let us synthesize a network for $f = \bar{w}\bar{y} \vee x\bar{y} \vee \bar{z}$ shown in the Karnaugh map in Fig. 31.3(a). Let us make the first rectangular loop as shown in Fig. 31.3(a). (Of course, the first loop can be chosen elsewhere.) This loop represents product $w\bar{x}$. Draw gate 1, corresponding to this loop and connect inputs w and $\bar{x}$ to this gate. Shade the entirety of this loop because this gate has no input from another gate and consequently the entirety of this loop is associated with the output function of gate 1.

2. Make a rectangular loop consisting of 2^i cells, encircling 1-cells, 0-cells, d-cells, or a mixture. Draw a NAND gate corresponding to this loop. To this gate, connect literals in the product that this loop represents.

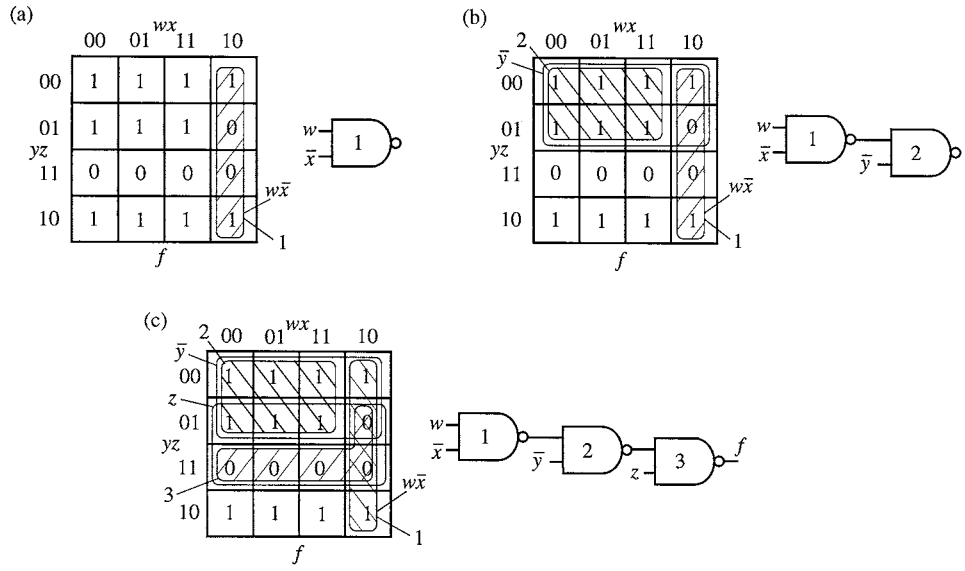

FIGURE 31.3 Example for Procedure 31.1.

Up to this point, this step is identical to Step 1. Now, to this new gate, we further connect the outputs of some or all of the gates already drawn, if we choose to do so. There are the following possibilities:

a. If we choose not to connect any previous gate to the new gate, the new loop is entirely shaded.
b. If we choose to connect some or all of the previously drawn gates to the new gate, encircle and shade the area inside the new loop, excluding the shaded loops of the previously drawn gates connected to the new gate. The shaded loop thus formed is associated with the output of this new gate.

Let us continue our example of Fig. 31.3. Let us make the loop labeled $\bar{y}$ shown in Fig. 31.3(b) as a next rectangular loop consisting of 2^i cells. Draw the corresponding gate 2. Connect input $\bar{y}$ to gate 2 because this loop represents $\bar{y}$. If we choose to connect the output of gate 1 also to gate 2 (i.e., by choosing the case b above), the shaded loop labeled 2 in Fig. 31.3(b) represents the output of gate 2.

3. Repeat Step 2 until the following condition is satisfied:

Termination condition: When a new loop and the corresponding new gate are introduced, all the 0-cells on the entire map and possibly some *d*-cells constitute the shaded loop associated with the output of the new gate.

Continuing our example, let us make the loop labeled z as a next rectangular loop consisting of 2^i, as shown in Fig. 31.3(c). Draw the corresponding gate 3 with input z connected. Choosing the case b in Step 2, connect the output of gate 2 as input of gate 3. (In this case b, we have three choices; that is., connection of the output of gate 1 only, connection of the output of gate 2 only, and connection of both outputs of gates 1 and 2. Let us take the second choice now.) Then, the output of gate 3 is expressed by the shaded loop labeled 3 in Fig. 31.3(c). Now, the termination condition is satisfied: all the 0-cells on the entire map constitute the shaded loop associated with the output of new gate 3. Thus, a network for the given function f has been obtained in Fig. 31.3(c).

For the sake of simplicity, the example does not contain *d*-cells. Even when a map contains *d*-cells, that is, cells for don't-care conditions, the map-factoring method, Procedure 31.1, can be easily used by appropriately interpreting each *d*-cell as a 0-cell or a 1-cell only when we examine the termination condition in Step 3. □

Notice that we can choose different loops (including the first one in Step 1) in each step, leading to different final networks.

Networks with AND and OR Gates in Two Levels, as a Special Case

If we circle only 1-cells possibly along with some *d*-cells but without any 0-cells in each step, we can derive a logic network with NAND gates in two levels, as illustrated in Fig. 31.4(a). This can be easily converted to the network with AND and OR gates in two levels shown in Fig. 31.4(b).

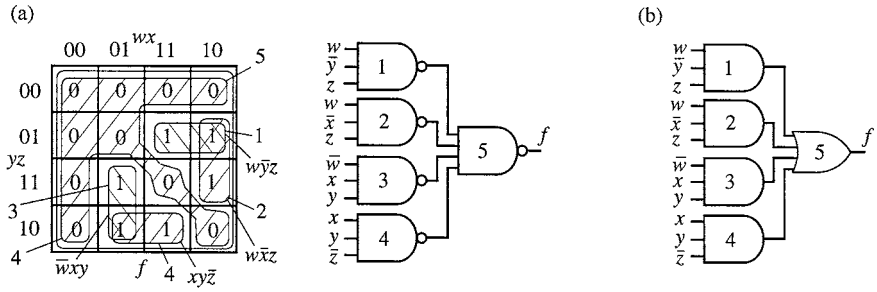

FIGURE 31.4 Network in two levels.

Consideration of Restrictions Such as Maximum Fan-in

If the restriction of maximum fan-in or fan-out is imposed, loops and connections must be chosen so as not to violate it. With the map-factoring method, it is easy to take such a restriction into consideration. Also, the maximum number of levels in a network can be easily controlled.

The Map-Factoring Method for NOR Network

A minimal network of NOR gates for a given function *f* can be designed by the following approach.

Use the map-factoring method to derive a minimal network of NAND gates for f^d, the dual of the given function *f*. Then replace NAND gates in the network with NOR gates. The result will be a minimal network of NOR gates for *f*.

31.3 Design of NAND (or NOR) Networks in Single-Rail Input Logic

In Section 31.2, we discussed the design of a multi-level NAND networks in double-rail input logic, using the map-factoring method. Now let us discuss the design of a multi-level NAND network in single-rail input logic (i.e., no complemented variables are available as inputs to the network) using the map-factoring method.

First let us define **permissible loops** on a Karnaugh map. A permissible loop is a rectangle consisting of cells that contains the cell whose coordinates are variable values of all 1's (i.e., the cell marked with the asterisk in each map in Fig. 31.5), where *i* is one of 0, 1, 2, …. In other words, **a permissible loop must contain the particular cell denoted by the asterisk in each map in Fig. 31.5, where this permissible loop consists of 1-cells, 0-cells, *d*-cells (i.e., don't-care cells), or a mixture**. All permissible loops for three variables are shown in Fig. 31.5.

In the following, let us describe the map-factoring method. The procedure is the same as Procedure 31.1 except the use of permissible loop, instead of rectangular loop of 2^i-cells at any place on the map, for representing a gate.

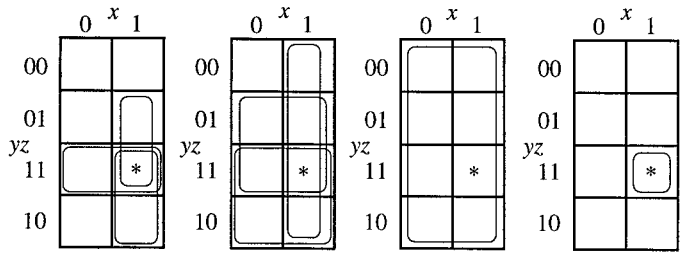

FIGURE 31.5 Permissible loops for three varibles.

Procedure 31.2: The Map-Factoring Method: Design of a Network in Single-Rail Input with as Few NAND Gates as Possible.

We want to design a network with as few NAND gates as possible, under **the assumption that non-complemented variables but no complemented variables are available as network inputs**.

1. Make the first permissible loop, encircling 1-cells, 0-cells, *d*-cells, or a mixture of them. Draw a NAND gate corresponding to this loop. As inputs to this gate, connect all the literals in the product that this loop represents. Shade the entirety of this loop.

For example, when a function $f = x \vee y \vee \bar{z}$ is given, let us choose the first permissible loop, as shown in Fig. 31.6(a), although there is no reason why we should choose this particular loop. (There is no guiding principle for finding which loop should be the first permissible loop. Another loop could be better, but we cannot guess at this moment which loop is the best choice. Another possibility in choosing the first permissible loop will be shown later in Fig. 31.7(a).) The loop we have chosen is labeled 1 and is entirely shaded. Then, NAND gate 1 is drawn. Since the loop represents x, we connect x to this gate.

2. Make a permissible loop, encircling 1-cells, 0-cells, *d*-cells, or mixture of them. Draw a NAND gate corresponding to this loop. To this new gate, connect literals in the product that this loop represents.

In the above example, a new permissible loop is chosen as shown in Fig. 31.6(b), although there is no strong reason why we should choose this particular permissible loop. This loop represents product yz, so y and z are connected to the new gate, which is labeled 2.

To this new NAND gate, we further connect the outputs of some gates already drawn, if we choose to do so. There are the following possibilities.

a. If we choose not to connect any previous gate to the new gate, the new permissible loop is entirely shaded.

If we prefer not to connect gate 1 to gate 2 in the above example, we get the network in Fig. 31.6(b). Ignoring the shaded loop for gate 1, the new permissible loop is entirely shaded and is labeled 2, as shown in Fig. 31.6(b).

b. If we choose to connect some previously drawn gates to the new gate, encircle and shade the area inside the new permissible loop, excluding the shaded loops of the previously drawn gates which are connected to the new gate. In other words, the new permissible loop, except its portion inhibited by the shaded areas associated with the outputs of the connected previously drawn gates, is shaded.

In the above example, if we choose to connect gate 1 to gate 2, we obtain the network in Fig. 31.6(b′). The portion of the new permissible loop that is not covered by the shaded loop associated with gate 1 is shaded and labeled 2.

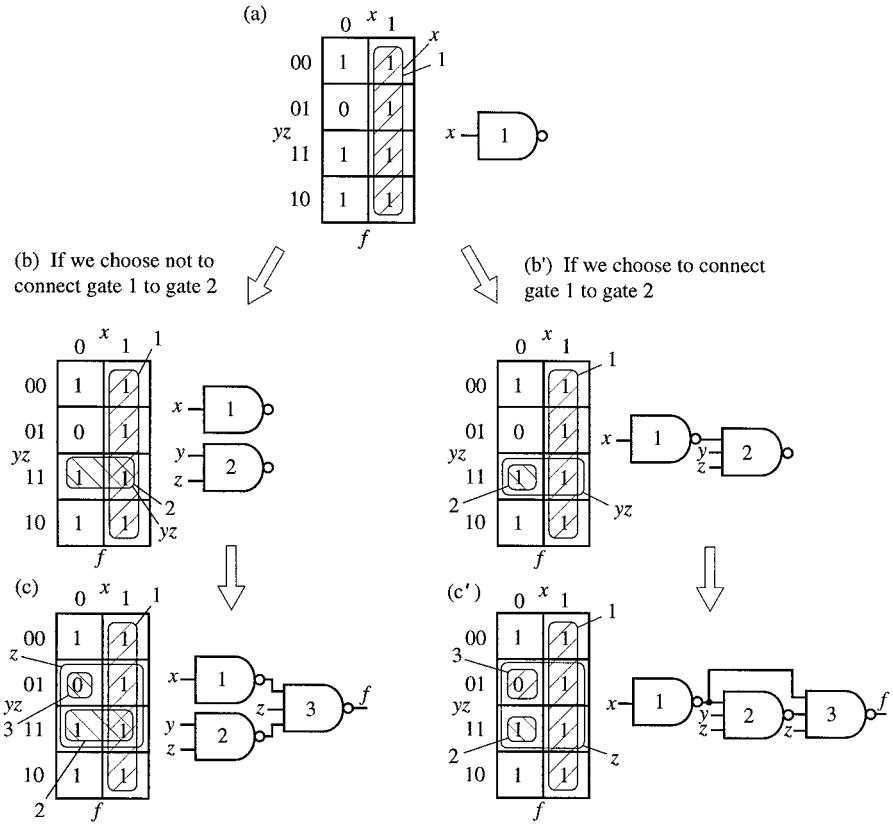

FIGURE 31.6 Map-factoring method applied for $f = x \vee y \vee \bar{z}$.

3. Repeat Step 2 until the following condition is satisfied:

Termination condition: When a new permissible loop and the corresponding new gate are introduced, all the 0-cells on the entire map and possibly some *d*-cells constitute the shaded loop associated with the output of the new gate (i.e., the shaded loop associated with the output of the new gate contains all the 0-cells on the entire map, but no 1-cell).

Let us continue Fig. 31.6(b). If we choose the new permissible loop as shown in Fig. 31.6(c), and if we choose to connect gates 1 and 2 to the new gate 3, the above termination condition has been satisfied; in other words, all the 0-cells on the entire map constitute the shaded loop associated with the output of the new gate 3.

We have obtained a network of NAND gates for the given function. Depending on what permissible loops we choose and how we make connections among gates, we can obtain different networks. After several trials, we choose the best network.

As an alternative for the network for f obtained in Fig. 31.6(c), let us continue Fig. 31.6(b′). If we choose the new permissible loop as shown in Fig. 31.6(c′), and gates 1 and 2 are connected to gate 3, we satisfy the termination condition in Step 3, and we have obtained the network in Fig. 31.6(c′), which is different from the one in Fig. 31.6(c).

If we choose the first permissible loop 1, as shown in Fig. 31.7(a), differently from Fig. 31.6(a), we can proceed with the map-factoring method as shown in Fig. 31.7(b), and we obtain the third network

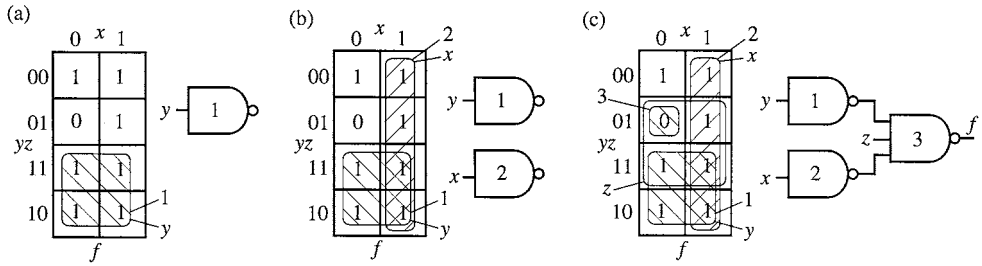

FIGURE 31.7 Network obtained by choosing permissible loops different from Fig. 31.6.

as shown in Fig. 31.7(c). Of course, we can continue differently in Figs. 31.7(b) and (c). Also, the first permissible loop can be chosen differently from Fig. 31.6(a) or 31.7(a), but it is too time-consuming to try all possibilities, so we have to be content with a few trials. We need a few trials to gain a good feeling of how to obtain good selections, and thereafter, we may obtain a reasonably good network. For the above example, $f = x \vee y \vee \bar{z}$, the network obtained in Fig. 31.7, happens to be the minimal network (the minimality of the number of gates and then, as the secondary objective, the minimality of the number of connections can be proved by the integer programming logical design method.).[4,6] □

As might be observed already, any permissible loop in the case of four variables represents a product of non-complemented literals (e.g., the loop chosen in Fig. 31.6(b) represents yz) by letting the permissible loop contain the cell with coordinates, $w = x = y = z = 1$, whereas any rectangular loop of 2^i cells, which does or does not contain this cell, represents a product of complemented literals, non-complemented literals, or a mixture as observed previously.

Extension of the Concept of Permissible Loop

By defining permissible loops differently, we can extend the map-factoring method to designing NAND gate networks with some variables complemented and others non-complemented as network inputs. This is useful when it is not convenient to have other combinations of complemented variables and non-complemented variables as network inputs (e.g., long connections are needed). For example, let us define a permissible loop as a rectangular loop consisting of 2^i cells which contains the cell with coordinates, $x = y = 0$ and $z = 1$. Then, we can design NAND networks with only $\bar{x}$, $\bar{y}$, and z as network inputs. Some functions can be realized with simpler networks by using some network inputs complemented. For example, the function in Fig. 31.7 can be realized with only one NAND gate by using $\bar{x}$, $\bar{y}$, and z as network inputs, instead of three gates in Fig. 31.7(c). Complemented inputs can be realized at the outputs of another network to be connected to the inputs of the network under consideration, or can be realized with inverters. When these network inputs run some distance on a PC board or a chip, the area covered by them is smaller than the case of double-rail input logic because the latter case requires another set of long-running lines for having their complements.

31.4 Features of the Map-Factoring Method

Very often in design practice, we need to design small networks. For example, we need to modify large networks by adding small networks, designing large networks by assembling small networks, or designing frequently used networks which are to be stored as cells in a cell library (these will be discussed in Chapter 45). Manual design is still useful in these cases because designers can understand very well the functional relationships among inputs, outputs, and gates and also complex constraints.

The map-factoring method has unique features that other design methods based on Karnaugh maps with AND and OR gates described in the previous sections do not have. The map-factoring method can synthesize NAND (or NOR) gate networks in single-rail input or double-rail input logic, in not only in two-levels but also in multi-levels. Also, constraints such as maximum fan-in, maximum fan-out, and the number of levels can be easily taken into account. In contrast, methods for designing logic networks with AND and OR gates on Karnaugh maps described in the previous sections can yield networks under several strong restrictions stated previously, such as only two levels and no maximum fan-in restriction. But networks in two levels in double-rail input logic with NAND (or NOR) gates derived by the map-factoring method are essentially networks in two-level of AND and OR gates in double rail-input logic. The usefulness of the map-factoring method is due to the use of a single gate type, NAND gate (or NOR gate type). Although the map-factoring method is intuitive, derivation of minimal networks with NAND gates in multi-levels is often not easy because there is no good guide line for each step (i.e., where we choose a loop) and in this sense, the method is heuristic.

The map-factoring method can be extended to a design problem where some inputs to a network are independent variables, x_1, x_2, ..., x_n and other inputs are logic functions of these variable inputs.

31.5 Other Design Methods of Multi-level Networks with a Minimum Number of Gates

If we are not content with heuristic design methods, such as the map-factoring method, that do not guarantee the minimality of networks and we want to design a network with a minimum number of NAND (or NOR) gates (or a mixture) under arbitrary restrictions, we cannot do so within the framework of switching algebra, unlike the case of minimal two-level AND/OR gate networks (which can be designed based on minimal sums or minimal products), and the **integer programming logic design method** is currently the only method available.[4,6] This method is not appropriate for hand processing, but can design minimal networks for up to about 10 gates within reasonable processing time by computer. The method can design multiple-output networks also, regardless of whether functions are completely or incompletely specified. Also, networks with a mixture of different gate types (such as NAND, NOR, AND, or OR gates), with gates having double outputs, or with wired-OR can be designed, although the processing time and the complexity of programs increase correspondingly. Also, the number of connections can be minimized as the primary, instead of as the secondary, objective.

Although the primary purpose of the integer programming logic design method is the design of minimal networks with a small number of variables, minimal networks for some important functions of an arbitrary number of variables (i.e., no matter how large n is for a function of n variables), such as adders[1,7] and parity functions,[2] have been derived by analyzing the intrinsic properties of minimal networks for these networks.

Logic Synthesis with a Minimum Number of Negative Gates

Saburo Muroga
University of Illinois at Urbana-Champaign

32.1 Logic Design of MOS Networks

A MOS logic gate can express a negative function and it is not directly associated with a simple logic expression such as a minimal sum. So, it is not a simple task to design a network with MOS logic gates so that the logic capability of each MOS logic gate to express a negative function is utilized to the fullest extent. Here let us describe one of few such design procedures that design transistor circuits directly from the given logic functions.[7,8]

A logic gate whose output represents a negative function is called a **negative gate**. A MOS logic gate is a negative gate. We now design a network with a minimum number of negative gates. The **feed-forward network** shown in Fig. 32.1 (the output of each gate feeds forward to the gates in the succeeding levels) can express any loopless network. Let us use Fig. 32.1 as the general model of a loopless network.

The following procedure designs a logic network with a minimum number of negative gates, assuming that only non-complemented input variables (i.e., $x_1, x_2, \ldots, x_n$) are available as network inputs (i.e., single-rail input logic), based on this model.[5,6,9]

Procedure 32.1: Design of Logic Networks with a Minimum Number of Negative Gates in Single-Rail Input Logic

We want to design a MOS network with a minimum number of MOS logic gates (i.e., negative gates) for the given function $f(x_1, x_2, \ldots, x_n)$. (The number of interconnections among logic gates is not necessarily minimized.) It is assumed that only non-complemented variables are available as network inputs. The network is supposed to consist of MOS logic gates g_i's whose outputs are denoted by u_i's, as shown in Fig. 32.1.

Phase 1

1. Arrange all input vectors $V = (x_1, x_2, \ldots, x_n)$ in a lattice, as shown in Fig. 32.2, where the nodes denote the corresponding input vectors shown in parentheses. White nodes, black nodes, and nodes with a cross in a circle, ⊗, denote true vectors, false vectors, and don't-care vectors, respectively. The number of 1's contained in each vector V is defined as the **weight** of the vector. All vectors with the same weight are on the same level, placing vectors with greater weights in higher levels, and every pair of vectors that differ only in one bit position is connected by a short line.

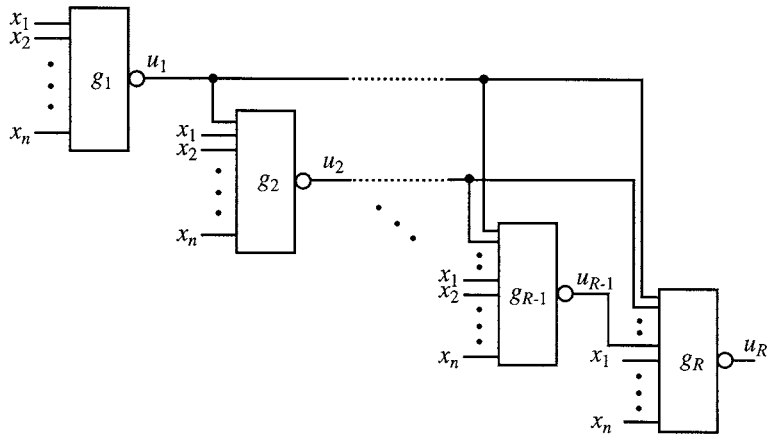

FIGURE 32.1 A feed-forward network of negative gates.

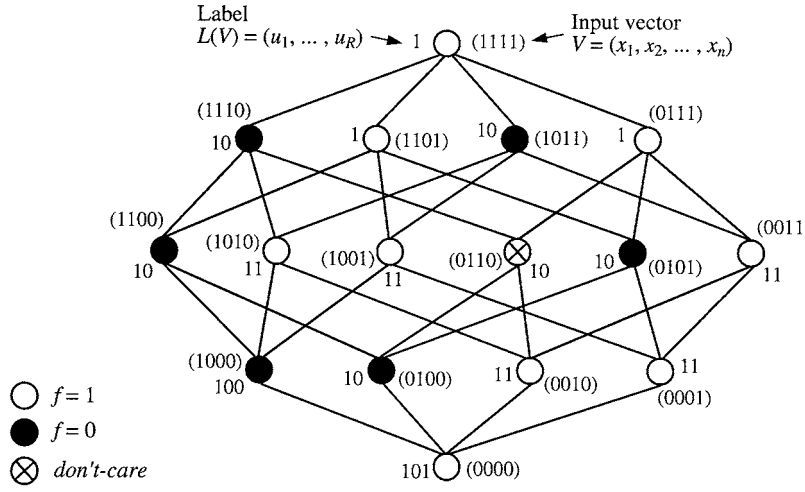

FIGURE 32.2 Lattice example for Procedure 32.1.

Figure 32.2 is a lattice example for an incompletely specified function of four variables.

2. We assign the label $L(V)$ to each vector $V = (x_1, x_2, \ldots, x_n)$ in the lattice in Steps 2 and 3. Henceforth, $L(V)$ is shown without parentheses in the lattice.

First assign the value of f to the vector $(11\ldots1)$ of weight n at the top node as $L(11\ldots1)$. If f for the top node is "don't-care," assign 0.

In the example in Fig. 32.2, we have $L(11\ldots1) = 1$ because the value of f for the top node is 1, as shown by the white node.

3. When we finish the assignment of $L(V)$ to each vector of weight w, where $0 < w \leq n$, assign $L(V')$ to each vector V' of weight $w-1$, the **smallest binary number** satisfying the following conditions:

If $f(V')$ is not "don't-care,"

a. The least significant bit of $L(V')$ is $f(V')$ (i.12e., the least significant bit of $L(V')$ is 0 or 1, according to whether f is 0 or 1), and

b. The other bits of $L(V')$ must be determined such that $L(V') \geq L(V)$ holds for every vector V of weight w that differs from V' in only one bit position. In other words, the binary number represented by $L(V')$ is not smaller than the binary number represented by $L(V)$.

If $f(V')$ is "don't-care," ignore (a), but consider (b) only. [Consequently, the least significant bit of $L(V')$ is determined such that (b) is met.]

For the example we get a label $L(1110) = 10$ for the node for vector $V' = (1110)$ because the last bit must be $0 = f(1110)$ by (a), and the number must be equal to or greater than the label 1 for the top node for vector (1111) by (b). Also, for vector $V' = (1000)$, we get a label $L(1000) = 100$ because the last bit must be $0 = f(1000)$ by (a), and the label $L(1000)$ as a binary number must be equal to or greater than each of the labels, 10, 11, and 11, already assigned to the three nodes (1100), (1010), and (1001), respectively.

4. Repeat Step 3 until a label $L(00\ldots0)$ is assigned to the bottom vector (00. . .0). Then the bit length of $L(00\ldots0)$ is the minimum number of MOS logic gates required to realize f. Denote it by R.

Then make all previously obtained $L(V)$ into binary numbers of the same length as $L(00\ldots0)$ by adding 0's in front of them such that every label $L(V)$ has exactly R bits. For the example, we have $R = 3$, so the label $L(11\ldots1) = 1$ obtained for the top node is changed to 001 by adding two 0's.

Phase 2

Now let us derive MOS logic gates from the $L(V)$'s found in Phase 1.

1. Denote each $L(V)$ obtained in Phase 1 as $(u_1,\ldots, u_i, u_{i+1},\ldots, u_R)$. As will be seen later, $u_1,\ldots, u_i, u_{i+1},\ldots, u_R$ are log functions realized at the outputs of logic gates, $g_1,\ldots, g_i, g_{i+1},\ldots, g_R$, respectively, as shown in Fig. 32.1.
2. For each $L(V) = (u_1,\ldots, u_i, u_{i+1},\ldots, u_R)$ that has $u_{i+1} = 0$, make a new vector $(V, u_1,\ldots, u_i)$ (i.e., $(x_1,\ldots, x_n, u_1,\ldots, u_i)$) which does not include $u_{i+1},\ldots, u_R$.

This means the following. For each i, find all labels $L(V)$'s whose $(i + 1)$-th bit is 0 and then for each of these labels, we need to create a new vector $(x_1,\ldots, x_n, u_1,\ldots, u_i)$ by containing only the first i bits of the label $L(V)$. For example, for $u_1 = 0$ (i.e., by setting i of "$u_{i+1} = 0$" to 0), the top node of the example lattice in Fig. 32.2 has the label $(u_1, u_2, u_3) = (001)$ which has $u_1 = 0$ (the label 1 which was labeled in Step 3 of Phase 1 was changed to 001 in Step 4). For this label, we need to create a new vector $(x_1, x_2, x_3, x_4, u_1,\ldots, u_i)$, but the last bit u_i becomes u_0 because we set $i = 0$ for $u_{i+1} = 0$. There is no u_0, so the new vector is $(x_1, x_2, x_3, x_4) = (1111)$, excluding $u_1,\ldots, u_i$. (In this sense, the case of $u_1 = 0$ is special, unlike the other cases of $u_2 = 0$ and $u_3 = 0$ in the following.) For other nodes with labels having $u_1 = 0$, we create new vectors in the same manner.

Next, for $u_2 = 0$ (i.e., by setting i of "$u_{i+1} = 0$" to 1), the top node has the label $(u_1, u_2, u_3) = (001)$ which has $u_2 = 0$. For this label, we need to create a new vector $((x_1, x_2, x_3, x_4, u_1)$, including u_1 this time. So, the new vector $((x_1, x_2, x_3, x_4, u_1) = (11110)$ results as the label $L(1111) = 001$ for the top node. Also, a new vector (11010) results for $L(1101) = 001$, and so on.

3. Find all the minimal vectors from the set of all the vectors found in Step 2, where the **minimal vectors** are defined as follows. When $a_k \geq b_k$ holds for every k for a pair of distinct vectors $A = (a_1,\ldots, a_m)$ and $B = (b_1,\ldots, b_m)$, then the relation is denoted by

$$A \succ B$$

and B is said to be smaller than A. In other words, A and B are compared bit-wise. If no vector in the set is smaller than B, B is called a minimal vector of the set. For example, $(10111) \succ (10101)$ because a bit (i.e., 1 or 0) in every bit position of (10111) is greater than or equal to the corresponding bit in

(10101). But (10110) and (10101) are **incomparable** because a bit in each of the first four bit positions of (10110) is greater than or equal to the corresponding bit of (10101), but the fifth bit of (10110) (i.e., 0) is smaller than the corresponding bit (i.e., 1) of (10101).

For the example, for $u_1 = 0$, the minimal vectors are (0100), (0010), (0001). Then, for $u_2 = 0$, we get (11110), (11010), (01110), (10001), and (00001) by Step 2. Then the minimal vectors are (11010), (01110), and (0000l). Here, notice that (11110), for example, cannot be a minimal vector because (11110) $\succ$ (11010). (11010) cannot be compared with other two, (01110) and (0001), with respect to $\succ$.

4. For every minimal vector, make the product of the variables that have 1's in the components of the vector, where the components of the vector (V, u_1,…, u_i) denote variables x_1, x_2, …, x_n, u_1, …, u_i, in this order. For example, we form $x_1x_2x_4$ for vector (11010). Then make a disjunction of all these products and denote it by $\bar{u}_{i+1}$.

For the example, we get

$$\bar{u}_2 = x_1x_2x_4 \vee x_2x_3x_4 \vee u_1$$

from the minimal vectors (11010), (01110), and (00001) for $u_2 = 0$.

5. Repeat Steps 2 through 4 for each of $i = 1, 2,\ldots, R-1$.

For the example, we get

$$\bar{u}_1 = x_2 \vee x_3 \vee x_4 \text{ and } \bar{u}_3 = x_1x_3x_4u_2 \vee x_1u_1 \vee x_2u_2$$

6. Arrange R MOS logic gates in a line along with their output functions, u_1, …, u_R. Then construct each MOS logic gate according to the disjunctive forms obtained in Steps 4 and 5, and make connections from other logic gates and input variables (e.g., MOS logic gate g_2, whose output function is u_2, has connections from x_1, x_2, x_3, x_4, and u_1 to the corresponding MOSFETs in g_2, according to disjunctive form $\bar{u}_2 = x_1x_2x_4 \vee x_2x_3x_4 \vee u_1$). The network output, u_3 (i.e., $u_3 = \overline{x_1x_3x_4u_2 \vee x_1u_1 \vee x_2u_2}$, which can be rewritten as $\bar{x}_1\bar{x}_2 \vee x_1\bar{x}_3x_4 \vee x_2x_3x_4 \vee \bar{x}_2x_3\bar{x}_4$) realizes the given function f.

For the example, we get the network shown in Fig. 32.3 (the network shown here is with logic gates in n-MOS only but it is easy to convert this into CMOS, as we will see in Chapter 36).

Phase 3

The bit length R in label $L(00\ldots0)$ for the bottom node shows the number of MOS logic gates in the network given at the end of Phase 2. Thus, if we do not necessarily choose the smallest binary number in Step 3 of Phase 1, but choose a binary number still satisfying the other conditions (i.e., (a) and (b)) in Step 3 of Phase 1, then we can still obtain a MOS network of the same minimum number of MOS logic gates as long as the bit length R of $L(00\ldots0)$ is kept the same. (For the top node also, we do not need to choose the smallest binary number as $L(1\,1\ldots)$, no matter whether f for the node is don't-care.)

This freedom may change the structure of the network, although the number of logic gates is still the minimum. Among all the networks obtained, there is a network that has a minimum number of logic gates as its primary objective, and a minimum number of interconnections as its secondary objective. (Generally, it is not easy to find such a network because there are too many possibilities.) □

Although the number of MOS logic gates in the network designed by Procedure 32.1 is always minimized, the networks designed by Procedure 32.1 may have the following problems: (1) the number

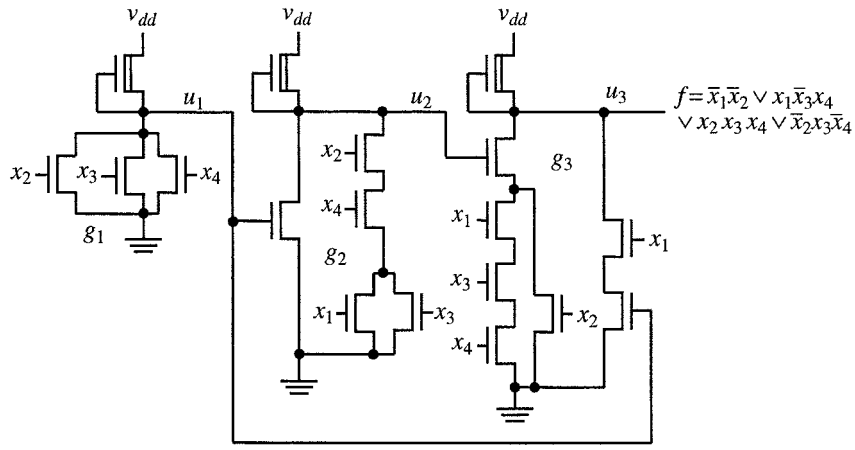

FIGURE 32.3 MOS network based on the labels $L(V)$ in Fig. 32.2.

of interconnections is not always minimized; (2) some logic gates may become very complex so that these logic gates may not work properly with reasonably small gate delay times. If so, we need to split these logic gates into a greater number of reasonably simple logic gates, giving up the minimality of the number of logic gates. Also, after designing several networks according to Phase 3, we may be able to find a satisfactory network.

32.2 Algorithm DIMN

Compared with the problem (1) of Procedure 32.1, problem (2) presents a far more serious difficulty. Thus, Algorithm DIMN (an acronym for Design of Irredundant Minimal Network) was developed to design a MOS network in single-rail input logic such that the number of gates is minimized and every connection among cells is irredundant (i.e., if any connection among logic gates is removed, the network output will be changed).[2,3] Algorithm DIMN is powerful but is far more complex than the minimal labeling procedure (i.e., Phases 1 and 2 of Procedure 32.1). So, let us only outline it.

Procedure 32.2: Outline of Algorithm DIMN

1. All the nodes of a lattice are labeled by the minimal labeling procedure (i.e., Phases 1 and 2 of Procedure 32.1), starting with the top node and moving downward. Let the number of bits of each label be R. Then all the nodes are labeled by a procedure similar to the minimal labeling procedure, starting with the bottom node which is now labeled with the largest binary number of R bits, and moving upward on the lattice. Then, the first negative gate with irredundant MOSFETs is designed after finding as many don't-cares as possible by comparing two labels at each node which are derived by these downward and upward labelings.
2. The second negative gate with irredundant MOSFETs is designed after downward and upward labelings to find as many don't-cares as possible. This process is repeated to design each gate until the network output gate with irredundant MOSFETs is designed. □

Unlike the minimal labeling procedure where the downward labeling is done only once and then the entire network is designed, Algorithm DIMN repeats the downward and upward labelings for designing each negative gate. The network derived by DIMN for the function $x_1x_2x_3x_4 \vee x_1x_2\bar{x}_3\bar{x}_4 \vee x_1\bar{x}_2x_3\bar{x}_4 \vee x_1\bar{x}_2\bar{x}_3x_4$, for example, has three negative gates, the same as that of the network derived by the minimal labeling procedure for the same function. The former, however, has only 12 n-channel MOSFETs, whereas the latter has 20 n-channel MOSFETs. DIMN usually yields networks that are substantially simpler than

those designed by the minimal labeling procedure, but it has the same problems as Procedure 32.1 when the number of input variables of the function becomes large.

The computational efficiency of DIMN was improved.[4] Also, a version of DIMN specialized to two-level networks was developed.[1]

Logic Synthesizer with Optimizations in Two Phases

Ko Yoshikawa
NEC Corporation

Saburo Muroga
University of Illinois at Urbana-Champaign

Logic networks and then their corresponding transistor circuits to be laid out on integrated chips have been traditionally designed manually, spending long time and repeatedly making mistakes and correcting them. As the cost and size of transistor circuits continue to decline, logic networks that are realized by transistor circuits have been designed with an increasingly large number of logic gates. Manual design of such large logic networks is becoming too time-consuming and prone to design mistakes, thus necessitating automated design. Logic synthesizers are automated logic synthesis systems used for this purpose and transform the given logic functions into technology-dependent logic circuits that can be easily realized as transistor circuits. The quality of technology-dependent logic circuits derived by logic synthesizers is not necessarily better than manually designed ones, at least for those with a small number of logic gates, but technology-dependent logic circuits for those with millions of logic gates cannot be designed manually for reasonably short times.

Automated design of logic networks has been attempted since the early 1960s.[3] Since the beginning of the 1960s, IBM has pushed research of design automation in logic design. In the 1970s, a different type of algorithm, called the Transduction method, was devised for automated design of logic networks, as described in Chapter 34. Since the beginning of the 1980s, the integration size of integrated chips has tremendously increased, research and development of automated logic synthesis has become very active at several places[1,2,4,9] and powerful logic synthesizers have become commercially available.[6]

There are different types of logic synthesizers. But here, let us describe a logic synthesizer that derives a technology-dependent logic circuit in two phases,[7] although there are logic synthesizers where, unlike the following **synthesizer in two phases**, only technology-dependent optimization is used throughout the transformation of the given logic functions into technology-dependent logic circuits that are easily realizable as transistor circuits:

> In the first phase, an optimum logic network that is not necessarily realizable as a transistor circuit is designed by Boolean algebraic approaches which are easy to use. This phase is called **technology-independent optimization**.
>
> In the second phase, the logic network derived in the first phase is converted into a technology-dependent logic circuit that is easily realizable as a transistor circuit. (Note that all logic synthesizers, including the logic synthesizer in two phases, must eventually have technology-dependent logic circuits that are easily realizable, as transistor circuits.) This phase is called **technology-dependent optimization**.

The logic synthesizer in two phases has variations, depending on what optimization algorithms are used, and some of them have the advantage of short processing time.

Suppose a logic network is designed for the given functions by some means, including design methods described in the previous chapters. Figure 33.1 is an example of such logic networks. Then the logic network is to be processed by many logic optimization algorithms in sequence, as shown in Fig. 33.2. As illustrated in Fig. 33.1, a subnetwork (i.e., several logic gates that constitute a small logic network by themselves) that has a single output logic function is called a **node,** and its output function is expressed as a sum-of-products form. Thus, the entire logic network is expressed as a network of the nodes. During the first phase of technology-independent optimization, each node does not correspond to a transistor circuit. But the second phase of technology dependent-optimization, as illustrated in Fig. 33.3, converts the logic network derived by the first phase into technology-dependent circuits, in which each node corresponds to a cell [i.e., a small transistor circuit (shown in each dot-lined loop in Fig. 33.3)] in a library of cells. The cell library consists of a few hundred cells where a cell is a small transistor circuit with good layout. These cells are designed beforehand and can be repeatedly used for logic synthesis.

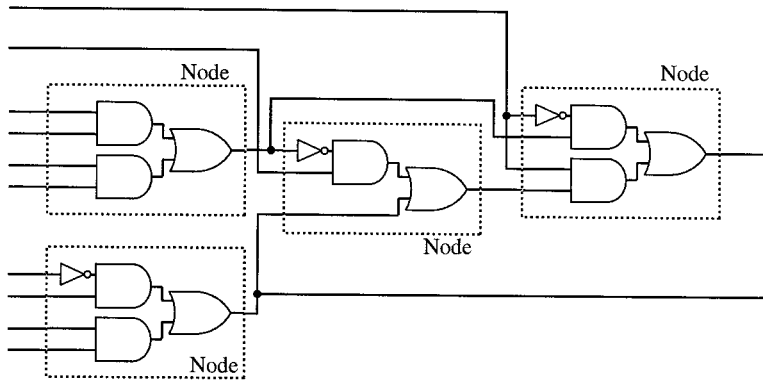

FIGURE 33.1 Logic network to be processed by a logic synthesizer.

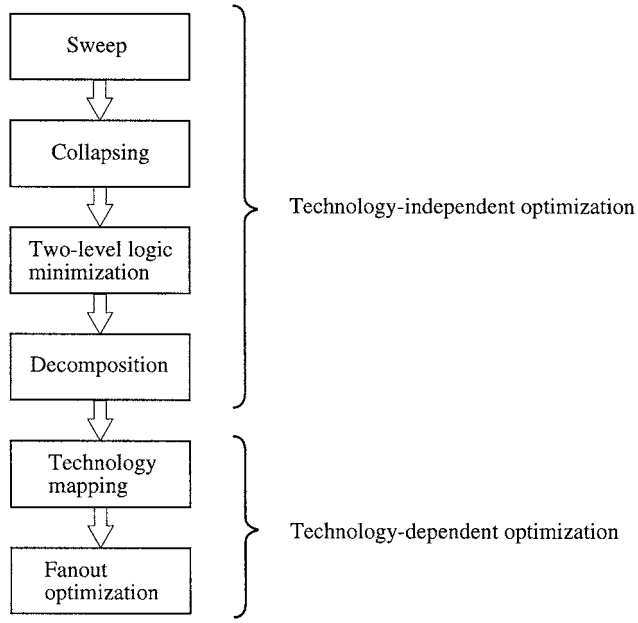

FIGURE 33.2 A logic optimization flow in the logic synthesizer in two phases.

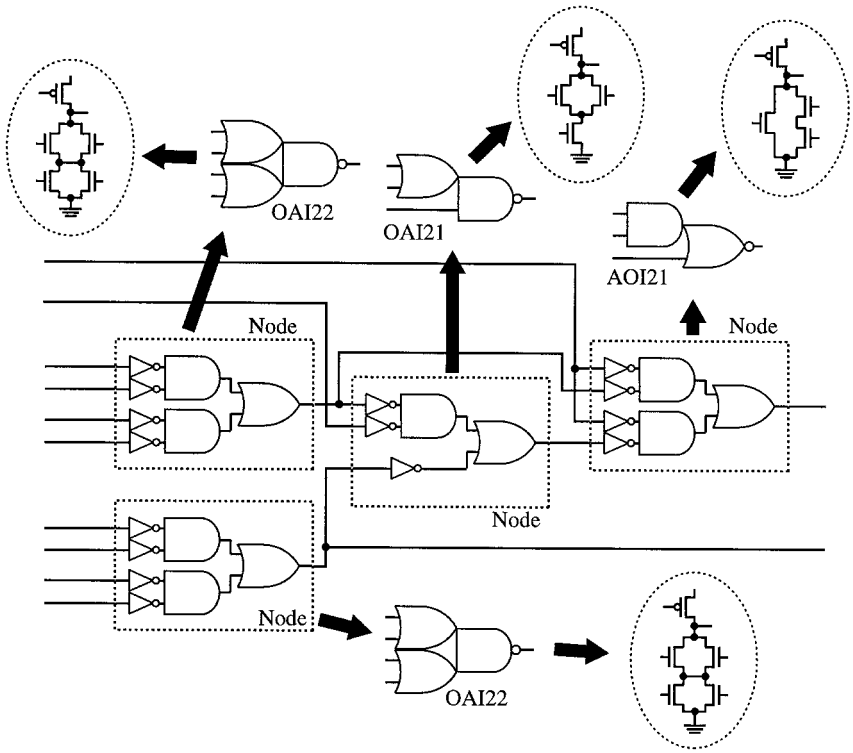

OAI22, OAI21, and AOI21 are the cells in the cell library.

FIGURE 33.3 Technology-dependent logic circuit.

A typical flow of logic optimization in the logic synthesis in two phases works as follows and is illustrated in Fig. 33.2, although there may be variations:

1. Sweep, illustrated in Fig. 33.4: Nodes that do not have any fan-outs are deleted. A node that consists of only a buffer or an inverter node is merged into next nodes. The following rules optimize nodes that have inputs of constant values, 0 or 1:

$$A \cdot 1 = A,\ A \cdot 0 = 0,\ A \vee 1 = 1,\ A \vee 0 = A$$

2. Collapsing (also often called flattening), illustrated in the upper part of Fig.33.5: More than one node is merged into one node, so that it has a more complicated logic function than before.
3. Two-level logic minimization: Two-level logic minimization[2] is carried out at each node, as illustrated in the lower part of Fig. 33.5. (PLA minimization programs to be described in Chapter 42 can be used for this purpose.)
4. Decomposition, illustrated in Fig. 33.6: Decomposition[4] extracts common expressions from the sum-of-products forms of nodes, adds intermediate nodes whose logic functions are the same as the common expressions, and re-expresses the sum-of-products form at the original nodes, using the intermediate nodes. This transformation, called **weak division** (described in Chapter 29), reduces the area of the circuit.
5. Technology mapping,[5] illustrated in Fig. 33.7: Technology mapping finds an appropriate mapping of the network of the nodes onto the set of cells in the target cell library. Technology mapping works as follows:

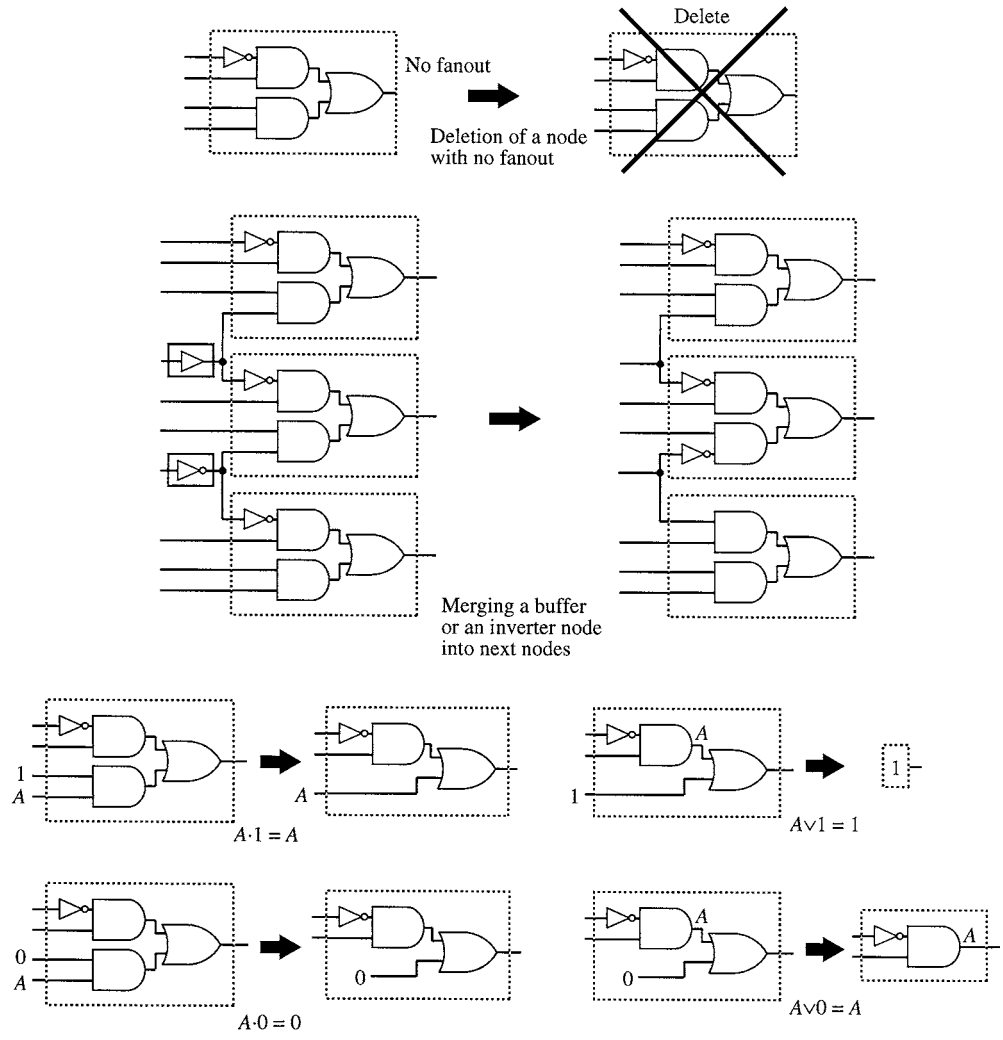

FIGURE 33.4 Sweep.

a. Select a tree structure: a tree structure where all nodes have one fan-out node is extracted from the circuit.

b. Decompose it to two-input NANDs and inverters: a selected tree is decomposed to two-input NANDs and inverters. The result of this decomposition is called a subject tree.

c. Matching: all cells in the target cell library are also decomposed to two-input NANDs and inverters, as shown in Fig. 33.8. Pattern matching between the subject tree and the cells in the cell library is carried out to get the best circuit.

Timing or power optimization, that is, minimization of delay time or power consumption under other conditions (e.g., minimization of delay time without excessively increasing power consumption, or minimization of power consumption without sacrificing speed too much) is also carried out by changing the structure of the nodes and their corresponding cells in the library.

6. Fanout optimization, illustrated in Fig. 33.9: Fanout optimization attempts to reduce delay time by the following transformations.

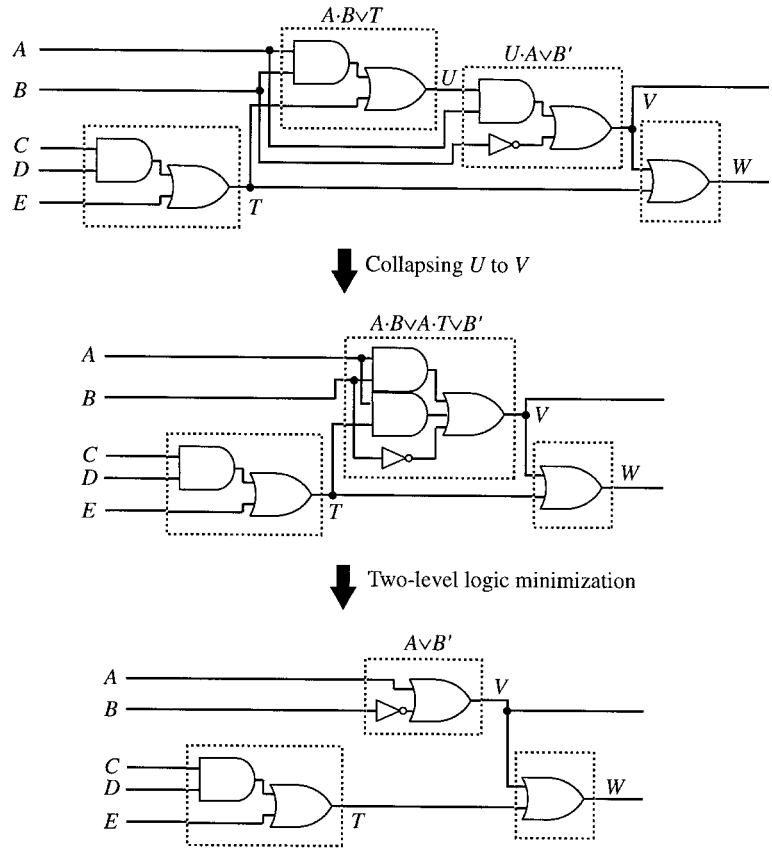

FIGURE 33.5 Collapsing and two-level logic minimization.

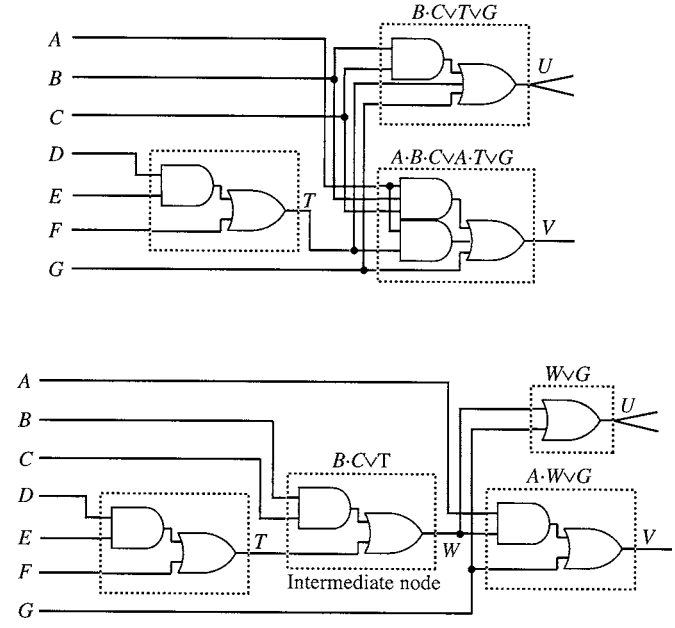

FIGURE 33.6 Decomposition.

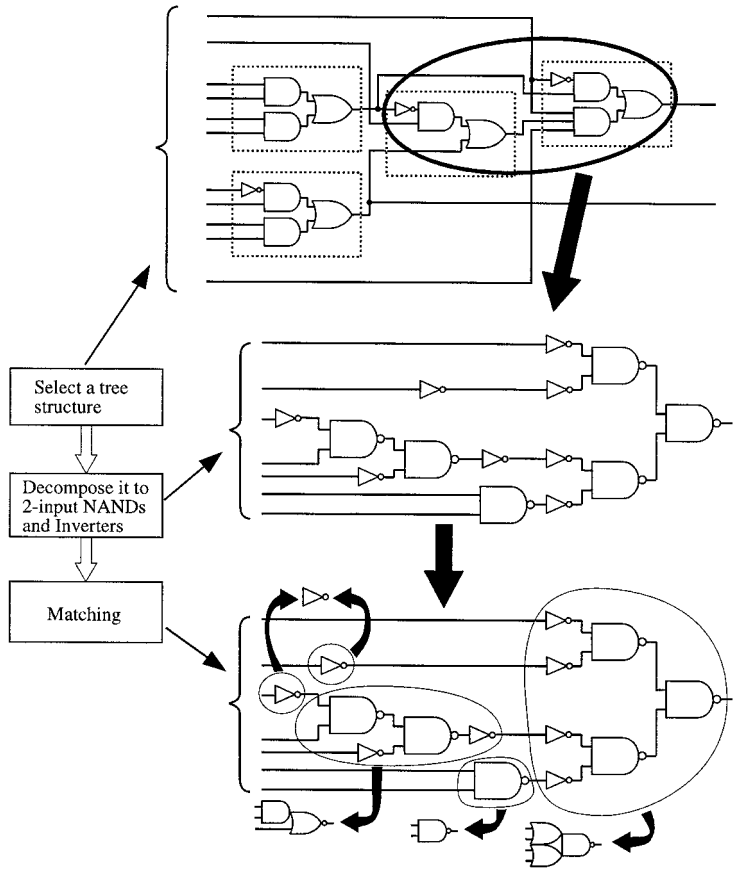

FIGURE 33.7 Technology mapping.

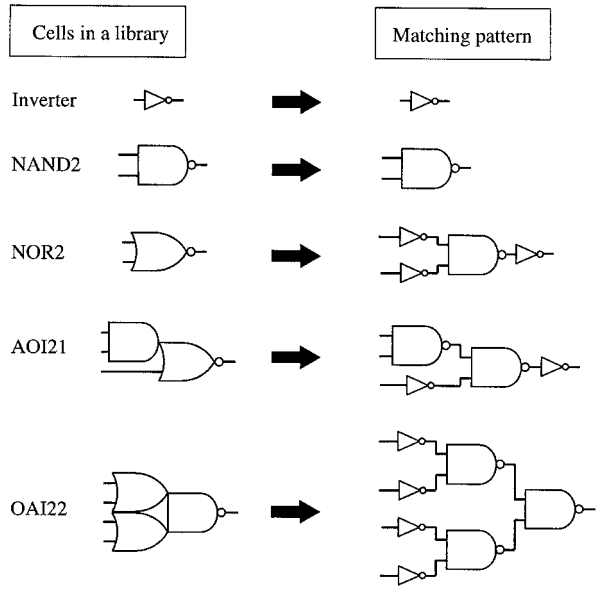

FIGURE 33.8 Pattern trees for a library.

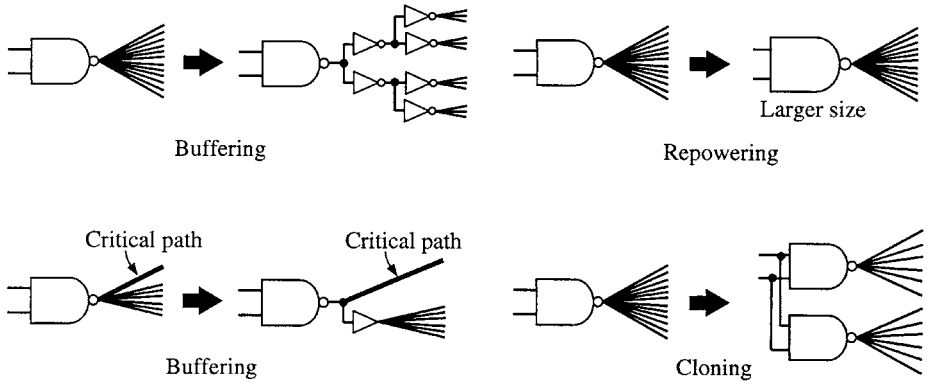

FIGURE 33.9 Fan-out optimization.

(a) Buffering: inserting buffers and inverters in order to reduce load capacitance of logic gates that have many fanouts. In particular, a critical path that is important for performance is separated from other fanouts.[8]
(b) Repowering: replacing a logic gate that has many fanouts, by another cell in the cell library that has greater output power (its cell is larger) and the same logic function as the original one. This does not change the structure of the circuit.[8]
(c) Cloning: creating a clone node for a logic gate that has many fanouts and distributing the fanouts among these nodes to reduce the load capacitance.

This is a typical logic optimization flow. Many other optimization algorithms can be incorporated within this flow to synthesize better circuits.

Logic Synthesizer by the Transduction Method

Saburo Muroga
University of Illinois at Urbana-Champaign

34.1 Technology-Dependent Logic Optimization

In this chapter, a logic optimization method called the transduction method, which was developed in the early 1970s, is described. Unlike the logic synthesizer in two phases described in Chapter 33, we can have logic synthesizers with totally technology-dependent optimization, based on the transduction method, and also can have transistor circuits with better quality, although it is more time-consuming to execute the method. Some underlying ideas in the method came from analyzing the minimal logic networks derived by the integer programming logic design method mentioned in Chapter 31, Section 31.5. The integer programming logic design method is very time-consuming, although it can design absolutely minimal networks. The processing time almost exponentially increases as the number of logic gates increases, and it appears to be excessively time consuming to design minimal logic networks with over about 10 logic gates. Unlike the integer programming logic design method, logic synthesizers based on the transduction method are heuristic, just like any other logic synthesizer for synthesizing large circuits, and the minimality of the transistor circuits derived is not guaranteed, but one can design circuits with far greater numbers of transistors.

34.2 Transduction Method for the Design of NOR Logic Networks

The transduction method can be applied on any types of gates, including negative gates (i.e., MOS logic gates), AND gates, OR gates, or logic gates for more complex logic operations; **but in the following, the transduction method is described with logic networks of NOR gates for the sake of simplicity**. The basic concept of the transduction method is "permissible functions," which will be explained later. This method, which is drastically different from any previously known logic design

method, is called the **transduction method** (**trans**formation and re**duction**) because it repeats the transformation and reduction as follows:

Procedure 34.1: Outline of the transduction method

Step 1. Design an initial NOR network by any known design method. Or, any network to be simplified can be used as an **initial network**.

Step 2. Remove the redundant part of the network, by use of permissible functions. (This is called the **pruning procedure**, as defined later).

Step 3. Perform **transformation** (which is local or global) of the current network, using permissible functions.

Step 4. Repeat Steps 2 and 3 until no further improvement is possible. □

Let us illustrate how Procedure 34.1 simplifies the initial network shown in Fig. 34.1(a), as an example. By a transformation (more precisely speaking, transformation called "connectable condition," which is explained later), we have the new network shown in Fig. 34.1(b), by connecting the output of gate v_6 to the gate v_8 (shown by a bold line). By the pruning procedure, the connection from gate v_6 to gate v_4 (shown by a dotted line) is deleted, deriving the new network shown in Fig. 34.1(c), and then the connection from gate v_9 to gate v_6 is deleted, deriving the new network shown in Fig. 34.1(d). Then, by a transformation ("connectable condition" again), we have the new network shown in Fig. 34.1(e), by connecting the output of gate v_6 to the gate v_7. By the pruning procedure, we can delete the output connection from gate v_{10} to gate v_7, and then we can delete gate v_{10}. During all these transformations and prunings, the network output f is not changed. Thus, the initial network with 7 gates and 13 connections, shown in Fig. 34.1(a), has been simplified to the one with 6 gates and 11 connections, shown in Fig. 34.1(f), by the transduction method.

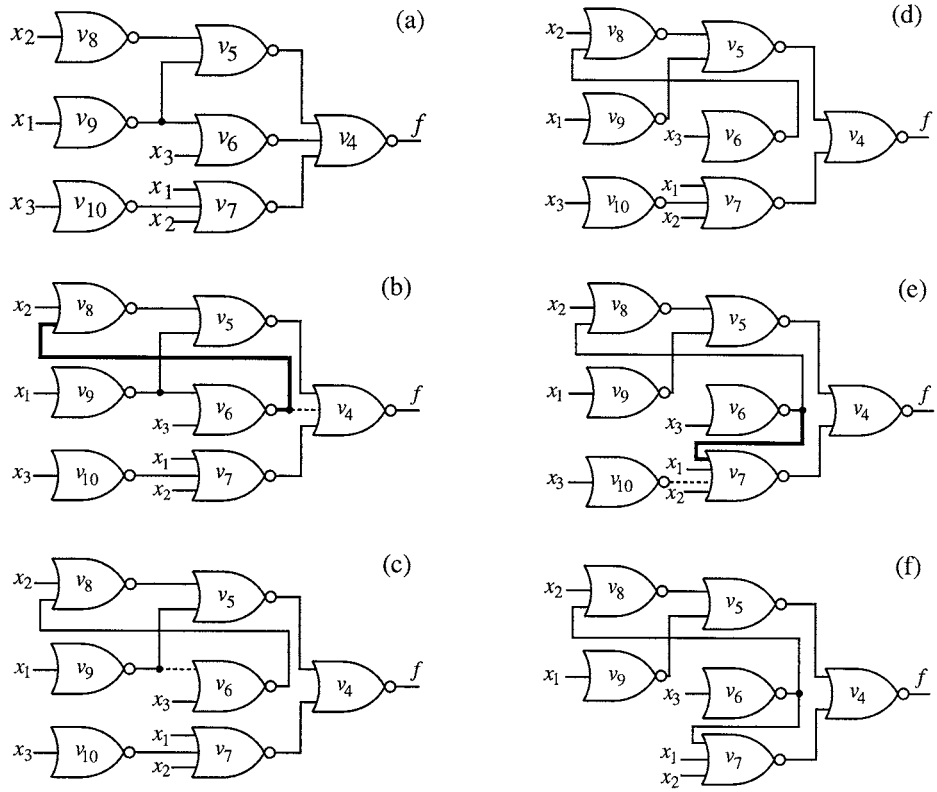

FIGURE 34.1 An example for the simplification of a logic network by the transduction method.

Many transformation procedures for Step 3 were devised to develop efficient versions of the transduction method. Reduction of a network is done in Step 2 and also sometimes in Step 3.

The initial network stated in Step 1 of Procedure 34.1 can be designed by any known method and need not be the best network. The transduction method is essentially an improvement of a given logic network, that is, the initial network by repeated transformation and reduction, as illustrated in the flow diagram in Fig. 34.2. In contrast, traditional logic design is the design of a logic network (i.e., the initial network in the case of the Transduction method) for given logic functions and once derived, no improvement is attempted. This was natural because it was not easy to find where to delete gates or connections in logic networks. For example, can we simplify the network in Fig. 34.1(a), when it is given? The transduction method shows how to do it.

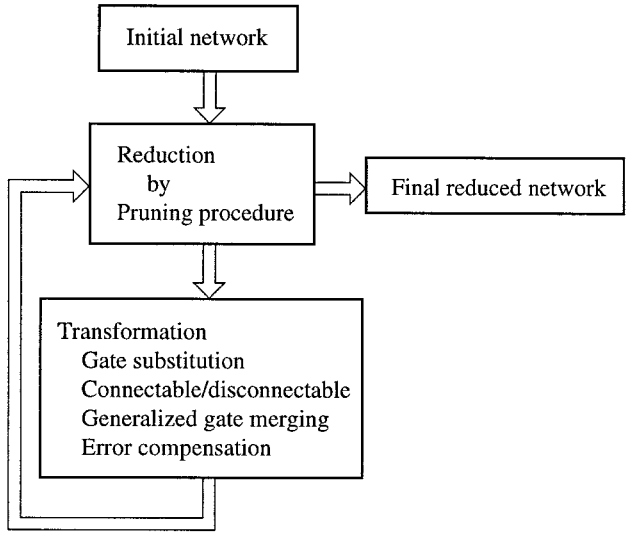

FIGURE 34.2 Basic structure of the transduction method.

The transduction method can reduce a network of many NOR gates into a new network with as few gates as possible. Also, for a given function, the transduction method can be used to generate networks of different configurations, among which we can choose those suitable for the most compact layouts on chips, since chip areas are greatly dependent on connection configurations of networks.

The transduction method was developed in the early 1970s with many reports and summarized in Refs. 9 and 10.

Permissible Functions

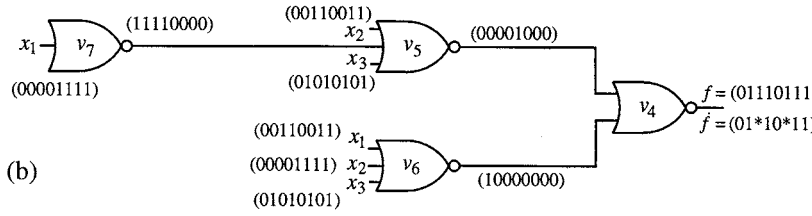
First, let us discuss the concept of permissible functions, which is the core concept for the transduction method.

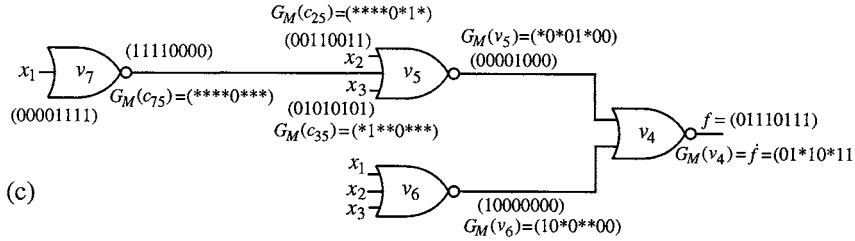
> **Definition 34.1**: If no output function of a network of NOR gates changes by replacing the function realized at a gate (or an input terminal) v_i, or a connection c_{ij}, with a function g, then function g is called a **permissible function** for that v_i, or c_{ij}, respectively. (Note that in this definition, changes in don't-care values, *, of the network output functions do not matter.)

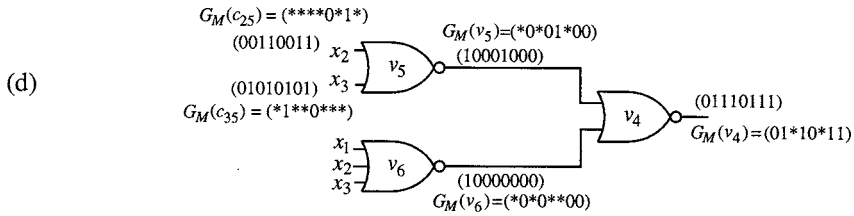
For example, we want to design a network for a function $\dot{f}(x_1, x_2, x_3)$ shown in the truth table in Fig. 34.3(a). Suppose the network in Fig. 34.3(b) is designed by some means to realize function $\dot{f}(x_1, x_2, x_3) = (01*10*11)$. The output function realized at each gate v_i in Fig. 34.3(b) is denoted by $f(v_i)$ in Fig. 34.3(a). The columns in Fig. 34.3(a) are shown horizontally as vectors in Fig. 34.3(b). For example, the

(a) Truth table

x_1	x_2	x_3	$f(v_7)$	$f(v_5)$	$f(v_6)$	$f(v_4)$	$\dot{f}$
0	0	0	1	0	1	0	0
0	0	1	1	0	0	1	1
0	1	0	1	0	0	1	*
0	1	1	1	0	0	1	1
1	0	0	0	1	0	0	0
1	0	1	0	0	0	1	*
1	1	0	0	0	0	1	1
1	1	1	0	0	0	1	1







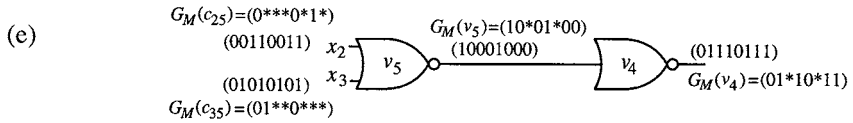


FIGURE 34.3 Permissible functions of a network.

output function of gate v_5, $f(v_5)$, is shown by vector (00001000) placed just outside gate v_5 in Fig. 34.3(b). (Henceforth, columns in a truth table will be shown by vectors in figures for logic networks.) Notice that the function $\dot{f}(x_1, x_2, x_3)$ = (01*10*11) (denoted by f with a dot on top of it) is a function to be realized by a network and generally is incompletely specified, containing don't cares (i.e., *'s), whereas the output function $f(v_4)$ (denoted by f without a dot on top of it) of gate v_4, for example, in the actually realized network in Fig. 34.3(b) is completely specified, containing no * because the value of the function $f(v_4)$ realized at the output of gate v_4 is 0 or 1 for each combination of values of input variables x_1 = (00001111), x_2 = (00110011), and x_3 = (01010101) (assuming x_i contains no *'s in its vector for each i).

Let us find permissible functions at the output of gate v_5. Because the first component of the output $\dot{f}$ of gate v_4 is 0, the first component of the output of gate v_6 is 1, and v_4 is a NOR gate, the first component

of a permissible function at the output of gate v_5 can be 0 or 1 (in other words, *). Because the second component of the output $\dot{f}$ of v_4 is 1 and v_4 is a NOR gate, the second component of a permissible function at the output of v_5 must be 0. Because the third component of $\dot{f}$ at v_4 is *, the third component of a permissible function at the output of gate v_5 can be 0 or 1 (i.e., *). Calculating every component in this manner, we will find that (00001000), (10001000), … are all permissible functions at the output of gate v_5, including the original vector (00001000) shown at v_5 in Fig. 34.3(b). In other words, even if we replace the function $f(v_5)$ realized at gate v_5 by any of these permissible functions, the network output at v_4 still realizes the given function $\dot{f}(x_1, x_2, x_3) = (01*10*11)$.

Notice that the value of the signal at a connection c_{ij} from gate v_i to v_j is always identical to the output value of v_i, but permissible functions for a connection c_{ij} are separately defined from those for a gate v_i. As we shall see later, this is important when gate v_i has more than one output connection. When v_i has only one output connection c_{ij}, permissible functions for v_i are identical to those for c_{ij} (the networks in Fig. 34.3 are such cases and the permissible functions for each c_{ij} are identical to those for v_i); but when v_i has more than one output connection, they are not necessarily identical, as we will see later.

Usually, there is more than one permissible function for each of v_i and c_{ij}. But when we find a set of permissible functions for a gate or connection, all the vectors representing these permissible functions can be expressed by one vector, as discussed in the following. This is convenient for processing.

For example, suppose the output function $f(v_i)$ of a gate v_i in a network has the values shown in the column labeled $f(v_i)$ in the truth table in Table 34.1, where the network has input variables $x_1, x_2, \ldots, x_n$. Let us write this column as a vector, $f(v_i) = (0011 \ldots)$. Suppose any outputs of the network do not change even if this function $f(v_i)$ in Table 34.1 is replaced by $g_1 = (0101 \ldots)$, $g_2 = (0001 \ldots)$, … , or $g_h = (0..1\ldots)$ shown in Table 34.1. In other words, $g_1, \ldots, g_h$ are permissible functions (they are not necessarily all the permissible functions at gate v_i). Then, permissible functions, g_1 through g_h, can be expressed by a single vector $G(v_i) = (0**1 \ldots)$ for the following reasons:

TABLE 34.1 Truth Table

x_1	…	x_{n-1}	x_n	$f(v_i)$	g_1	g_2	g_3	…	g_h	$G(v_i)$
0	…	0	0	0	0	0	0	…	0	0
0	…	0	1	0	1	0	1	…	…	*
0	…	1	0	1	0	0	1	…	…	*
0	…	1	1	1	1	1	1	…	1	1
…	…			…				…		…
…	…			…				…		…
…	…			…				…		…

1. Suppose permissible functions, g_1 and g_2, in Table 34.1 differ only in their second components. In other words, the second component is 1 in g_1 and 0 in g_2. Consequently, even if the second component of the output function of gate v_i is don't care (i.e., *), no network output will change. Thus, (0*01…) (i.e., the vector $g_1 = (0101\ldots)$ with the second component replaced by *) is another permissible function at gate v_i. This can be interpreted as follows. Original permissible functions, g_1 and g_2, can be replaced by the new permissible function, interpreting * to mean 0 or 1; in other words, (0*01…) means $g_1 = (0101\ldots)$ and $g_2 = (0001\ldots)$.
   When there is a permissible function g_j with * in the second component, any other permissible function, g_k, can be replaced by g_k itself with its second component replaced by *, even if other components of g_j may not be identical to those of g_k. For example, a permissible function, $g_3 = (0111\ldots)$, in Table 34.1 can be replaced by another permissible function (0*11…). This is because the value of each component of the output function is independent of any other component (in other words, the value of the output function at each gate for a combination of values of $x_1, x_2, \ldots, x_n$ is completely independent of those for other combinations). This means that if the second component of one permissible function, g_j, is *, then the second components of all other permissible functions can be *, where $1 \le j \le h$.

2. Suppose the first and fourth components are 0 and 1, respectively, in permissible functions, g_1 through g_h.
3. Then, the set of permissible functions, g_1, g_2, …, g_h, for gate v_i can be expressed as a single vector, $G(v_i) = (0{**}1\ldots)$, as shown in the last column in Table 34.1.

Pruning Procedure

From the basic properties of permissible functions just observed, we have the following.

Theorem 34.1: The set of all permissible functions at a gate (or an input terminal) or connection, or any subset of it, can be expressed by a single incompletely specified function.

Henceforth, let G denote the vector that this single incompletely specified function expresses. $G(v_i) = (0{**}1\ldots)$ in Table 34.1 is such an example.

When an arbitrary NOR gate network, such as Fig. 34.3(b), is given, it is generally very difficult to find which connections and/or gates are unnecessary (i.e., redundant) and can be deleted from the network without changing any output functions of the network. But, it is easy to do so by the following fundamental property based on the concept of permissible function:

If a set of permissible functions at a gate, a connection, or an input terminal in a given NOR gate network has no 1-component, in other words, consists of components, 0's, *'s, or a mixture of 0's and *'s, then that gate (and its output connections), connection, or input terminal, is redundant. In other words, it can be removed from the network without changing the network outputs, because the function on this gate, connection, or input terminal, can be the vector consisting of all 0-components (by changing every * to 0); and even if all the output connections of it are removed from the NOR gates whose inputs have these connections, the output functions of the network do not change. (This is because an input to a NOR gate that has more than one input is 0, and it will not affect the output of that NOR gate and hence is removable.)

Based on this property, we can simplify the network by the following procedure:

Procedure 34.2: Pruning procedure

We calculate a set of permissible functions for every gate, connection, and input terminal in a network of NOR gates, starting with the connections connected to output terminals of the network and moving toward the input terminals of the network. Whenever the single vector, G, that this set of permissible functions expresses, is found to consist of only 0 or * components, without 1-components during the calculation, we can delete that gate, connection, or input terminal without changing any network output. □

In this case, it is important to notice that we generally can prune only one of the gates, connections, and input terminals whose G's consist of only 0-components and *-components, as we will see later. If we want to prune more than one of them, we generally need to recalculate permissible functions of all gates, connections, and input terminals throughout the network after pruning one.

Calculation of Sets of Permissible Functions

Let us introduce simple terminology for later convenience. If there is a connection c_{ij} from the output of v_i to the input of v_j, v_i is called an **immediate predecessor** of v_j, and v_j is called an **immediate successor** of v_i. $IP(v_i)$ and $IS(v_i)$ denote the set of all immediate predecessors of v_i and the set of all immediate successors of v_i, respectively. If there is a path of gates and connections from the output of gate v_i to the input of v_j, then v_i is called a **predecessor** of v_j and v_j is called a **successor** of v_i. $P(v_i)$ and $S(v_i)$ denote the set of all predecessors of v_i and the set of all successors of v_i, respectively.

Thus far, we have considered only an arbitrary set of permissible functions at a gate, connection, or input terminal, v_i (or c_{ij}). Now let us consider the set of all permissible functions at v_i (or c_{ij}).

Definition 34.2: The set of all permissible functions at any gate, connection, or input terminal is called the **maximum set of permissible functions**, abbreviated as **MSPF**. This set can be expressed by a single vector, as already shown.

The MSPF of a gate, connection, or input terminal can be found by examining which functions change the network outputs. But MSPFs throughout the network can be far more efficiently calculated by the following procedure.

Procedure 34.3: Calculation of MSPFs in a network

MSPFs of every gate, connection, and input terminal in a network can be calculated, starting from the outputs of the network and moving toward the input terminals, as follows:

1. Suppose we want to realize a network that has input variables $x_1, x_2, \ldots, x_n$ and output functions $\dot{f}_1, \dot{f}_2, \ldots, \dot{f}_m$, that may contain don't-care components (i.e., $*$'s). Then, suppose we have actually realized a network with R NOR gates for these functions by some means and the output gates of this network realize $f_1, f_2, \ldots, f_m$, respectively. ($v_1, v_2, \ldots, v_n$ are regarded as input terminals where $x_1, x_2, \ldots, x_n$ are provided, respectively.) Notice that the output functions, $f_1, f_2, \ldots, f_m$, of this network do not contain any don't-care components because each network output function is 1 or 0 for each combination of values of $x_1, x_2, \ldots, x_n$. Calculate output function $f(v_j)$ at each gate v_j in this network.
   Then, the MSPF, $G_M(v_t)$, of each gate, v_t, whose output function is one of the network outputs, f_k, is set to $\dot{f}_k$ (not f_k, which is a completely specified function at v_t of the actually realized network); that is, $G_M(v_t) = \dot{f}_k$, where $k = 1, 2, \ldots, m$.
2. Suppose a gate v_j in the network has MSPF, $G_M(v_j)$. Then, the MSPF of each connection c_{ij} to the input of this gate can be calculated as follows:
   If a component of $G_M(v_j)$ is 0 and the disjunction (i.e., logical sum, or OR) of the values of the corresponding components of the input connections other than c_{ij} is 0, then the MSPF of input connection c_{ij} is 1. If they are 1 and 0, respectively, the MSPF of c_{ij} is 0. And so on. This operation, denoted by $\square$, is summarized in Table 34.2, where the first operand is a component of $G_M(v_j)$ and the second operand is the disjunction of the component values of the input connections other than c_{ij} and where "-" denotes "undefined" because v_j is a NOR gate and consequently these cases do not occur. Calculate each component of $G_M(v_j)$ in this manner.

TABLE 34.2 Definition of $\square$

	Second operand, $(\vee f(v))$ i.e., $v \in IP(v_j)$ $v \neq v_i$			
$\square$	0	1	*	
First operand, i.e., $G_M(v_j)$	0	1	*	–
	1	0	–	–
	*	*	*	–

– undefined

If this gate v_j has only one input connection c_{ij} (i.e., v_j becomes an inverter), the MSPF of c_{ij} is 1, 0, or $*$ according as $G_M(v_j)$ is 0, 1, or $*$.
This calculation can be formally stated by the following formula:

$$G_M(c_{ij}) = G_M(v_j) \square \left(\bigvee_{\substack{v \in IP(v_j) \\ v \neq v_i}} f(v) \right) \tag{34.1}$$

where if $IP(v_i) = \{v_i\}$ (in other words, gate v_j has only one input connection from v_i), then

$$\left(\bigvee_{\substack{v \in IP(v_j) \\ v \neq v_i}} f(v) \right)$$

is regarded as the function that is constantly 0.

For example, let us calculate MSPFs of the network shown in Fig. 34.3(b) which realizes the function $\dot{f}(x_1, x_2, x_3) = (01*10*11)$ given in Fig. 34.3(a). Because gate v_4 is the network output, this $\dot{f}$ is the MSPF of gate v_4 according to Step 1; that is, $G_M(v_4) = (01*10*11)$ as shown in Fig. 34.3(c). Gate v_4 has input connections realizing functions $f(c_{54}) = (00001000)$ and $f(c_{64}) = (10000000)$. Then, $G_M(c_{54})$, MSPF of c_{54}, can be calculated as follows.The first component of $G_M(c_{54})$ is $*$, using Table 34.2, because the first component of $G_M(v_4)$ is 0 and the first component of $f(c_{64})$ (which, in this case, is the disjunction of the first components of functions realized at connections other than c_{54} because c_{64} is the only connection other than c_{54}) is 1. Proceeding with the calculation based on Table 34.2, we have $G_M(c_{54}) = (*0*01*00)$. ($G_M(c_{54})$, and other $G_M(c_{ij})$'s are not shown in Fig. 34.3.)

3. The MSPF of a gate or input terminal, v_i, can be calculated from $G_M(c_{ij})$ as follows:
If a gate or input terminal, v_i, has only one output connection, c_{ij}, whose MSPF is $G_M(c_{ij})$, then $G_M(v_i)$, MSPF of v_i, is given by:

$$G_M(v_i) = G_M(c_{ij}) \tag{34.2}$$

Thus, we have $G_M(v_5) = G_M(c_{54})$ and this is shown in Fig. 34.3(c).
If v_i has more than one output connection to gates v_j's, then $G_M(v_i)$ is not necessarily identical to $G_M(c_{ij})$. In this case, the MSPF for any gate or input terminal, v_i, in the network is given by the following H:

$$H = (H^{(1)}, H^{(2)}, \ldots, H^{(2^n)}) \tag{34.3}$$

whose w-th component is given by:
$H^{(w)} = *$ if $f_k^{(w)} \supseteq f_k'^{(w)}$ for every k such that $1 \le k \le m$, and
$H^{(w)} = f^{(w)}(v_i)$ if $f_k^{(w)} \supseteq f_k'^{(w)}$ does not hold for some k such that $1 \le k \le m$,
where $f_k' = (f_k'^{(1)}, f_k'^{(2)}, \ldots, f_k'^{(2^n)})$ is the new k-th output function of the network, to which the k-th output of the original network, f_k, changes by the following reconfiguration: insert an inverter between gate or input terminal, v_i, and its immediate successor gates, v_j's (so the immediate successor gates receive $\bar{f}(v_i)$ instead of the original function $f(v_i)$ at v_i). Here, "$\supseteq$," which means $\supset$ or $=$, is used as an ordinary set inclusion, i.e., $* \supseteq 0$, $* \supseteq 1$, $1 \supseteq 1$, and $0 \supseteq 0$, interpreting $*$ as the set of 1 and 0. $f^{(w)}(v_i)$ is the w-th component of $f(v_i)$. Notice that the calculation of the MSPF for v_i, based on Eq. 34.3, is done by finding out the new values of the network outputs, $f_1, f_2, \ldots, f_m$, for the preceding reconfiguration, without using $G_M(c_{ij})$'s. Thus, this calculation is complex and time-consuming.

4. Repeat Steps 2 and 3 until finishing the calculation of MSPFs throughout the network.
Let us continue the example in Fig. 34.3(c), where input variables, x_1, x_2, and x_3, are at input terminals v_1, v_2, and v_3, respectively, and then for the input variables, $x_1 = f(v_1) = (0\,0\,0\,0\,1\,1\,1\,1)$, $x_2 = f(v_2) = (0\,0\,1\,1\,0\,0\,1\,1)$, and $x_3 = f(v_3) = (0\,1\,0\,1\,0\,1\,0\,1)$, the outputs of gates are $f(v_4) = (0\,1\,1\,1\,0\,1\,1\,1)$, $f(v_5) = (0\,0\,0\,0\,1\,0\,0\,0)$, $f(v_6) = (1\,0\,0\,0\,0\,0\,0\,0)$, and $f(v_7) = (1\,1\,1\,1\,0\,0\,0\,0)$. Because gate v_5 has only one output connection, $G_M(v_5) = G_M(c_{54})$, according to Step 3. The first component of $G_M(c_{25})$ (i.e., the MSPF of connection, c_{25}) from input terminal v_2 (which actually has input variable x_2), is $*$ by Table 34.2 because the first component of $G_M(v_5)$ is $*$. The second component of $G_M(v_2)$ is $*$ by Table 34.2 because the second component of $G_M(v_5)$ is 0 and the disjunction of the second components of $f(c_{75})$ and $f(c_{35})$ is $1 \vee 1 = 1$. And so on. □

Derivation of an Irredundant Network Using the MSPF

The following procedure provides a quick means to identify redundant gates, connections, or input terminals in a network. By repeating the calculation of MSPF at all gates, connections, and input terminals throughout the network and the deletion of some of them by the pruning procedure (Procedure 34.2), we can derive an irredundant logic network as follows, where "**irredundant network**" means that if any connection, gate, or input terminal is deleted, some network outputs will change; in other words, every connection, gate, or input terminal is not redundant.

Procedure 34.4: Derivation of an irredundant network using the MSPF

1. Calculate the MSPFs for all gates, connections, and input terminals throughout the network by Procedure 34.3, starting from each output terminal and moving toward input terminals.
2. During Step 1, we can remove a connection, gate, or input terminal, without changing any output function of the network, as follows:
   a. If there exists any input connection of a gate whose MSPF consists of 0's and $*$'s only, remove it. We can remove only one connection because if two or more connections are simultaneously removed, some network outputs may change.
   b. As a result of removing any connection, there may be a gate without any output connections. Then remove such a gate.
3. If a connection and possibly a gate are removed in Step 2, return to Step 1 with the new network. Otherwise, go to Step 4.
4. Terminate the procedure and we have obtained an irredundant network. □

This procedure does not necessarily yield a network with a minimum number of gates or connections, because an irredundant network does not necessarily have a minimum number of gates or connections. But the procedure is useful in many cases because every network with a minimum number of gates or connections must be irredundant and an obtained network may be minimal.

Example 34.1: Let us apply Procedure 34.4 to the network shown in Fig. 34.3(c). Because each gate has only one output connection, $G_M(v_i) = G_M(c_{ij})$ holds for every v_i. Thus, using Eq. 34.1 and $G_M(v_4) = \dot{f}(x_1, x_2, x_3)$, MSPFs are obtained as follows:

$$G_M(c_{54}) = G_M(v_5) = G_M(v_4) \square f(v_6) = (* \ 0 \ * \ 0 \ 1 \ * \ 0 \ 0),$$

$$G_M(c_{64}) = G_M(v_6) = G_M(v_4) \square f(v_5) = (1 \ 0 \ * \ 0 \ * \ * \ 0 \ 0), \text{ and}$$

$$G_M(c_{75}) = G_M(v_7) = G_M(v_5) \square (x_2 \vee x_3) = (* \ * \ * \ * \ 0 \ * \ * \ *)$$

Then we can remove connection c_{75} and consequently gate v_7 by the pruning procedure, as shown in Fig. 34.3(d). For this new network, we obtain the following:

$$f(v_4) = (0 \ 1 \ 1 \ 1 \ 0 \ 1 \ 1 \ 1), f(v_5) = (1 \ 0 \ 0 \ 0 \ 1 \ 0 \ 0 \ 0),$$

$$f(v_6) = (1 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0 \ 0),$$

$$G_M(v_4) = \dot{f}(x_1, x_2, x_3) = (0 \ 1 \ * \ 1 \ 0 \ * \ 1 \ 1),$$

$$G_M(c_{54}) = G_M(v_5) = (* \ 0 \ * \ 0 \ 1 \ * \ 0 \ 0), \text{ and}$$

$$G_M(c_{64}) = G_M(v_6) = G_M(v_4) \square f(v_5) = (* \ 0 \ * \ 0 \ * \ * \ 0 \ 0)$$

Then we can remove connection c_{64} and then gate v_6. Thus, the original network of four gates and nine connections is reduced to the network of two gates with three connections in Fig. 34.3(e), where G_M's are recalculated and no gate can be removed by the pruning procedure. □

Whenever we delete any one connection, gate, or input terminal by the pruning procedure, we need to calculate MSPFs of the new network from scratch. If we cannot apply the pruning procedure, the final logic network is irredundant. This means that if any gate, connection, or input terminal is deleted from the network, some of the network outputs change. It is important to notice that an irredundant network is completely testable; that is, we can detect, by providing appropriate values to the input terminals, whether or not the network contains faulty gates or connections. (A redundant network may contain gates or connections such that it is not possible to detect whether they are faulty.)

Use of MSPFs is time-consuming because the calculation of MSPFs by Eq. 34.3 in Step 3 of Procedure 34.3 is time-consuming and also because we must recalculate MSPFs whenever we delete a connection, gate, or input terminal by the pruning procedure.

Calculation of Compatible Sets of Permissible Functions

Reduction of calculation time is very important for developing a practical procedure. For this purpose, we introduce the concept of a compatible set of permissible functions which is a subset of an MSPF.

Definition 34.3: Let V be the set of all the gates and connections in a network, and e be a gate (or input terminal) v_i or a connection c_{ij} in this set. All the sets of permissible functions for all e's in V, denoted by $G_C(e)$'s, are called **compatible sets of permissible functions** (abbreviated as **CSPFs**), if the following properties hold with every subset T of V:

a. Replacement of the function at each gate or connection, t, in set T by a function $f(t) \in G_C(t)$ results in a new network where each gate or connection, e, such that $e \notin T$ and $e \in V$, realizes function $f(e) \in G_C(e)$.
b. The condition a holds, no matter which function $f(t)$ in $G_C(t)$ is chosen for each t. □

Consequently, even if the function of a gate or connection is replaced by $f(v_t) \in G_C(v_t)$, the function $f(v_u)$ at any other gate or connection still belongs to the original $G_c(v_u)$.

CSPFs at all gates and connections in a network can be calculated as follows.

Procedure 34.5: Calculation of CSPFs in a logic network

CSPFs of all gates, connections, and input terminals in a network can be calculated, starting from the network outputs and moving toward the input terminals, as follows:

1. Suppose we want to realize a network that has inputs $x_1, x_2 \ldots x_n$ and output functions $\dot{f}_1, \dot{f}_2, \ldots, \dot{f}_m$, which may contain don't-care components (i.e., *'s). Then, suppose we have actually realized a network with R NOR gates for these functions by some means.
   Calculate output function $f(v_j)$ at each gate v_j in this network.
   Then, CSPF of each gate, v_t, whose output function is one of the network outputs, f_k, is $G_C(v_t) = \dot{f}_k$ (not f_k), where $k = 1, 2, \ldots, m$.
2. Unlike MSPFs, the CSPF at each gate, connection, or input terminal is highly dependent on the order of processing gates, connections, and input terminals in a network. So, before starting the calculation of CSPFs, we need to determine an appropriate order of processing. Selection of a good processing **order**, denoted by r, is important for the development of an efficient transduction method. Let $r(v_i)$ denote the ordinal number of gates or connections, v_i in this order.
   Suppose a gate v_j in the network has CSPF, $G_C(v_j)$. Then, CSPF of each input connection c_{ij}, $G_C(c_{ij})$, of this gate can be calculated by the following formula which is somewhat different from Eq. 34.1:

$$G_C(c_{ij}) = \{G_C(v_j) \square (\underset{v \in IP(v_j)}{\underset{r(v) > r(v_i)}{\vee}} f(v))\} \# f(v_i) \tag{34.4}$$

by calculating the terms on the right-hand side in the following steps:

a. Calculate the disjunction (i.e., component-wise disjunction) of all the functions $f(v_i)$'s of immediate predecessor gates, v_i's, of the gate v_j, whose ordinal numbers $r(v_i)$'s are greater than the ordinal number $r(v_i)$ of the gate v_i. If there is no such gate v_i, the disjunction is 0.
b. Calculate the expression inside { } in Eq. 34.4 by using Table 34.2 (the definition of □). In this table, $G_C(v_j)$ is used as the first operand, and

$$\left(\bigvee_{\substack{v \in IP(v_j) \\ r(v) > r(v_i)}} f(v) \right)$$

(i.e., the disjunction calculated in Step a) is used as the second operand.
c. Calculate the right-hand side of Eq. 34.4 using Table 34.3, with the value calculated in Step b as the first operand and $f(v_i)$ as the second operand.

TABLE 34.3 Definition of #

First operand, i.e., $G_C(v_j) \square \left(\bigvee_{\substack{v \in IP(v_j) \\ r(v) > r(v_i)}} f(v) \right)$	Second operand, i.e., $f(v_i)$			
	#	0	1	*
	0	0	*	*
	1	*	1	*
	*	*	*	*

For example, suppose gate v_j in Fig. 34.4 has CSPF, $G_C(v_j) = (010^*)$, and input connections c_{ij}, c_{gj}, and c_{hj}, from gates v_i, v_g, and v_h, whose functions are $f(v_i) = (1001)$, $f(v_g) = (0011)$, and $f(v_h) = (0010)$. (Notice that $f(v_a) = f(c_{ab})$ always holds for any gate or input terminal, v_a, no matter whether v_a has more than one output connection.) Suppose we choose an order, $r(v_i) < r(v_g) < r(v_h)$. Then the first component of $G_C(c_{ij})$ is $\{ 0 \square (0 \vee 0) \}\#1$ because the first components of $G_C(v_j)$, $f(v_g)$, $f(v_h)$, and $f(v_i)$, which appear in this order in Eq. 34.4, are 0, 0, 0, and 1, respectively. Using Tables 34.2 and 34.3, this becomes $\{ 0 \square (0 \vee 0) \}\#1 = \{ 0 \square 0 \}\#1 = 1\#1 = 1$. Calculating other components similarly, we have $G_C(c_{ij}) = (10^{**})$. We have $G_C(c_{gj}) = (^*0^{**})$ because the fourth component of $G_C(c_{gj})$, for example, is $\{^* \square 0\}\#1$ since the fourth components of $G_C(v_j)$, $f(v_h)$, and $f(v_g)$ are *, 0, and 1, respectively. In this case, the value of $f(v_i)$ is not considered unlike the calculation of MSPF, $G_M(c_{gj})$, because $f(v_i)$ is not included in Eq. 34.4 due to the order, $r(v_i) < r(v_g)$. Also, we have $G_C(c_{hj}) = (^*01^*)$ because the fourth component of $G_C(c_{hj})$, for example, becomes $\{^* \square 0\}\#0$ since the fourth components of $G_C(v_j)$,

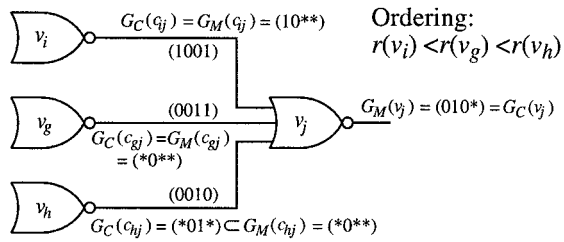

FIGURE 34.4 An example of the calculation of MSPFs and CSPFs.

$$\left(\bigvee_{v \in IP(v_j),\ r(v) > r(v_i)} f(v) \right),$$

and $f(v_h)$ are $*$, 0 (because no gate v such that $r(v) > r(v_h)$), and 0, respectively. In this case, $f(v_i)$ and $f(v_g)$ are not considered.

For comparison, let us also calculate MSPFs by Procedure 34.3. The MSPFs of connections c_{ij}, c_{gj}, and c_{hj} can be easily calculated as $G_M(c_{ij}) = (10^{**})$, $G_M(c_{gj}) = (^*0^{**})$, and $G_M(c_{hj}) = (^*0^{**})$, respectively, as shown in Fig. 34.4. Comparing with the CSPFs, we can find $G_C(c_{ij}) = G_M(c_{ij})$ and $G_C(c_{gj}) = G_M(c_{gj})$. But $G_C(c_{hj})$ is a subset of $G_M(c_{hj})$ (denoted as $G_C(c_{hj}) \subset G_M(c_{hj})$) because the third component of $G_C(c_{hj}) = (^*01^*)$ is 1, which is a subset of the third component, * (i.e., 0 or 1), of $G_M(c_{hj}) = (^*0^{**})$, while other components are identical.

The CSPF and MSPF of a gate, connection, or input terminal can be identical. For the gate with $G_C(v_j) = G_M(v_j) = (010^*)$ shown in Fig. 34.5, for example, we have $G_C(c_{ij}) = G_M(c_{ij}) = (10^{**})$, $G_C(c_{gj}) = G_M(c_{gj}) = (^*0^{**})$, and $G_C(c_{hj}) = G_M(c_{hj}) = (^*01^*)$ with the ordering $r(v_i) < r(v_g) < r(v_h)$.

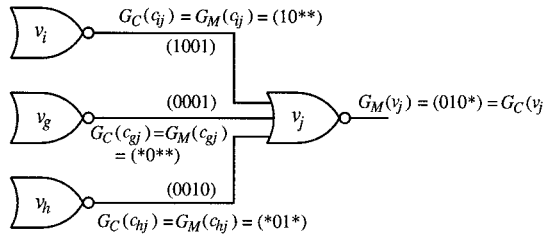

FIGURE 34.5 An example of the calculation of MSPFs and CSPFs.

As can be seen in the third components of G_M's in the example in Fig. 34.4, when gate v_j in a network has more than one input connection whose w-th component is 1 and we have $G_M^{(w)}(v_j) = 0$, the w-th components of MSPFs for all these input connections are $*$'s, as seen in the third components of $G_M(c_{ij})$, $G_M(c_{gj})$, and $G_M(c_{hj})$ in the example in Fig. 34.4. But the w-th components of CSPFs, however, are *'s except for one input connection whose value is required to be 1, as seen in the third components of $G_C(c_{hj})$ in the example in Fig. 34.4. Which input connection is such an input connection depends upon order r. Intuitively, an input connection to the gate v_j from an immediate predecessor gate that has a smaller ordinal number in order r will probably tend to have more *'s in its CSPF and, consequently, have a greater probability for this input connection to be removed.

3. The CSPF of a gate or input terminal, v_i, can be calculated from $G_C(c_{ij})$ as follows.
   If a gate or input terminal, v_i, has only one output connection, c_{ij}, whose CSPF is $G_C(c_{ij})$, then $G_C(v_i)$, CSPF of v_i, is given by

$$G_C(v_i) = G_C(c_{ij}) \tag{34.5}$$

If v_i has more than one output connection, then $G_C(v_i)$ is not necessarily identical to $G_C(c_{ij})$. In this case, the CSPF for any gate or input terminal, v_i, in a network is given by the following:

$$G_C(v_i) = \bigcap_{v_j \in IS(v_i)} G_C(c_{ij}) \tag{34.6}$$

where the right-hand side of Eq. 34.6 is the intersection of $G_C(c_{ij})$'s of output connections, c_{ij}'s, of gate v_i.

Unlike Eq. 34.3 for the case of MSPFs, Eq. 34.6 is simple and can be calculated in a short time.

4. Repeat Steps 2 and 3 until the calculation of CSPFs throughout the network is finished. □

A gate or connection may have different CSPFs if the order r of processing is changed. On the other hand, each gate or connection has a unique MSPF, independent of the order of processing.

Comparison of MSPF and CSPF

It is important to notice the difference in the ways of defining MSPF and CSPF. Any function $f(v_i)$ (or $f(c_{ij})$), that belongs to the MSPF of a gate, connection, or input terminal, v_i (or c_{ij}), can replace the original function realized at this v_i (or c_{ij}) without changing any network output, keeping the functions at all other gates, connections, or input terminals intact. If functions at more than one gate, connection, and/or input terminal are simultaneously replaced by permissible functions in their respective MSPFs, some network outputs may change. In the case of CSPF, simultaneous replacement of the functions at any number of gates, connections, and input terminals by permissible functions in their respective CSPFs does not change any network output.

Example 34.2: This example illustrates that if functions realized at more than one gate, connection, or input terminal are simultaneously replaced by permissible functions in their respective MSPFs, some network outputs may change, whereas simultaneous replacement by permissible functions in their respective CSPFs does not change any network outputs. Let us consider the network in Fig. 34.6(a) where all the gates have the same MSPFs as those in Fig. 34.4. In Fig. 34.6(a), let us simultaneously replace functions (1001), (0011), and (0010) realized at the inputs of gate v_j in Fig. 34.4 by (1000), (0001), and (1001), respectively, such that $(1000) \in G_M(c_{ij}) = (10^{**})$, $(0001) \in G_M(c_{gj}) = (*0^{**})$, and $(1001) \in G_M(c_{hj}) = (*0^{**})$ hold. Then the output function of gate v_j in Fig. 34.6(a) becomes (0110). But we have $(0110) \notin G_M(v_j)$ because the third component 1 is different from the third component 0 of $G_M(v_j)$. So, (0110) is not a permissible function in MSPF, $G_M(v_j)$. But if we replace the function at only one input to gate v_j by a permissible function of that input, the output function of v_j is still a permissible function in MSPF, $G_M(v_j)$. For example, if only (0011) at the second input of gate v_j in Fig. 34.4 is replaced by (0001), the output function of v_j becomes (0100), which is still a permissible function of $G_M(v_j)$, as shown in Fig. 34.6(b).

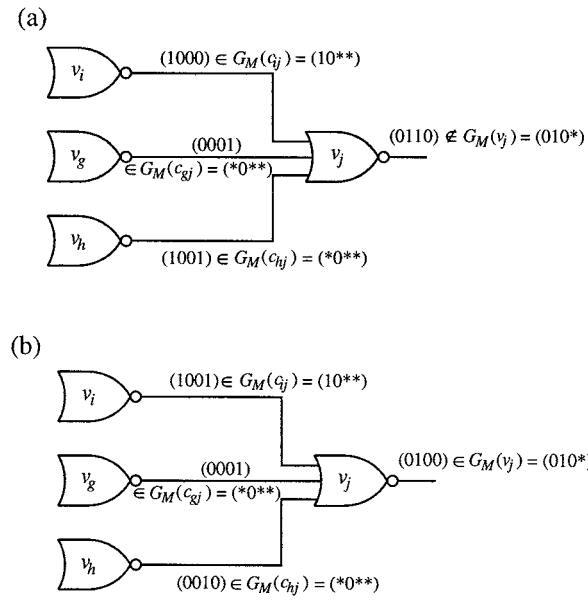

FIGURE 34.6 MSPFs.

If we use CSPF, we can replace more than one function. For example, let us consider the network in Fig. 34.7, where gate v_j has $G_C(v_j)$, the same as $G_C(v_j)$ in Fig. 34.4. The functions at the inputs of gate v_j in Fig. 34.7 belong to CSPFs calculated in Fig. 34.4; in other words, $(1000) \in G_C(c_{ij}) = (10{**})$, $(0001) \in G_C(c_{gj}) = (*0{**})$, and $(1010) \in G_C(c_{hj}) = (*01*)$. Even if all functions (1001), (0011), and (0010) in Fig. 34.4 are simultaneously replaced by these functions, function (0100) realized at the output of gate v_j is still a permissible function in $G_C(v_j)$. □

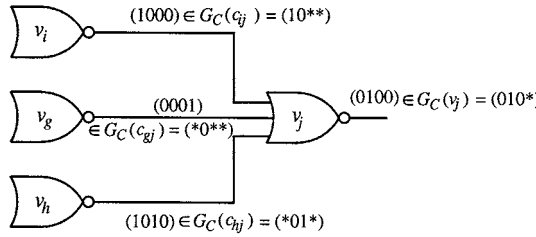

FIGURE 34.7 CSPFs.

Procedures based on CSPFs have the following advantages and disadvantages:

1. For the calculation of CSPFs, we need not use Eq. 34.3 which is time-consuming.
2. Even if a redundant connection is removed, we need not recalculate CSPFs for the new network. In other words, CSPFs at different locations in the network are independent of one another, whereas MSPFs at these locations may not be. Thus, using CSPFs, we can simultaneously remove more than one connection; whereas using MSPFs, we need to recalculate MSPFs throughout the network, whenever one connection is removed.
   If, however, we use CSPFs instead of MSPFs, we may not be able to remove some redundant connections by the pruning procedure because each CSPF is a subset of its respective MSPF and depends on processing order *r*. Because gates with smaller ordinal number in order, *r*, tend to have more ∗-components, the probabilities of removing these gates (or their output connections) are greater. Thus, if a gate is known to be irredundant, or hard to remove, we can assign a larger ordinal number in order *r* to this gate and this will help giving ∗-components to the CSPFs of other gates.
3. The property (2) is useful for developing network transformation procedures based on CSPFs, which will be discussed later.
4. Because each CSPF is a subset of a MSPF, the network obtained by the use of CSPFs is not necessarily irredundant. But if we use MSPFs for pruning after repeated pruning based on CSPFs, then the final network will be irredundant.

For these reasons, there is a tradeoff between the processing time and the effectiveness of procedures.

Transformations

We can delete redundant connections and gates from a network by repeatedly applying the pruning procedure (in other words, by repeating only Step 2, without using Step 3, in Procedure 34.1, the outline of the transduction method). In this case, if MSPF is used, as described in Procedure 34.4, the network that results is irredundant. However, to have greater reduction capability, we developed several transformations of a network. By alternatively repeating the pruning procedure (Step 2 in Procedure 34.1) and transformations (Step 3), we can reduce networks far more than by the use of only one of them.

The following gate substitution procedure is one of these transformations.

Procedure 34.6: Gate substitution procedure

If there exist two gates (or input terminals), v_i and v_j, satisfying the following conditions, all the output connections of v_j can be replaced by the output connections of v_i without changing network outputs. Thus, v_j is removable.

1. $f(v_i) \in G(v_j)$, where $G(v_j)$ is a set of permissible functions of v_j which can be an MSPF or a CSPF.
2. v_i is not a successor of v_j (no loop will be formed by this transformation). □

This is illustrated in Fig. 34.8. The use of MSPFs may give a better chance for a removal than their subsets such as CSPFs, although the calculation of MSPFs is normally time-consuming.

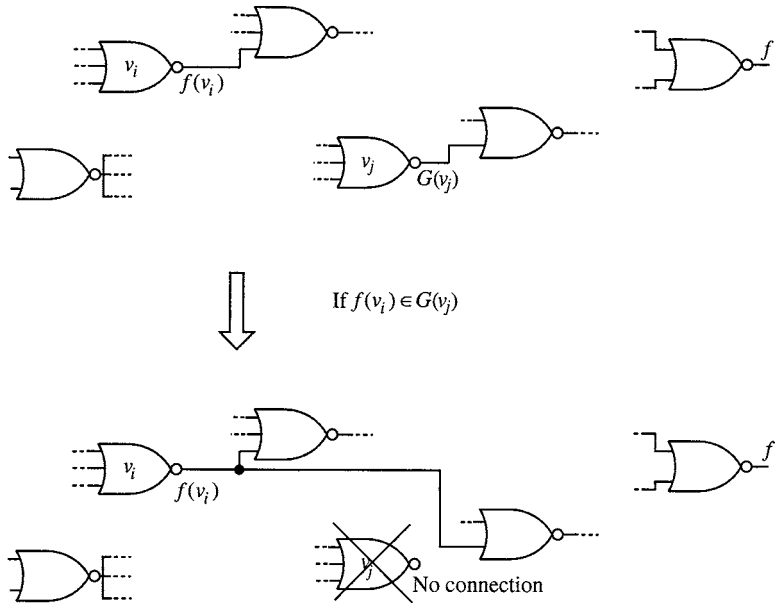

FIGURE 34.8 Gate substitution.

Example 24.3: Let us apply Procedure 34.6 to the network shown in Fig. 34.9(a), which realizes the function $f = \bar{x}_1 x_2 \vee \bar{x}_1 x_3 \vee x_2 x_3$. Functions realized at input terminals and gates are as follows:

$$x_1 = f(v_1) = (0\ 0\ 0\ 0\ 1\ 1\ 1\ 1),\ x_2 = f(v_2) = (0\ 0\ 1\ 1\ 0\ 0\ 1\ 1),$$
$$x_3 = f(v_3) = (0\ 1\ 0\ 1\ 0\ 1\ 0\ 1),$$
$$f(v_4) = (0\ 1\ 1\ 1\ 0\ 0\ 0\ 1),\ f(v_5) = (0\ 0\ 0\ 0\ 1\ 0\ 1\ 0),$$
$$f(v_6) = (1\ 0\ 0\ 0\ 1\ 1\ 0\ 0),\ f(v_7) = (1\ 1\ 1\ 1\ 0\ 0\ 0\ 0),$$
$$f(v_8) = (0\ 1\ 1\ 1\ 0\ 0\ 0\ 0),\ \text{and}\ f(v_9) = (1\ 0\ 0\ 0\ 1\ 0\ 0\ 0)$$

Let us consider the following two different approaches.

1. Transformation by CSPFs: CSPFs for the gates are calculated as follows if at each gate, the input in the lower position has higher processing order than the input in the upper position:

$$G_C(v_4) = (0\ 1\ 1\ 1\ 0\ 0\ 0\ 1),\ G_C(v_5) = (*\ 0\ 0\ 0\ *\ *\ 1\ 0),$$
$$G_C(v_6) = (1\ 0\ 0\ 0\ 1\ 1\ *\ 0),\ G_C(v_7) = (*\ *\ 1\ *\ *\ *\ 0\ *),$$
$$G_C(v_8) = (0\ 1\ *\ *\ 0\ 0\ *\ *),\ \text{and}\ G_C(v_9) = (1\ 0\ *\ *\ *\ *\ *\ *)$$

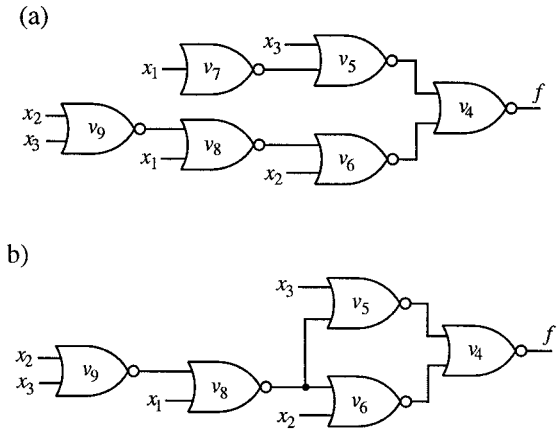

FIGURE 34.9 An example of gate substitution.

Because $f(v_8) \in G_C(v_7)$, the network in Fig. 34.9(b) is obtained by substituting connection c_{86} for c_{75}. Then, gate v_7 is removed, yielding a simpler network.

2. Transformation by MSPFs: In this case, the calculation of MSPFs is very easy because each gate in Fig. 34.9(a) has only one output connection. MSPFs for gates are as follows:

$$G_M(v_4) = (0\ 1\ 1\ 1\ 0\ 0\ 0\ 1),\ G_M(v_5) = (*\ 0\ 0\ 0\ *\ *\ 1\ 0),$$
$$G_M(v_6) = (1\ 0\ 0\ 0\ *\ 1\ *\ 0),\ G_M(v_7) = (*\ *\ 1\ *\ *\ *\ 0\ *),$$
$$G_M(v_8) = (0\ 1\ *\ *\ *\ 0\ *\ *),\ \text{and}\ G_M(v_9) = (1\ 0\ *\ *\ *\ *\ *\ *)$$

Here, $G_M(v_7) = G_C(v_7)$, and we get the same result in Fig. 34.9(b).

This result cannot be obtained by the gate merging to be discussed later. □

This gate substitution can be further generalized. In other words, a gate, v_j, can be substituted by more than one gate, instead of by only one gate v_i in Procedure 34.6.

If we connect a new input to a gate or disconnect an existing input from a gate, the output of the gate may be modified. But if the new output is still contained in the set of permissible functions at this gate, the modification does not change the network outputs. By applying this procedure, we can change the network configuration and possibly can remove connections and/or gates. Even if we cannot reduce the network, a modification of the network is useful for further applications of other transformations. We have such a procedure if the connectable condition stated in the following or the disconnectable condition stated after the following is satisfied.

Procedure 34.7: Connectable condition

Let $G(v_j)$ be a set of permissible functions for gate v_j which can be an MSPF or a CSPF. We can add a connection from input terminal or gate, v_i, to v_j without changing network outputs, if the following conditions are satisfied:

1. $f^{(w)}(v_i) = 0$ for all w's such that $G^{(w)}(v_j) = 1$.
2. v_i is not a successor of v_j (no loop will be formed by this transformation).

This is illustrated in Fig. 34.10.

This transformation procedure based on the connectable condition can be extended into the forms that can be used to change the configuration of a network. When we cannot apply any transformations to a given network, we may be able to apply those transformations after these extended transformations.

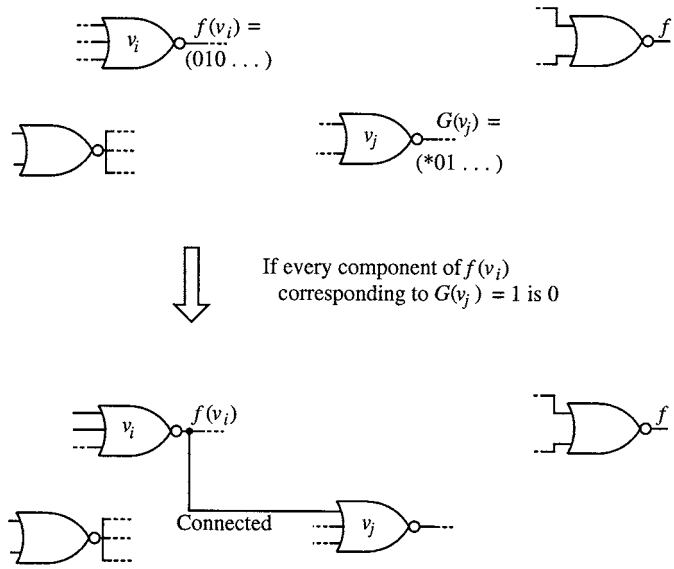

FIGURE 34.10 Connectable condition.

Example 34.4: If we add two connections to the network in Fig. 34.11(a), as shown in bold lines in Fig. 34.11(b), then the output connection (shown in a dotted line) of gate v_{12} becomes disconnectable and v_{12} can be removed. Then we have the network shown in Fig. 34.11(c). □

Procedure 34.8: Disconnectable condition

If we can find a set of inputs of gate v_k such that the disjunction of the w-th component of the remaining inputs of v_k is 1 for every w satisfying $G^{(w)}(v_k) = 0$, then this set of inputs can be deleted, as being redundant, without changing network outputs. □

Procedures 34.7 and 34.8 will be collectively referred as the **connectable/disconnectable conditions** (or **procedures**).

In the network in Fig. 34.12(a), x_2 is connectable to gate v_6, and x_1 is connectable to gate v_7. After adding these two connections, the outputs of v_6 and v_7 become identical, so v_7 can be removed as shown in Fig. 34.12(b). This transformation is called **gate merging**. This can be generalized, based on the concept of permissible functions, as follows.

Procedure 34.9: Generalized gate merging

1. Find two gates, v_i and v_j, such that the intersection, $G_C(v_i)G_C(v_j)$, of their CSPFs is not empty, as illustrated in Fig. 34.13.
2. Consider an imaginary gate, v_{ij}, whose CSPF is to be $G_C(v_i)G_C(v_j)$.
3. Connect all the inputs of gate v_i and v_j to v_{ij}. If v_{ij} actually realizes a function in $G_C(v_i)G_C(v_j)$, then v_{ij} can be regarded as a merged gate of v_i and v_j. Otherwise, v_i and v_j cannot be merged without changing network outputs in this generalized sense.
4. If v_{ij} can replace both v_i and v_j, then remove redundant inputs of v_{ij}. □

Next, let us outline another transformation, called the **error compensation procedure**. In order to enhance the gate removal capability of the transduction method, the concept of permissible function is generalized to "a permissible function with errors."[5] Because the transformation procedures based on the error compensation are rather complicated, we outline the basic idea of these procedures along with an example, as follows:

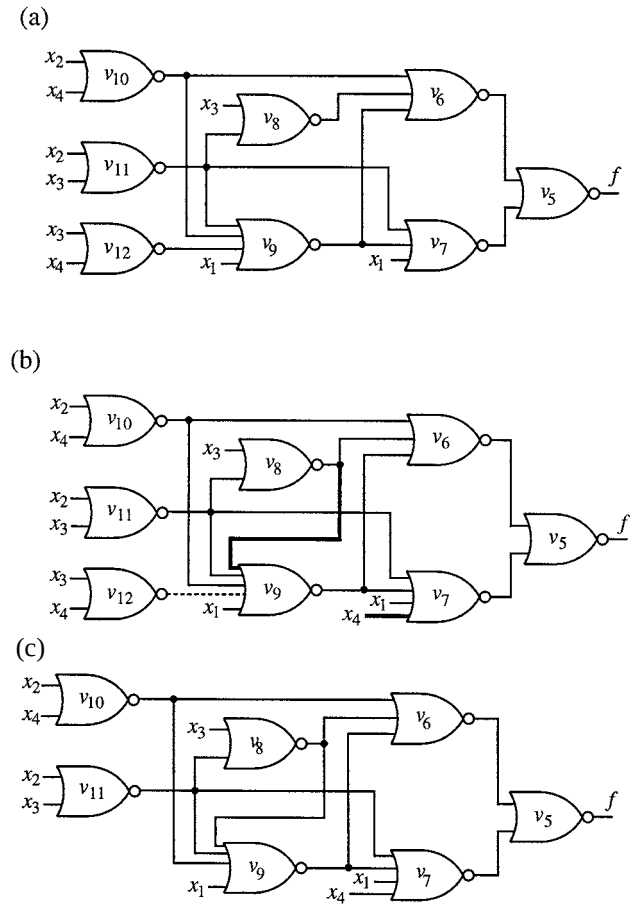

FIGURE 34.11 An example of the connectable/disconnectable conditions.

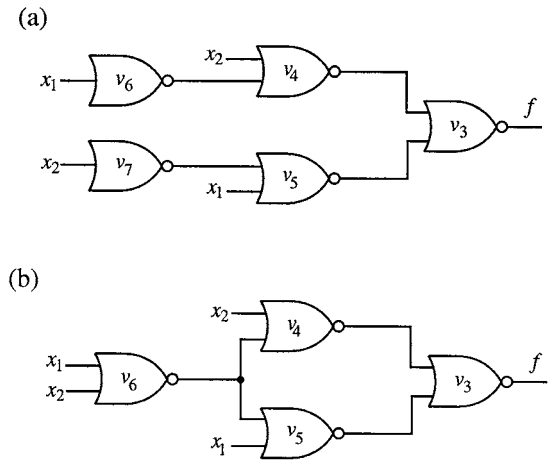

FIGURE 34.12 An example of gate merging.

1. Remove an appropriate gate or connection from the network.

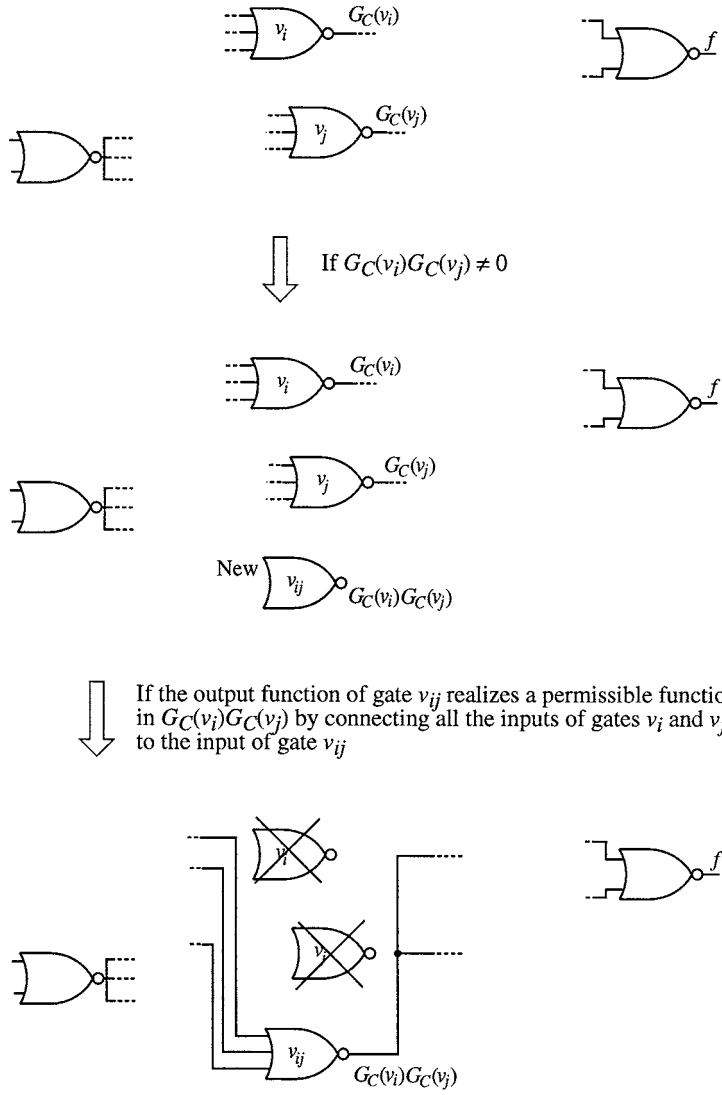

FIGURE 34.13 Generalized gate merging.

2. Calculate errors in components of functions at gates or connections that are caused by the removal of the gate or connection, and then calculate permissible functions with errors throughout the network. These permissible functions with errors represent functions with erroneous components (i.e., components whose values are erroneous) as well as ordinary permissible functions that have no erroneous components.
3. Try to compensate for the errors by changing the connection configuration of the network. In order to handle the errors, the procedures based on ordinary permissible functions are modified.

Example 34.5: Figure 34.14(a) shows a network whose output at gate v_5 realizes

$$(1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 1\ 0\ 1\ 1\ 0\ 1)$$

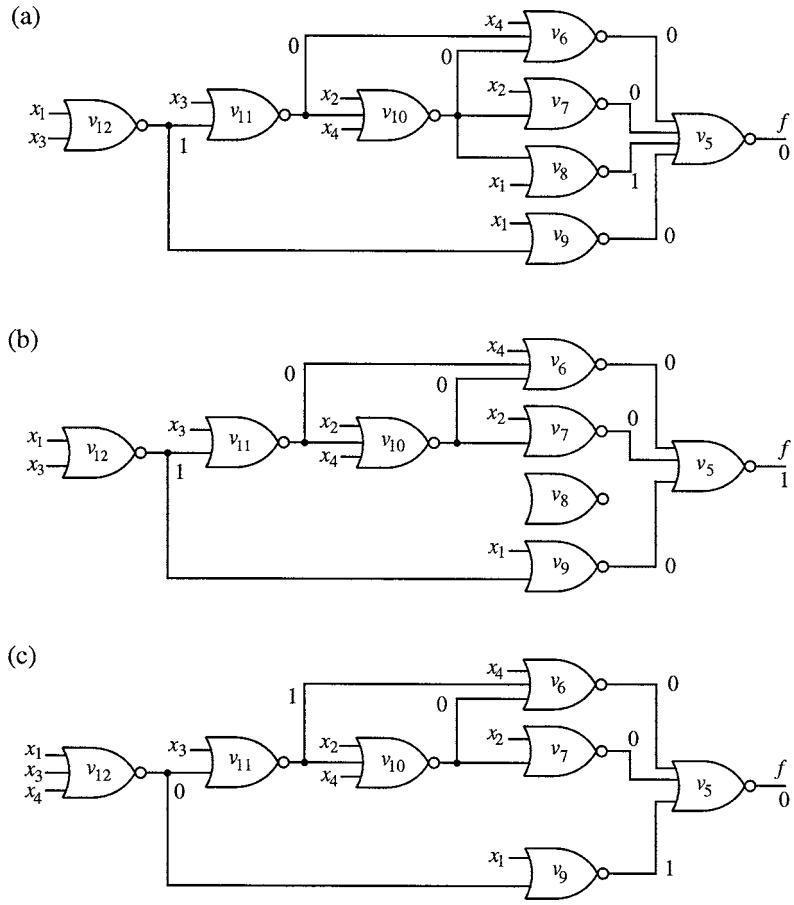

FIGURE 34.14 An example of error compensation.

In order to reduce the network, let us remove gate v_8, having the network in Fig. 34.14(b) whose output at gate v_5 is (1 0 0 0 0 $\underline{1}$ 0 0 0 0 1 0 1 1 0 1)

Note that the outputs of the two networks differ only in the 6-th components (underlined). We want to compensate for the value of the erroneous component of the latter network by adding connections. Functions realized at the input terminals v_1 through v_4 and gates v_5 through v_{12} in the original network in Fig. 34.14(a) are as follows:

$$
\begin{aligned}
x_1 = f(v_1) &= (0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 1\ 1\ 1\ 1\ 1\ 1\ 1\ 1)\\
x_2 = f(v_2) &= (0\ 0\ 0\ 0\ 1\ 1\ 1\ 1\ 0\ 0\ 0\ 0\ 1\ 1\ 1\ 1)\\
x_3 = f(v_3) &= (0\ 0\ 1\ 1\ 0\ 0\ 1\ 1\ 0\ 0\ 1\ 1\ 0\ 0\ 1\ 1)\\
x_4 = f(v_4) &= (0\ 1\ 0\ 1\ 0\ 1\ 0\ 1\ 0\ 1\ 0\ 1\ 0\ 1\ 0\ 1)\\
f(v_5) &= (1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 1\ 0\ 1\ 1\ 0\ 1)\\
f(v_6) &= (0\ 0\ 0\ 0\ 1\ 0\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 1\ 0)\\
f(v_7) &= (0\ 1\ 0\ 1\ 0\ 0\ 0\ 0\ 1\ 1\ 0\ 1\ 0\ 0\ 0\ 0)\\
f(v_8) &= (0\ 1\ 0\ 1\ 1\ 1\ 1\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0)\\
f(v_9) &= (0\ 0\ 1\ 1\ 0\ 0\ 1\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0)\\
f(v_{10}) &= (1\ 0\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 1\ 0\ 0\ 0\ 0\ 0)\\
f(v_{11}) &= (0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 1\ 1\ 0\ 0\ 1\ 1\ 0\ 0)\\
f(v_{12}) &= (1\ 1\ 0\ 0\ 1\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0)
\end{aligned}
$$

The values of the 6-th component (i.e., the values corresponding to the input combination $x_1 = x_3 = 0$ and $x_2 = x_4 = 1$) are shown in Figs. 34.14(a) and (b). Components of vectors representing CSPFs can be calculated independently, so we calculate CSPFs for all components except the 6-th component (shown by "-") of the network in Fig. 34.14(b), as follows:

$$
\begin{aligned}
G_C(v_5) &= (1\ 0\ 0\ 0\ 0 - 0\ 0\ 0\ 0\ 1\ 0\ 1\ 1\ 0\ 1)\\
G_C(v_6) &= (0\ *\ *\ *\ 1 - 1\ *\ *\ *\ 0\ *\ 0\ 0\ 1\ 0)\\
G_C(v_7) &= (0\ 1\ *\ 1\ *\ - *\ *\ 1\ 1\ 0\ 1\ 0\ 0\ *\ 0)\\
G_C(v_9) &= (0\ *\ 1\ *\ *\ - *\ 1\ *\ *\ 0\ *\ 0\ 0\ *\ 0)\\
G_C(v_{10}) &= (1\ 0\ *\ 0\ 0 - 0\ *\ 0\ 0\ 1\ 0\ *\ *\ 0\ *)\\
G_C(v_{11}) &= (0\ *\ *\ *\ 0 - 0\ *\ 1\ *\ 0\ *\ 1\ *\ 0\ *)\\
G_C(v_{12}) &= (1\ *\ 0\ *\ 1 - *\ 0\ 0\ *\ *\ *\ 0\ *\ *\ *)
\end{aligned}
$$

If we can change the 6-th component of any of $f(v_6)$, $f(v_7)$, or $f(v_9)$ (i.e., immediate predecessors of gate v_5) from 0 to 1, the error in the network output can be compensated, as can be seen in Fig. 34.14(b) where v_8 is removed. The value 0 in the 6-th component of the output at gate, v_6, v_7, or v_9, is due to $x_4 = 1$, $x_2 = 1$, or $f(v_{12}) = 1$, respectively. If we want to change the output of v_9 from 0 to 1, the 6-th component of $f(v_{12})$ must be 0. If we can change the output of v_{12} to any function in the set of permissible functions

$$H = (1\ *\ 0\ *\ 1\ 0\ *\ 0\ 0\ *\ *\ *\ 0\ *\ *\ *)$$

that is $G_C(v_{12})$ except the 6-th component specified to 0, the error will be compensated. We can generate such a function by connecting x_4 to gate v_{12} and consequently by changing the output of v_{12} into

$$(1\ 0\ 0\ 0\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0\ 0)$$

which is contained in H. The network obtained is shown in Fig. 34.14(c). Thus, the network with 8 gates and 20 connections shown in Fig. 34.14(a) is reduced to the network with 7 gates and 18 connections in Fig. 34.14(c). □

Let us describe the error compensation procedure illustrated by Example 34.5:

1. Remove a gate or a connection from a given network N, having a new network N'.
2. Calculate the erroneous components in the outputs of network N'.
3. Calculate the components of vectors representing MSPFs or CSPFs for the functions realized at the remaining gates and connections, corresponding to all error-free components of the outputs of N'.
4. Compensate for the errors by adding or removing connections.

This procedure can remove gates and connections in a more systematic manner than the other transformation procedures discussed so far.

34.3 Various Transduction Methods

In addition to **gate substitution**, **connectable/disconnectable conditions**, **generalized gate merging**, and **error compensation**, outlined thus far, some known transformations can be generalized for efficient processing, using permissible functions. In the gate merging procedure, for example, a permissible function which is common to two gates, v_i and v_j, can be easily found. Without permissible functions, the transformations would be excessively time-consuming.

We can have different transduction methods by combining different transformations and the pruning procedure. In other words, we can have different transduction methods based on different orders in processing gates, connections, and components of MSPFs or CSPFs.

These transduction methods can be realized in Fig. 34.2, which illustrates the basic structure of the transduction method outlined in Procedure 34.1. We can use these transduction methods in the following different manners:

1. An initial network can be designed by any conventional logic design method. Then we apply the transduction methods to such an initial network. The transduction methods applied to different initial networks usually lead to different final networks.
2. Instead of applying a transduction method only once, we can apply different transduction methods to an initial network in sequence. In each sequence, different or identical transduction methods can be applied in different orders. This usually leads to many different final networks.

Thus, if we want to explore the maximum potential of the transduction methods, we need to use them in many different ways, as explained in 1 and 2.[3,4]

Computational Example of the Transduction Method

Let us show a computational example of the transduction method. Suppose the initial network, which realizes a four-variable function, given as illustrated in Fig. 34.15(a), and this function has a minimal network shown in Fig. 34.15(b) (its minimality is proved by the integer programming logic design method). Beginning with the initial network of 12 gates shown in Fig. 34.15(a), the transduction method with error-compensation transformation (this version was called NETTRA-E3) produced the tree of solutions shown in Fig. 34.16. The size of the tree can be limited by the program parameter, NEPMAX.[6] (In Fig. 34.16, NEPMAX was set to 2. If set to 8, we will have a tree of 81 networks). The notation "*a*/*b*:*c*" in Fig. 34.16 means a network numbered *a* (numbered according to the order of generation), consisting of *b* gates and *c* connections, and a line connecting a larger network with a smaller one means that the smaller is derived, treating the larger as an initial network. In Fig. 34.16, it is important to notice that while some paths lead to terminal nodes representing minimal networks, others lead to terminal nodes representing networks not very close to the minimal. By comparing the numbers of gates and connections in the networks derived at the terminal nodes of this solution tree, a best solution can be found.

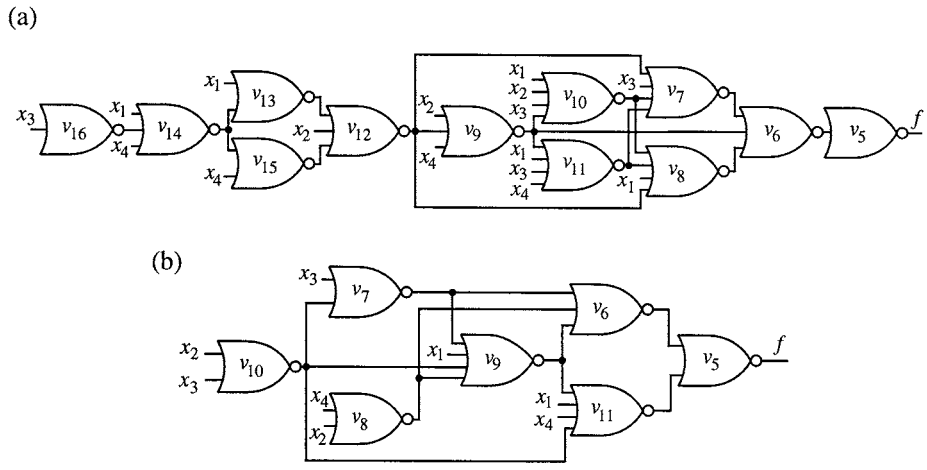

FIGURE 34.15 Initial and final networks for Fig. 34.6.

Intermediate solutions are logic networks with different connection configurations of negative gates, so some of them may be more appropriate for layout than others.

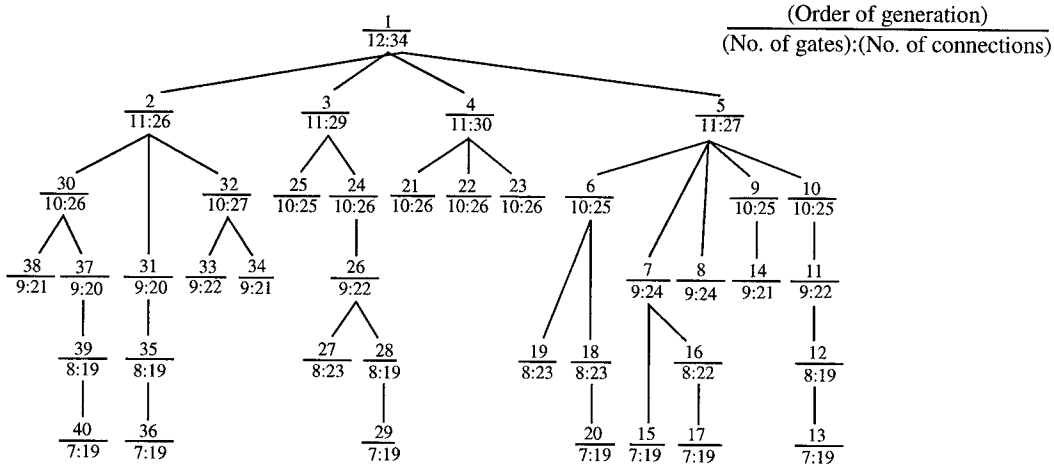

FIGURE 34.16 A tree of solutions generated by the transduction method based on error compensation.

34.4 Design of Logic Networks with Negative Gates by the Transduction Method

The transduction method has been described for the logic networks of NOR gates for the sake of simplicity, but it can be applied to logic networks of other types of gates, such as MOS logic gates and a mixture of AND gates and OR gates, tailoring its basic concepts (i.e., permissible functions and transformation). In this sense, it is important to understand what features different types of logic gates and consequently corresponding transistor circuits have in terms of logic operations and network transformations. In order to test the feasibility of design of logic networks with negative gates (MOS logic gates are negative gates) by the transduction method, a few synthesizers, called **SYLON** (an acronym for SYnthesis of LOgic Networks), were developed by modifying the transduction method.[1,2,7,8,11,12]

Some SYLON logic synthesizers consist of a mixture of technology-dependent optimization and technology-independent optimization. Here, let us outline **SYLON-REDUCE**,[7] a logic synthesizer which is of totally technology-dependent optimization and is more algorithmic, wherein a logic network is processed in its target technology throughout the execution of REDUCE. REDUCE reduces an initial network, using permissible functions, where in order to make each logic gate easily realizable as a MOS logic circuit, each logic gate throughout the execution of REDUCE is a negative gate that satisfies prespecified constraints on the maximum numbers of MOSFETs connected in series in each path and the maximum number of parallel paths. The reduction is done by repeatedly resynthesizing each negative gate. In other words, the outputs of some candidate gates or network inputs are connected to a gate under resynthesis and the connection configuration inside the gate is restructured, reducing the complexity of the gate and disconnecting unnecessary candidate gates or network inputs. The resynthesized cell is adopted if it has no more MOSFETs than the old gate and does not violate the constraints on the complexity (i.e., the specified maximum number of MOSFETs connected in series or the specified maximum number of parallel paths) otherwise, it is discarded, restoring the old gate. This resynthesis of each gate is repeated until no improvement can be done. Thus, the network transformation is done in a more subtle manner than the original transduction method. The result is a network where each gate still satisfies the same constraints on the complexity and contains no more MOSFETs than the corresponding gate in the original network and the connection configuration of the network may be changed.

35.1 Introduction

ECL, which stands for emitter-coupled logic, is based on bipolar transistors and is currently the logic family with the highest speed and a high output power capability, although power consumption is also the highest. ECL is more complicated to fabricate, covers a larger chip area, and is more expensive than any other logic family. As the speed of CMOS improves, ECL is less often used but is still useful for the cases where high speed, along with large output power, are necessary, such as high-speed transmission over communication lines. ECL has three types of transistor circuits: standard ECL logic gates, their modification with wired logic, and ECL series-gating.[4,6,10,13]

35.2 Standard ECL Logic Gates

A standard ECL logic gate is a stand-alone logic gate, and logic networks can be designed using many as building blocks. Its basic circuit is shown in Fig. 35.1. ECL has unique logic capability, as explained in the following.

The logic operation of the ECL gate shown in Fig. 35.1 is analyzed in Fig. 35.2, where the input z in Fig. 35.1 is eliminated for simplicity. The resistors connected to the bases of transistors, T_x and T_y, are for protecting these transistors from possible damage due to heavy currents through a transistor, but not for logic operations, and can be eliminated if there is no possibility for an excessively heavy current to flow. When input x has a high voltage representing logic value 1 and y has a low voltage representing logic value 0, transistor T_x becomes conductive, T_y becomes non-conductive, and a current flows through T_x and resistor R_1, as illustrated in Fig. 35.2(a). In this case the voltage at the emitter of transistor T_r becomes higher than –4 V due to the current through resistor R_p, as shown. Consequently, the voltage at this emitter becomes higher and the voltage at its base becomes not sufficiently high against its emitter to make T_r conductive, so there is no current through T_r and resistor R_2. Consequently, transistor T_f has a high voltage at its base, which makes T_f conductive, and output f has a high voltage representing logic value 1. On the other hand, transistor T_g is almost non-conductive (actually a small current flows, but let us ignore it for simplicity), since its base has a low voltage due to the voltage drop developed across resistor R_1 by the current shown. Thus, output g has a low voltage representing logic value 0.

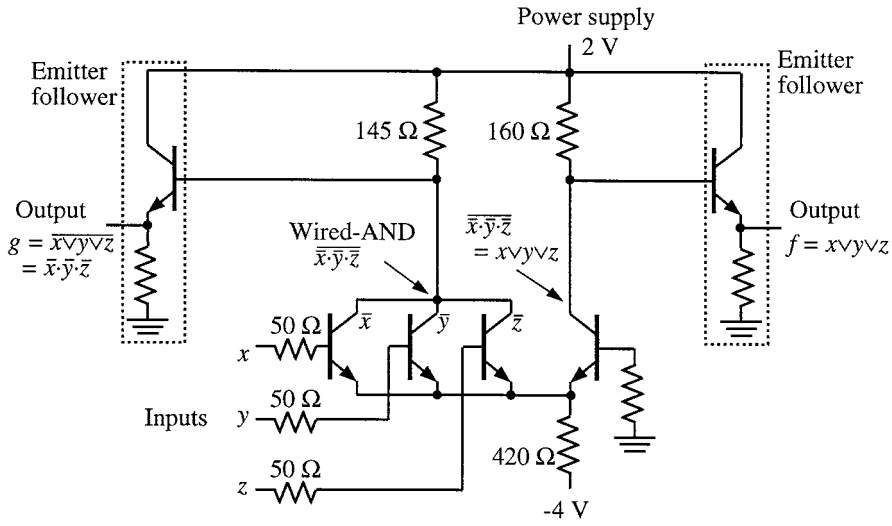

FIGURE 35.1 Basic circuit of standard ECL logic gate.

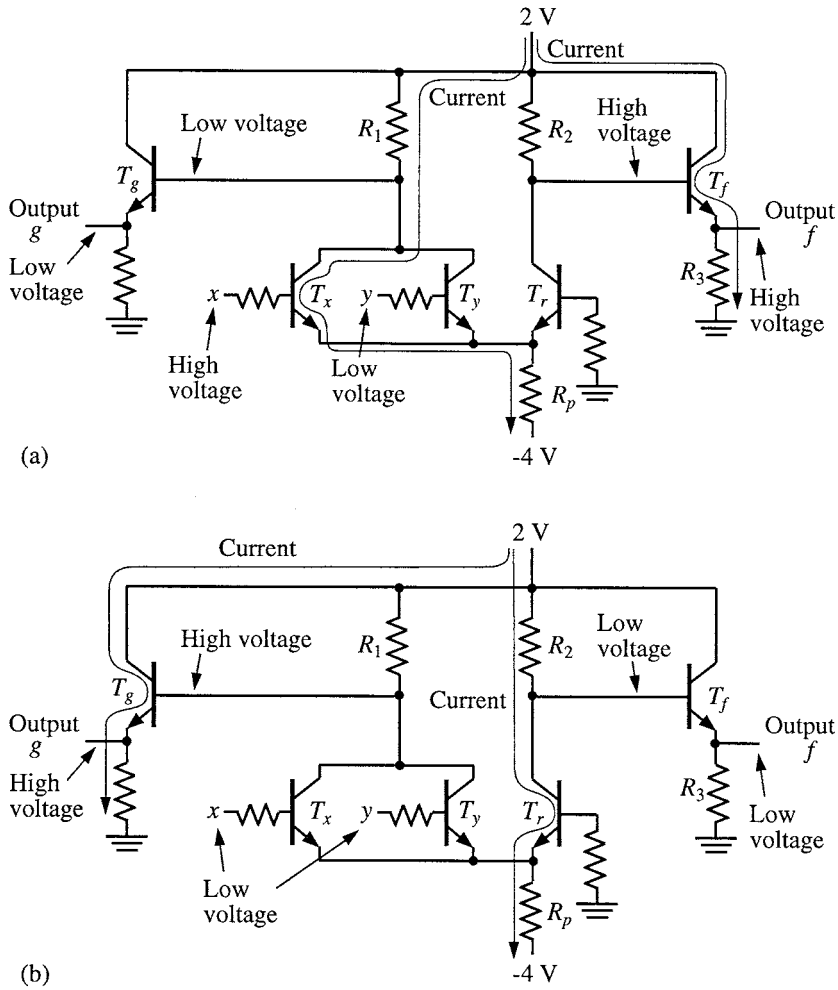

FIGURE 35.2 Logic operation of ECL gate in Fig. 35.1.

Even when y (instead of x), or both x and y, has a high voltage, the above situation is not changed, except for the current through T_y.

Next, suppose that both inputs x and y have low voltages, as shown in Fig. 35.2(b). Then there is no current through resistor R_1. Since the base of transistor T_r has a higher voltage than its emitter (0 V at the base and –0.8 V at the emitter), a current flows through R_2 and T_r, as illustrated in Fig. 35.2(b). Thus, T_f has a low voltage at its base and becomes almost non-conductive (more precisely speaking, less conductive). Output f has, consequently, a low voltage, representing logic value 0. Transistor T_g has a high voltage at its base and becomes conductive. Thus, output g has a high voltage, representing logic value 1.

Therefore, a current flows through only one of R_1 and R_2, switching quickly between these two paths. Notice that resistor R_p in Fig. 35.2 which is connected to a power supply of minus voltage is essential for this current steering because the voltage at the top end of R_p determines whether T_r becomes conductive or not. The emitter followers (shown in the dot-lined rectangles in Fig. 35.1) can deliver heavy output currents because an output current flows only through either transistor T_f or T_g and the on-resistance of the transistor is low.

The above analysis of Fig. 35.2 leads to the truth table in Table 35.1. From this table, the network in Fig. 35.2 has two outputs: $f = x \vee y$ and $g = \overline{x \vee y}$.

TABLE 35.1 Truth Table for Fig. 35.2

Inputs		Outputs	
x	y	f	g
0	0	0	1
0	1	1	0
1	0	1	0
1	1	1	0

In a similar manner, we can find that the ECL gate in Fig. 35.1 has two outputs: $f = x \vee y \vee z$ and $g = \overline{x \vee y \vee z}$.

The gate is denoted by the symbol shown in Fig. 35.3. The simultaneous availability of OR and NOR as the double-rail output logic, with few extra components, is the unique feature of the ECL gate, making its logic capability powerful.

FIGURE 35.3 Symbol for the standard ECL logic gate of Fig. 35.1.

Emitter-Dotting

Suppose we have the emitter follower circuit shown in Fig. 35.4(a) (also shown in the dot-lined rectangles in Fig. 35.1), as part of an ECL logic gate. Its output function, f, at the emitter of the bipolar transistor is 1 when the voltage at the emitter is high (i.e., the bipolar transistor in (a) is conductive), and f is 0 when the voltage at the output terminal is low (i.e., the bipolar transistor in (a) is non-conductive). Then, suppose there is another alike circuit whose output function at the emitter is g. If the emitters of these two circuits are tied together as shown in Fig. 35.4(b), the new output function at the tied point is $h = f \vee g$, replacing the original functions, f and g. This connection is called **emitter-dotting**, realizing **Wired-OR**. The tied point represents the new function $f \vee g$ because if both transistors, T_1 and T_2, are non-conductive, the voltage at the tied point is low; otherwise (i.e., if one of T_1 and T_2, or both, is conductive), the voltage at the tied point is high.

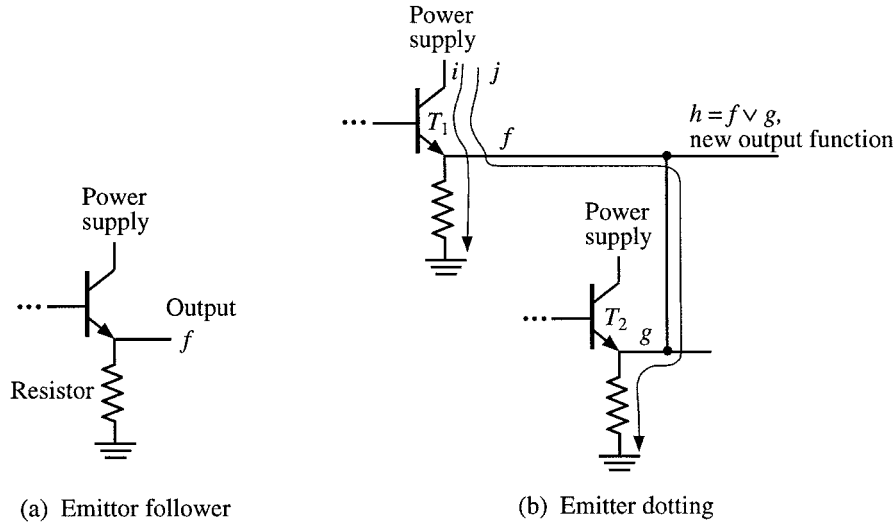

FIGURE 35.4 Emitter-dotting.

Wired-OR is an important feature of the ECL gate. The ECL gate in Fig. 35.1 has two emitter followers: one for f and the other for g. As shown in Fig. 35.5, the OR of the outputs can be realized without using an extra gate, simply by tying together these outputs. This is very convenient in logic design. **If one output is Wired-ORed with another ECL gate, it does not express the original function. And it cannot be further Wired-ORed to other gates if we want to realize Wired-OR with the original function.** But if the same output is repeated by adding an emitter follower inside the gate, as shown in Fig. 35.6 (i.e., the emitter follower inside a dot-lined rectangle in Fig. 35.1), then the new output can be Wired-ORed with another gate output or connected without Wired-OR to the succeeding gates. In the ECL gate at the top position in Fig. 35.6, for example, the first output $f = x \vee y \vee z$ is connected to gates in the next level, while the same f in the second output is used to produce the output $\overline{u \vee v} \vee x \vee y \vee z$ by Wired-ORing with the output of the second ECL gate.

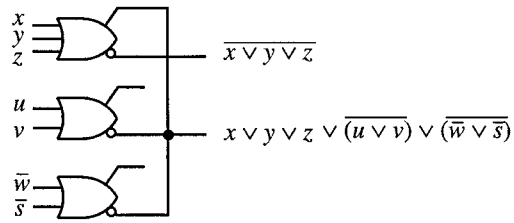

FIGURE 35.5 Wired-OR of ECL gates.

Design of a Logic Network with Standard ECL Gates

An ECL gate network can be designed, starting with a network of only NOR gates, for the following reason. Consider a logic network of ECL logic gates shown in Fig. 35.7(a), where Wired-ORs are included. This network can be converted into the network without Wired-OR shown in (b) by directly connecting connections in each Wired-OR to the inputs of a NOR gate without changing the outputs at gates 4 and 5, possibly sacrificing the maximum fan-in restriction. Then, two NOR outputs of gate 2 in (a), for example, can be combined into one in (b). Then, this network can be converted into the network shown

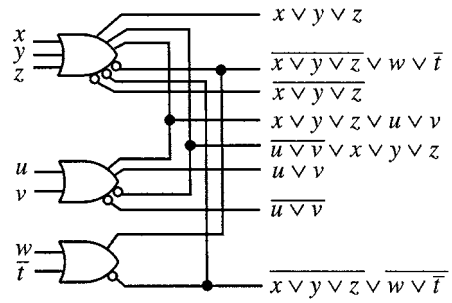

FIGURE 35.6 Multiple-output ECL gates for Wired-OR.

in (c) by eliminating OR outputs of all gates 1, 2, and 3 in (b), and connecting inputs of these gates directly to gates 4 and 5. Thus, the network in (c) that expresses the same outputs as the network in (a) consists of NOR gates only (i.e., the outputs of gates 4 and 5 in (c) are the same as those in (a)), possibly further sacrificing the maximum fan-in restriction at some gates. Notice that in this conversion, the number of gates does not change or decreases (if an ECL gate, like gate 1 in (c), has no outputs used, it can be deleted from (c)). Thus, from the given network of standard ECL gates with Wired-ORs, we can derive a NOR network of the same or fewer number of gates, possibly with greater fan-in at some gates, as shown in Fig. 35.7(d). Even if each gate has many NOR outputs or OR outputs, the situation does not change.

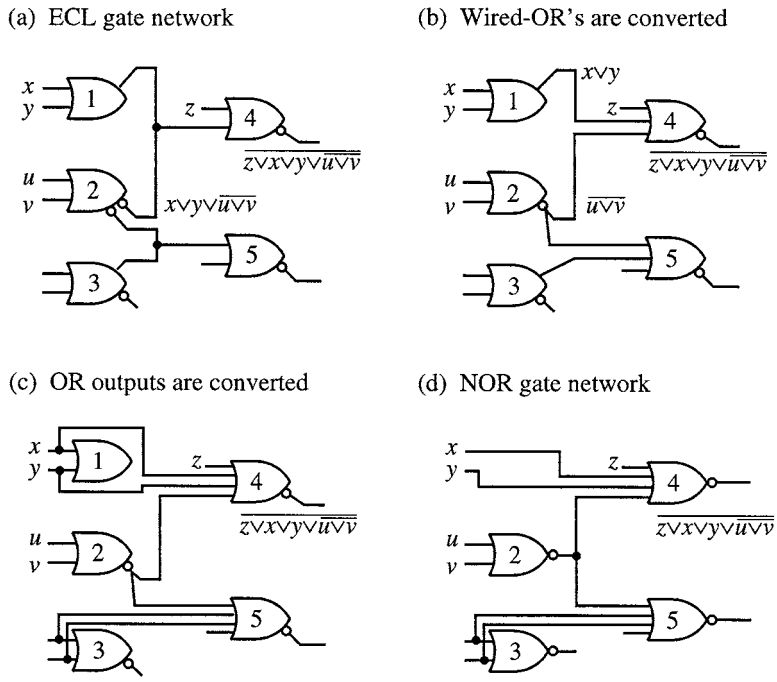

FIGURE 35.7 Conversion of an ECL gate network into a NOR gate network.

When we want to design a minimal standard ECL gate network for given functions f and $\bar{f}$, it can be designed by reversing the preceding conversion, as follows.

Procedure 35.1: Design of logic networks with standard ECL logic gates

1. Design a network for a given logic function f and another network for its complement, $\bar{f}$ using NOR gates only without considering maximum fan-in or fan-out restriction at each gate. Use a minimum number of NOR gates in each case. (The map-factoring method described in Chapter 31 is usually convenient for manual design of logic networks with a minimum number of NOR gates in single- or double-rail input logic.)
2. Choose one among the two logic networks obtained. Reduce the number of input connections to each gate, by providing Wired-ORs, or by using OR-outputs of other gates, if possible. In this case, extra NOR or OR outputs at each ECL gate must be provided whenever necessary (like the reverse conversion from Fig. 35.7(b) to Fig. 35.7(a), or from Fig. 35.7(c) to Fig. 35.7(b)). Thus, if any gate violates the maximum fan-in restriction, we can try to avoid it by using Wired-ORs or OR outputs.
3. This generally reduces fan-out of gates also; but if any gate still violates the maximum fan-out restriction, try to avoid it by using extra ECL gates (no simple good methods are known for doing this). The output ECL gate of this network presents f and $\bar{f}$.
   If no gate violates the maximum fan-in and fan-out restrictions in Steps 2 and 3, the number of NOR gates in the original NOR network chosen in Step 2 is equal to the number of ECL gates in the resultant ECL network. So, if we originally have a network with a minimum number of NOR gates, the designed ECL network also has the minimum number of standard ECL logic gates. But extra ECL gates have to be added if some gates violate the maximum fan-in restriction, maximum fan-out restriction, or other constraints.
4. Repeat Steps 2 and 3 for the other network. Choose the better one. □

Notice that the use of OR outputs and Wired-ORs generally reduces the number of connections or fan-ins (i.e., input transistors) and also reduces the total sum of connection lengths, thus saving chip area. For example, the total length of the connections for x and y in Fig. 35.7(c) can be almost twice the connection length between two gates in Fig. 35.7(b). Also, the total length of two connections in Fig. 35.7(b) can be almost twice the length for Wired-OR in Fig. 35.7(a). In Procedure 35.1, NOR networks with a minimum number of gates are important initial networks. It is known that when the number of gates is minimized, the number of connections in the networks also tends to be minimized.[11] (For the properties of wired logic, see Ref. 7.)

35.3 Modification of Standard ECL Logic Gates with Wired Logic

More complex logic functions than the output functions of the standard ECL logic gate shown in Fig. 35.1 can be realized by changing the internal structures of the standard ECL logic gates. In other words, if we connect points inside one ECL gate to some points of another ECL gate, we can realize a complex logic function with a simpler electronic circuit configuration. In other words, we can realize logic functions by freely connecting transistors, resistors, and diodes, instead of regarding the fixed connection configuration of transistors, resistors, and diodes as logic gates whose structure cannot be changed. This approach could be called **transistor-level logic design**. Wired logic is a powerful means for this, and collector-dotting and emitter-dotting are the basic techniques of wired logic.

Collector-Dotting

Collector-dotting is commonly used in bipolar transistor circuitry to realize the **Wired-AND operation**. Suppose we have the inverter circuit shown in Fig. 35.8(a) as part of an ECL logic gate. Its output function, f, at the collector of the bipolar transistor is 1 when the voltage at the collector is high, and f is 0 when the voltage at the collector is low. Then, suppose there is another like circuit whose output function at the collector is g. If the collectors of these two circuits, instead of the emitters for emitter-dotting in Fig. 35.4(b), are tied together as shown in Fig. 35.8(b), the new output function at the tied point is $h = f \cdot g$, replacing the original functions, f and g. This connection is called **collector-dotting**, realizing **Wired-**

AND. The tied point represents the new function $f \cdot g$ because if one of T_1 and T_2, or both is conductive in Fig. 35.8(b), the voltage at the tied point is low; otherwise (i.e., only when both transistors, T_1 and T_2, are non-conductive), the voltage at the tied point can be high.

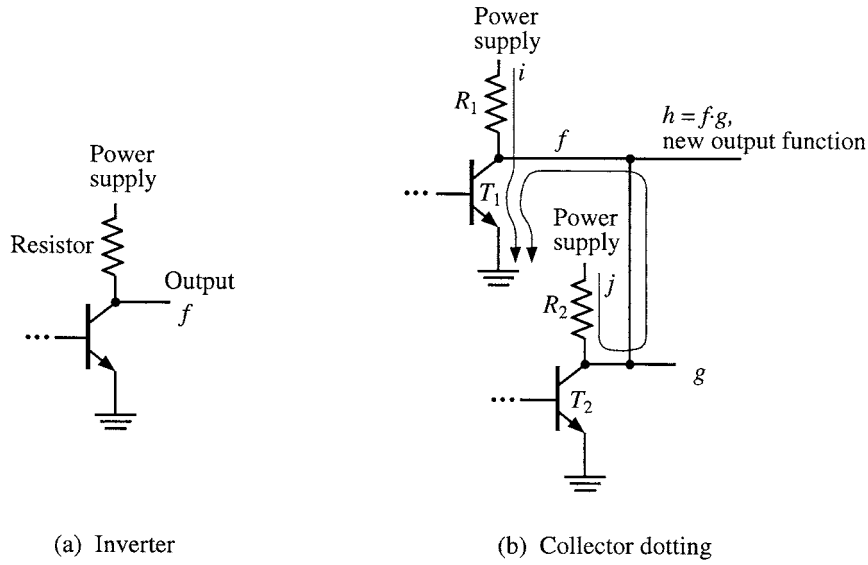

FIGURE 35.8 Collector-dotting.

In Fig. 35.9(a), Fig. 35.2 is repeated as gate 1 and gate 2. Transistor T_x has input x at its base, and its collector represents function $\bar{x}$ if T_y does not exist because when its base has a low voltage (i.e., logic value 0), its collector has a high voltage (i.e., logic value 1) and vice versa. Similarly, the collector of transistor T_y represents $\bar{y}$, if T_x does not exist. Then by tying together these collectors (i.e., collector-dotting), the tied point (i.e., point A) represents $\bar{x} \cdot \bar{y} = \overline{x \vee z}$, as already explained with respect to Fig. 35.2. Notice that the collector of T_x and the collector of T_y do not represent the original functions $\bar{x}$ and $\bar{y}$ respectively, after collector-dotting. Since the voltage level at B is always opposite to that at A, point B represents $x \vee y$.

We can use collector-dotting more freely. Point A in gate 1 in Fig. 35.9(a) can be connected to point A' or B' in gate 2. Point B can also be connected to point A' or B'. Such connections realize Wired-AND or collector-dotting. By collector-dotting points B and B' as shown in Fig. 35.9(b), point B 7 (also B') represents new function $(x \vee y) \cdot (z \vee w)$, which also appears at the emitter of transistor T. After this collector-dotting, points B and B' do not represent the original functions $x \vee y$ and $z \vee w$, respectively, anymore. Also, note that the function at any point that is not collector-dotted, such as A and A', is unchanged by collector-dotting of B and B'. In Fig. 35.9(b), two transistors, two diodes, and resistors (shown in the dotted line) are added for adjustment of voltage and current. But they have nothing to do with logic operations.

Another example is the parity function $\bar{x}y \vee x\bar{y}$ realized by connecting two ECL gates as shown in Fig. 35.10. The parity function requires four ECL gates if designed with the standard ECL logic gates as shown in Fig. 35.10(c), but can be realized by the much simpler electronic circuit of Fig. 35.10(b). In other words, $\bar{x}y$ and $x\bar{y}$ are realized by Wired-AND, then these two products are Wired-ORed in order to realize $\bar{x}y \vee x\bar{y}$. In Fig. 35.10 as well as Fig. 35.9, some resistors or transistors may be necessary for electronic performance improvement (since resistors R_1 and R_2 draw too much current in gate 1 in Fig. 35.10(a), new resistors are added in Fig. 35.10(b) in order to clamp the currents), and unnecessary resistors or transistors may be deleted, although such an addition or elimination of resistors or transistors has nothing to do with logic operations.

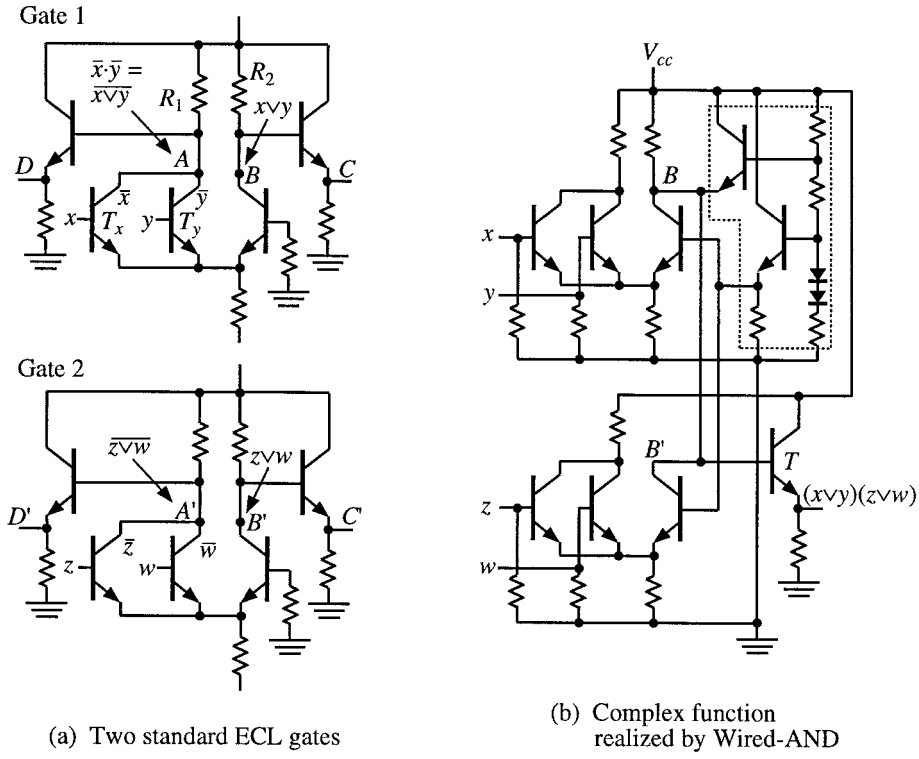

FIGURE 35.9 Example of Wired-AND.

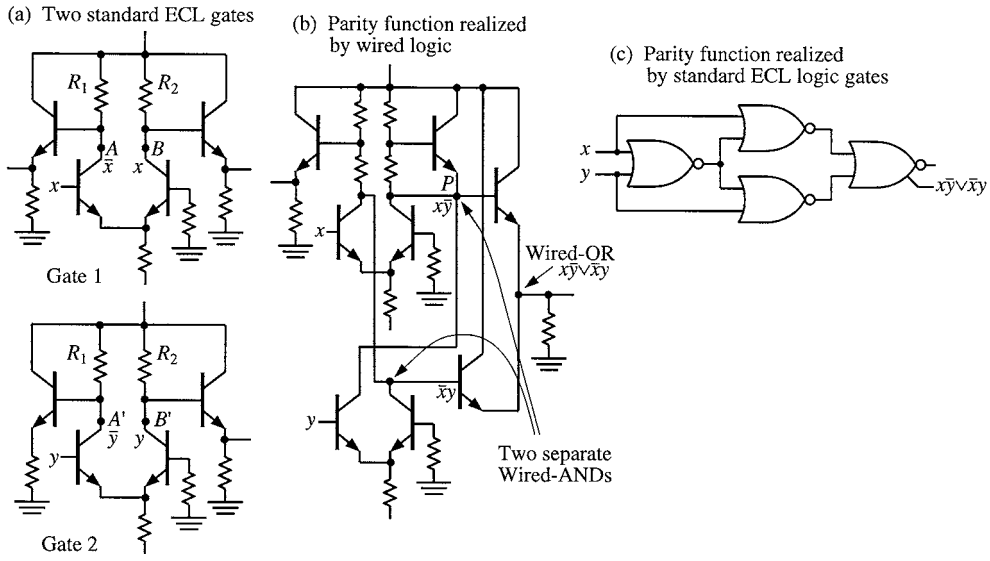

FIGURE 35.10 Parity function realized by ECL gate with Wired logic.

35.4 ECL Series-Gating Circuits

Figure 35.11(a) shows the basic pair of bipolar transistors in **series-gating ECL**, where A is connected to a power supply and B is connected to another power supply of minus voltage through a resistor. (Notice that this pair is T_x and T_r in Fig. 35.2, from which T_y is eliminated.) Transistor T_1 has an input x connected to its base and the other transistor T_2 has a constant voltage v_{ref} at its base. As illustrated in Fig. 35.2, v_{ref} is grounded through a resistor (i.e., $v_{ref} = 0$), where this resistor is for protection of transistor T_r from damage by a heavy current, and v_{ref} works as a reference voltage against changes of x. (The voltage at v_{ref} can be provided by a subcircuit consisting of resistors, diodes, and transistors, like the one in Fig. 35.9(b).) The collector of T_1 represents a logic function $\bar{x}$ because the collector of T_1 can have a high voltage (i.e., logic value 1) only when T_1 is non-conductive, that is, the input is a low voltage ($x = 0$).

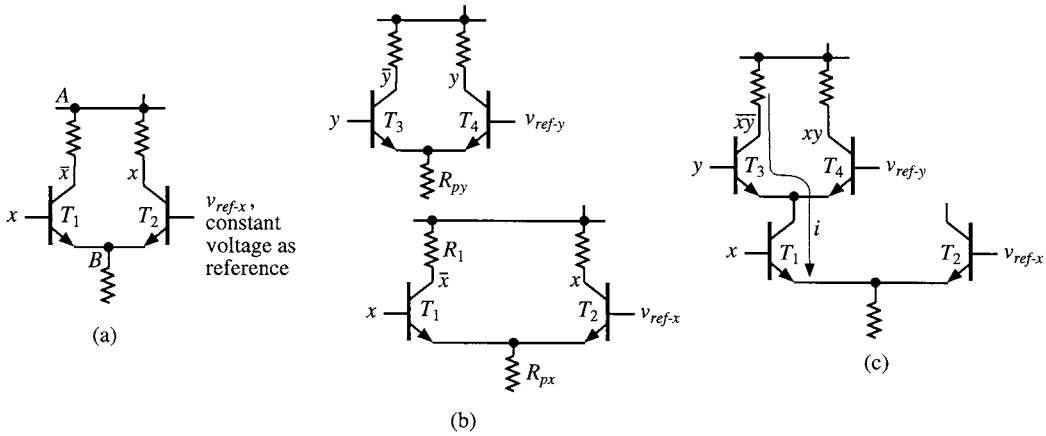

FIGURE 35.11 Series-gating.

The collector of T_2 represents function x because it becomes a high voltage only when the input x is a high voltage (i.e., when the input is a high voltage, T_1 becomes conductive and T_2 becomes non-conductive because a current flows at any time through exactly one of two transistors, T_1 and T_2. Thus, the collector of T_2 becomes a high voltage).

In Fig. 35.11(b), we have two pairs of transistors. In other words, we have the pair with input y, in addition to the pair with input x shown in (a). Then let us connect them in series without R_{py}, R_1 and the power supply for R_1, as shown in (c). The voltage at the collector of T_3 is low only when T_3 and T_1 are both conductive and, consequently, a current i flows through T_3 and T_1. The voltage at the collector of T_3 is high when either T_3 or T_1 is non-conductive (i.e., $x = 0$ or $y = 0$) and consequently no current (i.e., i) flows through T_3 and T_1. Thus, the collector of T_3 represents the function $\overline{xy}$, replacing the original function $\bar{y}$ shown in (b). This can be rewritten as $\overline{xy} = \bar{x} \vee \bar{y}$, so **series-gating can be regarded as the OR operation**.

Many of the basic pair of transistors shown in Fig. 35.11(a) are connected in a tree structure, as shown in Fig. 35.12, where inputs x, y, and z, as well as reference voltages, $v_{ref\text{-}1}$, $v_{ref\text{-}2}$, and $v_{ref\text{-}3}$, need to be at appropriate voltage levels. Then the complement of all minterms can be realized at the collectors of transistors in the top level of the series connections. Two of these complemented minterms (i.e., $\overline{\bar{x} \vee \bar{y} \vee z}$ and $\overline{\bar{x} \vee \bar{y} \vee \bar{z}}$) are shown with emitter followers, as examples at the far right end of Fig. 35.12.

Some of these collectors of transistors in the top level can be collector-dotted to realize the desired logic functions, as illustrated in Fig. 35.13. Notice that **once collectors are collector-dotted, these collectors do not express their respective original functions.**

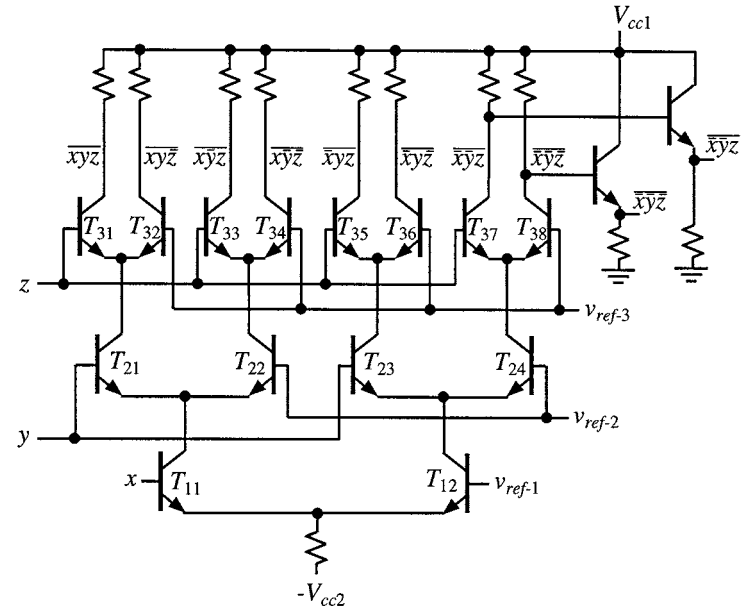

FIGURE 35.12 ECL series-gating.

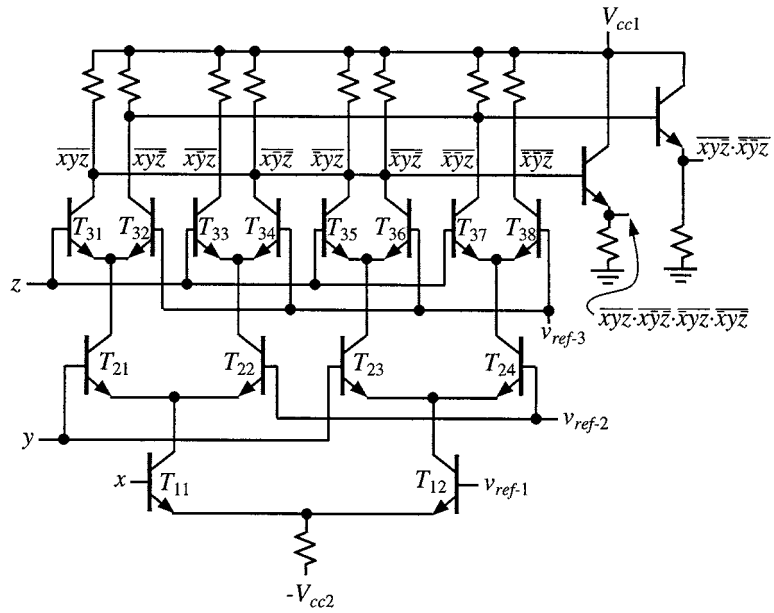

FIGURE 35.13 ECL series-gating.

The full adder in Fig. 35.14 is a more complex example of series-gating.[3] In this figure, we use collector-dotting by tying together some of collectors to realize Wired-AND, as explained already. For example, the voltage at the collector of transistor T_{31} represents function $\overline{xyc}$ because of series-gating with T_{11}, T_{21}, and T_{31}. Usually, at most, three transistors are connected in series (the two transistors in the bottom

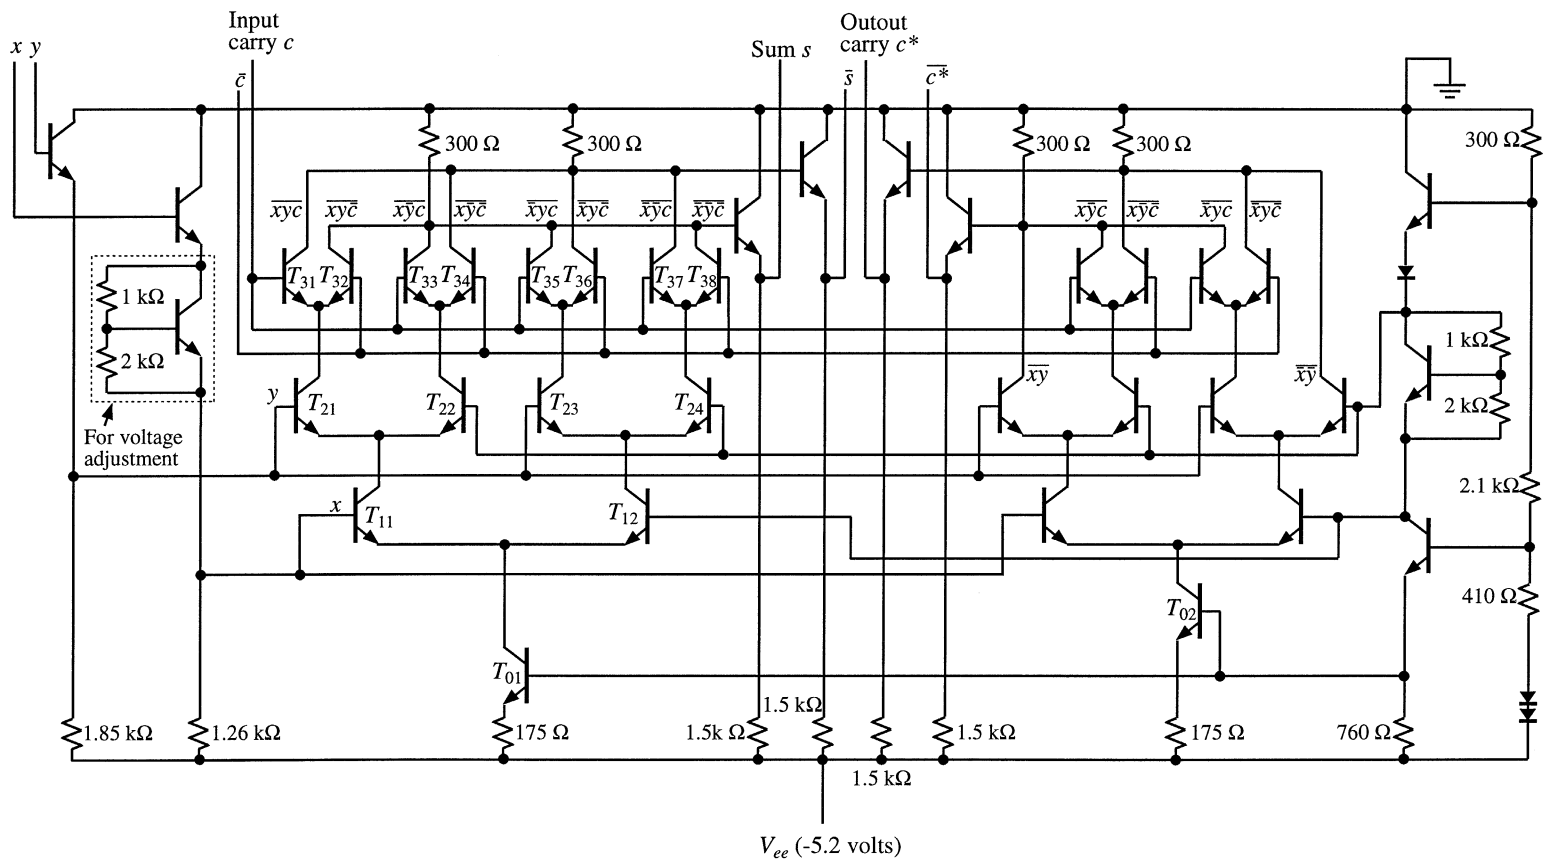

FIGURE 35.14 ECL full adder with series-gating. (From Ref. 3.)

level, T_{01} and T_{02}, in Fig. 35.14 are for controlling the amount of current as part of the power supply). This is because too many transistors in series tend to slow down the speed of the gate due to parasitic capacitances to ground. Then, by collector-dotting, some collectors of the transistors in the top level, sum s, and carry $c*$ are realized, as well as their complements, $\bar{s}$ and $\overline{c*}$.

Baugh and Wooley have designed a full adder in double-rail logic.[2] Ueda designed a full adder with ECL gates in single-rail logic with fewer transistors.[16]

The implementation of Wired-AND in this manner requires careful consideration of readjustments of voltages and currents. (Thus, transistors or resistors may be added or changed in order to improve electronic performance, but this is not directly related to logic operations.)

ECL series-gating can be extended as follows. Unlike the series-gating in Figs. 35.12, 35.13, and 35.14, the same input variables are not necessarily used in each level. For example, in the top level in Fig. 35.15, y and z are connected to the bases of transistors, instead of all y's. Then, collectors can be collector-dotted, although collector-dotting is not done in this figure. Complements of products, such as $\overline{xy}$ and $\overline{\bar{x}z}$, can be realized at collectors in the top level by the series-gating, as shown in Fig. 35.15. By this free connection of input variables, functions can be generally realized with fewer transistors.

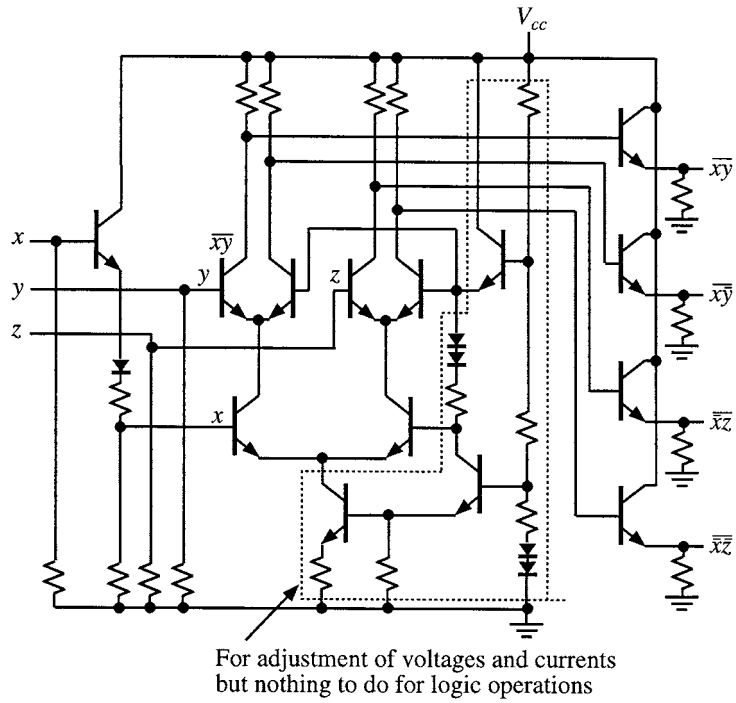

FIGURE 35.15 Series-gating.

CMOS has very low power consumption at low frequency but may consume more power than ECL at high speed (i.e., at high frequency). This is because the power consumption of CMOS is proportional to CFV^2, where C is parasitic capacitance, F is a switching frequency, and V is the power supply voltage. Thus, at high frequency, the power consumption of CMOS exceeds that of ECL, which is almost constant.

It is important to note that compared with the standard ECL logic gate illustrated in Fig. 35.1, series-gating ECL is faster with low power consumption for the following reasons:

- Because of speed-up of bipolar transistor (reduction of base thickness, and others), delay time over connections among standard ECL logic gates is greater than delay time inside logic gates and

then series-gating ECL, which can realize far more complex logic functions than NOR or OR realized by standard ECL gate and consequently eliminates long connections required among standard ECL logic gates, can have shorter delay.

- A series-gating ECL circuit has lower power consumption than a logic network with standard ECL logic gates because power supplies to all standard ECL logic gates are combined into one for the series-gating ECL circuit and a current flows in only one path at any time.[1,5,9,12]
- Then, in recent years, the power consumption of series-gating ECL is reduced with improved circuits.[8]
- The power consumption of series-gating ECL can also be reduced by active pull-down of some emitters.[14,15]

36.1 CMOS (Complementary MOS)

A CMOS logic gate consists of a pair of subcircuits, one consisting of nMOSFETs and the other pMOSFETs, where all MOSFETs are of enhancement mode described in Chapter 30, Section 30.3. **CMOS**, which stands for complementary MOS,[6,8–10] means that the nMOS and pMOS subcircuits are complementary. As a simple example, let us explain CMOS with the inverter shown in Fig. 36.1. A p-channel MOSFET is connected between the power supply of positive voltage V_{dd} and the output terminal, and an n-channel MOSFET is connected between the output terminal and the negative side, V_{ss}, of the above power supply, which is usually grounded. When input x is a high voltage, pMOS becomes non-conductive and nMOS becomes conductive. When x is a low voltage, pMOS becomes conductive and nMOS becomes non-conductive. This is the property of pMOS and nMOS when the voltages of the input and the power supply are properly chosen, as explained with Fig. 30.19. In other words, when either pMOS or nMOS is conductive, the other is non-conductive. When x is a low voltage (logic value 0), pMOS is conductive, with non-conductive nMOS, and the output voltage is a high voltage (logic value 1), which is close to V_{dd}. When x is a high voltage, nMOS is conductive, with non-conductive pMOS, and the output voltage is a low voltage. Thus, the CMOS logic gate in Fig. 36.1 works as an inverter. The pMOS subcircuit in this figure essentially works as a variable load.

When x stays at either 0 or 1, one of pMOS and nMOS subcircuits in Fig. 36.1 is always non-conductive, and consequently no current flows from V_{dd} to V_{ss} through these MOSFETs. In other words, when no input changes, the power consumption is simply the product of the power supply voltage V (if V_{ss} is grounded, V is equal to V_{dd}) and a very small current of a non-conductive MOSFET. (Ideally, there should be no current flowing through a non-conductive MOSFET, but actually a very small current which is less than 10 nA flows. Such an undesired, very small current is called a **leakage current**.) This is called the **quiescent power consumption**. Since the leakage current is typically a few nanoamperes, the quiescent power consumption of CMOS is less than tens of nW, which is very small compared with those for other logic families.

Whenever the input x of this CMOS logic gate changes to a low voltage (i.e., logic value 0), the parasitic capacitance C at the output terminal (including parasitic capacitances at the inputs of the succeeding

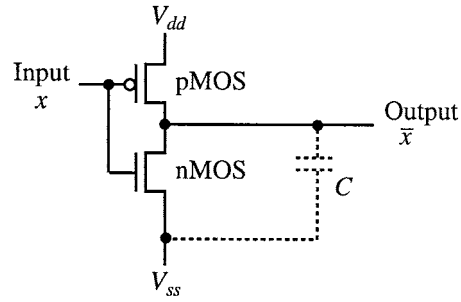

FIGURE 36.1 CMOS inverter.

CMOS logic gates, to which the output of this logic gate is connected) must be charged up to a high voltage through the conductive pMOS. (A current can be as large as 0.3 milliamperes or more.) Then, when the input x changes to a high voltage (i.e., logic value 1) at the next input change, the electric charge stored in the parasitic capacitance must be discharged through the conductive nMOS. Therefore, much larger power consumption than the quiescent power consumption occurs whenever the input changes. This dynamic power consumption due to the current during this transition period is given by CFV^2, where C is the parasitic capacitance, V is the power supply voltage, and F is the switching frequency of the input. Thus the power consumption of CMOS is a function of frequency. CMOS consumes very little power at low frequency, but it consumes more than ECL as the frequency increases. As the integration size increases, CMOS is being almost exclusively used in VLSI because of low power consumption. But even CMOS has difficulty in dissipation of the heat generated in the chip when switching frequency increases. In order to alleviate this difficulty, valiants, such as dynamic CMOS, have been used which will be described later.

Output Logic Function of a CMOS Logic Gate

Let us consider a CMOS logic gate in which many MOSFETs of the enhancement mode are connected in each of the pMOS and nMOS subcircuits (e.g., the CMOS logic gate in Fig. 36.2). By regarding the pMOS subcircuit as a variable load, the output function f can be calculated in the same manner as the one of an nMOS logic gate:

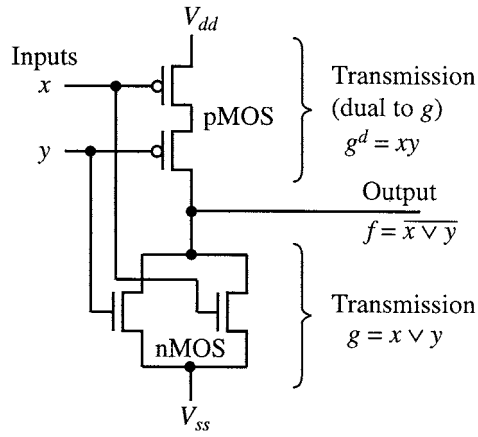

FIGURE 36.2 CMOS NOR gate.

1. Calculate the transmission between the output terminal and V_{ss} (or the ground), considering nMOSFETs as make-contacts of relays (transmission and relays are described in Chapter 30).
2. Then, its complement is the output function of this CMOS logic gate.

Thus, the CMOS logic gate in Fig. 36.2, for example, has the output function $f = \overline{x \vee y}$.

We can prove that if the pMOS subcircuit of any CMOS logic gate has the transmission between V_{dd} and the output terminal, calculated by regarding each pMOS as a make-contact relay, and this transmission is the dual of the transmission of the nMOS subcircuit, then one of the pMOS and nMOS subcircuits is always non-conductive, with the other conductive, for any combination of input values. (Note that regarding each pMOS as a make-contact relay, as we do each nMOS as a make-contact relay, means finding a relationship of connection configuration between nMOS subcircuit and pMOS subcircuit.) In the CMOS logic gate of Fig. 36.2, the pMOS subcircuit has transmission $g^d = xy$, which is dual to the transmission $g = x \vee y$ of the nMOS subcircuit, where the superscript d on g means "dual." Thus, any CMOS logic gate has the unique features of unusually low quiescent power consumption and dynamic power consumption CV^2F.

The input resistance of a CMOS logic gate is extremely high and at least 10^{14} **Ω**. This permits large fan-outs from a CMOS logic gate. Thus, if inputs do not change, CMOS has almost no maximum fan-out restriction. The practical maximum fan-out is 30 or more, which is very large compared with other logic families. If the number of fan-out connections from a CMOS logic gate is too many, the waveform of a signal becomes distorted. Also, fan-out increases the parasitic capacitance and consequently reduces the speed, so fan-out is limited to a few when high speed is required.

In addition to extremely low power consumption, CMOS has the unique feature that CMOS logic networks work reliably even if power supply voltage fluctuates, temperature changes over a wide range, or there is plenty of noise interference. This makes use of CMOS appropriate in rugged environments, such as for automobile, in factories, and weapons.

Problem of Transfer Curve Shift

Unfortunately, when a CMOS logic gate has many inputs, its transfer curve (which shows the relationship between input voltage and output voltage of a CMOS logic gate) shifts, depending on how many of the inputs change values. For example, in the two-input NAND gate shown in Fig. 36.3(a), the transfer curve for the simultaneous change of the two inputs (1 and 2) is different from that for the change of only input 1, with input 2 kept at a high voltage. This is different from an nMOS logic gate (or a pMOS logic gate) discussed in the previous sections, where every driver MOSFET in its conductive state must have a much lower resistance than the load MOSFET in order to have a sufficiently large voltage swing. But if only input 1 in Fig. 36.3(a), for example, changes, the resistance of the pMOS subcircuit is twice as large as that for the simultaneous change of the two inputs 1 and 2; so parasitic capacitance, C, is charged in a shorter time in the latter case. Other examples are shown in (b) and (c) in Fig. 36.3. Because of this problem of transfer curve shift, the number of inputs to a CMOS logic gate is practically limited to four if we want to maintain good noise immunity. If we need not worry about noise immunity, the number of inputs to a CMOS logic gate can be greater.

36.2 Logic Design of CMOS Networks

The logic design of CMOS networks can be done in the same manner as that of nMOS logic networks, because the nMOS subcircuit in each CMOS logic gate, with the pMOS subcircuit regarded as a variable load, essentially performs the logic operation, as seen from Fig. 36.2. The design procedures discussed for nMOS networks in Chapter 30, Section 30.3 can be used more effectively than in the case of nMOS networks, because more than four MOSFETs can be in series inside each logic gate, unless we are concerned about the transfer-curve shift problem or high-speed operation. Also, an appropriate use of transmission gates, discussed in the next paragraph, often simplifies networks.

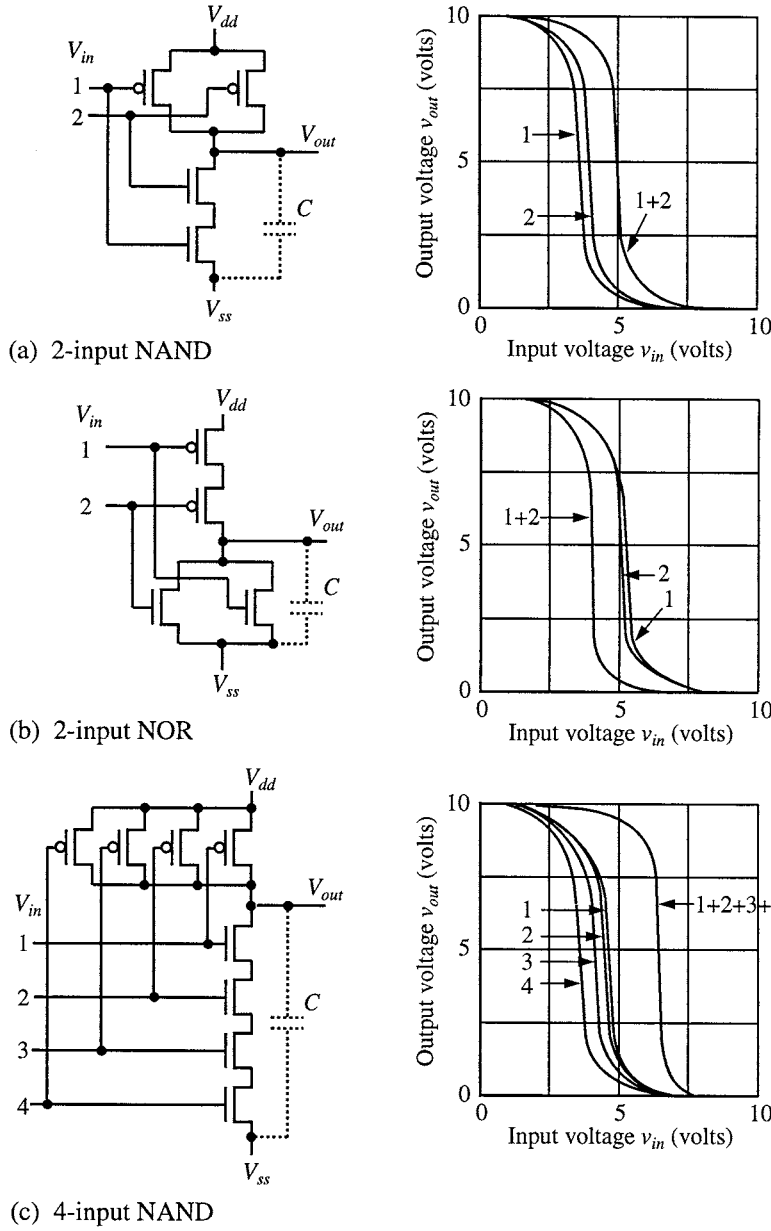

FIGURE 36.3 CMOS transfer curves for different numbers of inputs.

The **transmission gate** shown in Fig. 36.4 is a counterpart of the pass transistor (i.e., transfer gate) of nMOS, and is often used in CMOS network design. It consists of a pair of p-channel and n-channel MOSFETs. The control voltage d is applied to the gate of the n-channel MOSFET, and its complement $\bar{d}$ is applied to the gate of the p-channel MOSFET. If d is a high voltage, both MOSFETs become conductive, and the input is connected to the output. (Unlike a pass transistor with nMOS whose output voltage is somewhat lower than the input voltage, the output voltage of the transmission gate in CMOS is the same as the input voltage after the transition period.) If d is a low voltage, both MOSFETs become non-conductive, and the output is disconnected from the input, keeping the output

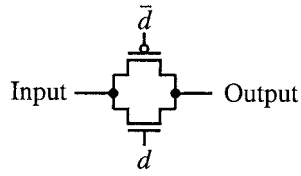

FIGURE 36.4 Transmission gate.

voltage (which gradually becomes low because of current leakage) at its parasitic capacitance, as it was before the disconnection. Since the input and output are interchangeable, the transmission gate is bidirectional. A D-type flip-flop is shown in Fig. 36.5, as an example of CMOS circuits designed with transmission gates.

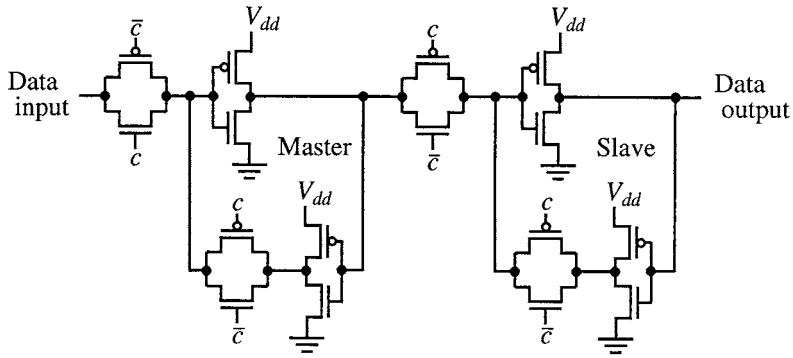

FIGURE 36.5 D-type flip-flop (c is a clock).

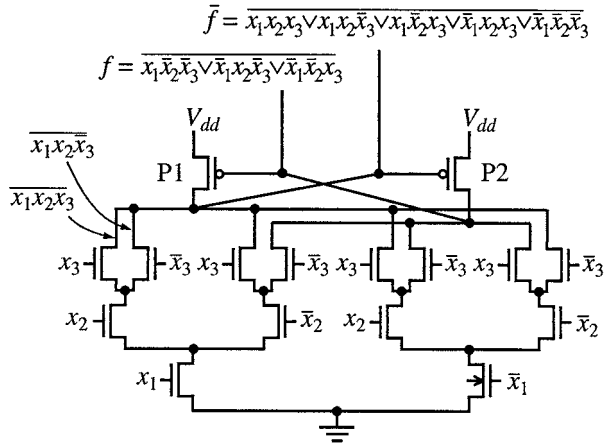
A full adder in CMOS with transmission gates is shown in Chapter 38. Also, pass transistors realized in nMOS can been used mixed with CMOS logic gates to reduce area or power consumption, as will be discussed in Chapter 37.

36.3 Logic Design in Differential CMOS Logic

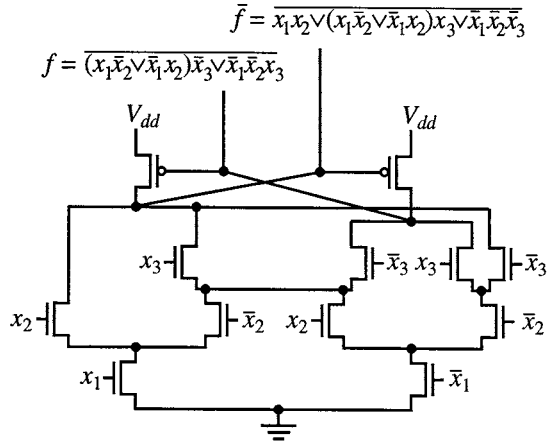
Differential CMOS logic is a logic gate that works very differently from the CMOS logic gate discussed so far. It has two outputs, f and its complement, $\bar{f}$, and works like a flip-flop such that when one output is a high voltage, it always makes the other output have a low voltage.

A logic gate in **cascode voltage switch logic**, which is abbreviated as **CVSL**, is illustrated in Fig. 36.6. CVSL is sometimes called **differential logic** because CVSL is a CMOS logic gate that realizes both an output function, f, and its complement, $\bar{f}$, switching their values quickly. The CVSL gate shown in Fig. 36.6(a) has a driver that is a tree consisting of nMOSFETs, where each pair of nMOSFETs in one level has input x_i and its complement $\bar{x}_i$. The top end of each path in the tree expresses the complement of a minterm (just like series-gating ECL described in Chapter 35). Then by connecting some of these top ends to both the gate of one pMOSFET (i.e., P1), and the drain of the other pMOSFET (i.e., P2), we can realize the complement of a sum-of-products. The connection of the remaining top ends to both the gate of P2 and the drain of P1 realizes its complement. The outputs in Fig. 36.6(a) realize

$$f = \overline{x_1\bar{x}_2\bar{x}_3 \vee \bar{x}_1x_2\bar{x}_3 \vee \bar{x}_1\bar{x}_2x_3}$$



(a)



(b)

FIGURE 36.6 (a) Static CVSL; (b) Static CVSL for the same functions as in (a).

and

$$\bar{f} = \overline{x_1x_2x_3 \vee x_1x_2\bar{x}_3 \vee x_1\bar{x}_2x_3 \vee \bar{x}_1x_2x_3 \vee \bar{x}_1\bar{x}_2\bar{x}_3}$$

When one path in the tree is conductive, the output of it, say the output f, has a lower voltage, and P1 (i.e., the pMOSFET whose gate is connected to f) becomes conductive. Then, the other output $\bar{f}$ has a high voltage. The driver tree in Fig. 36.6(a), which resembles series-gating ECL, can be simplified as shown in (b). (The tree structure in CSVL in (b) can be obtained from an ordered reduced binary decision diagram described in Chapters 23 and 26.) Notice that P1 and P2 in (a) are cross-connected for fast switching.

CVSL can be realized without tree structure. Figure 36.7 shows such a CSVL gate, for $f = \overline{xy}$ and its complement. The connection configuration of nMOSFETs connected to one output terminal is dual to that connected to the other output terminal (in Fig. 36.7, nMOSFETs for the output terminal for f are connected in series, while nMOSFETs for $\bar{f}$ are connected in parallel).

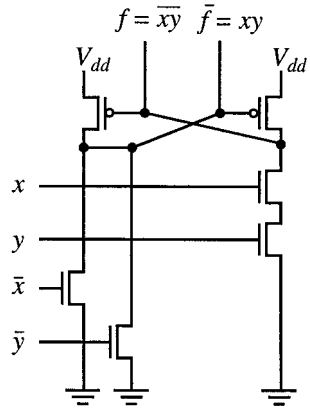


FIGURE 36.7 Static CVSL.

CVSL has a variant called dynamic CVSL, to be described later. In order to differentiate from this, CVSL here is usually called **static CVSL**.

36.4 Layout of CMOS

Layout of CMOS logic networks is more complex than logic networks where only nMOSFETs or pMOSFETs are used because in CMOS networks, nMOSFETs and pMOSFETs need to be fabricated with different materials. This makes layout of CMOS complicated. We often need to consider appropriate connection configuration of MOSFETs inside each logic gate and a logic network such that speed or area is optimized.

When we want to raise the speed, the switching speed of the pMOS subcircuit should be comparable to that of the nMOS subcircuit. Since the mobility of electrons is roughly 2.5 times higher than that of holes, the channel width W of p-channel MOSFETs must be much wider (often 1.5 to 2 times because the width can be made smaller than 2.5 times due to different doping levels) than that of n-channel MOSFETs (which work based on electrons) in order to compensate for the low speed of p-channel MOSFETs (which work based on holes) if the same channel length is used in each. Thus, for high-speed applications, NAND logic gates such as Fig. 36.3(a) are preferred to NOR logic gates, because the channel width of p-channel MOSFETs in series in a NOR logic gate such as Fig. 36.3(b) must be further increased such that the parasitic capacitance C can be charged up in a shorter time with low series resistance of these p-channel MOSFETs.

When designers are satisfied with low speed, the same channel width is chosen for every p-channel MOSFET as for n-channel MOSFETs, since a CMOS logic gate requires already more area than a pMOS or nMOS logic gate and a further increase by increasing the channel width is not desirable unless really necessary.

36.5 Pseudo-nMOS

In the case of the CMOS discussed so far, each CMOS logic gate consists of a pair of pMOS and nMOS subcircuits which realize dual transmission functions, as explained with Fig. 36.2. In design practice, however, some variations are often used. For example, Fig. 36.8 realizes NOR. The pMOS subcircuit consists of only a single MOSFET. Thus, the chip area is reduced and the speed is faster than static CMOS discussed so far because of a smaller parasitic capacitance. But more power is dissipated for some combinations of input values[1] because the pMOS subcircuit in (a) is always conductive.[9,10]

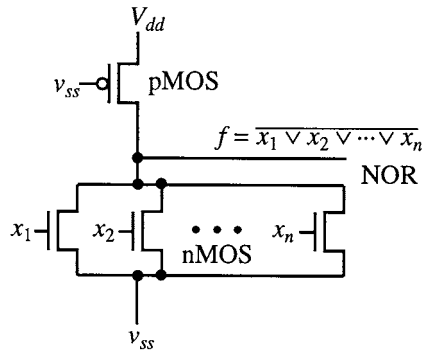

FIGURE 36.8 Peudo-nMOS.

36.6 Dynamic CMOS

Dynamic CMOS[4] is a CMOS logic gate that works in a manner very different from the CMOS logic gates discussed so far, which are usually called static CMOS. Using clock pulse, a parasitic capacitance is precharged, and then it is evaluated whether the parasitic capacitance is discharged or not, depending on the values of input variables. Dynamic CMOS has been used often for high speed because parasitic capacitance can be made small due to unique connection configuration of MOSFETs inside a logic gate, although good layout is not easy. Power consumption is not necessarily small. (In static CMOS, a current flows from the power supply to the ground during transition period. But in dynamic CMOS, there is no such current. But this does not mean that dynamic CMOS consumes less power because when input variables do not change their values, static CMOS does not consume power at all, whereas dynamic CMOS may consume power by repeating precharging. Dynamic CMOS and static CMOS have completely different power consumption mechanisms.)

Domino CMOS

Domino CMOS, illustrated in Fig. 36.9, consists of pairs of a CMOS logic gate and an inverter CMOS logic gate.[4] The first CMOS logic gate in each pair (such as logic gates 1, 3, and 5) has the pMOS subcircuit, consisting of a single pMOSFET with clock, and the nMOS subcircuit, consisting of many nMOSFETs with logic inputs and a single nMOSFET with a clock. The first CMOS logic gate is followed by an inverter CMOS logic gate (such as logic gates 2, 4, and 6). When a clock pulse is absent at all terminals labeled c, all parasitic capacitances (shown by dotted lines) are charged to value 1 (i.e., a high voltage) because all pMOSFETs are conductive. This process is called **precharging**. Thus, the outputs of all inverters become value 0. Suppose that $x = v = 1$ (i.e., a high voltage) and $y = z = u = 0$ (i.e., a low voltage). When a clock pulse appears, that is, $c = 1$, all pMOSFETs become non-conductive but the nMOS subcircuit in each of logic gates 1 and 5 becomes conductive, discharging parasitic capacitance. Then the outputs of logic gates 1, 2, 3, 4, 5, and 6 become 0, 1, 1, 0, 0, and 1, respectively. Notice that the output of logic gate 3 remains precharged because its nMOSFET for u remains non-conductive. Domino CMOS has the following advantages:

- It has a small area because the pMOS subcircuit in each logic gate consists of a single pMOSFET.
- It is faster (about twice) than the static CMOS discussed so far because parasitic capacitances are reduced by using a single pMOS in each logic gate and the first logic gate is buffered by an inverter. Also, an inverter, such as logic gate 2, has smaller parasitic capacitance at its output because it connects to only nMOSFET in logic gate 3, for example, compared to static CMOS where it connects to both pMOSFET and nMOSFET in each of next static CMOS logic gates, to which the output of this static CMOS is connected. This also makes domino CMOS faster.

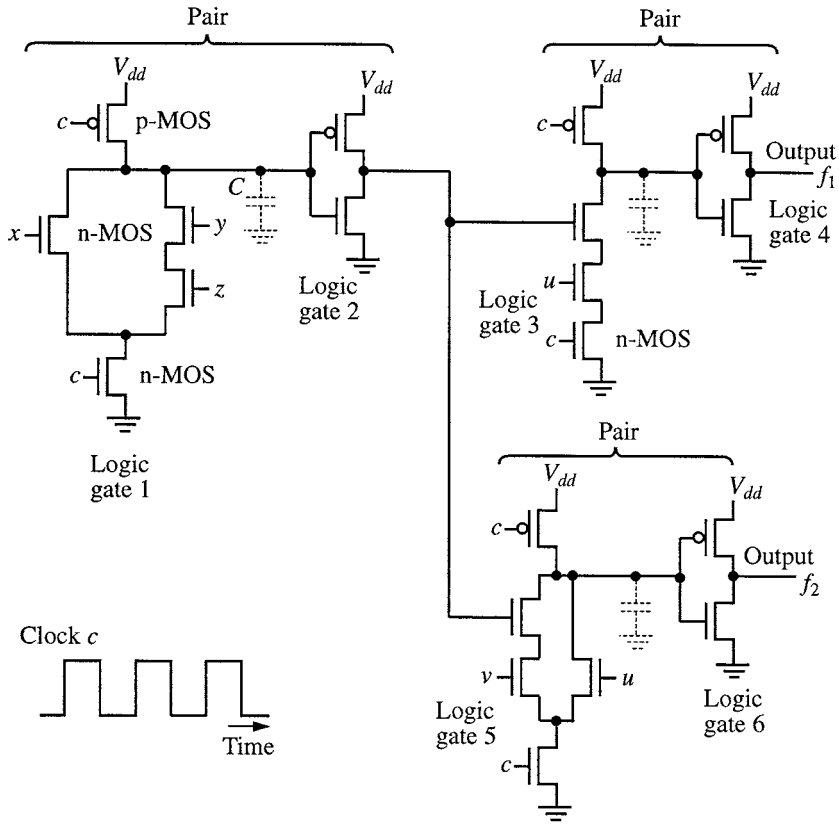

FIGURE 36.9 Domino CMOS.

- It is free of glitches (i.e., transition is smooth) because at the output of each logic gate, a high voltage remains or decreases, but no voltage increases from low to high.[7]

Domino CMOS has the following disadvantage:

- Only positive functions with respect to input variables can be realized. (If both x_i and $\bar{x}_i$ for each x_i is available as network inputs, the network can realize any function. But if only one of them, say x_i, is available, functions that are dependent on $\bar{x}_i$ cannot be realized by a domino CMOS logic network.)

So we have to have domino CMOS networks in double-rail input logic (e.g., Ref. 2), or to add inverters, whenever necessary. Thus, although the number of MOSFETs in domino CMOS networks in single-rail input logic, such as Fig. 36.9, is almost half of static CMOS networks, the number of MOSFETs in such domino CMOS networks to realize any logic functions may become comparable to the number of MOSFETs in static CMOS networks in single-rail input logic.

Dynamic CVSL

Static CVSL, which is previously described, can be easily converted into **dynamic CVSL** which is faster, as illustrated in Fig. 36.10. The parasitic capacitance of two output terminals are precharged through each of the two pMOSFETs during the absence of a clock pulse. Dynamic CVSL works in a similar manner to domino CMOS. Notice that two pMOSFETs are not cross-connected like static CVSL and

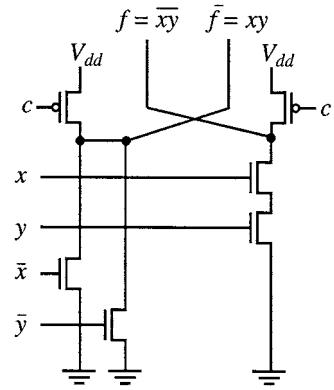

FIGURE 36.10 Dynamic CVSL.

we have essentially two independent logic gates. Dynamic CSVL with two outputs, f and $\bar{f}$, is in double-rail logic, so unlike domino CMOS, not only positive functions but also any logic functions can be realized. It is fast because the pMOS subcircuit of static CMOS is replaced by one pMOSFET and consequently parasitic capacitance is small and also because the output of a dynamic CSVL is connected only to the nMOS subcircuits, instead of to both the nMOS and pMOS of a next static CMOS logic gate. It is also free of glitches.

Problems of Dynamic CMOS

Dynamic CMOS, such as domino CMOS and differential CMOS logic, is increasingly important for circuits that require high speed, such as arithmetic/logic units,[5] although design and layout of appropriate distribution of voltages and currents are far trickier than static CMOS. Dynamic CMOS with a single-phase-clock has advantage of simple clock distribution lines.[3]

37.1 Introduction

A MOSFET is usually used such that a voltage at the gate terminal of the MOSFET controls a current between its source and drain. When the voltages at the gate terminals of MOSFETs that constitute a logic gate are regarded as input variables x, y, and so on, the voltage at the output terminal represents the output function f. Here, $x = 1$ means a high voltage and $x = 0$ a low voltage. For example, MOSFETs in the logic gate in CMOS shown in Fig. 37.1(a) are used in this manner and the output function f represents $\overline{x \vee y}$. But a MOSFET can be used such that an input variable x applied at one of source and drain of the MOSFET is delivered to the other or not, depending on whether a voltage applied at the gate terminal of the MOSFET is high or low. For example, the n-channel MOSFET shown in Fig. 37.1(b) works in this manner and the MOSFET used in this manner is called a **transfer gate** or, more often, a **pass transistor**. When the control voltage c is high, the MOSFET becomes conductive and the input voltage x appears at the output terminal f (henceforth, let letters, f, x, and others represent terminals as well as voltages or signal values), no matter whether the voltage x is high or low. When the control voltage c is low, the MOSFET becomes non-conductive and the input voltage at x does not appear at the output terminal f.

Pass transistors have been used for simplification of transistor circuits. Logic functions can be realized with fewer MOSFETs than logic networks of logic gates where MOSFETs are used like those in Fig. 37.1(a). The circuit in Fig. 37.2, for example, realizes the even-parity function $\overline{x \oplus y}$[2]. This circuit works in the following manner. When x and y are both low voltages, n-channel MOSFETs, 1 and 2, are non-conductive and consequently no current flows from the power supply V_{dd} to the terminal x or y. Thus, the output voltage f is high because it is the same as the power supply voltage at V_{dd}. When x is a low voltage and y is a high voltage, MOSFET 1 becomes conductive and 2 is non-conductive. Consequently, a current flows from the power supply to x because x is a low voltage. Thus, the output voltage at f is low. Continuing the analysis, we have the truth table shown in Fig. 37.3(a). Then we can derive the truth table for function $f = \overline{x \oplus y}$ in Fig. 37.3(b) by regarding a low and high voltages as 0 and 1, respectively. A logic gate for this function in CMOS requires 8 MOSFETs, as shown in Fig. 37.4, whereas the circuit realized with pass transistors in Fig. 37.2 requires only three MOSFETs. Notice that inputs x and y are connected to the sources of MOSFETs 1 and 2, unlike MOSFET in ordinary logic gates. Signal x at the source of MOSFET 1 is either sent to the drain or not, according to whether or not its MOSFET gate has a high voltage.

Pass transistors, however, are sometimes used inside an ordinary logic gate, mixed with ordinary MOSFETs. MOSFETs 1, 2, and 3 in Fig. 37.5 are such pass transistors. (Actually, the pair of 1 and 2 is a transmission gate to be described in the following and also in Chapter 36, Section 36.2) Logic networks

in CMOS where MOSFETs are used in the same way as those in Fig. 37.1(a) can sometimes be simplified by an appropriate use of pass transistors, possibly with speed-up.

The wide use of a pass transistor is found in the DRAM memory cell, which consists of one capacitor and one pass transistor. The control of charging to or discharging from the memory capacitor is done through the pass transistor. This shows the impact of this technique in area reduction, power consumption reduction, and possibly also in speed-up. Pass transistors are also used in the arithmetic-logic unit of a computer, which requires speed and small area, such as fast adders (actually the logic gate in Fig. 37.5 is part of such an adder), multipliers and multiplexers.[3,7,11,12]

The circuit in Fig. 37.6(a) in double-rail input logic (i.e., x, $\bar{x}$, y, and $\bar{y}$ are available as inputs) realizes the odd-parity function $x \oplus y$. A circuit for the inverter shown by the triangle with a circle in Fig. 37.6(a) is shown in (b).

Pass transistors are often used for forming a demultiplexer, as illustrated in Fig. 37.7. Series connection of pass transistors has some resistance. So the number of control variables (here, x and y) is limited to at most four and the inverter shown in Fig. 37.6(b) is added after input g as a buffer.

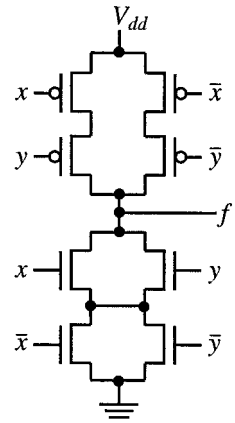

FIGURE 37.4 CMOS logic gate for function $f = \overline{x \oplus y}$

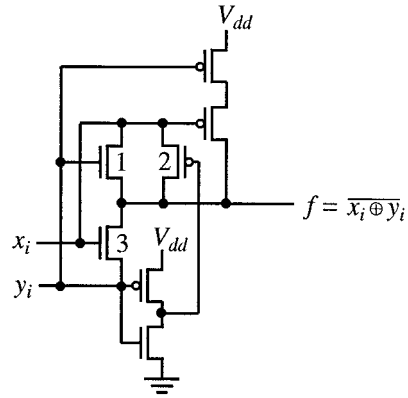

FIGURE 37.5 Pass transistors in a logic gate.

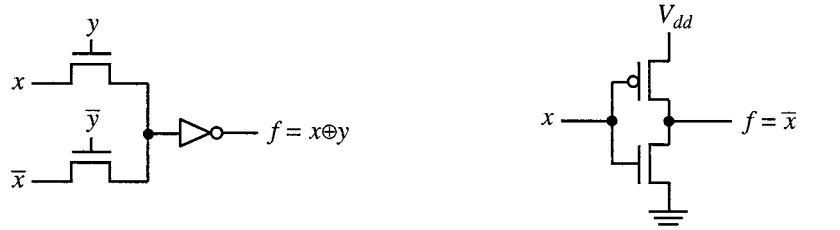

FIGURE 37.6 Parity function realized with pass transistors.

Using pass transistors, a latch (more precisely speaking, a D latch to store data) can be constructed as shown in Fig. 37.8. When control input c is a high positive voltage, the feedback loop is cut by the pass transistor with $\bar{c}$, and the input value is fed into the cascade of two inverters. When c becomes a low voltage, the input is cut off and the loop that consists of two inverters and one pass transistor retains the information.

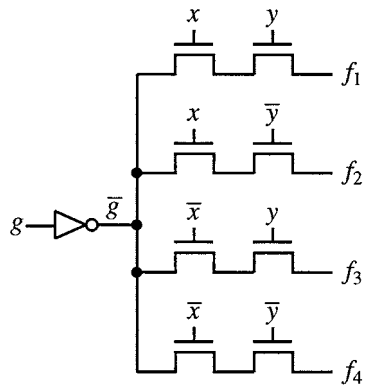

FIGURE 37.7 Demultiplexer with pass transistors.

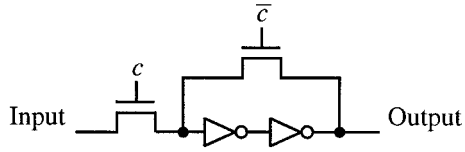

FIGURE 37.8 Latch with pass transistors.

The use of pass transistors in logic networks, however, has been very limited because of electronics problems to be discussed in the following. The majority of commercially available logic networks have been in static CMOS circuits. But as higher speed and smaller area are desired, this situation is gradually changing. The pass-transistor logic has recently attracted much attention under these circumstances and is anticipated to be widely used in the near future for its area/power saving and high-performance benefits.

Beside pass transistors, there are many other unconventional MOS networks. All these networks are useful for simplification of electronic realization of logic networks or for improvement of performance, although complex adjustments of voltages or currents are often required.

37.2 Electronic Problems of Pass Transistors

Suppose an n-channel MOSFET is used as a pass transistor, as shown in Fig. 37.9. Then, the MOSFET behaves electronically as follows. When the control voltage at *c* is high, the voltage at the input *x* is delivered to the output terminal *f*, no matter whether the voltage at the input *x* is high or low. But if the voltage at the input *x* is high, a current flows through the MOSFET to charge up the parasitic capacitance (shown in the dotted lines in Fig. 37.9) at *f* and stops when the difference between the voltage at *f* and the voltage at *c* reaches the threshold voltage, making the voltage at *f* somewhat lower than the

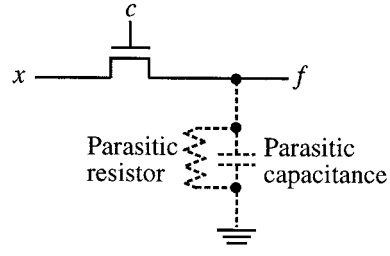

FIGURE 37.9 Electronic behavior of a pass transistor.

voltage at x. When the voltage at c becomes low, the pass transistor becomes non-conductive and the electric charge stored on the parasitic capacitance gradually leaks to the ground through the parasitic resistor. If the voltage at the input x is low when the control voltage at c is high, the electric charge stored on the parasitic capacitance flows to the ground through the pass transistor and input terminal x also if it has not completely leaked to the ground yet.
