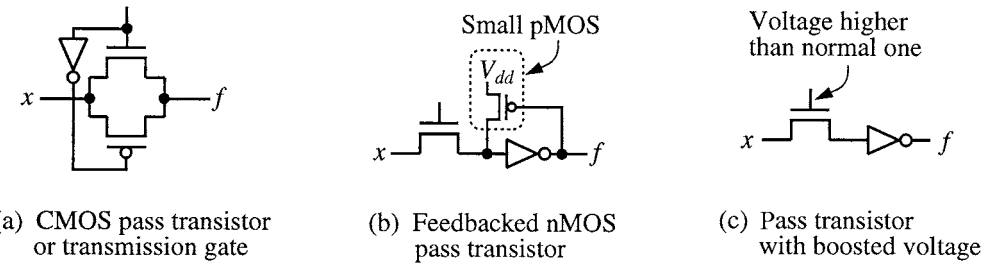
This complex electronic behavior of the pass transistor makes a circuit with pass transistors unreliable. The intermediate value of the voltage at f, which is lower by the threshold voltage than the voltage at x or partially leaked voltage, causes unpredictable operations of the logic network when the voltage at f is fed to ordinary CMOS logic gates in the next stage. Moreover, it degrades the switching speed of the CMOS logic gates. In the worst case, the circuit loses noise margin or it does not operate properly.

There are three techniques to avoid this drawback. The first one is to combine an nMOS pass transistor and a pMOS pass transistor in parallel, as shown in Fig. 37.10(a). With this technique, when the pass transistor is conductive, the output voltage at f reaches exactly the same value as the input voltage at x, no matter whether the input voltage is high or low. This pair of nMOS and pMOS pass transistors is sometimes called a **transmission gate**. Although this has better stability over the pass transistor circuit in Fig. 37.9, it consumes roughly twice as large an area.



(a) CMOS pass transistor or transmission gate

(b) Feedbacked nMOS pass transistor

(c) Pass transistor with boosted voltage

FIGURE 37.10 Techniques to avoid the influence of the low output voltage.

The second approach is to use a pMOS feedback circuit at the output of the nMOS pass transistor, as shown in Fig. 37.10(b). The gate of a p-channel MOSFET is driven by the CMOS inverter (shown as the triangle with a small circle), which works as an amplifier. When the CMOS inverter discharges the electric charge at the output, it also turns on the feedback pMOS to raise the pass transistor output to the power supply voltage, eliminating the unreliable operation. One limitation of this approach is that it does not solve the degradation of switching speed due to low voltage, because the speed is determined by the initial voltage swing before the pMOS turns on. Area increase with this approach is smaller than the transmission gate in Fig. 37.10(a).

The third approach is to raise the gate voltage swing up to the normal voltage plus threshold voltage, which is used in DRAM and referred to as "word boost," as shown in Fig. 37.10(c). This approach requires a boost driver every time the gate signal is generated, which is difficult to use in logic functions in general. In addition, a voltage that is higher than the power supply voltage is applied to the gate of a MOSFET, which requires special care against breakdown and reliability problems (these need to be solved by increasing the thickness of gate insulation).

Another important consideration for pass-transistor operation is how many pass transistors can be connected in series without buffers. Many pass transistors connected in series can be treated as a serially connected resister-capacitor circuit. The delay of this RC (resistor-capacitor) circuit, which is proportional to the product of R and C, becomes roughly four times larger when both R and C are doubled. Thus, the delay of this circuit is proportional to the square of the number of pass transistors. This means that it is not beneficial to increase the number of pass transistors too many. However, short-pitch insertion of CMOS inverters increases the delay overhead of the buffers themselves. Empirically, the optimal pass-transistor stages for delay minimization is known to be about two to three. In design practice, the number

of pass transistors cannot be arbitrarily chosen because designers want to have a certain number of fan-out connections and a buffer cannot support too many fan-outs and pass transistors. Also, the structure of a logic network cannot be arbitrarily chosen because of area size and power consumption.

37.3 Top-down Design of Logic Functions with Pass-Transistor Logic

After designing logic networks manually or by CAD programs, computer systems have been designed. This is called a bottom-up design approach. In the 1990s, so-called top-down design has been accepted as the mainstream design approach. In the top-down logic design, register-transfer-level functionality is described with a hardware-description language, such as Verilog-HDL and VHDL (Very High Speed Integrated Circuit Hardware Description Language) rather than directly designing gate-level structure of logic networks, or "netlist." And then, this is converted to logic networks of logic gates using a logic synthesizer (i.e., CAD programs for automated design of logic networks). This process resembles the compilation process of the software construction and it is sometimes referred to as "compile." Based on this netlist, placement and routing of transistors are done automatically on an IC chip. By using this top-down approach, a logic designer can focus on the functional aspect of the logic rather than the in-depth structural aspect. This enhances the productivity. Also, this enables one to easily port one design in one technology to another.

Automated design of logic networks with pass transistors has been difficult to realize because of complex electronic behavior. So, conventionally, pass-transistor logic has been manually designed, particularly in arithmetic modules as shown in this section. But as reduction of power consumption, speedup or area reduction is strongly desired, this is changing. Logic design based on selectors with pass-transistors can be done in this top-down manner.[10] Pass transistors have been used often as a selector by combing two pass transistors, as shown in Fig. 37.11(a). A selector is also called a multiplexer. The output f of the selector becomes input x when $c = 1$ and input y when $c = 0$. Figure 37.11(b) shows a selector realized in a logic gate and also in pass transistors. Compared with the selector in a CMOS logic gate shown on the left side of Fig. 37.11(b) which consists of ten MOSFETs, the selector in pass transistors shown on the right side of Fig. 37.11(b) consists of only four MOSFETs, reducing the number of MOSFETs to less than half, and consequently the area. A selector is known to be a universal logic element because

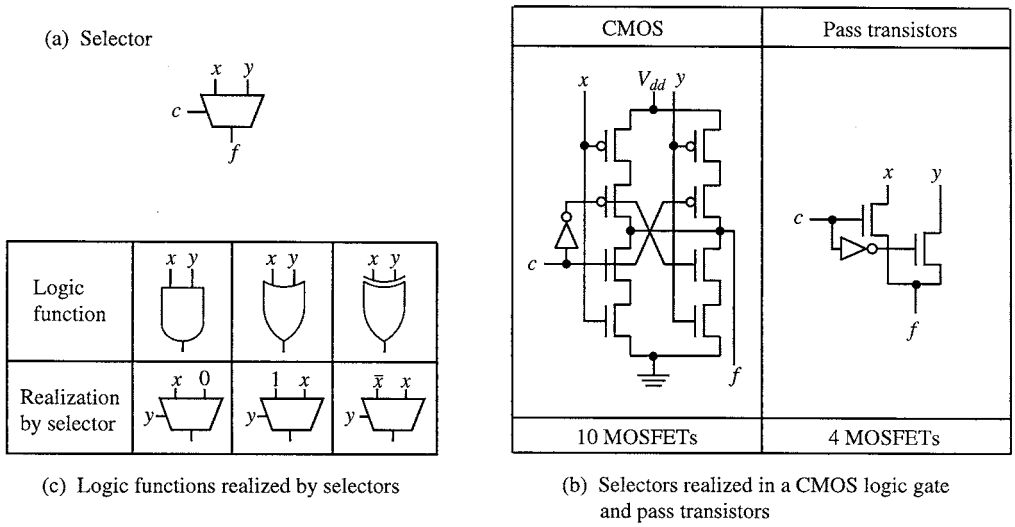


FIGURE 37.11 Selectors and various logic functions realized by pass transistors.

it can be used as an AND, an OR, and an XOR (i.e., Exclusive-OR) by changing its inputs, as shown in Fig. 37.11(c). This property is also useful in the top-down design approach discussed in the following. The speed of a logic network with pass transistors is sometimes improved up to 2 times better than a conventional CMOS logic network, depending on logic functions.

One limitation of this pass-transistor selector is that it suffers a relatively slow switching speed when the control signal arrives later than selected input signals. This is because an inverter is needed for the selector to have a complementary signal applied to the gate of a pass transistor.

To circumvent this limitation, CPL (which stands for the complementary pass-transistor logic) has been conceived.[11,12] In CPL, complementary signals are used for both inputs and outputs, eliminating the need for the inverter. The circuits that require complementary signals like CPL are sometimes categorized as dual-rail logics. Because of the need for complementary signal, CPL is sometimes twice as large as CMOS, but is sometimes surprisingly small if a designer succeeds in fully utilizing the functionality of a pass-transistor circuit. A very fast and compact CPL full adder, a multiplier, and a carry-propagate-chain circuit have been reported. A full adder realized with CMOS logic gates is compared with a full adder realized with selectors in pass transistors in Fig. 37.12. Speed and power consumption are significantly improved.

Variants of CPL have been also reported, including DPL,[8] SRPL,[5] and SAPL.[4]

However, conventional switching theory, on which widely used logic synthesizers are based, cannot be conveniently used for this purpose because it is very difficult to derive convenient logic expressions based on the output function $xc \vee y\bar{c}$ of the selector. Instead, BDD (i.e., binary decision diagrams) are used, as follows.

A simple approach to use a selector as the basic logic element is to build a binary tree of pass-transistor selectors, as shown in Fig. 37.13. The truth table shown in Fig. 37.13(a) is directly mapped into the tree structure shown in Fig. 37.13(b). When $x = 1$, $y = 0$, and $z = 1$, for example, the third 1 from the left in the top of Fig. 37.13(b) is connected to the output as $f = 1$. This original tree generally has redundancy, so it should be reduced to an irredundant form as shown in Fig. 37.13(c). This approach is simple and effective when the number of input variables is less than 5 or so. However, this does not work for functions with more input variables, because of the explosive increase of the tree size.

To solve this, a binary decision diagram (i.e., BDD), has been utilized.[10] Basic design flow of BDD-based pass-transistor circuit synthesis is shown in Fig. 37.14. The logic expressions for functions f_1 and f_2 shown in Fig. 37.14(a) are converted to the BDD in (b). Then, buffers (shown as triangles) are inserted in Fig. 37.14(c). In this case, only locations where the buffers should be inserted in Fig. 37.14(d) are specified and the nature of the BDD in Fig. 37.14(c) is not changed. In both Figs. 37.14(b) and (c), each solid line denotes the value 1 of a variable and each dotted line the value 0. For example, the downward solid line from the right-hand circle with w inside denotes $w = 1$. From f_1, if we follow dotted lines three times and then the solid line once in each of (b) and (c), we reach the 0 inside the rectangle in the bottom. This means that $f_1 = 0$ for $w = x = y = 0$ and $z = 1$.

Preparation of an appropriate cell library based on selectors is required, as shown in Fig. 37.15, which consists of a simple two-input selector (Cell 1) and its variants (Cells 2 and 3). The inverters shown with a dot inside the triangle in Fig. 37.15, which is different from the simple inverter shown in Fig. 37.6(b), is to keep the electric charge on the parasitic capacitance at its input. In Fig. 37.14(d), the inverters of this kind have to be inserted corresponding to the buffers shown in (c). But in this case, the insertion has to be done such that the outputs f_1 and f_2 have the same polarity in both (c) and (d) because the inverters change signal values from 1 to 0 or from 0 to 1.

In the design flow in Fig. 37.14, starting from the logic functions which are represented with logic equations or a truth table, the logic functions are then converted to a BDD. Each node of the BDD represents two-input selector logic, and, in this way, mapping to the above selector-based cells is straightforward, requiring only consideration of the fan-out and signal polarity.

One difficulty of this approach with BDD is optimization of the logic depth, that is, the number of pass transistors from an input to an output. One important desired capability of a logic synthesizer for

	CMOS	CPL

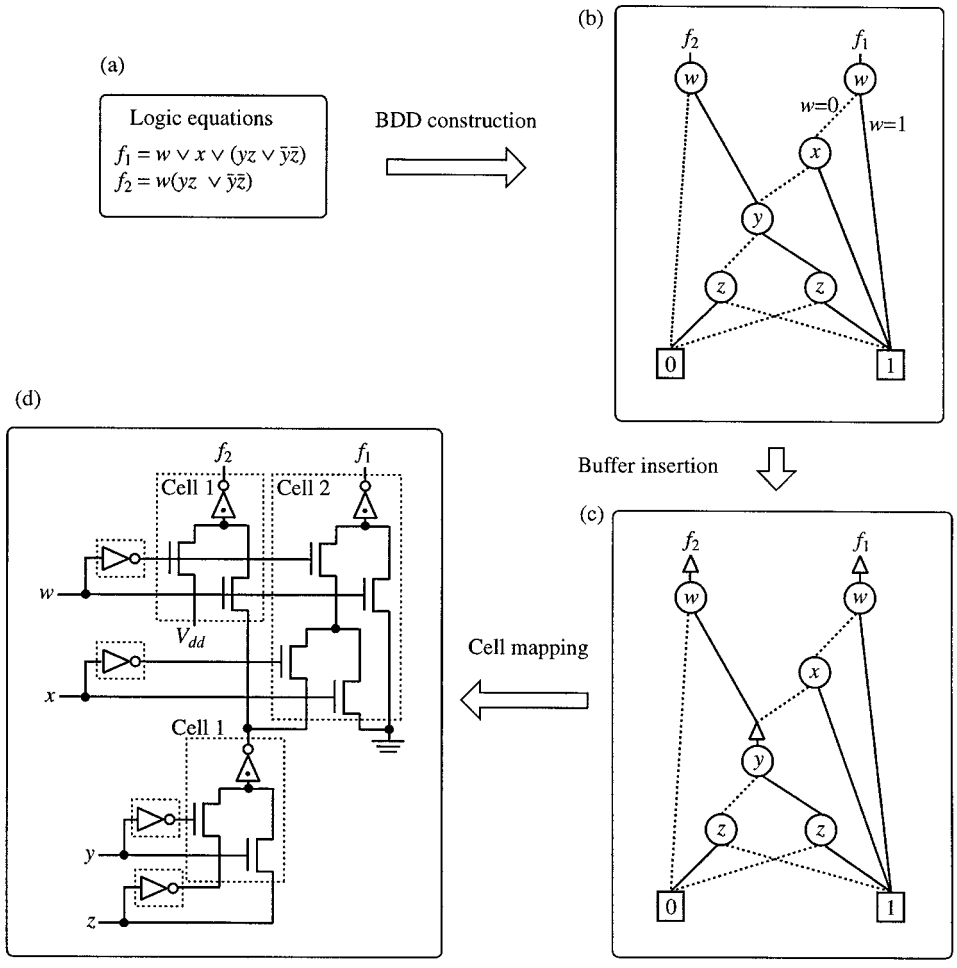

FIGURE 37.14 Design flow of BDD-based pass-transistor logic synthesis.

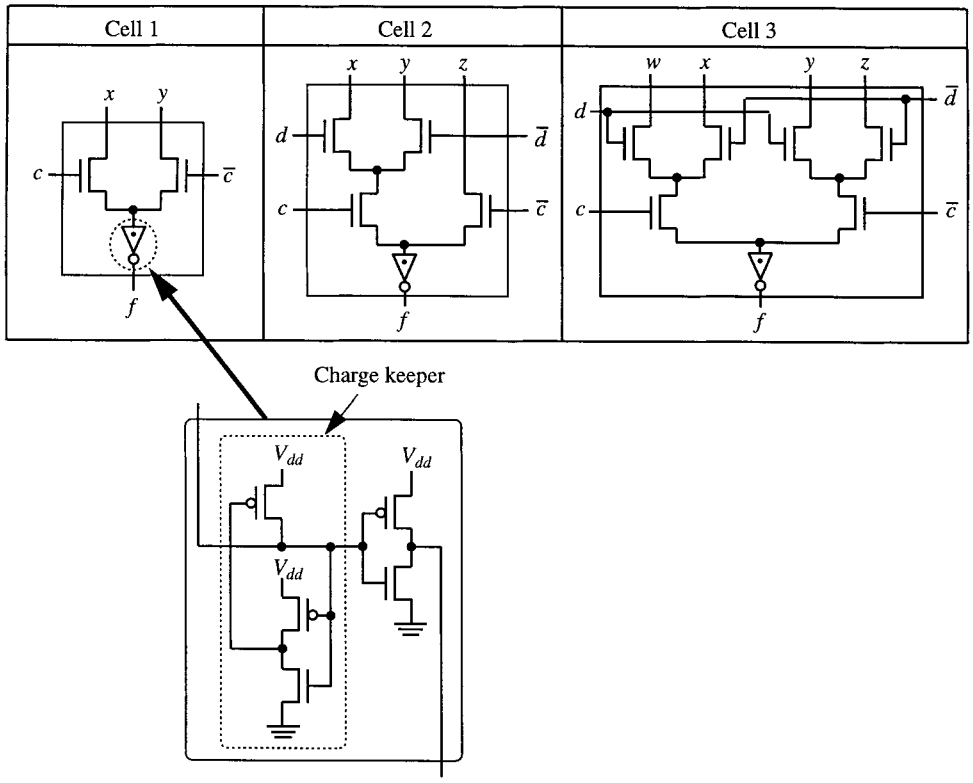

FIGURE 37.15 Pass-transistor-based cell library.

this approach is the control of the logic depth, for example, so that a designer can limit the delay time from an input to an output. It is difficult to incorporate this requirement in the framework of a BDD. Another difficulty of the BDD-based synthesis is that the number of pass transistors connected in series increases linearly as the number of inputs increases and this number may become excessive.

To solve these difficulties, MPL (which stands for multi-level pass-transistor logic) and its representation, multi-level BDD, have been proposed.[6] In the above simple BDD-based approach, the output of a pass-transistor selector is connected only to the source-drain path of another pass-transistor selector. This causes the above difficulty. In MPL, the output of a pass-transistor selector is flexibly connected to either a source-drain path or the gate of another MOSFET. Because of this freedom, the delay of the circuit can be flexibly controlled. It is known empirically that the delay, especially of a logic network having a large number of input variables, is reduced by a factor of 2, compared to the simple BDD approach.

Another important extension of pass-transistor logic is to incorporate CMOS circuits in a logic network.[9] Logic networks based on pass transistors are not always smaller than CMOS logic networks in area, delay, and power consumption. They are effective when selectors fit well to the target logic functions. Otherwise, conventional CMOS logic networks are a better choice. For example, a simple NAND function implemented in CMOS logic network has better delay, area, and power consumption than its pass-transistor-based counterpart. Combining pass-transistor logic and CMOS logic gives the best solution.

Pass-transistor logic synthesis is still not as well developed as CMOS-based logic synthesis. However, even at its current level of development, it has shown generally positive results. In other words, 10 to 30% power reduction is possible, as compared with pure CMOS,[9] showing enough potential[1] to be further exploited in future research.

38.1 Introduction

Adders are the most common arithmetic circuits in digital systems. Adders are used to do subtraction and also are key components of multipliers and dividers, as described in Chapters 39 and 40. There are various types of adders with different speeds, areas, and configurations. We can select an appropriate one which satisfies given requirements. For the details of adders and addition methods, see Refs. 2, 4–6, 12, 15, 17, and 20.

38.2 Addition in the Binary Number System

Before considering adders, let us take a look at addition in the binary number system.

In digital systems, numbers are usually represented in the binary number representation, although the most familiar number representation to us is the decimal number representation. The binary number representation is with the radix (base) 2 and the digit set {0, 1}, while the decimal number representation is with the radix 10 and the digit set {0, 1, 2, …, 9}. For example, a binary number (i.e., a number in the binary number representation) [1101] represents $1\cdot2^3 + 1\cdot2^2 + 0\cdot2^1 + 1\cdot2^0 = 13$, whereas a decimal number (i.e., a number in the decimal number representation) [8093] for example, represents $8\cdot10^3 + 0\cdot10^2 + 9\cdot10^1 + 3\cdot10^0 = 8093$.

In the binary number representation, an integer is represented as $[x_{n-1}x_{n-2}\ldots x_0]$ where each binary digit, called a bit, x_i, is one of the elements of the digit set {0, 1}. The binary representation $[x_{n-1}x_{n-2}\ldots x_0]$ represents the integer $\sum_{i=0}^{n-1} x_i \cdot 2^i$.

By the binary number representation, we can represent not only an integer, but also a number that has a fractional part as well as an integral part, as by the decimal number representation. The binary representation $[x_{n-1}x_{n-2}\ldots x_0.x_{-1}x_{-2}\ldots x_{-m}]$ represents the number $\sum_{i=-m}^{n-1} x_i \cdot 2^i$. For example, [1101.101] represents 13.625. By a binary representation with n-bit integral part and m-bit fractional part, we can represent 2^{n+m} numbers in the range from 0 to $2^n - 2^{-m}$.

Let us consider addition of two binary numbers, $X = [x_{n-1}x_{n-2}\ldots x_0.x_{-1}x_{-2}\ldots x_{-m}]$ and $Y = [y_{n-1}y_{n-2}\ldots y_0.y_{-1}y_{-2}\ldots y_{-m}]$. We can perform addition by calculating the sum at the i-th position, s_i and the carry to the next higher position c_{i+1} from x_i, y_i, and the carry from the lower position c_i according to the truth

TABLE 38.1 Truth Table for One-bit Addition

x_i	y_i	c_i	c_{i+1}	s_i
0	0	0	0	0
0	0	1	0	1
0	1	0	0	1
0	1	1	1	0
1	0	0	0	1
1	0	1	1	0
1	1	0	1	0
1	1	1	1	1

table shown in Table 38.1, successively from the least significant bit to the most significant one, that is, from $i = -m$ to $n - 1$, where $c_{-m} = 0$. Then, we have a sum $S = [s_n s_{n-1} s_{n-2} \ldots s_0 . s_{-1} s_{-2} \ldots s_{-m}]$, where $s_n = c_n$. (i.e., s_n is actually a carry c_n from the $(n-1)$-th position).

There are two major methods for representing negative numbers in the binary number representation. One is **sign and magnitude representation**, and the other is **two's complement representation**.

In the sign and magnitude representation, the sign and the magnitude are represented separately, as in the usual decimal representation. The first bit is the sign bit and the remaining bits represent the magnitude. The sign bit is normally selected to be 0 for positive numbers and 1 for negative numbers. For example, 13.625 is represented as [01101.101] and –13.625 is represented as [11101.101]. The sign and magnitude binary representation $[x_{n-1} x_{n-2} \ldots x_0 . x_{-1} x_{-2} \ldots x_{-m}]$ represents the number $(-1)^{x_{n-1}} \cdot \sum_{i=-m}^{n-2} x_i \cdot 2^i$. By the sign and magnitude representation with n-bit integral part (including a sign bit) and m-bit fractional part, we can represent $2^{n+m} - 1$ numbers in the range from $-2^{n-1} + 2^{-m}$ to $2^{n-1} - 2^{-m}$.

In the two's complement representation, a positive number is represented in exactly the same manner as in the sign and magnitude representation. On the other hand, a negative number $-X$, where X is a positive number, is represented as $2^n - X$. For example, –13.625 is represented as [100000.000] – [01101.101], i.e., [10010.011]. The first bit of the integral part (the most significant bit) is 1 for negative numbers, indicating the sign of the number. The binary representation of $2^n - X$ is called the **two's complement of *X***. We can obtain the representation of $-X$, i.e., $2^n - X$ by complementing the representation of X bitwise and adding [0.00…001] (i.e., 1 in the position of 2^{-m} but 0 in all other positions). It is because when $X = [x_{n-1} x_{n-2} \ldots x_0 . x_{-1} x_{-2} \ldots x_{-m}] = \sum_{i=-m}^{n-1} x_i \cdot 2^i$, the negation of X, i.e., $-X$, becomes $2^n - X = (\sum_{i=-m}^{n-1} 2^i + 2^{-m}) - X = \sum_{i=-m}^{n-1} (1 - x_i) \cdot 2^i + 2^{-m}$, where $1 - x_i$ is 1 or 0, according to whether x_i is 0 or 1, i.e., $1 - x_i$ is the complement of x_i. For example, given a binary number [01101.101], we can obtain its negation [10010.011] by complementing [01101.101] bitwise and adding [0.001] to it, i.e., by [10010.010] + [0.001]. By a two's complement representation with n-bit integral part (including a sign bit) and m-bit fractional part, we can represent 2^{n+m} numbers in the range from -2^n to $2^n - 2^{-m}$.

Each of all the binary number representations described so far (i.e., the positive number representation, sign and magnitude representation, and two's complement representation) can express essentially the same numbers, that is, 2^{n+m} numbers, although the second case expresses $2^{n+m} - 1$ numbers (i.e., one number less) when a number is expressed with $n + m$ bits. Thus, these representations essentially do not lose the precision, no matter whether or not one of the $n + m$-bits is used as a sign bit, although the range of the numbers is different in each case.

When we add two numbers represented in the sign and magnitude representation, we calculate the sign and the magnitude separately. When the operands (the augend and the addend) are with the same sign, the sign of the sum is the same as that of the operands, and the magnitude of the sum is the sum of those of the operands. A carry, 1, from the most significant position of the magnitude part indicates overflow. On the other hand, when the signs of the operands are different, the sign of the sum is the same as that of the operand with larger magnitude, and the magnitude of the sum is the difference of those of the operands.

The addition of two numbers represented in the two's complement representation, $X + Y$, for $X = [x_{n-1}x_{n-2}\ldots x_0.x_{-1}x_{-2}\ldots x_{-m}]$ and $Y = [y_{n-1}y_{n-2}\ldots y_0.y_{-1}y_{-2}\ldots y_{-m}]$ where x_{n-1} and y_{n-1} are their sign bits, can be done as follows, no matter whether each of X and Y is a positive or negative number:

1. The sign bits are added in the same manner as the two bits, x_i and y_i, in any other bit position, that is, according to Table 38.1. As illustrated in Fig. 38.1(a), the sign bits, x_{n-1} and y_{n-1}, and the carry, c_{n-1}, from the $(n-2)$-th position are added, producing the sum bit s_{n-1} (in the sign bit position) and the carry c_n. Always, c_n is ignored, no matter whether it is 1 or 0.
2. When $x_{n-1} = y_{n-1}$ (i.e., X and Y have the same sign bit), an overflow occurs if s_{n-1} is different from x_{n-1} and y_{n-1} (i.e., $c_n \oplus c_{n-1} = 1$ means an overflow, as can be seen from Table 38.1). This case is illustrated in Fig. 38.1(b) because we have $s_{n-1} = 0$ while $x_{n-1} = y_{n-1} = 1$ and hence s_{n-1} is not equal to x_{n-1} or y_{n-1}.

FIGURE 38.1 Examples of addition of numbers in two's complement representation.

Next let us consider the subtraction of two numbers represented in the two's complement representation, $X - Y$, that is, subtraction of Y from X, where each of X and Y is a positive or negative number. This can be done as addition as explained in the previous paragraph after taking the two's complement of Y (i.e., deriving $2^n - Y$), no matter whether Y is a negative or positive number. Actually, the subtraction, $X - Y$, can be realized by the addition of X and the bitwise complement of Y with a carry input of 1 to the least significant position. This is convenient for realizing a subtracter circuit, whether it is a serial or parallel adder (to be described later).

Henceforth, let us consider addition of n-bit positive binary integers (without the sign bit) for the sake of simplicity. Let the augend, addend, and sum be $X = [x_{n-1}x_{n-2}\ldots x_0]$, $Y = [y_{n-1}y_{n-2}\ldots y_0]$, and $S = [s_n s_{n-1} s_{n-2}\ldots s_0]$ with $s_n = c_n$, respectively, where each of x_i, y_i, and s_i assumes a value of 0 or 1.

38.3 Serial Adder

A serial adder operates similarly to manual addition. The serial adder, at each step, calculates the sum and carry at one bit position. It starts at the least significant bit position (i.e., $i = 0$) and each successive next step it sequentially moves to the next more significant bit position where it calculates the sum and carry. At the n-th step, it calculates the sum and carry at the most significant bit position (i.e., $i = n - 1$). In other words, the serial adder serially adds augend X and addend Y by adding x_i, y_i, and c_i at the i-th bit position from $i = 0$ to $n - 1$. From the truth table shown in Table 38.1, we have sum bit $s_i = x_i \oplus y_i \oplus c_i$ and carry to the next higher bit position $c_{i+1} = x_i y_i \vee c_i(x_i \vee y_i)$ (also $c_{i+1} = x_i \cdot y_i \vee c_i \cdot (x_i \oplus y_i)$), where "$\cdot$" is AND, "$\vee$" is OR, and "$\oplus$" is XOR, and henceforth, "$\cdot$" will be omitted. This serial addition can be realized by the logic network, called a **serial adder**, or **bit-serial adder**, shown in Fig. 38.2, where its operation is synchronized by a clock. The addition of each i-th bit is done at a rate of one bit per cycle of clock, producing sum bits, s_i's, at the same rate, from the least significant bit to the most significant one. In each cycle, s_i and c_{i+1}, are calculated from x_i, y_i, and the carry from the previous cycle, c_i. The core logic network, shown in the rectangle in Fig. 38.2, for this one-bit addition for the i-th bit position

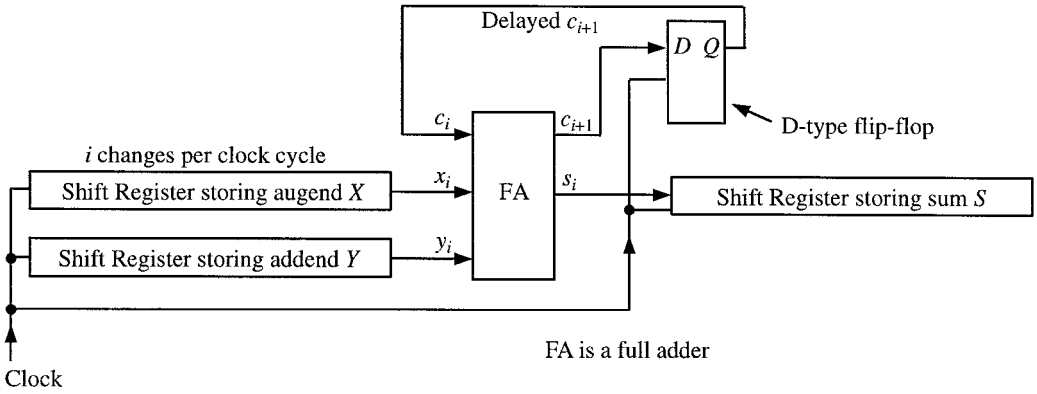

FIGURE 38.2 A serial adder.

is called a **full adder** (abbreviated as **FA**). We obtain a logic network for an FA shown in Fig. 38.3 using AND, OR, and XOR gates. A D-type flip-flop may be used as a delay element which stores the carry for a cycle. Full adders realized in ECL (emitter-coupled logic) are described in Chapter 35. FAs with a minimum number of logic gates are known for different types of logic gates.[10]

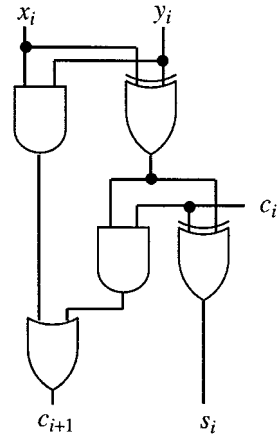

FIGURE 38.3 A full adder.

A serial subtracter can be constructed with a minor modification of a serial adder, as explained in the last paragraph of Section 38.2.

38.4 Ripple Carry Adder

A parallel adder performs addition at all bit positions simultaneously, so it is faster than serial adders.

The simplest parallel adder is a **ripple carry adder**. An n-bit ripple carry adder is constructed by cascading n full adders, as shown in Fig. 38.4. The carry output of each FA is connected to the carry input of the FA of the next higher position. The amount of its hardware is proportional to n. Its worst-case delay is proportional to n because of ripple carry propagation. In designing an FA for a fast ripple carry adder, it is critical to minimize the delay from the carry-in, c_i, to the carry-out, c_{i+1}.

An FA can be realized with logic gates, such as AND gates, OR gates, and XOR gates, as exemplified in Fig. 38.3, and also can be realized with MOSFETs, including pass transistors,[18,23] such that a carry

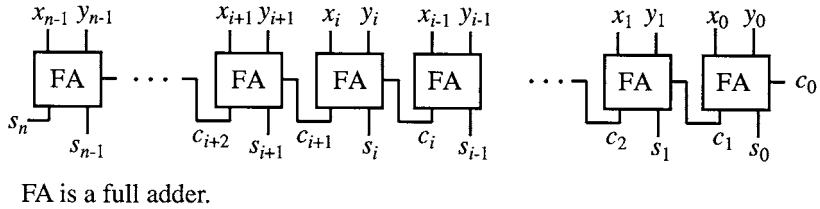

FIGURE 38.4 A ripple carry adder..

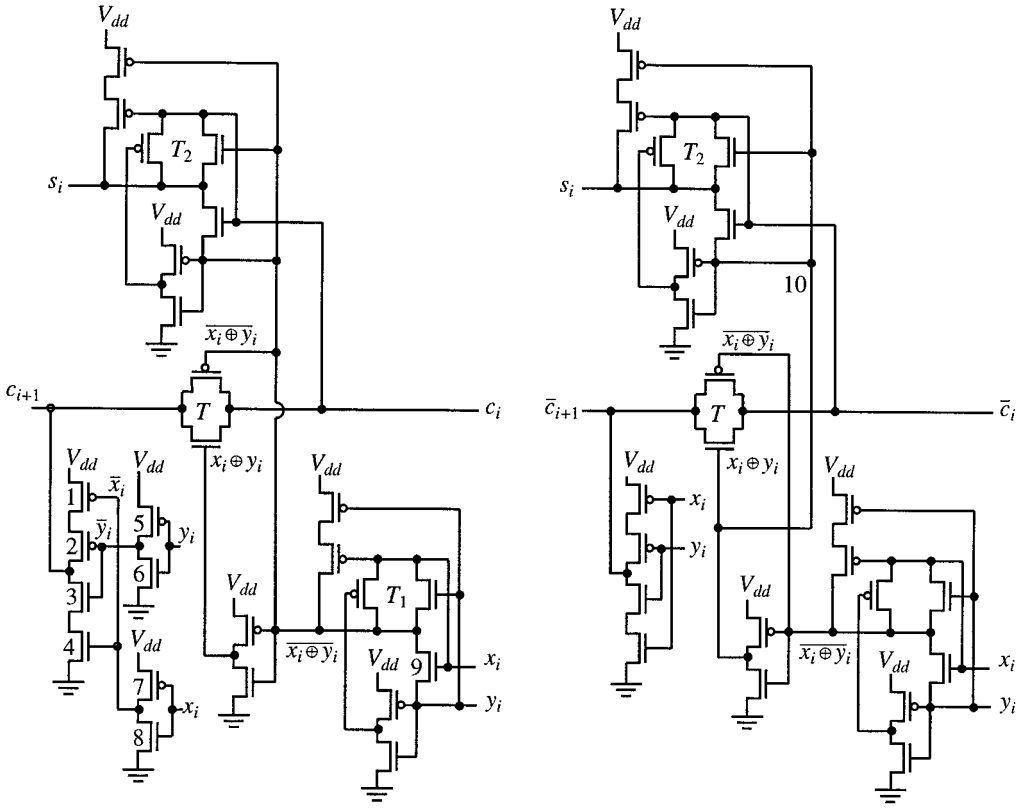
c_i goes through logic gates which have some delays. But the speed of adders is very important for the speed of the entire computer. So, FAs are usually realized with more sophisticated transistor circuits using MOSFETs such that a carry c_i can propagate fast to higher bit positions through pass transistors.[22] An example of such an adder is shown in Fig. 38.5, being realized in CMOS. In Fig. 38.5(a), a carry propagates through transmission gate, T (described in Chapter 36, Section 36.2). When we have $x_i = y_i = 0$, T becomes non-conductive and nMOSFETs, 3 and 4, become conductive. Then, the carry-out, c_{i+1}, becomes 0 because the carry-out terminal c_{i+1} is connected to the ground through 3 and 4. When $x_i = y_i = 1$, T becomes non-conductive and pMOSFETs, 1 and 2, become conductive. Then, the carry-out, c_{i+1}, becomes 1 because the carry-out terminal c_{i+1} is connected to the power supply V_{dd} through 1 and 2. When $x_i = 0$ and $y_i = 1$, or $x_i = 1$ and $y_i = 0$, T becomes conductive and the carry-out terminal is connected to neither V_{dd} nor the ground, so a carry-in c_i is sent to c_{i+1} as a carry-out. Thus, we have the values of c_{i+1} for different combinations of values of



(a) Full adder with non-complemented carries.

(b) Full adder with complemented carries.

FIGURE 38.5 A Manchester-type full adder in CMOS.

x_i, y_i, and c_i, as shown in Table 38.1. This carry-path is called a Manchester carry chain. (T_1 is another transmission gate, whereby a circuit on the carry path is simplified and carry propagation is sped up and nMOSFET 9 works as a pass transistor.) A ripple carry adder with Manchester carry chain is referred to as **Manchester adder**. This idea combines very well with the carry skip technique to be mentioned in section 38.5.

The FA in Fig. 38.5(a) cannot send a carry over many positions in a ripple carry adder. For speed-up, we need to insert an inverter in every few positions to send a high output power over many higher bit positions. In order to reduce the number of inverters which have delays in themselves, we can use the FA shown in Fig. 38.5(b) which works with complemented carries. An example with insertion of an inverter at the end of every four cascaded FAs is shown in Fig. 38.6, where a block of four of Fig. 38.5(a) and a block of four of Fig. 38.5(b) are alternated. In Fig. 38.5(b), inverters consisting of MOSFETS 5, 6, 7, and 8 are eliminated from (a), and the function $x_i \oplus y_i$ at point 10 in (b) is the complement of the function at the corresponding point in (a).

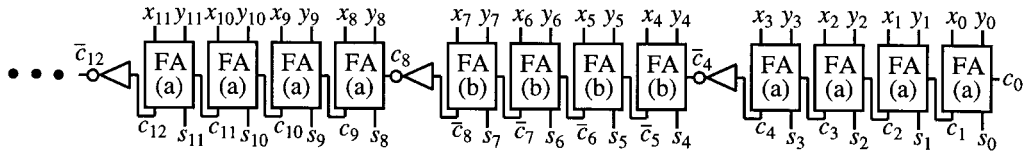


FIGURE 38.6 A ripple carry adder realized by connecting Figs. 38.5(a) and (b).

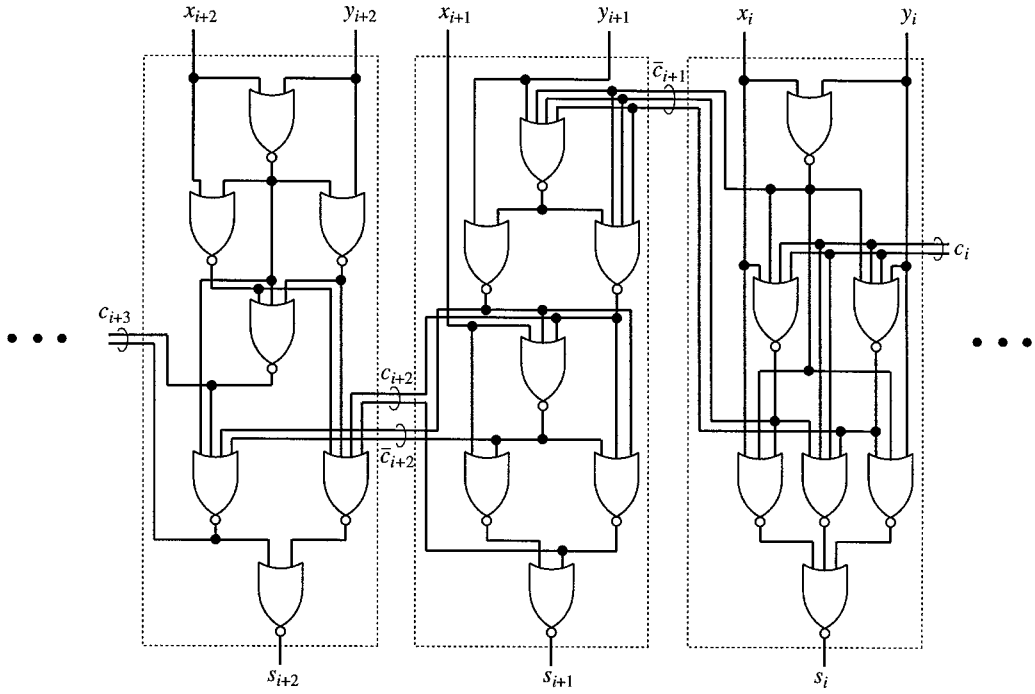
For high speed, a Manchester full adder realized in dynamic CMOS is used instead of the Manchester full adder shown in static CMOS, where dynamic CMOS and static CMOS are two different variations of CMOS. For example, a Manchester full adder in dynamic CMOS is used inside an adder (to be mentioned later) which is more complex but faster than ripple carry adders.[7]

In the simultaneous addition in all n-bit positions, a carry propagates n positions in the worst case, but on the average, it propagates only about $\log_2 n$ positions.[13] The average computation time of a ripple carry adder can be reduced by detecting the carry completion, because we need not always wait for the worst delay. An adder with such a mechanism is called a carry completion detection adder[3] and is useful for asynchronous systems.

When an FA is realized with ordinary logic gates, say NOR gates only, the total number of logic gates in the ripple carry adder is not minimized, even if the number of logic gates in each FA is minimized. But the number of logic gates in the ripple carry adder can be reduced by using modules that have more than one input for a carry-in (the carry-in c_i, for example in Fig. 38.7 is represented by two lines, instead of one line) and more than one output for a carry-out (the complemented carry-out $\bar{c}_{i+1}$ in Fig. 38.7 is represented by three lines), as shown in Fig. 38.7 (where modules are shown in dot-lined rectangles), instead of using FAs which have only one input for a carry-in and only one output for a carry-out. The number of NOR gates of such a module is minimized by the integer-programming logic design method[11] and it is found that there are 13 minimal modules. Different types of ripple carry adders can be realized by cascading such minimal modules. Some of these adders have carry propagation times shorter than that of the ripple carry adder realized with FAs with NOR gates. Besides, there is an adder that has a minimum number of NOR gates — when this adder is constructed by cascading the three consecutive minimal modules shown in dot-lined rectangles in Fig. 38.7, where the module for the least significant bit position is slightly modified (i.e., replacement of the two carry inputs by a single carry input) and one NOR gate is added to convert the carry out in multiple-lines from the adder into the carry out in a single line. Then it is proved that the total number of NOR gates in this ripple carry adder is minimum for any value of n.[8] Also, there is a ripple adder such that the number of connections, instead of the number of logic gates, is minimized.[14] Related adders are referred to in Section 2.4.3 of Ref. 11.



A ripple adder that has the minimal number of NOR gates for any arbitrary bit length can be realized by cascading these three consecutive minimal modules.

FIGURE 38.7 Three consecutive minimal modules for a ripple carry adder that has the minimal number of NOR gates for any arbitrary bit length.

38.5 Carry Skip Adder

In a ripple carry adder, a carry propagates through the i-th FA when $x_i \neq y_i$, i.e., $x_i \oplus y_i = 1$. Henceforth, we denote $x_i \oplus y_i$ as p_i. A carry propagates through a block of consecutive FAs, when all p_i's in the block are 1. This condition (i.e., all p_i's are 1) is called the carry propagation condition of the block.

A **carry skip adder** is a ripple carry adder that is partitioned into several blocks of FAs, attaching a carry skip circuit to each block, as shown in Fig. 38.8.[9] A carry skip circuit detects the carry propagation condition of the block and lets the carry from the next lower block bypass the block when the condition holds. In Fig. 38.8, carry skip circuits are not attached to the blocks at the most and least significant few positions because the attachment does not speed up the carry propagation much.

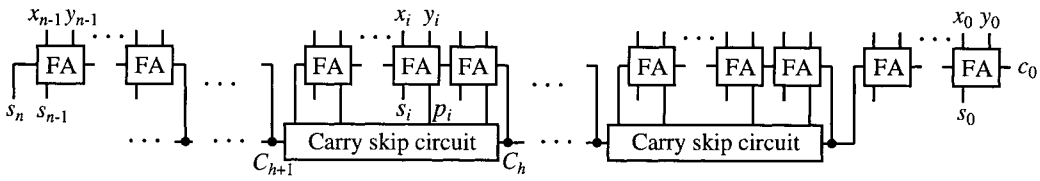


FIGURE 38.8 A carry skip adder.

In the carry skip circuit included in Fig. 38.8, the carry output, C_{h+1}, from block h that consists of k FAs starting from j-th position is calculated as:

$$C_{h+1} = c_{j+k} \vee P_h C_h$$

where c_{j+k} is the carry from the FA at the most significant position of the block,

$$P_h = p_{j+k-1}p_{j+k-2} \cdots p_j$$

is the formula for the carry propagation condition of the block, C_h is the carry from the next lower block, and p_i's are calculated in FAs. An example of carry skip circuit is shown in Fig. 38.9.

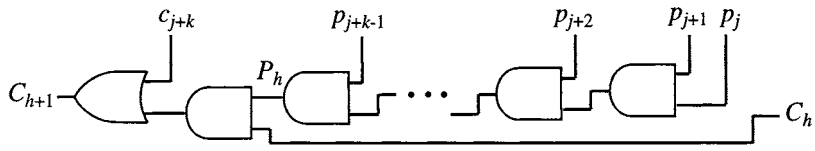

FIGURE 38.9 A carry skip circuit used in Fig. 38.8.

A carry may ripple through FAs in the block where it is generated, bypass the blocks where the carry propagation condition holds, and then, ripple through FAs in the block where the carry propagation condition does not hold. When all blocks are of the same size, k FAs, the worst case occurs when a carry is generated at the least significant position and propagate to the most significant position. The worst delay is the sum of the delay for rippling through $k-1$ FAs, the delay for bypassing $n/k-2$ blocks, and the delay for rippling through $k-1$ FAs. In the case that k is a constant independent of n, as well as in the case that k is proportional to n, the delay is proportional to n. We can reduce the worst delay to being proportional to $\sqrt{n}$, by letting k be proportional to $\sqrt{n}$. The amount of hardware for the entire adder is proportional to n in any case.

Applying the principle used to develop the carry skip adder borrowed from the ripple carry adder, we have a two-level carry skip adder from the basic carry skip adder, for further improvements. Recursive application of the principle yields a multi-level carry skip adder.[12]

38.6 Carry Look-Ahead Adder

As previously stated, the carry, c_{i+1}, produced at the i-th position is calculated as $c_{i+1} = x_i \cdot y_i \vee c_i \cdot (x_i \oplus y_i)$. This means that a carry is generated if both x_i and y_i are 1, or an incoming carry is propagated if one of x_i and y_i is 1 and the other is 0. Therefore, letting g_i denote $x_i y_i$, we have $c_{i+1} = g_i \vee c_i p_i$, where $p_i = x_i \oplus y_i$. Here, g_i is the formula for the carry generation condition at the i-th position, i.e., when g_i is 1, a carry is generated at this position. Substituting $g_{i-1} \vee p_{i-1}c_{i-1}$ for c_i, we get

$$c_{i+1} = g_i \vee p_i g_{i-1} \vee p_i p_{i-1} c_{i-1}$$

Recursive substitution yields

$$c_{i+1} = g_i \vee p_i g_{i-1} \vee p_i p_{i-1} g_{i-2} \vee \ldots \vee p_i p_{i-1} \ldots p_0 c_0$$

A **carry look-ahead adder** can be realized according to this expression, as illustrated in Fig. 38.10 for the case of four bits.[21] According to this expression, c_{i+1}'s are calculated at all positions in parallel.

It is hard to realize an n-bit carry look-ahead adder precisely according to this expression, unless n is small, because maximum fan-in and fan-out restriction is violated at higher positions. Large fan-out causes large delay, so the maximum fan-out is restricted. Also, the maximum fan-in is usually limited to 5 or less. There are some ways to alleviate this difficulty, as follows.

One way is the partition of carry look-ahead adders into several blocks such that each block consists of k positions, starting from the j-th one. In a block h, the carry at each position, c_{i+1}, where $j \le i \le j+k-1$, is calculated as

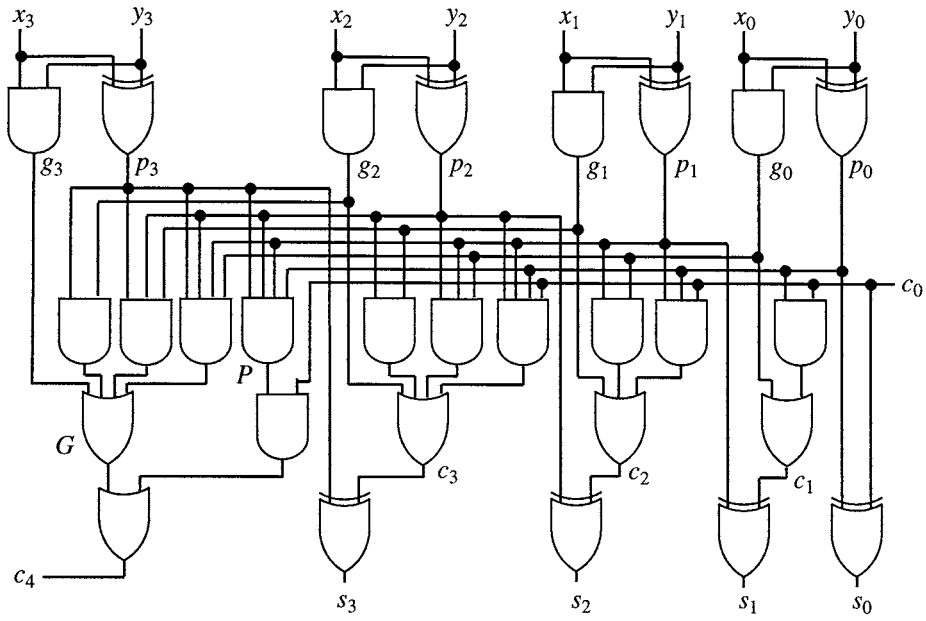

FIGURE 38.10 A 4-bit carry look-ahead adder.

$$c_{i+1} = g_i \vee p_i g_{i-1} \vee \ldots \vee p_i p_{i-1} \cdots p_{j+1} g_j \vee p_i p_{i-1} \cdots p_{j+1} p_j C_h$$

where C_h, i.e., c_j is the carry from the next lower block. The carry from the next lower block, C_h, goes to only the positions of the block h, so the fan-outs and fan-ins do not increase beyond a certain value. Therefore, we can form an n-bit adder by cascading n/k k-bit carry look-ahead adders, where k is a small constant independent of n, often 4. The worst delay of this type of adder and also the hardware amount are proportional to n.

Another way of alleviating the difficulty is recursively applying the principle of carry look-ahead to groups of blocks. The carry output of block h, C_{h+1} $(= c_{j+k})$, is calculated as

$$C_{h+1} = g_{j+k-1} \vee p_{j+k-1} g_{j+k-2} \vee \ldots \vee p_{j+k-1} p_{j+k-2} \cdots p_{j+1} g_j \vee p_{j+k-1} p_{j+k-2} \cdots p_{j+1} p_j C_h$$

This means that in the block, a carry is generated if

$$G_h = g_{j+k-1} \vee p_{j+k-1} g_{j+k-2} \vee \ldots \vee p_{j+k-1} p_{j+k-2} \cdots p_{j+1} g_j$$

is 1, and an incoming carry is propagated if $P_h = p_{j+k-1} p_{j+k-2} \cdots p_{j+1} p_j$ is 1. G_h is the formula for the carry generation condition of the block and P_h is the formula for the carry propagation condition of the block. (They are shown as P and G in Fig. 38.10) Let us consider a super-block, that is, a group of several consecutive blocks. The carry generation and the carry propagation condition of a super-block are detected from those of the blocks, in the same way that G_h and P_h are detected from g_i's and p_i's. Once the carry input to a super-block is given, carry outputs from the blocks in the super-block are calculated immediately. Consequently, we obtain a fast adder in which small carry look-ahead circuits which include carry calculation circuits are connected in a tree form. Figure 38.11 shows a 4-bit carry look-ahead circuit and Fig. 38.12 shows a 16-bit carry look-ahead adder using the 4-bit carry look-ahead circuits, where carry look-ahead circuits are shown as CLA in Fig. 38.12. The worst delay of this type of adder is proportional to log n. The number of logic gates is proportional to n.

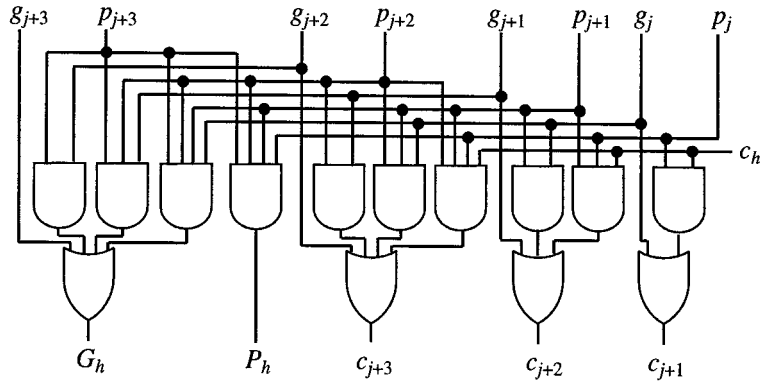

FIGURE 38.11 A 4-bit carry look-ahead circuit.

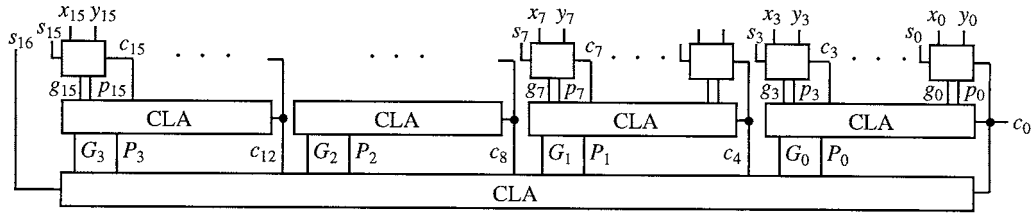

FIGURE 38.12 A 16-bit carry look-ahead adder. CLA stands for a carry look-ahead circuit which includes the carry calculation circuit shown in Fig. 38.10.

38.7 Carry Select Adder

We can reduce the worst delay of a ripple carry adder by partitioning the adder into two blocks: one for higher bit positions and the other for lower bit positions. In the block for higher bit positions, we calculate two candidate sums in parallel, one assuming a carry input of 0 from the block for lower bit positions and the other assuming a carry input of 1, then we select the correct sum based on the actual carry output from the block for lower bit positions. When we partition the adder into two blocks of the same size, the delay becomes about half because the calculations in these two blocks are carried out concurrently. An adder based on this principle is called a **carry select adder**.[1]

We can further reduce the delay by partitioning the adder into more blocks. Figure 38.13 shows a block diagram of a carry select adder. When all blocks are of the same size, k positions, the worst case occurs when a carry is generated at the least significant position and stops at the most significant position. The worst delay is the sum of the delay for rippling through $k-1$ FAs, and the delay for $n/k-1$ selectors.

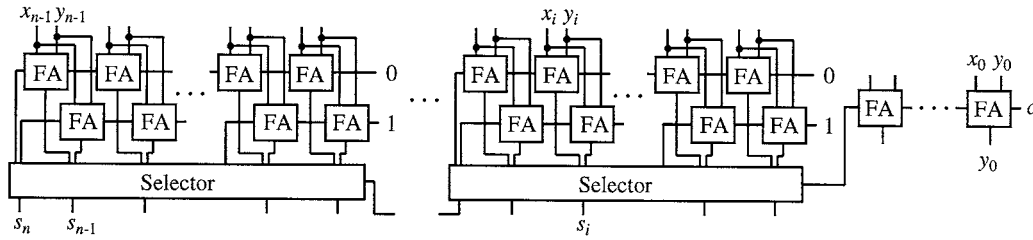

FIGURE 38.13 A carry select adder.

In the case that k is a constant independent of n, as well as in the case that k is proportional to n, the delay is proportional to n. We can reduce the worst delay to being proportional to $\sqrt{n}$, by letting k be proportional to $\sqrt{n}$. The amount of hardware is proportional to n in any case. It is to be noticed that a selector is unnecessary to the least significant few positions (probably less than k) in Fig. 38.13 because it is known whether the carry-in is 0 or 1.

We can reduce the amount of hardware by calculating two candidate sums using only one adder in each block.[19]

Applying the principle used to develop the carry select adder to each block, we can realize a two-level carry select adder. Recursive application of the principle yields a multi-level carry select adder. A conditional sum adder[16] can be regarded as the extreme case.

A carry select adder is used in a microprocessor with high performance.[7]

38.8 Carry Save Adder

When we add up several numbers sequentially, it is not necessary to propagate the carries during each addition. Instead, the carries generated during an addition may be saved as partial carries and added with the next operand during the next addition. Namely, we can accelerate each addition by postponing the carry propagation. This leads to the concept of carry save addition. We may add up numbers by a series of carry save additions, followed by a carry propagate addition. Namely, for multiple-operand addition, only one carry propagate addition is required.

An adder for carry save addition is referred to as a **carry save adder**, while the adders mentioned in the previous section are called **carry propagate adders**. A carry save adder sums up a partial sum and a partial carry from the previous stage as well as an operand and produces a new partial sum and partial carry. An n-bit carry save adder consists of just n full adders without interconnections among them.

39.1 Introduction

Many microprocessors and digital signal processors now have fast multipliers in them. There are several types of multipliers with different speeds, areas, and configurations. For the details of multipliers and multiplication methods, see Refs. 3–5, 7–10, and 14.

Here, let us consider multiplication of n-bit positive binary integers (without the sign bit) where a multiplicand $X = [x_{n-1}x_{n-2}\ldots x_0]$ is multiplied by a multiplier $Y = [y_{n-1}y_{n-2}\ldots y_0]$ to derive the product $P = [p_{2n-1}p_{2n-2}\ldots p_0]$, where each of x_i, y_i, and p_i takes a value of 0 or 1.

39.2 Sequential Multiplier

A **sequential multiplier** works in a manner similar to manual multiplication of two decimal numbers, although two binary numbers are multiplied in this case. A multiplicand $X = [x_{n-1}x_{n-2}\ldots x_0]$ is multiplied by each bit of a multiplier $Y = [y_{n-1}y_{n-2}\ldots y_0]$, forming the multiplicand-multiple $Z = [z_{n-1}z_{n-2}\ldots z_0]$, where $z_i = x_i y_j$ for each $i = 0, \ldots, n-1$. Then, Z is shifted left by j bit positions and is added, in all digit positions in parallel, to the partial product P_{j-1} which has been formed by the previous steps, to generate the partial product P_j. Repeating this step for $j = 0$ to $n-1$, the product $P = [p_{2n-1}p_{2n-2}\ldots p_0]$ of $2n$ bits is derived. The only difference of this sequential multiplier from the manual multiplication is the repeated addition of each multiplicand-multiple, instead of one-time addition of all multiplicand-multiples at the end.

This sequential multiplier is realized, as shown in Fig. 39.1, which consists of a Multiplicand Register of n-bits for storing multiplicand X, a Shift Register of $2n$-bits for storing multiplier Y and partial product P_{j-1}, a Multiplicand-Multiple Generator (denoted as MM Generator) for generating a multiplicand-multiple $y_j \cdot X$, and a Parallel Adder of n-bits. Initially, X is stored in the Multiplicand Register and Y is stored in the lower half (i.e., the least significant bit positions) of the Shift Register where the upper half of the Shift Register stores 0. This sequential multiplier performs one iteration step described above in each clock cycle. In other words, in each clock cycle, a multiplier bit y_j is read from the right-most position of Shift Register. A multiplicand-multiple $y_j \cdot X$ is produced by Multiplicand-Multiple Generator, which is X or 0 based on whether y_j is 1 or 0, and is fed to Parallel Adder. The upper n-bit of the partial product is read from the upper half of Shift Register and also fed to Parallel Adder. The content of Shift Register is shifted one position to the right. The $(n+1)$-bit output of Parallel Adder including the carry output, which is the upper part of the updated partial product, is stored into the upper $(n+1)$ positions of Shift Register. After n cycles, Shift Register holds the $2n$-bit product, P.

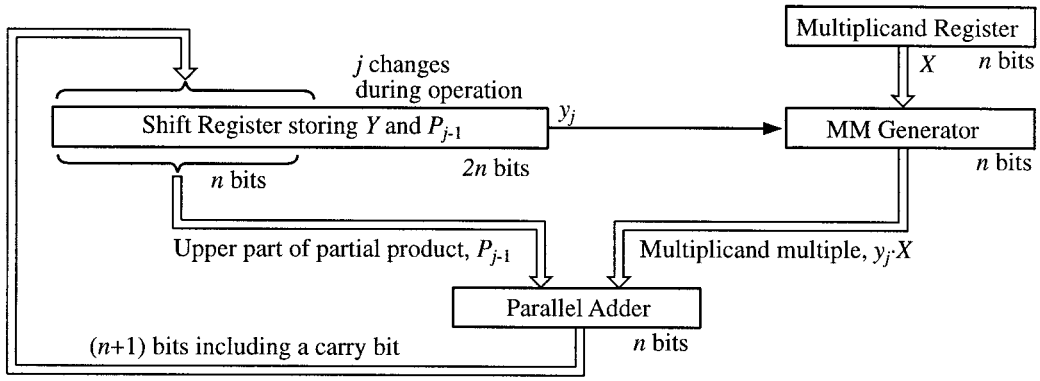

FIGURE 39.1 A sequential multiplier.

We can use any adder described in Chapter 38. The faster the adder, the shorter the clock cycle and hence the faster the multiplier. When we use a carry save adder as Parallel Adder, we have to modify Shift Register so that its upper half stores two binary numbers (i.e., a partial sum and a partial carry). Besides the carry save adder, we need a carry propagate adder for summing up the final partial sum and carry.

We can accelerate sequential multiplication by processing multiple-bits of the multiplier per clock cycle. When k-bits of multiplier Y are processed per cycle, an n-bit multiplication is performed through n/k clock cycles. There are two methods for processing multiple-bits of the multiplier per cycle. One is generating several candidate multiplicand-multiples and then choosing an appropriate one among them. The other is generating k multiplicand-multiples and summing them up in one cycle. Also, these two methods can be combined.

In the first method, Multiplicand-Multiple Generator generates 2^k different multiplicand-multiples, 0, X, $2X$, $3X$, …, $(2^k - 1)X$. For example, when $k = 2$, Multiplicand-Multiple Generator generates $2X$ and $3X$, as well as X and 0. Multiplicand-Multiple Generator consists of a look-up table containing the necessary multiples of the multiplicand and a selector for selecting an appropriate multiple. The look-up table need not hold all multiples, because several of them can be generated from others by shifting whenever necessary. For example, when $k = 2$, only $3X$ must be pre-computed and be held. **Extended Booth's method**[13] is useful for reducing the number of pre-computed multiples. When k-bits are processed per cycle, k-bit Booth's method is applied, which recodes multiplier Y into radix-2^k redundant signed-digit representation with the digit set $\{-2^{k-1}, -2^{k-1}+1, \ldots, 0, \ldots, 2^{k-1} - 1, 2^{k-1}\}$, where each digit in radix 2^k takes a value among those in this digit set. Y is recoded into $\hat{Y}$ by considering $k + 1$ bits of Y, i.e., $y_{kj+k-1}, y_{kj+k-2}, \ldots, y_{kj+1}, y_{kj}, y_{kj-1}$, (i.e., $k + 1$ bits among $y_{n-1}, y_{n-2}, \ldots, y_0$ of Y) per cycle, instead of only a single bit of Y (say, y_j) per cycle, as illustrated in Fig. 39.2(a). More specifically, the j-th digit $\hat{y}_j$ of the recoded multiplier, where $j = 0, 1, \ldots, \lceil (n+1)/k \rceil - 1$, is calculated as $\hat{y}_j = -2^{k-1} \cdot y_{kj+k-1} + 2^{k-2} \cdot y_{kj+k-2} + \ldots + 2 \cdot y_{kj+1} + y_{kj} + y_{kj-1}$. In this case, since all components of $Y = [y_{n-1} y_{n-2} \ldots y_0]$ are recoded for every k components at a time, the recoded number becomes $\hat{Y} = [\hat{y}_{\lceil (n+1)/k \rceil - 1} \hat{y}_{\lceil (n+1)/k \rceil - 2} \ldots \hat{y}_0]$ with $\lceil (n+1)/k \rceil$ components, in contrast to multiplier $Y = [y_{n-1} y_{n-2} \ldots y_0]$ which has n components. Then we have a multiplicand-multiple $\hat{y}_j \cdot X$. Since the negation of a multiple can be produced by complementing it bitwise and adding 1 at the least significant position (this 1 is treated as a carry into the least significant position of Parallel Adder), the number of multiples to be held is reduced. For example, when $k = 2$, the multiplier is recoded to radix-4 redundant signed-digit representation with the digit set $\{-2, -1, 0, 1, 2\}$ by means of the 2-bit Booth's method (i.e., the extended Booth's method with $k = 2$) as $\hat{y}_j = -2y_{2j+1} + y_{2j} + y_{2j-1}$ and all multiples are produced from X by shift and/or complementation. In 2-bit Booth recoding, multiplier Y is partitioned into 2-bit blocks, and then at the j-th block, the recoded multiplier digit $\hat{y}_j$ is calculated from the two bits of the block, i.e., y_{2j+1} and y_{2j}, and the higher bit of the next lower block, i.e., y_{2j-1}, according to the rule shown in Table 39.1. For example, 11110001010 is recoded to $2\ 0\ \bar{2}\ 1\ \bar{1}\ \bar{2}$, where $\bar{1}$ and $\bar{2}$ denote –1

1	1	0	–1
1	1	1	0

and –2, respectively, as illustrated in Fig. 39.2(b). (In this case, whenever a bit is not available in Y, such as the next lower bit of the least significant bit, it is regarded as 0.) When the extended Booth's method is employed, Parallel Adder is modified such that negative numbers can be processed.

In the second method for processing multiple-bits of the multiplier per clock cycle, Parallel Adder sums up $k + 1$ numbers, using k adders. Any adder can be used, but usually carry save adders are used for the sake of speed and cost. Carry save adders can be connected either in series or in tree form. Of course, the latter is faster, but the structure of Parallel Adder becomes more complicated because of somewhat irregular wire connections. By letting k be n, we have a parallel multiplier, processing the whole multiplier-bits in one clock cycle, as will be mentioned in the following section.

39.3 Array Multiplier

The simplest parallel multiplier is an **array multiplier**[2] in which the multiplicand-multiples (i.e., $(y_j \cdot X)$'s) are summed up one by one by means of a series of carry save adders. It has a two-dimensional array structure of full adders as shown in Fig. 39.3. Each row of full adders except the bottom one forms

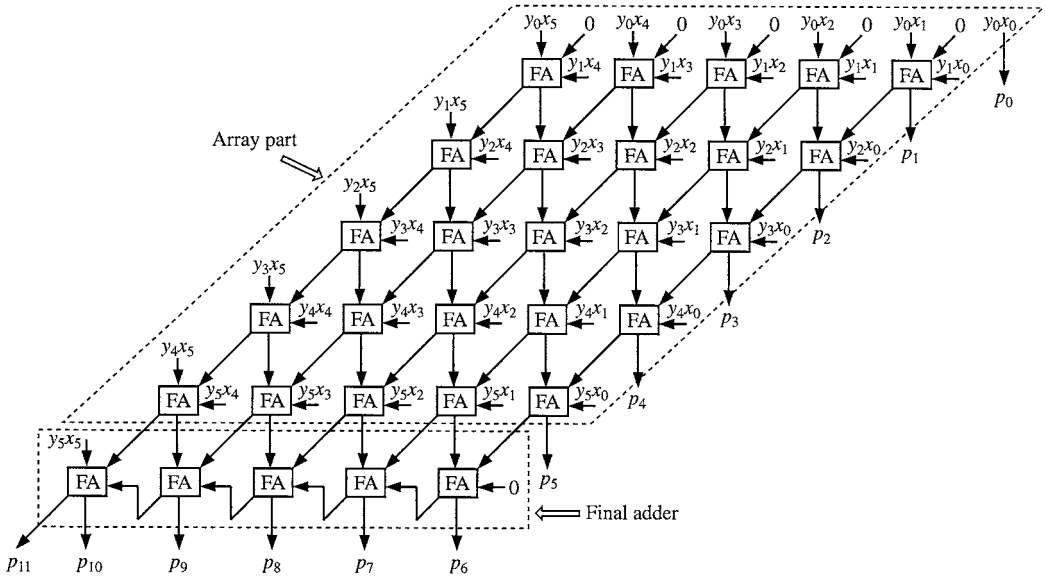

FIGURE 39.3 An array multiplier.

a carry save adder. The bottom row forms a ripple carry adder for the final carry propagate addition. An array multiplier is suited for VLSI realization because of its regular cellular array structure. The number of logic gates is proportional to n^2. The delay is proportional to n.

We can reduce the delay in the final adder by using a faster carry propagate adder such as a carry select adder. Also, we can reduce the delay in the array part in Fig. 39.3 by means of 2-bit Booth's method mentioned in Section 39.2. Since 2-bit Booth's method reduces the number of multiplicand-multiples to about half, the number of necessary carry save additions is also reduced to about half, and hence, the delay in the array part is reduced to about half. But the amount of hardware is not reduced much because a 2-bit Booth recoder and multiplicand-multiple generators, which essentially work as selectors, are required.

Another method to reduce the delay in the array part is to double the accumulation stream.[6] Namely, we divide the multiplicand-multiples into two groups, sum up the members of each group by a series of carry save adders independently of the other group, and then sum up the two accumulations into one. The delay in the array part is reduced to about half. The 2-bit Booth's method can be combined with this method. We can further reduce the delay by increasing the number of accumulation streams, although it complicates the circuit structure.

39.4 Multiplier Based on Wallace Tree

In the **multiplier based on Wallace tree**,[13] the multiplicand-multiples are summed up in parallel by means of a tree of carry save adders. A carry save adder sums up three binary numbers and produces two binary numbers (i.e., a partial sum and a partial carry). Therefore, using $n/3$ carry save adders in parallel, we can reduce the number of multiplicand-multiples from n to about $2n/3$. Then, using about $2n/9$ carry save adders, we can further reduce it to $4n/9$. Applying this principle about $\log_{3/2} n$ times, the number of multiplicand-multiples can be reduced to only two. Finally, we sum up these two multiplicand-multiples by means of a fast carry propagate adder.

Figure 39.4 illustrates a block diagram of a multiplier based on Wallace tree. This consists of full adders, just like the array multiplier described previously. (Recall that a carry save adder consists of full

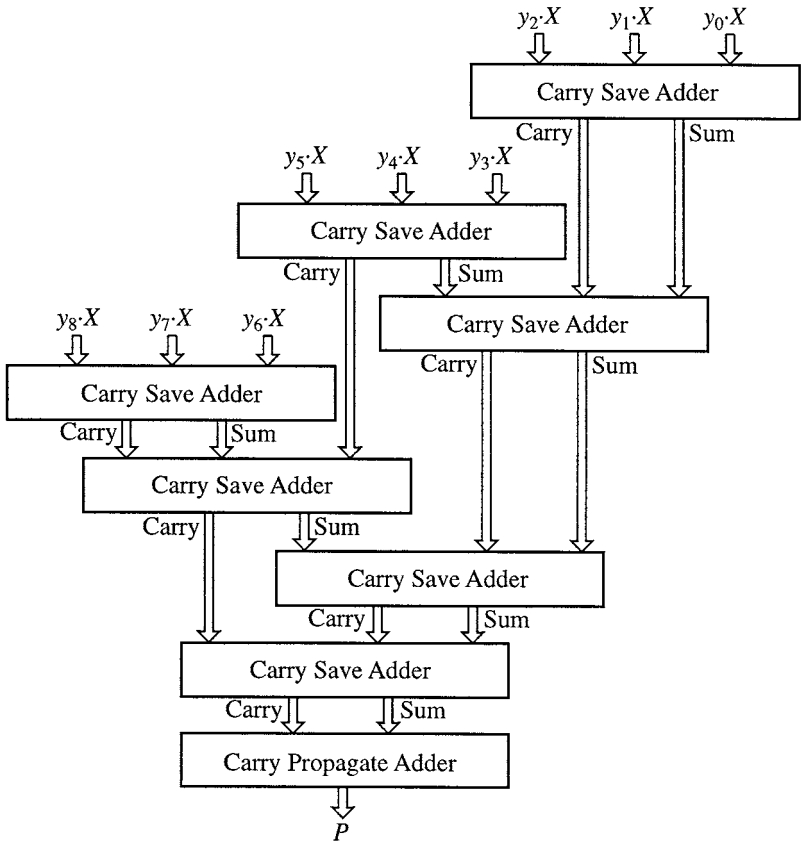

FIGURE 39.4 A multiplier with Wallace tree.

adders.) The delay is small. It is proportional to log n when a fast carry propagate adder with $O(\log n)$ delay is used for the final addition. The number of logic gates is about the same as that of an array multiplier and is proportional to n^2. However, its circuit structure is not suited for VLSI realization because of the complexity.

The 2-bit Booth's method can be also applied to this type of multiplier. However, it is not as effective as in the array multiplier, because the height of the Wallace tree decreases by only one or two, even though the number of the multiplicand-multiples is reduced to about half.

A full adder, which is used as the basic cell in a multiplier based on Wallace tree, can be regarded as a counter which counts up 1's in the three-input bits and outputs the result as a 2-bit binary number. Namely, a full adder can be regarded as a 3-2 counter. We can also use larger counters, such as 7-3 counters and 15-4 counters, as the basic cells, instead of full adders.

We can increase the regularity in the circuit structure by replacing Wallace tree with a 4-2 adder tree,[12] where a 4-2 adder is formed by connecting two carry save adders, shown in the dot-lined rectangles, in series, as shown in Fig. 39.5. A 4-2 adder is an adder that sums up four binary numbers, $A = [a_{n-1} \ldots a_0]$, $B = [b_{n-1} \ldots b_0]$, $C = [c_{n-1} \ldots c_0]$, and $D = [d_{n-1} \ldots d_0]$, and produces two binary numbers, $E = [e_n \ldots e_0]$ and $F = [f_n \ldots f_0]$, where $f_0 = 0$. We can form a 4-2 adder tree by connecting 4-2 adders in a binary tree form. The delay of a multiplier based on a 4-2 adder tree is slightly larger than that of a multiplier with Wallace tree but is still proportional to log n. The number of logic gates is about the same as a multiplier based on Wallace tree, and is proportional to n^2. It is more suited for VLSI realization than the Wallace tree.

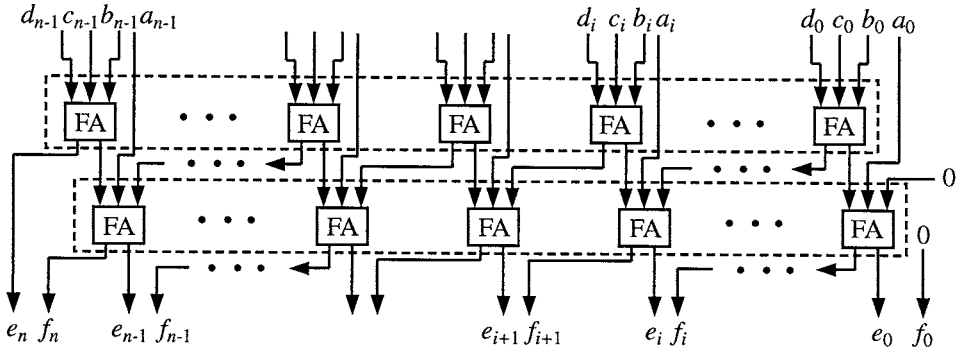

FIGURE 39.5 A 4-2 adder.

39.5 Multiplier Based on a Redundant Binary Adder Tree

There is another fast multiplier based on a rather regular structure called a **multiplier based on a redundant binary adder tree**.[11] In it, multiplicand-multiples are generated first as in other parallel multipliers, being regarded as redundant binary numbers, and are summed up pairwise by means of redundant binary adders connected in binary tree form. Then, finally, the product represented in the redundant binary representation is converted into the ordinary binary representation. The redundant binary representation, also called the binary signed-digit representation, is a binary representation with a digit set $\{\bar{1}, 0, 1\}$, where $\bar{1}$ denotes -1.[1] An n-digit redundant binary number $A = [a_{n-1}a_{n-2}\ldots a_0]$ has the value $\sum_{i=0}^{n-1} a_i \cdot 2^i$, where a_i takes a value $\bar{1}$, 0, or 1. There may be several redundant binary numbers which have the same value. For example, [0101], $[0 1 1 \bar{1}]$, $[1 \bar{1} 0 1]$, $[1 \bar{1} 1 \bar{1}]$, and $[1 0 \bar{1} \bar{1}]$ all represent 5. Because of this redundancy, we can add two redundant binary numbers without carry propagation.

Let us consider the addition of two redundant binary numbers, that is, the augend, $A = [a_{n-1}a_{n-2}\ldots a_0]$, and the addend, $B = [b_{n-1}b_{n-2}\ldots b_0]$ to derive the sum, $S = [s_n s_{n-1}\ldots s_0]$, where each of a_i, b_i, and s_i takes a value -1, 0, or 1. The addition without carry propagation is done in two steps. In the first step, an intermediate carry c_{i+1}, and intermediate sum d_i in the i-th position are determined such that $a_i + b_i = 2c_{i+1} + d_i$ is satisfied (the 2 of $2c_{i+1}$ means shifting c_{i+1} to the next higher digit position as a carry), where each of c_{i+1} and d_i is -1, 0, or 1. In this case, c_{i+1} and d_i are determined such that a new carry will not be generated in the second step. In the second step, in each digit position, sum s_i is determined by adding intermediate sum d_i and intermediate carry c_i from the next lower position, where c_i takes a value, -1, 0, or 1.

Suppose one of addend digit a_i and addend digit b_i is 1 and the other is 0. If $c_{i+1} = 0$ and $d_i = 1$ in the first step, a new carry will be generated for $c_i = 1$ from the next lower digit position in the second step. So, if there is a possibility of $c_i = 1$, we choose $c_{i+1} = 1$ and $d_i = \bar{1}$. On the other hand, if there is a possibility of $c_i = \bar{1}$, we choose $c_{i+1} = 0$ and $d_i = 1$. This makes use of the fact that 1 can be expressed by [01] and $[1 \bar{1}]$ in the redundant binary number representation. Whether c_i becomes 1 or $\bar{1}$ can be detected by examining a_{i-1} and b_{i-1} in the next lower digit position but not further lower digit positions. For other combinations of the values of a_i, b_i, and c_i, c_{i+1} and d_i can be similarly determined.

In the second step, s_i is determined by adding only two digits, c_i and d_i. Suppose $c_i = 1$. Then s_i is 0 or 1, based on whether d_i is $\bar{1}$ or 0. Notice that two combinations, $c_i = d_i = 1$ and $c_i = d_i = \bar{1}$, never occur. For other combinations of the values of c_i and d_i, s_i is similarly determined. Consequently, sum digit s_i at each digit position can be determined by the three digit positions of the angend and addend, a_i, a_{i-1} and a_{i-2}, and b_i, b_{i-1}, and b_{i-2}.

A binary number is a redundant binary number as it is, so there is no need for converting it to the redundant binary number representation. But conversion of a redundant binary number to a binary number requires an ordinary binary subtraction. Namely, we subtract the binary number that is derived by replacing every 1 by 0 and $\bar{1}$ by 1 in the redundant binary number, from the binary number that is

derived by replacing $\bar{1}$ by 0. For example, $[1\bar{1}0\bar{1}1]$ is converted to [00111] by the subtraction [10001] – [01010]. We need borrow propagate subtraction for this conversion. This conversion in a multiplier based on a redundant binary adder tree corresponds to the final addition in the ordinary multipliers.

40.1 Introduction

There are two major classes of division methods: subtract-and-shift methods and multiplicative methods. For details of division methods and dividers, see Refs. 2, 5–11, and also Ref. 3 for subtract-and-shift division.

Suppose two binary numbers, X and Y, are normalized in the range equal to or greater than 1/2 but smaller than 1 and also $X < Y$ holds for the sake of simplicity. Then, a dividend $X = [0.1x_2 \ldots x_n]$, which is an n-bit normalized binary fraction, is to be divided by a divisor, $Y = [0.1y_2 \ldots y_n]$, which is another n-bit normalized binary fraction, where each of x_i and y_i takes a value of 0 or 1. We assume to calculate the quotient $Z = [0.1z_2 \ldots z_n]$ which satisfies $|X/Y - Z| < 2^{-n}$, where z_i takes a value of 0 or 1.

40.2 Subtract-And-Shift Dividers

The **subtract-and-shift divider** works in a manner similar to manual division of one decimal number by another, using paper and pencil. In the case of manual division of decimal numbers, each x_i of dividend X and y_i of divisor Y is selected from {0, 1, …, 9} (i.e., the radix is 10). Each z_i of quotient Z is selected from {0, 1, …, 9}. In the following case of dividers for a digital system, dividend X and divisor Y are binary numbers, so each x_i of X and y_i of Y is selected from {0, 1}, but the quotient (which is not necessarily represented as a binary number) is expressed in radix r. The radix r, is usually chosen to be 2^k (i.e., 2, 4, 8, and so on.) So, a quotient is denoted with $Q = [0.q_1q_2 \ldots q_{\lceil n/k \rceil}]$, to be differentiated from $Z = [0.1z_2 \ldots z_n]$ expressed in binary numbers, although both Q and Z will henceforth be called quotients.

The subtract-and-shift method with a radix r iterates the recurrence step of replacing R_j by $r \cdot R_{j-1} - q_j \cdot Y$, where q_j is the j-th quotient digit and R_j is the partial remainder after the determination of q_j. Initially, R_{j-1} for $j - 1 = 0$; that is, R_0 is X. Each recurrence step consists of the following four substeps. Suppose that $r = 2^k$.

1. Shift of the partial remainder R_{j-1} to the left by k bit positions to produce $r \cdot R_{j-1}$.
2. Determination of the quotient digit q_j by quotient-digit selection.
3. Generation of the divisor multiple $q_j \cdot Y$.
4. Subtraction of $q_j \cdot Y$ from $r \cdot R_{j-1}$ to calculate R_j.

The dividers for a digital system have many variations, depending on the methods in choosing the radix, the quotient-digit set from which q_j is chosen (q_j is not necessarily 0 or 1, even if it is in radix 2),

and the representation of the partial remainder. The simplest cases are with a radix of 2 and the partial remainder represented in the non-redundant form. When $r = 2$, the recurrence is $R_j = 2R_{j-1} - q_j \cdot Y$. There are three methods: the restoring, the non-restoring, and the SRT methods.

Restoring Method

In the radix-2 restoring method, a quotient digit, q_j, is chosen from the quotient-digit set {0, 1}. When $2R_{j-1} - Y \geq 0$ ($2R_{j-1}$ means shift of R_{j-1} by one bit position to the left), 1 is selected, and otherwise 0 is selected. Namely, $R_j' = 2R_{j-1} - Y$ is calculated first, and then, when $R_j' \geq 0$ holds, we set $q_j = 1$ and $R_j = R_j'$, and otherwise $q_j = 0$ and $R_j = R_j' + Y$ (i.e., Y is added back to R_j'). For every j, R_j is kept in the range, $0 \leq R_j < Y$. The j-th bit of the quotient in binary number $Z = [0.1z_2 \ldots z_n]$, z_j, is equal to q_j (i.e., z_j is the same as q_j in radix 2 in this case of the restoring method). This method is called the **restoring method**, because Y is added back to R_j' when $R_j' < 0$. For speed-up, we can use $2R_{j-1}$ as R_j by keeping R_{j-1}, instead of adding back Y to R_j', when $R_j' < 0$. Figure 40.1 shows an example of radix-2 restoring division.

FIGURE 40.1 An example of radix-2 restoring division. (Each of *A*, *B*, and *C* is a sign bit. Notice that *D* is always equal to *E* and is ignored.)

Non-Restoring Method

In the radix-2 non-restoring method, a quotient digit, q_j is chosen from the quotient-digit set {–1, 1}. Quotient digit q_j is chosen according to the sign of R_{j-1}. In other words, we set $q_j = 1$ when $R_{j-1} \geq 0$ and, otherwise, we set $q_j = -1$, abbreviated as $q_j = \bar{1}$. Then, $R_j = 2R_{j-1} - q_j \cdot Y$ is calculated. Even if R_j is

negative, Y is not added back in this method, so this method is called the **non-restoring method**. Note that since we have $R_0 = X > 0$ and $(1/2) \le X < Y < 1$ by the assumption, we always have $q_1 = 1$ and $R_1 = 2R_0 - Y = 2X - Y > 0$, and hence, $q_2 = 1$. For every j, R_j is kept in the range, $-Y \le R_j < Y$. The j-th bit of the quotient in binary number $Z = [0.1z_2 \ldots z_n]$, z_j, is 0 or 1, based on whether q_{j+1} is -1 or 1. And we have always $z_n = 1$. For example, when $Q = [0.111\bar{1}\bar{1}1]$ where $\bar{1}$ denotes -1, we have $Z = [0.110011]$. (The given number $[0.111\bar{1}\bar{1}1]$ is calculated as $[0.111001] - [0.000110] = [0.110011]$. In other words, the number derived by replacing all 1's by 0's and all $\bar{1}$'s by 1's in the given number is subtracted from the number derived by replacing all $\bar{1}$'s by 0's in the given number. This turns out to be a simple conversion between z_j and q_{j+1}, as stated above, without requiring the subtraction.) Combining this conversion with the recurrence on R_j yields the method in which $R_1 = 2X - Y$, and for $j \ge 2$, when $R_{j-1} \ge 0$, $z_{j-1} = 1$ and $R_j = 2R_{j-1} - Y$ and, otherwise, $z_{j-1} = 0$ and $R_j = 2R_{j-1} + Y$. Figure 40.2 shows an example of radix-2 non-restoring division. Note that the remainder for the restoring method is always negative, whereas the remainder for the non-storing method (also the SRT method to be described in the following) can be negative, and consequently when the remainder is negative, the quotient of the latter is greater by 2^{-n} than the former. (This explains the difference between the quotients in Figs. 40.1 and 40.2, where $R_6 = 1$ in Fig. 40.2 indicates that the remainder is negative.)

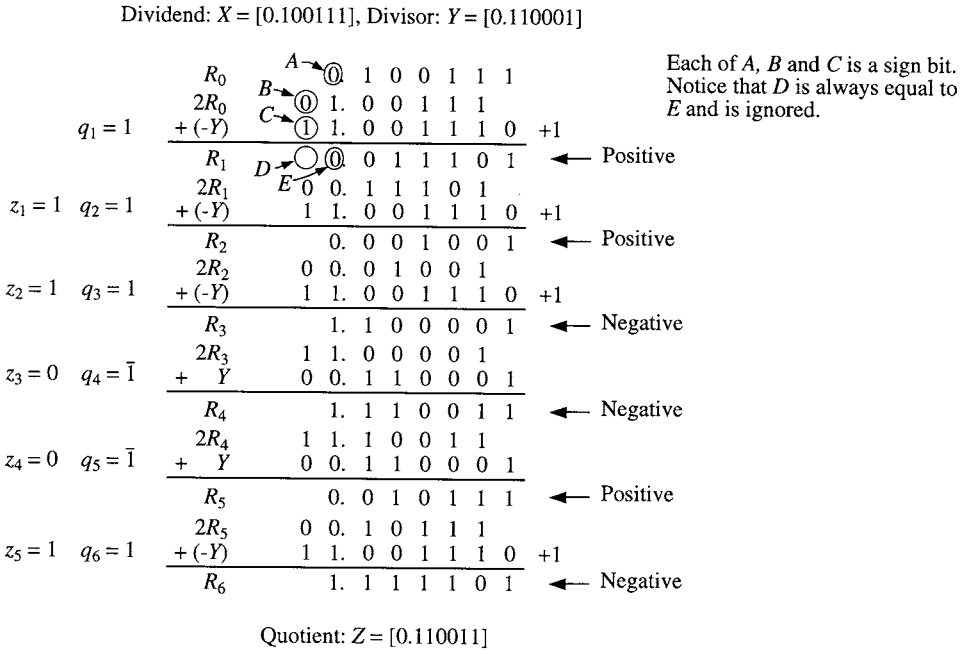

FIGURE 40.2 An example of radix-2 non-restoring division.

Figure 40.3 shows a radix-2 non-restoring divider that performs one recurrence step in each clock cycle. Register For Partial Remainder R_{j-1} initially stores the dividend X and then, during the division, stores a partial remainder R_{j-1} which may become negative. Divisor, Y, in Register For Divisor Y is added to or subtracted from the twice of the R_{j-1} stored in Register For Partial Remainder R_{j-1} by Adder/Subtracter, based on whether the left-most bit of Register For Partial Remainder R_{j-1} (i.e., the sign bit of R_{j-1}) is 1 or 0, and then the result (i.e., R_j) is stored back into Register For Partial Remainder R_{j-1}. Concurrently, the complement of the sign bit of R_{j-1} (i.e., z_{j-1}) is fed to Shift Register For Z_{j-2} (which stores the partial quotient $Z_{j-2} = [0.1z_2 \ldots z_{j-2}]$) from the right end, and the partial quotient stored in Shift Register For Z_{j-2} is shifted one position to the left. The divider performs one recurrence step in each clock cycle. After n cycles, Shift Register For Z_{j-2} holds the quotient Z. We can use any carry propagate adder (subtracter) as the Adder/Subtracter. The faster the adder, the shorter the clock cycle, and hence, the faster the divider.

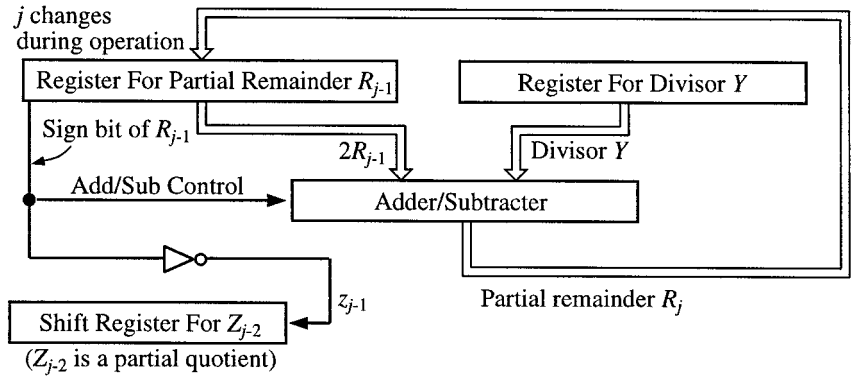

FIGURE 40.3 A radix-2 non-restoring divider.

SRT Method

In the radix 2 SRT method, the quotient-digit set is {–1, 0, 1}. In this case, –1 or 0 or 1 is selected as q_j, based on whether $2R_{j-1} < -(1/2)$ or $-(1/2) \le 2R_{j-1} < (1/2)$ or $(1/2) \le 2R_{j-1}$. When 0 is selected as q_j, no addition or subtraction is performed for the calculation of R_j, and hence, the computation time may be shortened. Quotient digit q_j is determined from the values of the three most significant bits (shown in each of the dot-lined rectangles in Fig. 40.4) of $2R_{j-1}$, as the radix-2 SRT division is exemplified in Fig. 40.4. R_{j-1} satisfies $-Y \le R_{j-1} < Y$ and is represented in a two's complement representation with 1-bit integral part (and n-bit fractional part).

Dividend: $X = [0.100111]$, Divisor: $Y = [0.110001]$

	R_0	A→	0.	1	0	0	1	1	1	
	$2R_0$	B→	0	1.	0	0	1	1	1	← $1/2 \le 2R_0$ (actually, $1 < 2R_0$)
$q_1 = 1$	+ (-Y)	C→	1	1.	0	0	1	1	1	0 +1
	R_1	D→	0	0.	0	1	1	1	0	1
	$2R_1$	E→	0	0.	1	1	1	0	1	← $1/2 \le 2R_1$
$q_2 = 1$	+ (-Y)		1	1.	0	0	1	1	1	0 +1
	R_2			0.	0	0	1	0	0	1
	$2R_2$		0	0.	0	1	0	0	1	← $-1/2 \le 2R_2 < 1/2$
$q_3 = 0$										← No addition
	R_3			0.	0	1	0	0	1	0
	$2R_3$		0	0.	1	0	0	1	0	← $1/2 \le 2R_3$
$q_4 = 1$	+ (-Y)		1	1.	0	0	1	1	1	0 +1
	R_4			1.	1	1	0	0	1	1
	$2R_4$		1	1.	1	0	0	1	1	← $-1/2 \le 2R_4 < 1/2$
$q_5 = 0$										← No addition
	R_5			1.	1	0	0	1	1	0
	$2R_5$		1	1.	0	0	1	1	0	← $2R_5 < -1/2$
$q_6 = \bar{1}$	+ Y		0	0.	1	1	0	0	0	1
	R_6			1.	1	1	1	1	0	1

Quotient: $Q = [0.11010\bar{1}] \rightarrow Z = [0.110011]$

FIGURE 40.4 An example of radix-2 SRT division. (Each of *A*, *B*, and *C* is a sign bit. Notice that *D* is always equal to *E* and is ignored.)

In the above three methods, carry (or borrow) propagates in the calculation of R_j in each recurrence step because the partial remainder is represented in the non-redundant form. We can accelerate the SRT method by using a redundant form for representing the partial remainder, and performing the calculation of R_j without carry (or borrow) propagation. Let us consider the use of the carry save form. R_j, which satisfies $-Y \le R_j < Y$, is represented in a two's complement carry save form with 1-bit integral part (and n-bit fractional part.) (In the two's complement carry save form, both the partial carry and the partial sum are represented in the two's complement representation.) In this case, –1 or 0 or 1 is selected as q_j, based on whether $2\hat{R}_{j-1} \le -1$ or $2\hat{R}_{j-1} = -(1/2)$, or $2\hat{R}_{j-1} \ge 0$, where $2\hat{R}_{j-1}$ denotes the value of the three most significant digits (shown in each of the dot-lined rectangles in Fig. 40.5), i.e., down to the first binary position, of $2R_{j-1}$. Note that $2\hat{R}_{j-1} \le 2R_{j-1} < 2\hat{R}_{j-1} + 1$. Figure 40.5 shows an example of radix-2 SRT division with the partial remainder represented in the carry save form.

Quotient: $Q = [0.111\bar{1}0\bar{1}] \rightarrow Z = [0.110011]$

FIGURE 40.5 An example of radix-2 SRT division with partial remainder represented in the carry save form. (The bits shown inside *A* are calculated from the bits shown inside *B*.)

In the radix-2 SRT method with the partial remainder represented in the carry save form, as in the original SRT method, the conversion of the quotient into the ordinary binary representation is required because the quotient is represented in the redundant binary representation with digit set {–1, 0, 1}. There is a method called the **on-the-fly conversion**[4] that performs the conversion without carry propagate addition. It converts the quotient on-the-fly as quotient digits are produced. Expressing the bits up to the j-th of Q and Z as $Q_j = [0.q_1q_2 \ldots q_j]$ and $Z_j = [0.z_1z_2 \ldots z_j]$ respectively, Z_j is the ordinary binary representation of Q_j or that of $Q_j - 2^{-j}$. The latter is the case when the remaining (lower) part of Q_n is negative. Therefore, we can obtain Z immediately after q_n is determined (i.e., all quotient digits are determined), by holding the ordinary binary representation of Q_j and that of $Q_j - 2^{-j}$ at each recurrence step. Let them be ZP_j and ZN_j, respectively. At each step, ZP_j and ZN_j are calculated as follows. When $q_j = -1$, $ZP_j = ZN_{j-1} + 2^{-j}$ and $ZN_j = ZN_{j-1}$. When $q_j = 0$, $ZP_j = ZP_{j-1}$ and $ZN_j = ZN_{j-1} + 2^{-j}$. When $q_j = 1$, $ZP_j = ZP_{j-1} + 2^{-j}$ and $ZN_j = ZP_{j-1}$. In any case, each calculation of ZP_j and ZN_j is performed by a selection of ZP_{j-1} or ZN_{j-1} and a concatenation of 0 or 1. Figure 40.6 shows an example of on-the-fly conversion.

$$

FIGURE 40.6 An example of on-the-fly conversion.

Figure 40.7 shows a radix-2 SRT divider with a carry save adder. Register For Partial Carry For R_{j-1} and Register For Partial Sum For R_{j-1} together store partial remainder R_{j-1} represented in the carry save form, i.e., by two binary numbers, partial carry, and partial sum. The three most significant bits of these two registers are fed to the Quotient-Digit Selector, which produces q_j. Divisor Multiple Generator generates Y, 0, or $-Y$, based on whether q_j is –1, 0, or 1. Shift Registers For Z_{j-1} consists of two shift registers for storing ZP_{j-1} and ZN_{j-1} and two selectors controlled by q_j.

40.3 Higher Radix Subtract-and-Shift Dividers

In the previous subsection, we considered radix-2 dividers. In this subsection, let us consider higher radix dividers. When the radix r is 2^k, the number of iterations of the recurrence step is n/k. The larger the k, the fewer the iterations but the longer the time of each recurrence step, because of the additional complexity in the quotient-digit selection and the generation of the divisor multiples.

A redundant digit set, especially a redundant symmetric signed-digit set $\{-a, -a+1, \ldots, -1, 0, 1, \ldots, a-1, a\}$, where $a \geq r/2$, is often used to obtain fast algorithms. A larger a reduces complexity of the quotient-digit selection but increases the complexity of the generation of the divisor multiples. The use of the signed-digit set makes the conversion of the quotient into the ordinary binary representation necessary. The partial remainder can be represented in either non-redundant form, or redundant form

(e.g., carry save form). By the use of a redundant form, we can perform addition/subtraction without carry/borrow propagation, and hence fast. However, it slightly complicates the quotient-digit selection and doubles the number of register bits required for storing the partial remainder.

Among the radix-4 methods, the method with the quotient-digit set of {–2, –1, 0, 1, 2} and the redundant partial remainder is the most popular, because the generation of the divisor multiples is easy and carry save addition can be used for speed-up. In this method, R_j, which satisfies $-(2/3)Y \le R_j < (2/3)Y$, is represented in the carry save form (or redundant binary representation with the digit set {–1, 0, 1}) with 1-bit integral part (and n-bit fractional part). ($R_0 = X$ and $X < (2/3)Y$ must hold.) Quotient digit q_j is determined from the seven most significant digits of R_{j-1} and the five most significant bits of Y. (Actually not five but four bits of Y are required, since its most significant bit is always 1.) The on-the-fly conversion of the quotient can be extended to radix-4. The essential part of a divider based on this method is very similar to that shown in Fig. 40.7. The seven most significant bits of the content of Register For Partial Carry For R_{j-1} and Register For Partial Sum For R_{j-1}, as well as the five (actually four) significant bits of the content of Register For Divisor Y are fed to Quotient Digit Selector. Divisor Multiple Generator generates $-2Y, -Y, 0, Y$, and $2Y$. This type of divider is used in floating point arithmetic units of several microprocessors.

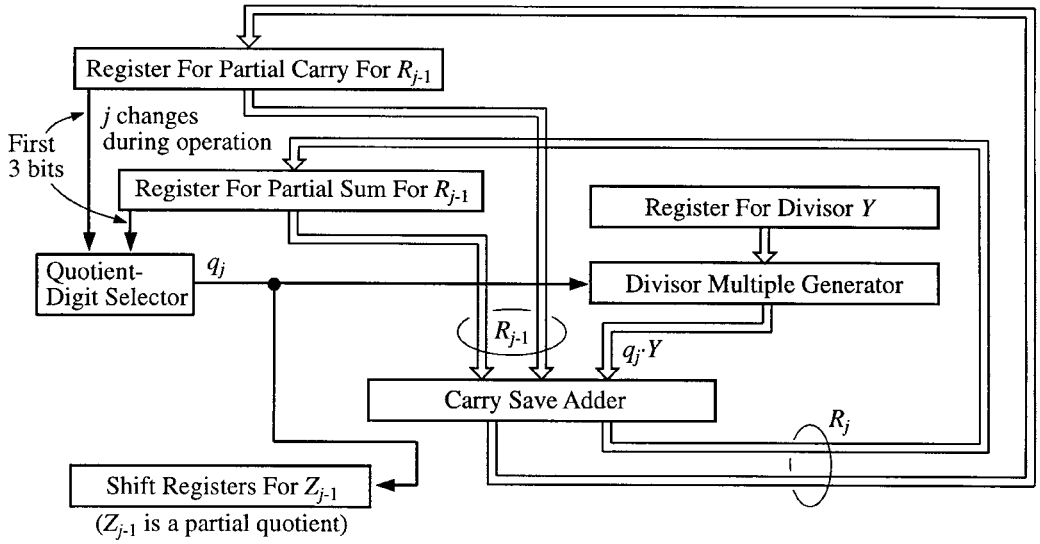

FIGURE 40.7 A radix-2 SRT divider with carry save adder.

An efficient radix-8 method is with the quotient-digit set of {–7, –6, … , –1, 0, 1, … , 6, 7} and the redundant partial remainder. Quotient digit q_j is determined from the eight most significant digits of R_{j-1} and the four most significant bits of Y. Quotient digit q_j is decomposed into two components, $qh_j \in \{-8, -4, 0, 4, 8\}$ and $ql_j \in \{-2, -1, 0, 1, 2\}$, and R_j is calculated through two carry save additions.

As the radix increases, the quotient-digit selection becomes more complex. This complexity can be reduced by restricting the divisor to a range close to 1, by prescaling the divisor. We can preserve the value of the quotient by prescaling the dividend with the same factor as the divisor. For example, we can design an efficient radix-16 method with the quotient-digit set of {–10, –9, … , –1, 0, 1, … , 9, 10}, where q_j is determined from the ten most significant digits of R_{j-1}, by scaling the divisor into $(8107/8192) \le Y \le (8288/8192)$. In this method, q_j is decomposed into two components, $qh_j \in \{-8, -4, 0, 4, 8\}$ and $ql_j \in \{-2, -1, 0, 1, 2\}$, and R_j is calculated through two carry save additions.

Since the recurrence step becomes more complex as the radix increases, a higher radix division step is implemented by several lower radix (i.e., radix of 2 or 4) stages. We can design a more efficient divider by not merely concatenating lower radix stages but overlapping them so that the delay and the cost of the hardware for the recurrence step are reduced.

40.4 Even Higher Radix Dividers with a Multiplier

Division with even higher radix, say radix-2^8, based on the iteration of calculating R_j by $r \cdot R_{j-1} - q_j \cdot Y$, requires a multiplier for the generation of the divisor multiple $q_j \cdot Y$. This multiplier is also used for prescaling the divisor very close to 1, so that the quotient digit is produced by truncation or rounding of the shifted partial remainder to the left of the radix point.

Many variations of the method are feasible, depending on the choice of the radix, the quotient-digit set, the representation of the partial remainder (non-redundant or redundant), quotient-digit selection (by truncation or rounding), calculation of the scaling factor, and scaling. The scaling factor can be calculated by any method that produces an approximation of the reciprocal of the divisor. Direct approximation by table look-up and linear interpolation by table look-up followed by multiply-addition are examples. There are three ways of performing scaling: scaling the divisor and the dividend, scaling the divisor and the quotient, and scaling the partial remainder in each iteration. A version of this method is realized in a math-coprocessor.[1]

40.5 Multiplicative Dividers

Multiplicative methods perform division through iterative multiplications and are employed in systems that have fast multipliers. The Newton method and Goldschmidt's algorithm are well-known.

The Newton method calculates the reciprocal of the divisor Y by the Newton-Raphson method. Beginning with an approximation to the reciprocal of the divisor, U_0, $1/Y$ is obtained through the iterative calculation of $U_{i+1} = U_i \cdot (2 - U_i \cdot Y)$. Multiplying the dividend X with the obtained $1/Y$, we can obtain the quotient.

Goldschmidt's algorithm is based on the fact that the value of a fraction is unchanged by multiplying both the numerator and the denominator by the same number. Namely, $X/Y = (X \cdot D_0 \cdot D_1 \cdot D_2 \ldots)/(Y \cdot D_0 \cdot D_1 \cdot D_2 \ldots)$ holds. When D_i's are selected so that $Y \cdot D_0 \cdot D_1 \cdot D_2 \ldots$ approaches to 1, $X \cdot D_0 \cdot D_1 \cdot D_2 \ldots$ approaches X/Y. We can obtain the quotient through the iterative calculations of $D_i = 2 - Y_i$, $Y_{i+1} = Y_i \cdot D_i$, and $X_{i+1} = X_i \cdot D_i$. We use an approximation to $1/Y$ as D_0.

In either method, an approximation to the reciprocal of the divisor is required. Direct approximation by table look-up or linear interpolation by table look-up followed by multiply-addition can be used. When the precision of the approximation is m-bits, n-bit division can be done through about $\log_2(n/m)$ iterations. Two multiplications and a complementation are performed in each iteration. The required calculations are almost the same in both methods. The two multiplications in the Goldschmidt's algorithm are independent of each other, whereas those in the Newton method are performed serially.

Multiplicative division methods are employed in mainframe computers as well as some microprocessors.

Full-Custom and Semi-Custom Design

Saburo Muroga
University of Illinois at Urbana-Champaign

41.1 Introduction

As integrated circuits become more inexpensive and compact, many new types of products, such as digital cameras, digital camcorders, and digital television,[2] are being introduced, based on digital systems. Consequently, logic design must be done under many different motivations. Since each case is different, we have different design problems. For example, we have to choose an appropriate IC (integrated circuit) logic family, since these cases have different performance requirements (scientific computers require high speed, but wristwatches require very low power consumption), although in recent years, CMOS has been more widely used than other IC logic families, such as ECL, which has been used for fast computers.

Logic functions that are frequently used by many designers, such as a full adder, are commercially available as off-the-shelf IC packages. (A package means an IC chip or a discrete component encased in a container.) Logic networks that realize such logic networks are often called **standard (logic) networks**. A single component, such as a resistor and a capacitor, is also commercially available as an off-the-shelf discrete component package. Logic networks can be assembled with these off-the-shelf packages. In many cases, not only performance requirements but also compactness and low cost are very important for products such as digital cameras. So, digital systems must accordingly be realized in IC packages that are designed, being tailored to specific objectives, rather than assembling many of these off-the-shelf packages on pc-boards, although assembling with these off-the-shelf packages has the advantage of ease of partial design changes.

Here, however, let us consider two important cases of designing an IC chip inside such an IC package, which is not off-the-shelf, that leads to two sharply contrasting logic design approaches: quick design and high-performance design. Quick design of IC chips is called **semi-custom design** (recently called **ASIC design**, abbreviating Application Specific Integrated Circuit design), whereas deliberate design for high performance is called **full-custom design** because full-custom design is fully customized to high performance. Full-custom design is discussed in this chapter, and different approaches of semi-custom design will be discussed in the succeeding chapters.

Semi-Custom Design

When manufacturers introduce new products or computers, it is ideal to introduce them with the highest performance in the shortest time. But it is usually very difficult to attain both, so one of them must be

emphasized, based on the firm's marketing strategy against competitors. Often, quick introduction of new computers or new merchandise with digital systems is very important for a manufacturer in terms of profits. (In some cases, introduction of a new product one year earlier than a competitor's generates more than twice the total income that the competitor gets.[1]) This is because the firm that introduces the product can capture all initial potential customers at highest prices, and latecomers are left with only the remaining fewer customers, selling at lower prices. This difference in timing often means a big difference in profits. In other words, the profits due to faster introduction of new products on a market often far exceed the profits due to careful design. The use of off-the-shelf IC packages, including off-the-shelf microprocessors, is used to be a common practice for shortening design time. But recent progress enables us to design digital systems in an IC chip more compactly with higher performance than before by curtailing time-consuming layout of transistor circuits on chips and by extensively using CAD programs. Thus, in the case of small volume production, the design cost, part of the product cost, is reduced. This makes semi-custom design appropriate for debugging or prototyping of new design. But extensive use of CAD programs tends to sacrifice the performance or compactness of the semi-custom-designed IC chips. Semi-custom design, or ASIC design, has several different approaches, as will be discussed in later chapters.[3,4] Design of logic networks with the highest performance requires deliberate design of logic networks, design of transistor circuits, layout of these transistor circuits most compactly, and manufacturing of them. Such logic networks are called **random-logic gate networks** and are realized by full-custom design. In contrast to full-custom design, semi-custom design simplifies design and layout of transistor circuits to save expenses and design time. Depending on how design and layout of transistor circuits are simplified (e.g., repetition of small transistor subcircuit, or not so compact layout) and even how logic design is simplified, we have variants of semi-custom design.

Full-Custom Design

Full-custom design is logic design to attain the highest performance or smallest size, utilizing the most advanced technology. Designers usually try to improve the economic aspect, that is, performance per cost, at the same time. Full-custom design with the most advanced technology usually takes many years to achieve final products, because new technology must often be explored at the same time. Hence, this is the other extreme to the above quick design in terms of design time. Every design stage is carefully done for the maximum performance, and transistor circuits are deliberately laid out on chips most compactly, spending months by many draftpeople and engineers. CAD programs are used but not extensively as in the case of semi-custom design. When CAD programs for high performance are not available, for example, for the most compact layout of transistor circuits to which is required for high performance — manual design is used, possibly mixed with the use of some CAD programs. Also, once mistakes sneak into some stages in the long sequence of design, designers have to repeat at least part of the long sequence of design stages to correct them. So, every stage is deliberately tested with substantial effort.

Motivation for Semi-Custom Design

It should be noticed that the cost of a digital system highly depends on the production volume of a chip. The cost of an IC package can be approximately calculated by the following formula:

$$\begin{bmatrix}\text{Total cost}\\ \text{of an IC}\\ \text{package}\end{bmatrix} = \frac{[\text{Design expenses}]}{[\text{Production volume}]} + \begin{bmatrix}\text{Manufacturing}\\ \text{cost per IC}\\ \text{package}\end{bmatrix} \tag{41.1}$$

The second term on the right-hand side of Eq. 41.1, [Manufacturing cost per IC package], is fairly proportional to the size of each chip when the complexity of manufacturing is determined, being usually on the order of dollars, or tens of dollars in the case of commercial chips. In the case of full-custom design, chips are deliberately designed by many designers spending many months. So, [Design

expenses], the first term on the right-hand side of Eq. 41.1 is very high and can easily be on the order of tens of millions of dollars. Thus, the first term is far greater than the second term, making [Total cost of an IC package] very expensive, unless [Production volume] is very large, being on the order of more than tens of millions. Many digital systems that use IC chips are produced in low volume and [Design expenses] must be very low. Semi-custom design is for this purpose and CAD programs need to be used extensively for shortening design time and manpower in order to reduce [Design expenses]. In this case, [Manufacturing cost per IC chip] is higher than that in the case of full-custom design because the size of each chip is larger.

Thus, we can see the following from the formula in Eq. 41.1: chips by semi-custom design are cheaper in small production volume than those by full-custom design, but more expensive in high production volume. But chips by full-custom design are cheaper in the case of high volume production, and are expensive for low volume production.

41.2 Full-Custom Design Sequence of a Digital System

Full-custom design flow of a digital system follows a long sequence of different design stages, as follows.

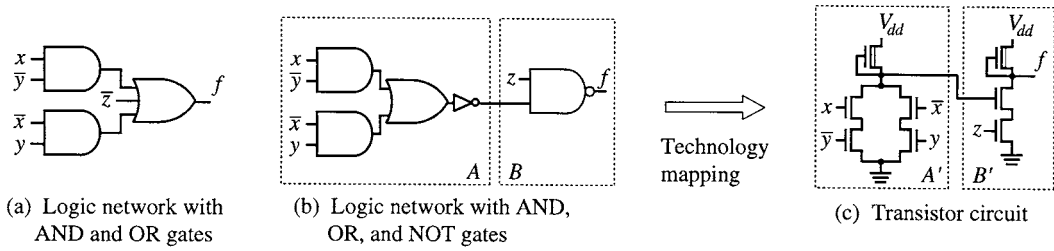
First, the architecture of a digital system is designed by a few people. The performance or cost of the entire system is predominantly determined by architectural design, which must be done based on good knowledge of all other aspects of the system, including logic design and also software to be run. If an inappropriate architecture is chosen, the best performance or lowest cost of the system cannot be achieved, even if logic networks, or other aspects like software, are designed to yield the best results. For example, if microprogramming is chosen for the control logic of a microcomputer based on ROM, it occupies too much of the precious chip area, sacrificing performance and cost, although we have the advantages of short design time and design flexibility. Thus, if performance or manufacturing cost is important, realization of control logic by logic networks (i.e., hard-wired control logic) is preferred. Actually, every design stage is important for the performance of the entire system. **Logic design is also one of key factors for computer performance, such as architecture design, transistor circuit design, layout design, compilers, and application programs. Even if other factors are the same, computer speed can be significantly improved by deliberate logic design.**

Next, appropriate IC logic families and the corresponding transistor circuit technology are chosen for each segment of the system. Other aspects such as memories are simultaneously determined in greater detail. We do not use expensive, high-speed IC logic families where speed is not required.

Architecture and transistor circuits are outside the scope of this handbook, so they are not discussed here further.

The next stage in the design sequence is the design of logic networks, considering cost reduction and the highest performance, realizing functions for different segments of the digital system. Logic design requires many engineers for a fairly long time.

Then, logic networks are converted into transistor circuits. This conversion is called **technology mapping**. It is difficult to realize the functions of the digital system with transistor circuits directly, skipping logic design, although experienced engineers can design logic networks and technology mapping at the same time, at least partly. Logic design with AND, OR, and NOT gates, using conventional switching theory, is convenient for human minds because AND, OR, and NOT gates in logic networks directly correspond, respectively, to basic logic operations, AND, OR, and NOT in logic expressions. Thus, logic design with AND, OR, and NOT gates is usually favored for manual design by designers and then followed by technology mapping. For example, the logic network with AND and OR gates shown in Fig. 41.1(a) is technology-mapped into the MOS circuit shown in Fig. 41.1(c). A variety of IC logic families, such as static MOS circuits and dynamic MOS circuits, are now used to realize logic gates. Thus, the relationships between logic networks with AND, OR, and NOT gates and those in transistor circuits are complex because logic gates realized in transistor circuits do not have one-to-one correspondence with AND, OR, and NOT gates, as illustrated in Fig. 41.1. The function $f = x\bar{y} \vee \bar{x}y \vee \bar{z}$ in Fig. 41.1 can be realized with two AND gates realizing $x\bar{y}$ and $\bar{x}y$, and then with an OR gate which has inputs from the AND



(a) Logic network with AND and OR gates

(b) Logic network with AND, OR, and NOT gates

(c) Transistor circuit

FIGURE 41.1 Technology mapping.

gates and $\bar{z}$, as shown in Fig. 41.1(a). But if the function is realized with AND, OR, and NOT gates, as shown in Fig. 41.1(b), then conversion of it into the MOS circuit shown in Fig. 41.1(c) is easier because correspondence between subnetworks in (b) and transistor logic gates in (c) is clear, where dot-lined rectangles, A and B, in (b) correspond A' and B' in (c), respectively.

Then, after technology mapping, these transistor circuits are laid out on a chip. Layout is also a painstaking endeavor for many draftpersons. The above design stages are highly interactive and iterative because, if bad design is made in a certain stage, good design in other stages cannot compensate for it, thus yielding poor performance or cost increase of the entire chip. In particular, logic network design and layout design are highly interactive.

In this case, it is important to notice the difference of delay time of signal propagation in logic networks from that in transistor circuits laid out on a chip. In previous chapters, we have assumed for the sake of simplicity that signal propagation has delay time only on gates (for the sake of simplicity, equal delay time is assumed on every gate) but not on connections. But in the case of transistor circuits, signal propagation on each connection has significant delay time, which can be greater than delay time of gates. The longer the connection, the greater the delay time on that connection. The larger the number of connections (i.e., fan-out connections) from the output of a gate, the greater the delay time of each connection. Also, each logic gate realized in transistor circuit may have a different delay time. The greater the fan-in of a gate, the greater the delay time. Restrictions on maximum fan-out and maximum fan-in are very important for the performance of logic networks. Thus, if we want to have fast transistor circuits, we need to consider these relationships in designing logic networks with AND and OR gates. Consideration of only the number of levels is not sufficient.

Then, IC chips are manufactured and are assembled with pc-boards into a digital system.

In the case of the high-performance design discussed above, every effort is made to realize digital systems with the best performance (usually speed), while simultaneously considering the reduction of cost.

When we want to develop digital systems of high performance, using the most advanced technology, much greater manpower and design time are required than that needed for semi-custom design approaches. The actual design time requirement depends on how ambitious the designers are. High-performance microprocessor chips are usually designed by full-custom design, typically taking 3 to 5 years with a large number of people, perhaps several dozen engineers. If the digital system is not drastically different from previous models, design time can be shorter with fewer people; but if the system is based on many new ideas, it may be longer.

As we become able to pack an increasingly large number of networks in a single IC chip every year, the full-custom design of VLSI chips (including microcomputers) of high performance with the most advanced technology is beginning to require far greater design effort and longer time. Thus, more extensive use of improved CAD programs is inevitable. This is because a new generation of microprocessor chips has been introduced every 4 years, having a few times as many transistors on a chip. Compared with systems of 10 years ago, contemporary systems consist of two or three order more transistors, although the physical size of these systems are far smaller. For example, IBM's first personal computer, introduced in 1981, was installed with only 16 kilobytes RAM (expandable to 64 kilobytes) and Intel's

microprocessor 8080, which consists of 4800 transistors. But Intel's microprocessor, Pentium III with 500 MHz, introduced in 1999 consists of about 9,500,000 transistors (an approximate number of logic gates can be obtained by dividing the number of transistors by a number between 3 and 5).

In addition to the use of transistor circuits as logic gates, memories are becoming widely used to implement logic networks, being mixed with gates. Also, software is often implemented with ROMs (read-only memories) as firmware, since ROMs are cheaper and smaller than RAMs (random-access memories). Because of these developments, we have complex problems in designing logic networks with a mixture of gates, software, and memories. Essentially, boundaries among logic design, transistor circuits, software, and architecture have disappeared. The number of transistors, or logic gates, used in digital systems is increasing all the time. In designing such gigantic digital systems, it is becoming extremely important to design without errors, necessitating extensive testing in every design stage. To cope with these complex problems, CAD programs with new logic design methods have been developed in recent years. For example, recent CAD programs for logic design can synthesize far larger logic networks than manual design can, and appropriate logic expressions can be derived for functions with a large number of variables by using BDDs.

Programmable Logic Devices

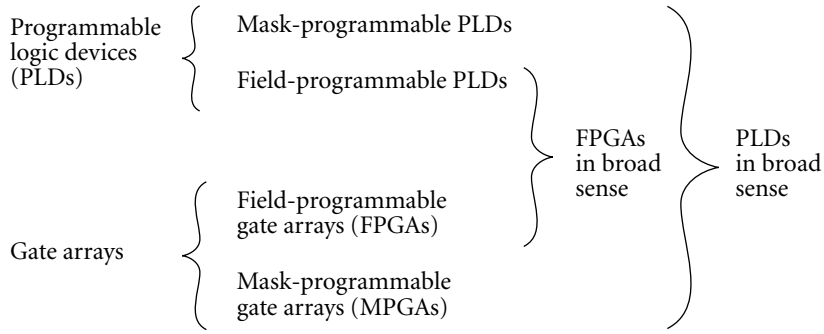
Saburo Muroga
University of Illinois at Urbana-Champaign

42.1 Introduction

Hardware realization of logic networks is generally very time-consuming and expensive. Also, once logic functions are realized in hardware, it is difficult to change them. In some cases, we need logic networks that are easily changeable. One such case is logic networks whose output functions need to be changed frequently, such as control logic in microprocessors, or logic networks whose outputs need to be flexible, such as additional functions in wrist watches and calculators. Another case is logic networks that need to be debugged before finalizing. **Programmable logic devices** (i.e., **PLD**s) are for this purpose. On these PLDs, all transistor circuits are laid out on IC chips prior to designers' use, considering all anticipated cases. With PLDs, designers can realize logic networks on an IC chip, by only deriving concise logic expressions such as minimal sums or minimal products, and then making connections among pre-laid logic gates on the chip. So, designers can realize their own logic networks quickly and inexpensively using these pre-laid chips, because they need not design logic networks, transistor circuits, and layout for each design problem. Thus, designers can skip substantial time of months for hardware design. CAD programs for deriving minimal sums or minimal products are well developed,[1] so logic functions can be realized very easily and quickly as hardware, using these CAD programs. The ease in changing logic functions without changing hardware is just like programming in software, so the hardware in this case is regarded as "programmable." Programmable logic arrays (i.e., PLAs) and FPGAs are typical programmable logic devices.

PLDs consists of mask-programmable PLDs and field-programmable PLDs. **Mask-programmable PLD**s (i.e., **MPLD**s) can be made only by semiconductor manufacturers because connections are made by custom masks. Manufacturers need to make few masks for connections out of all of more than 20 masks, according to customer's specification on what logic functions are to be realized. Unlike mask-programmable PLDs, **field-programmable PLD**s (i.e., **FPLD**s) can be programmed by users and are economical only for small production volume, whereas MPLDs are economical for high production volume. Logic functions can be realized quicker on FPLDs than on MPLDs, saving payment of charges for custom masks for connections to semiconductor manufacturers, but they are larger, more expensive, and slower because of addition of electronic circuits for programmability.

Classification of PLDs is somewhat confusing in publications. Gate arrays to be described in Chapter 43 are regarded as PLDs in a broad sense in some publications, as shown in the following table, though PLDs may not include **field-programmable gate array**s (i.e., **FPGAs**) in some publications. Field-programmable PLDs and FPGAs, are regarded as FPGAs in a broad sense. FPGAs in some cases have arrays of PLDs inside and are sometimes called **complex PLD**s to differentiate them from PLDs which are simpler.



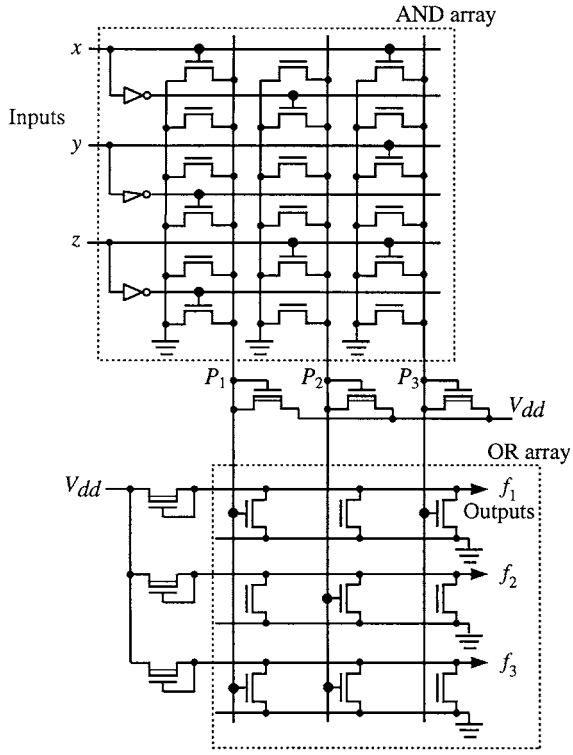
42.2 PLAs and Variations

Programmable logic arrays (i.e., PLAs) are one of programmable logic devices. Logic functions realized in PLAs can be as easily changed as software is.

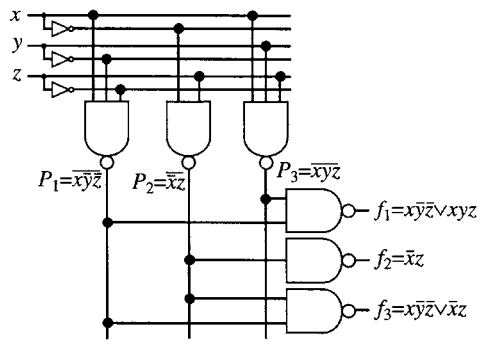
A **programmable logic array** (abbreviated as **PLA**), which was devised by Proebsting,[9] is a special type of ROM (which stands for **Read-Only Memory**), although its usage is completely different from that of ROMs. MOSFETS are arranged in a matrix on a chip, as illustrated in Fig.42.1(a). A PLA consists of an **AND array** and an **OR array**. In order to store logic expressions, connections between the MOSFET gates and the vertical lines in the AND array and also connections between the MOSFET gates and the horizontal lines in the OR array are set up by semiconductor manufacturers during fabrication according to customer' specifications. Since for these connections only one mask out of many necessary masks needs to be custom-made, PLAs are inexpensive when the production volume is high enough to make the custom preparation cost of the connection mask negligibly small. Because of low cost and design flexibility, PLAs are extensively used in VLSI chips, such as microprocessor chips for general computation and microcontroller chips for home appliances, toys, and watches.

When MOSFET gates are connected, as denoted by the large dots in Fig. 42.1(a), we have, $\overline{x\bar{y}\bar{z}}$, $\overline{\bar{x}z}$, $\overline{xyz}$, at the outputs P_1, P_2, P_3 of the AND array, respectively, since P_1, P_2, and P_3 represent the outputs of NAND gates, if negative logic is used with n-MOS. Here, **negative logic, where a high voltage and a low voltage are regarded as signal 0 and 1, respectively, is used for the sake of the convenience in deriving sums-of-products, i.e., disjunctive forms for the output functions f_1, f_2, and f_3.** (If positive logic is used, where a high voltage and a low voltage are regarded as signal 1 and 0, respectively, then P_1, P_2, and P_3 represent the outputs of NOR gates, and f_1, f_2, and f_3 are expressed in the forms of product-of-sums, i.e., in conjunctive forms. Since most people prefer disjunctive forms, negative logic is usually used in the case of PLAs.) Then, the outputs f_1, f_2, and f_3 of the OR-array also represent the outputs of NAND gates with P_1, P_2, P_3 as their inputs. Thus,

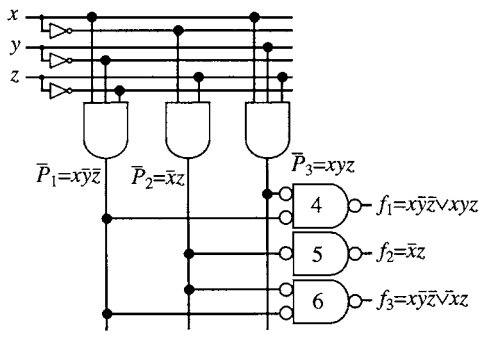
$$f_1 = \overline{P_1 P_3} = \bar{P}_1 \vee \bar{P}_3 = x\bar{y}\bar{z} \vee xyz$$
$$f_2 = \overline{P_2} = \bar{x}z$$
$$f_3 = \overline{P_1 P_2} = \overline{P_1} \vee \overline{P_2} = x\bar{y}\bar{z} \vee \bar{x}z$$



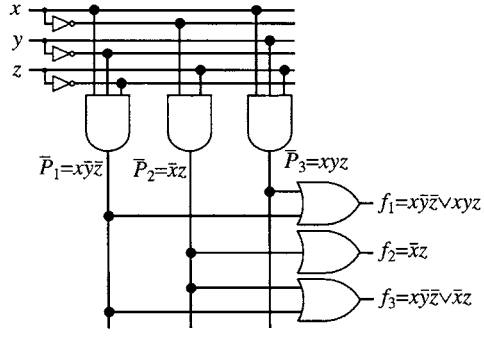
(a) PLA without flip-flops.



(b) Two-level NAND network which is equivalent to (a).



(c) Network converted from (b).



(d) Two-level AND-OR network which is equivalent to (a).

FIGURE 42.1 A PLA and equivalent logic networks.

(It is to be noted that in the AND array, the inputs x, y, and z have thier complements by inverters.) Therefore, the two arrays in Fig.42.1(a) represent a network of NAND gates in two levels, as illustrated in Fig. 42.1(b). This can be redrawn in Fig. 42.1(c) by moving the bubbles (i.e., inverters) to the inputs of the NAND gates 4, 5, and 6 without changing the outputs f_1, f_2, and f_3. Then, gate 4, for example, can be replaced by an OR gate because f_1 is

$$f_1 = \overline{P_1 P_3} = \bar{P}_1 \vee \bar{P}_3$$

by De Morgan's theorem. Thus, this is interpreted as a network of AND gates in the first level and OR gates in the second (output) levels, as illustrated in Fig. 42.1(d). This is the reason why the upper and lower matrices in Fig. 42.1(a) are called AND and OR arrays, respectively. The vertical lines which run through the two arrays in Fig. 42.1(a) are called the **product lines**, since they correspond to the product terms in disjunctive forms for the output functions f_1, f_2, and f_3 . Thus, any combinational network (or networks) of AND and OR gates in two levels can be realized by a PLA. The connections of MOSFET gates to horizontal or vertical lines are usually denoted by dots, as shown in Fig. 42.2.

Sequential networks can also be easily realized on a PLA, as shown in Fig. 42.2. Some outputs of the OR array are connected to the inputs of master-slave flip-flops (usually *J-K* master-slave flip-flops), whose outputs are in turn connected to the AND array as its inputs. More than one sequential network can be realized on a single PLA, along with many combinational networks. Flip-flops can be also realized inside the AND and OR arrays without providing them outside the arrays.

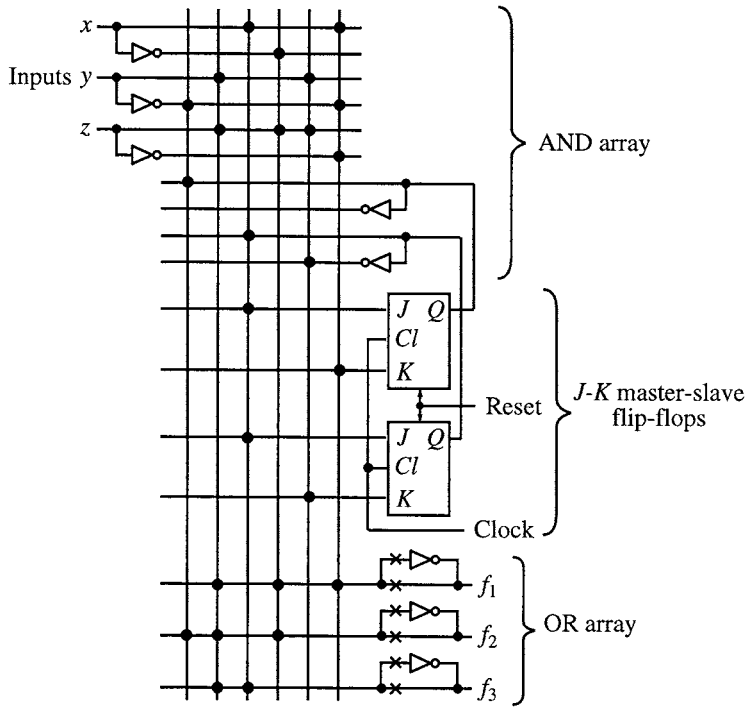


FIGURE 42.2 PLA with flip-flops and output-complementation choice.

In many PLAs, the option of an output f_1 or its complement $\bar{f}_1$ is provided in order to give flexibility, as illustrated in the lower right-hand corner of Fig. 42.2. By disconnecting one of the two ×'s at each output, we can have either f_1 or $\bar{f}_1$ as output, as illustrated in Fig. 42.3. When f_1 has too many products in its disjunctive form and cannot be realized on a PLA, its complement $\bar{f}_1$ may have a sufficiently small number of terms to be realizable on the PLA, or vice versa.

If the number of product lines in a PLA is too many, each horizontal line gets too long with a significant increase in parasitic capacitance. Then, if the majority of the MOSFET gates provided are connected to this horizontal line, the input or its inverter has too many fan-out connections on this horizontal line. Similarly, the total number of horizontal lines cannot be too large. In other words, the array size of a PLA is limited because of speed considerations. In contrast, the size of a ROM can be much larger, since we can use more than one decoder, or use a complex decoding scheme.

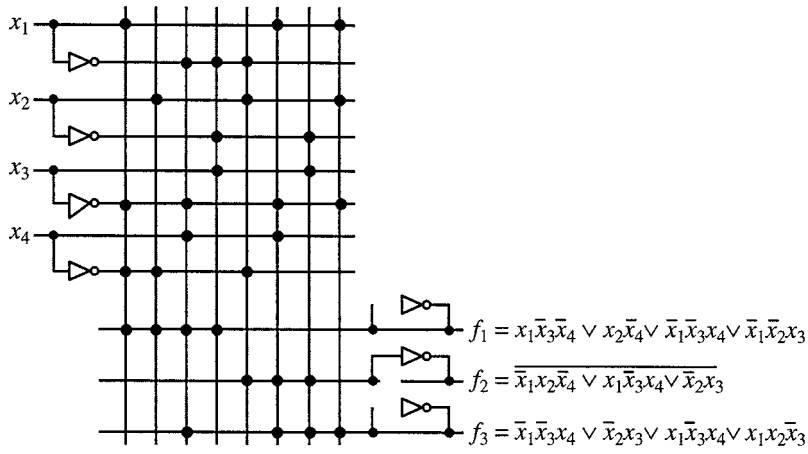

FIGURE 42.3 A PLA minimized for the given functions, f_1, f_2, and f_3.

The PLAs whose connections of some MOSFETs to lines are made by custom masks by semiconductor manufacturers are called **mask-programmable PLAs** (abbreviated as **MPLAs**).

A **field-programmable PLA** (abbreviated as **FPLA**) is also available, using fuses or anti-fuses, where unlike fuses, anti-fuses are initially not connected but can be connected by applying a voltage that is higher than a normal voltage. In an FPLA, a user can set up a dot pattern by blowing fuses or connecting anti-fuses connected to some MOSFETs by temporarily feeding excessively high voltages. In this realization, a special electronic circuit to blow fuses or to connect anti-fuses must be provided in addition to the PLA arrays, and this adds extra area to the entire area. In large-volume production, FPLAs are more expensive due to this extra size than PLAs, but when users need a small number of PLAs, FPLAs are much cheaper and convenient, since users can program FPLAs by themselves, inexpensively and quickly, instead of waiting weeks for the delivery of MPLAs from semiconductor manufacturers.

In contrast to the above FPLAs based on fuses, FPLAs whose undesired connections are disconnected by laser beam are also available. In this case, the chip size is smaller than that of the above FPLAs, since the electronic circuits to blow fuses are not necessary, but special laser equipment is required.

FPLAs are less expensive than MPLAs for small production volumes, although for high production volumes, MPLAs are much less expensive. In particular, when designers want to use MPLAs but their design is not completely debugged, they should try their design ideas with FPLAs and then switch to MPLAs only after debugging is complete, because if a semiconductor manufacturer is already working on MPLAs, sudden interruption of the work due to the discovery of design mistakes is unprofitable for both the manufacturer and the customer.

42.3 Logic Design with PLAs

Minimization techniques for multiple-output logic functions discussed in Chapter 27 can be used to minimize the size of a PLA. If the number of AND gates in a two-level AND-OR network (i.e., the number of distinct multiple-output prime implicants in disjunctive forms) for the given output functions is minimized, we can minimize the number of product lines, *t*. thus, the array size $(2n + m)t$ of a PLA is minimized when the PLA has n inputs, m outputs, and t product lines, where n and m are given. Also, if the total number of connections in a two-level AND-OR network is minimized as the secondary objective, as we do in the minimization of a multiple-output logic function, then the number of dots (i.e., connected intersections) of the product lines and the horizontal lines) in the PLA is minimized. Therefore, the derivation of a minimal two-level network with AND and OR gates by the minimization techniques known in switching theory is very important for the minimal and reliable design of PLAs.

The PLA show in Fig. 42.3, for example, is minimized for the given functions f_1, f_2, and f_3, with 8 product lines and array size, $(2 \times 4 + 3) \times 8 = 88$.

However, the minimization of the number of connections in a minimal two-level AND-OR network may not be as important as the minimization of the number of AND gates, although it tends to reduce the power consumption, because the chances of faulty PLAs can be greatly reduced by careful fabrication of chips. But the PLA size is determined by the number of AND gates and cannot be changed by any other factors. Also, instead of making connections (i.e., dots) as they become necessary on a PLA, a PLA is sometimes prepared by disconnecting unnecessary connections by laser beam or by blowing fuses after it has been manufactured with all MOSFET gates connected to the lines. In this case, the chances of faults can be reduced by increasing the number of connections (i.e., the number of dots) in the two-level AND-OR network.

For comparison with a PLA, the MOS realization of a ROM is shown in Fig. 42.4. The upper matrix is a decoder which has 2^n vertical lines if there are n input variables. The lower matrix stores information by connecting or not connecting MOSFET gates. Figure 42.4 actually realizes the same output functions (in negative logic) as those in Fig. 42.1(a). The AND array in Fig. 42.1(a) is essentially a counterpart of the decoder in Fig. 42.4, or the decoder may be regarded as a fixed AND array with 2^n product lines, which is the maximum number of the product lines in a PLA. The AND array in Fig. 42.1(a) has only three vertical lines, whereas the decoder in Fig. 42.4 has eight fixed vertical lines. This indicates the compact information packing capability of PLAs. PLAs are smaller than ROMs, although the packing advantage of PLAs varies, depending on functions. For example, if we construct a ROM that realizes the functions of the PLA of Fig. 42.3, in a manner similar to Fig. 42.4, the decoder consists of 8 horizontal lines and 16 vertical lines, and the lower matrix for information storage consists of 16 vertical lines and 3 horizontal lines. Thus, the ROM requires the array size of $16 \times (8 + 3) = 176$, compared with 88 in Fig 42.3.

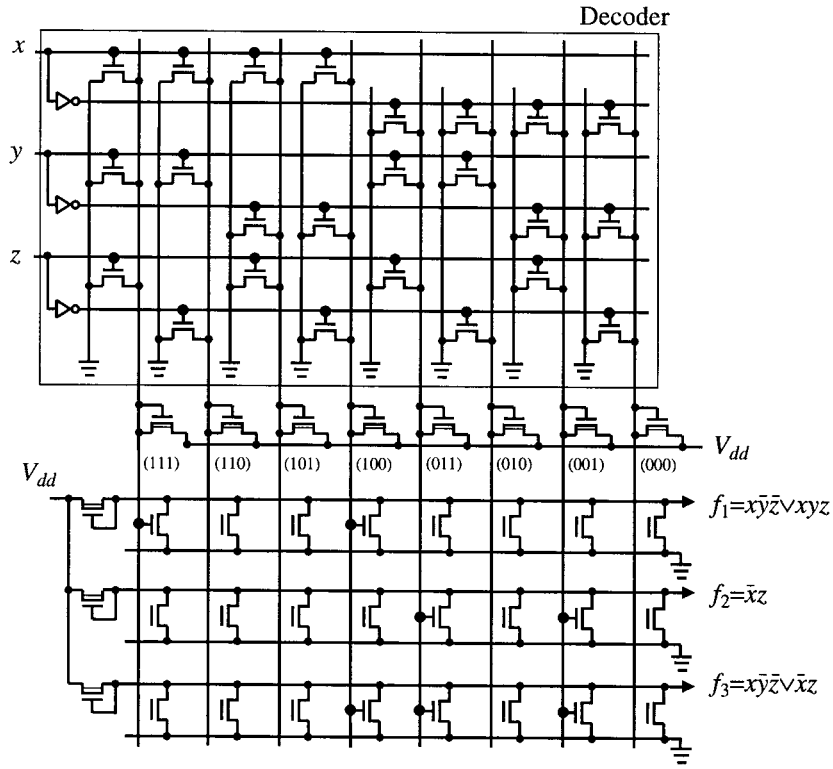

FIGURE 42.4 ROM that corresponds to the PLA in Fig. 42.1.

Generally, the size difference between PLAs and ROMs sharply increases as the number of input variables increases.

A PLA, however, cannot store some functions, such as $x_1 \oplus x_2 \oplus \ldots \oplus x_n$ if n is large, because 2^{n-1} product lines are required and the number of these lines is excessively large for a PLA. (The horizontal lines become too long with excessive fan-out and parasitic capacitance.) However, we can store these functions in a ROM with an appropriate decoding scheme.

Of course, in the case of ROMs, storing a truth table without worrying about conversion of given logic functions into a minimal sum is convenient, although it makes the ROM size bigger than the PLA size.

Minimal two-level networks of AND and OR gates for the absolute minimization of the PLA size can be derived by the minimization methods discussed in earlier chapters, if a function to be minimized has either at most several variables, or many more variables but with a simple relationship among its prime implicants.[8] But otherwise, we have to be content with near-minimal networks instead of minimal networks. In many cases, efforts to reduce the PLA size, even without reaching an absolute minimum, result in significant size reduction. Also, CAD programs have been developed with heuristic minimization methods,[12,13] such as the one by Hong et al.,.[7] which was the first powerful heuristic procedure drastically different from conventional minimization procedures. MINI, PLA minimization program of Hong, et al., was later improved to ESPRESSO by Rudell, Brayton, et al.[1,10,11] Recently, however, Coudert and Madre[2–6] developed a new method for absolute minimization by implicitly expressing prime implicants and minterms using BDDs described in Chapter 26. By this method, absolute minimization of functions with greater numbers of variables is more feasible than before, although it is still time-consuming.

42.4 Dynamic PLA

If we want to realize a PLA in CMOS, instead of static nMOS circuit that has been discussed in Chapter 30, Section 30.3, in order to save power consumption, then a PLA in CMOS requires a large area because we need pMOS and nMOS subcircuits. Thus, instead of static CMOS, the dynamic CMOS illustrated in Fig. 42.5(a) is usually used. During the absence of a clock pulse of the first- and second-phase clocks, ϕ_1 and ϕ_2 (i.e., during $\phi_1 = \phi_2 = 0$ (low voltage, using positive logic)) shown in Fig. 42.5(b), pMOSFETs, T_1, T_2, and T_3, become conductive and nMOSFETs, T_4, T_5, and T_6 become non-conductive precharging vertical lines, P_1, P_2, and P_3. When a clock pulse of the first-phase clock, ϕ_1, appears but a clock-pulse of the second-phase clock, ϕ_2, does not appear yet, i.e., when $\phi_1 = 1$ (high voltage) and $\phi_2 = 0$, pMOSFETs, T_1, T_2, and T_3, become non-conductive and nMOSFETs, T_4, T_5, and T_6, become conductive. Then, depending on the values of x, y, and z, some verticle lines, P_1, P_2, and P_3 are discharged through some of the nMOSFETs in the AND array. (For example, if y = 0 (low voltage), P_1 is discharged through nMOSFETs A.) A clock pulse of the second-phase clock, ϕ_2, is still absent (i.e., $\phi_2 = 0$), so pMOSFETs, T_7, T_8, and T_9, become conductive and nMOSFETs T_{10}, T_{11}, and T_{12}, become non-conductive, precharging horizontal lines, f_1, f_2, and f_3. When a clock pulse of the first-phase clock, ϕ_1, is still present, and a clock pulse of the second-phase clock, ϕ_2, appears, i.e., when $\phi_1 = \phi_2 = 1$, pMOSFETs, T_7, T_8, and T_9, become non-conductive and nMOSFETs, T_{10}, T_{11}, and T_{12}, become conductive. Then, some of horizontal lines, f_1, f_2, and f_3, are discharged through some of the nMOSFETs in the OR array, depending on which of the vertical lines, P_1, P_2, and P_3, are still charged.

42.5 Advantages and Disadvantages of PLAs

PLAs, like ROMs which are more general, have the following advantages over random-logic gate networks, where random-logic gate networks are those that are compactly laid out on an IC chip:

1. There is no neeed for the time-consuming logic design of random-logic gate networks and even more time-consuming layout.
2. Design checking is easy, and design change is also easy.
3. Layout is far simpler than that for random-logic gate networks, and thus is far less time-consuming.
4. When new IC fabrication technology is introduced, we can use previous design information with ease but without change, making adoption of the new technology quick and easy.

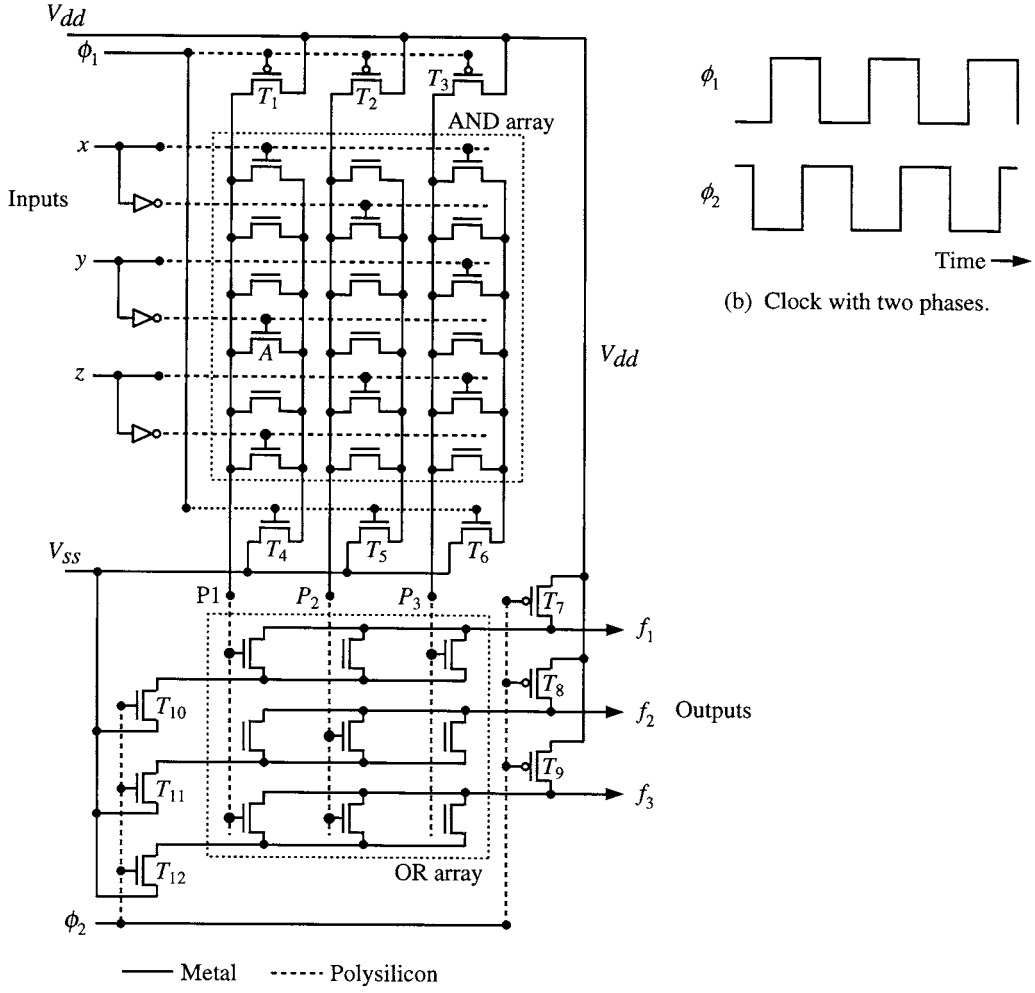

FIGURE 42.5 Dynamic PLA.

5. Only the connection mask needs to be custom-made.
6. Considering all these, PLA is a very inexpensive approach, greatly shortening desing time.

PLAs have the following disadvantages compared with random-logic gate networks:

1. Random-logic gate networks have higher speed than PLAs or ROMs.
2. Random-logic gate networks occupy smaller chip areas than PLAs or ROMs, although the logic design and the layout of random-logic gate networks are far more tedious and time-consuming.
3. Also, with large production volumes, random-logic gate networks are cheaper than PLAs or ROMs.

PLAs have the following advantage and disadvantage, compared with ROMs:

- For storing the same functions or tasks, PLAs can be smaller than ROMs; generally, the size difference sharply increases as the number of input variables increases.
- The small size advantages of PLAs diminishes as the number of terms in a disjunctive form increases. Thus, PLAs cannot store complex functions, i.e., functions whose disjunctive forms consist of many product terms.

Applications of PLAs

Considering the above advantages and disadvantages, PLAs have numerous unique applications. A microprocessor chip uses many PLAs because of easy of design change and check. In particular, PLAs are used in its control logic, which is complex and requires many changes, even during its design. Also, PLAs are used for code conversions, microprogram address conversions, decision tables, bus priority resolvers, and memory overlay.

When a new product is to be manufactured in small volume or test-marketed, PLAs is a choice. When the new product is well received in the market and does not need further changes, PLAs can be replaced by random-logic gate networks for low cost for high volume production and high speed. Also, a full-custom design approach is very time-consuming, probably taking months or years, but if PLAs are used in the control logic, a number of different custom-design chips with high performance can be made quickly by changing only one connection mask for the PLAs, although these chips cannot have drastically different performance and functions.

42.6 Programmable Array Logic

A **programmable array logic** (**PAL**) is a special type of a PLA where the OR array is not programmable. In other words, in a PAL, the AND array is programmable but the OR array is fixed; whereas in a PLA, both arrays are programmable. The advantage of PALs is the elimination of fuses in the OR array in Fig. 42.1(a) and special electronic circuits to blow these fuses. Since these special electronic circuits and programmable OR array occupy a very large area, the area is significantly reduced in PAL. Since single-output, two-level networks (i.e., many AND gates in the first level and one OR gate as the network output) are needed most often in desing practice, many single-output two-level networks which are mutually unconnected are placed in some PAL packages.

In digital systems, many non-standard networks are still used because designers want to differentiate their computers from competitors'. But logic functions that designers want to have are too diverse to be standardized by semiconductor manufacturers. When off-the-shelf IC packages for standard networks, including microprocessors and their peripheral networks, are assembled on pc boards, many non-standard networks are usually required for interfacing them to other key networks or for minor modifications. So, they require many discrete components and IC packages, each of which has a smaller number of transistors, in addition to a microprocessor package with millions of gates, occupying a significant share of the areas on pc boards. Now, we can make connections inside PALs, instead of custom-making pc boards. Custom-made pc boards are expensive and time-consuming because connection patterns on pc boards need to be designed, these pc boards need to be manufactured and then the holes of pc boards have to be soldered to the pins of IC packages. The replacement by PAL packages can substantially reduce the area, time, and cost. If we consider related factors such as reductions of cabinet size, power consumption, and fans, the significance of this reduction is further appreciated.

There are mask-programmable PALs and field-programmable PALs (i.e., FPALs). When logic design is not finalized and needs to be changed often, FPAL packages can reduce expense and time for repeatedly redesigning and remaking pc boards.

Gate Arrays

Saburo Muroga
University of Illinois at Urbana-Champaign

43.1 Mask-Programmable Gate Arrays

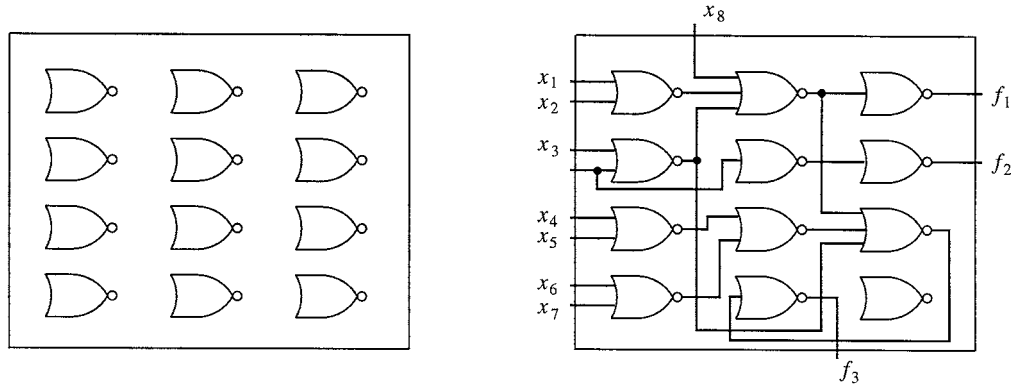
Among all ASIC chips, gate arrays are most widely used because with gate arrays, we can easily realize logic functions that require a far more logic gates than with PLAs. If PLAs are used, such logic functions would require far larger area and delay time. Also, design time with gate arrays is shorter than with the standard cell design approach to be described in Chapter 45.

A gate array is an IC chip on which gates are placed in matrix form without connections among the gates, as illustrated in Fig. 43.1(a). By connecting gates, we can realize logic networks, as exemplified in Fig. 43.1(b). But actually, logic gates are not realized in a gate array. Instead of gates, cells, each of which consists of unconnected components, are arranged in matrix form, and each cell can realize one of a few different types of gates by connecting these components. Then, by connecting these gates as illustrated in Fig. 43.1(b), networks can be realized. Only two or three masks for connections and contact windows (i.e., small metallic areas between MOSFETs and connections) have to be custom-made, instead of all two dozen masks required for full-custom design. Also, because only the connection layout, along with the placement of gates, needs to be considered, CAD can be effectively used, thereby greatly reducing the layout time. Thus, the design with gate arrays is very inexpensive and quick, compared with full-custom design. Gate arrays of CMOS have been extensively used in many computers.[1–3]

In Fig. 43.1(b), connections among gates are run in narrow strips of space between columns or rows of gates. These strips of space are called **routing channels**. In gate arrays that were commercially available for the first time, routing channels were provided between columns or rows of logic gates. Now, gate arrays without routing channels are also available, running connections over gates, as it becomes easy to do so because many metal layers are available. Such gate arrays are called **sea-of-gate array**s. Gate arrays with a large number of gates are usually sea-of-gates without routing channels. But gate arrays with routing channels are still used for those with a small number of gates. A relatively large number of pads are necessary, even for such small gate arrays. Then, the number of pads determines the area size of gate arrays and it does not matter whether or not routing channels are provided. If routing channels are provided, then two metal layers are sufficient for a higher yield. Gate arrays in sea-of-gates require three or more metal layers, so they are expensive.

43.2 CMOS Gate Arrays

CMOS gate arrays are commercially available from many manufacturers in slightly different layout forms. As an example, Fig. 43.2 shows a cell of a CMOS gate array, where a pair of pMOSFETs and a pair of nMOSFETs are placed on the left and right, respectively, without connections between them. The NAND



(a) Before making connections

(b) After connections made

FIGURE 43.1 Gate array.

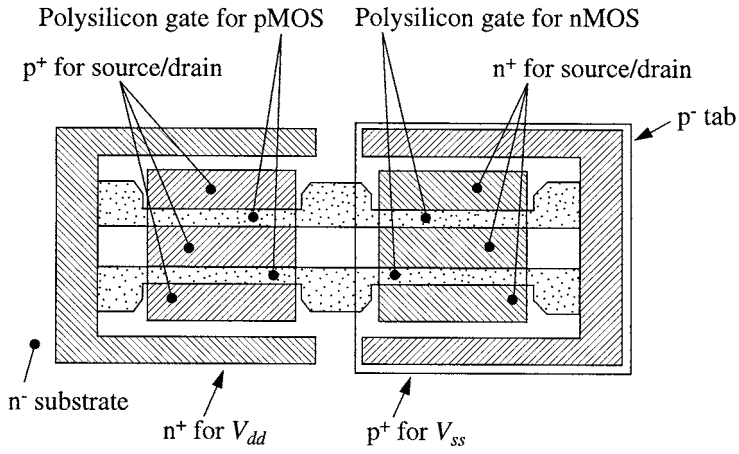


FIGURE 43.2 A cell of CMOS gate array. (Courtesy of Fujitsu Ltd. With permission.)

gate shown in Fig. 43.3(a) can be realized by connecting the components shown in Fig. 43.2 by two metal layers as shown in Fig. 43.3(b). These two metal layers are formed by forming the first metal layer shown in Fig. 43.3(c), the insulation layer (not shown), and then the second metal layer shown in (d). The inverter shown in Fig. 43.4(a) can be realized by connections as shown in Fig. 43.4(b).

Many different patterns other than that in Fig. 43.2 are available for the components of a cell.

43.3 Advantages and Disadvantages of Gate Arrays

Gate arrays have the following advantages:

1. Even when fabrication technology or electronic circuitry changes, gate arrays can be designed in a short time. In other words, only one cell of transistors (or few different cells) needs to be carefully designed and laid out, and this layout can be repeated on a chip.
2. After designers design logic gate networks (although this is still very time-consuming, the minimization of the number of gates or delays, under constraints such as maximum fan-out, would be a designer's primary concern, but connections are a less significant problem), CAD programs

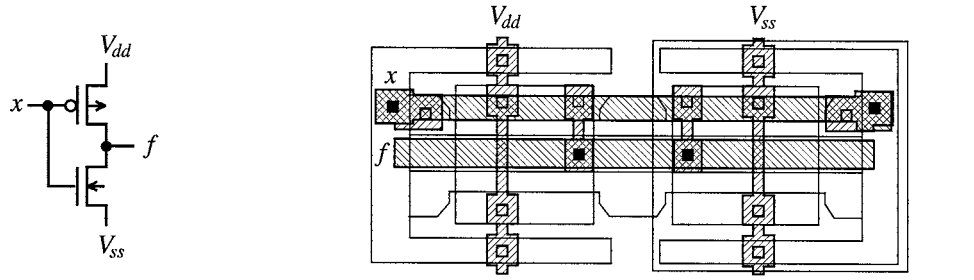
automatically do the placement of logic gates and the routing of connections on a chip, although in complex cases, placement, which is more difficult than routing, must be done manually by designers, possibly using a placement library of standard networks. (Often, a small percent of the connections cannot be processed well by CAD programs and must be rerouted manually. Thus, when the number of connections is very large, even a few percent means a large number of connections need to be rerouted. So, it is important to reduce this percentage.) It is to be noted that because the gate positions are prefixed on the array, CAD for placement and routing becomes much easier to use than other cases. For the above reasons, the layout time is greatly reduced, shortening the design time, and consequently design expenses. (Delivery time by vendors is usually at least a few weeks.)



(a) Inverter. (b) Connection layout to realize (a) (Courtesy of Fujitsu Ltd.)

FIGURE 43.4 Connection layout example of the cell in Fig. 43.2.

3. Only a few masks for connections and contact windows must be custom-made for each design case, and all other masks are common to all cases, spreading the initial investment for the preparation of all these common masks over all cases. Thus, gate arrays are cost-effective in low production volumes of hundreds or thousands.
4. Speed is improved over logic networks realized with off-the-shelf packages or PLAs because interconnections among gates are shortened on the average (most interconnections are inside gate array chips rather than on pc boards).
5. The power consumption is reduced, compared with logic networks realized with off-the-shelf packages or PLAs.
6. Logic gates and connections are placed in a very different manner from full-custom-designed networks, where logic gates and connections that are functionally closely related are placed in nearby places. Thus, even if competitors look at the layout of the gate array chips, the layouts are too cryptic to understand the nature of logic networks. In this sense, gate arrays are good for protection of proprietary logic design.

On the other hand, gate arrays have the following disadvantages.

1. Chip size is large because logic gates are not compactly laid out. For example, each pair of nMOSFETs is placed in an individual p^--tab without sharing p^--tab with many other nMOSFETs, as can be seen in Fig. 43.2.
2. The percentage of unused gates is possibly high, for the following reasons. Depending on the types of networks or which parts of a large network are placed in a gate array chip, all spacings provided for connections can be used up (by taking a detour if the shortest paths are filled up by other connections), or all the pins of the chip can be used up by incoming and outgoing connections. In either case, many gates may not be used at all, and fewer than half the gates on a chip are used in some cases. Because of these disadvantages, the average size of a gate array chip is easily four or five times as large as that of a full-custom-designed chip, or it can be even greater, for the same logic networks. The cost difference would be greater (the cost is not necessarily linearly proportional to chip size) for the same production volume.
3. It is difficult to keep gate delays uniform. As the number of fan-outs and the length of fan-out connections increase, delays increase dramatically. (If delay times of gates are not uniform, the network tends to generate spurious output signals.) In the case of full-custom design, the increase of gate delay by long or many-output connections of a gate can be reduced by redesigning the transistor circuit (e.g., increasing transistor size for delivering greater output power and accordingly reducing the delay). But such a precise adjustment is not possible in the case of gate arrays.

Responding to a variety of different user needs in terms of speed, power consumption, cost, design time, ease of change, and possibly others, a large number of different gate arrays are commercially available from semiconductor manufacturers or are used in-house by computer manufacturers. Different numbers of gates are placed on a chip, with different configuration capabilities. Some gate arrays contain memories, for example.

Field-Programmable Gate Arrays

Saburo Muroga
University of Illinois at Urbana-Champaign

44.1 Introduction

Field-programmable gate arrays or **FPGAs** are programmable by users. In other words, users easily and inexpensively realize their own logic networks in hardware, using FPGAs. The change of the logic networks is as easy as software is. FPGAs, however, have a greater variety of hardware and architecture than PLAs or gate arrays. If fuses or anti-fuses are used for hardware programmability, logic functions realized on an FPGA cannot be changed, once realized. But the addition of random-access memory (RAM) to hardware of FPGAs by Freeman[6,7] such that logic functions can be easily changed by changing information stored in the RAM substantially has enhanced the usefulness of FPGAs. By storing information into RAMs of FPGAs, logic functions can be rewritten in a short time as frequently as we need. In this sense, FPGAs with RAMs are not a straightforward extension of the gate arrays in Chapter 43, which are mask-programmable, and are very different from the gate arrays. With the changeability of the logic functions on an FPGA by changing information in its RAMs, the nature of programmability of an FPGA is essentially the same as that of software which is stored in the RAM of a general-purpose computer. With FPGAs, debugging or prototyping of new design can be done as easily and quickly as software. But an FPGA performs much faster than software on computer.

FPGAs have other types of hardware, in addition to those with RAMs. Thus, hardware of FPGAs consists of PLDs, logic gates, random-access memory, and often other types of components such as non-volatile memory. FPGAs from different manufacturers have different organization of PLDs, logic gates, random-access memory, and other types of components. In other words, different manufacturers have FPGAs in different architectures, but all of them have the same common feature: that the layout of a unit is repeated in matrix form. In this case, the unit is a circuit consisting of PLDs, logic gates, random-access memory, and other types of components that is far more complex than "gates" which are repeated in matrix in gate arrays. Logic networks realized in FPGAs are slower by two or three orders of magnitude than those realized in full-custom design, but are much faster by several orders than simulation of logic functions by software. Even application programs can be run on FPGAs and perform much faster than on general-purpose computer in many cases.

As the price of FPGAs goes down with higher speed, FPGAs are replacing other semi-custom design approaches in many applications.

44.2 Basic Structures of FPGAs

In the case of mask-programmable gate arrays, designers have to wait a few weeks for delivery of finished gate arrays from semiconductor manufacturers because the semiconductor manufacturers must prepare custom masks (although the number of custom masks for gate arrays is fewer than the case of the standard-cell library approach described in Chapter 45). With FPGAs, designers can realize their design on FPGA chips by themselves in minutes. Thus, FPGAs are becoming popular.[1,2,8–10]

Several different types of structures for FPGAs are available commercially. All of them have a basic structures that consists of many logic blocks or logic cells, accompanied by a large number of pre-laid lines for connecting these logic blocks. So, some manufacturers call FPGAs **logic block arrays** (**LBA**s). One has a structure similar to a gate array with routing channels where each logic cell in a gate array is replaced with a logic block, as shown in Fig. 44.1. Another one is similar to sea-of-gate array, as shown in Fig. 44.2 illustrated with 16 logic blocks. Also, there is a structure similar to standard cells (to be discussed in the next chapter) where there are routing channels between a pair of rows of logic blocks, as shown in Fig. 44.3. There is a structure where outputs of logic blocks are connected to the inputs of other logic blocks through bus lines, as shown in Fig. 44.4.

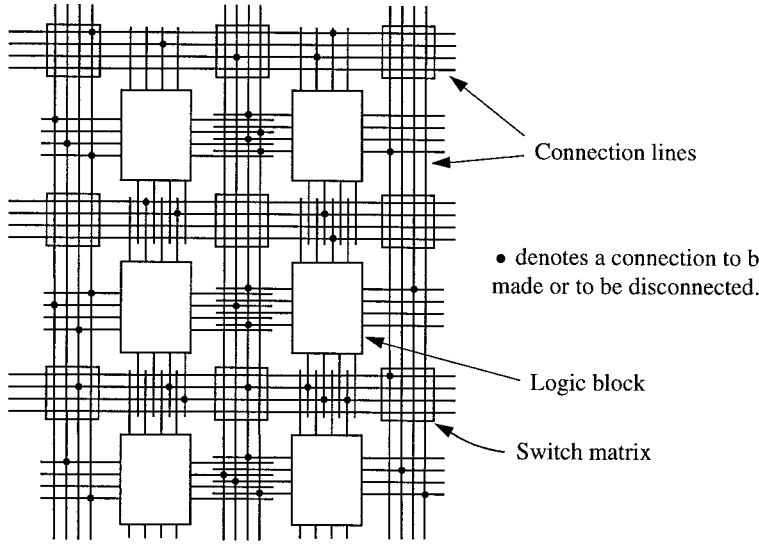

FIGURE 44.1 FPGA type of gate array with routing channels.

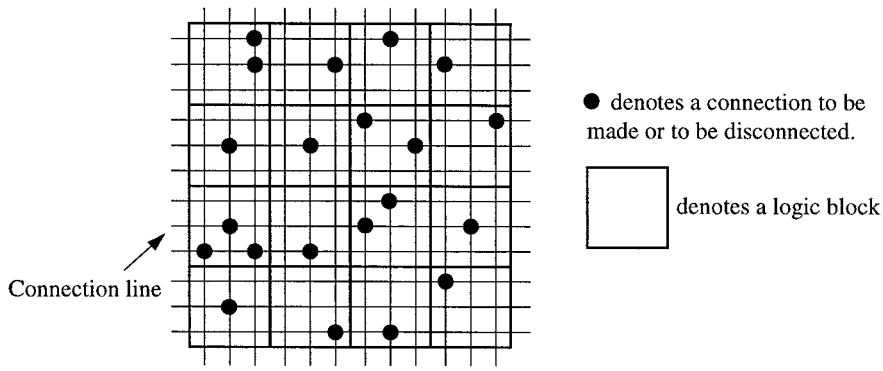

FIGURE 44.2 FPGA type of sea-of-gate array.

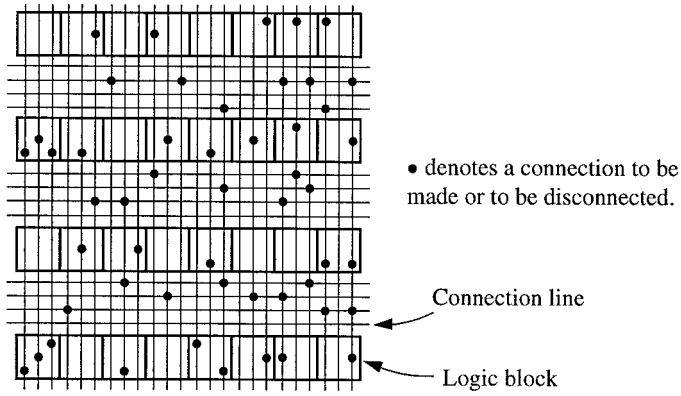

FIGURE 44.3 FPGA type of row-based array.

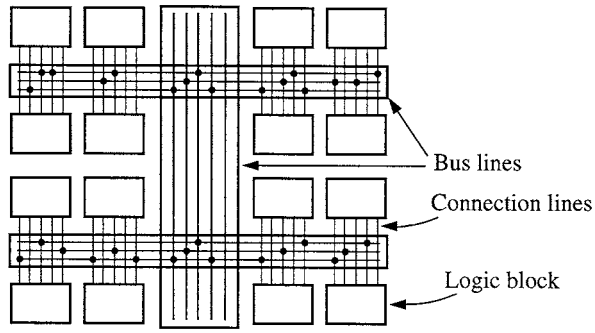

FIGURE 44.4 FPGA type of bus-based array.

The internal structure of logic blocks or logic cells differs, depending on the manufacturer. A logic block consists of SRAMs (used as look-up tables), PALs, NAND gates, along with multiplexers, flip-flops, and others. Lines are pre-laid horizontally and vertically and are connected to the inputs and outputs of logic blocks by **programmable switches**. Various programmable switches, such as fuses, anti-fuses, RAMs, and non-volatile memories, are provided by different manufacturers. Each line actually consists of many short line segments and only necessary line segments are connected in order not to add unnecessary delay due to parasitic capacitance by using an excessive number of line segments. Line segments are also connected by programmable switches.

In addition to these logic blocks and pre-laid lines, there are different types of input/output control blocks, that is, blocks for inputs for receiving signals from the outside of the FPGA and for outputs for sending signals to the outside.

Each programmable switch consists of many switching elements. A typical FPGA contains hundreds of thousands or more switching elements and how these elements are realized is essential for performance, costs, and size of the FPGA. Fuses, anti-fuses, SRAMs, and non-volatile memories are used as switching elements. They are either volatile or non-volatile, either rewritable or non-rewritable, and all have different programming times (or writing times). Thus, depending on which of these are used, different FPGAs have significantly different applications.

44.3 Various Field-Programmable Gate Arrays

FPGAs have different basic structures, as already discussed. If we look at their details beyond this, there are different types of FPGAs, as follows.

FPGAs Based on SRAMs

FPGAs based on SRAMs connect lines by controlling a pass transistor, a transmission gate, or a multiplexer, each of which is controlled by a flip-flop (i.e., one memory cell of SRAM) as shown in Fig. 44.5. Any horizontal line and a vertical line shown in Fig. 44.1 can be connected at some of their cross points (shown with dots in Fig. 44.1). Suppose a flip-flop is used. If the flip-flop is on, these two connection lines are connected; if it is off, they are not. By connecting horizontal connection lines and vertical connection lines at appropriate cross points in this manner, the outputs of one logic block can be connected to the inputs of other blocks.

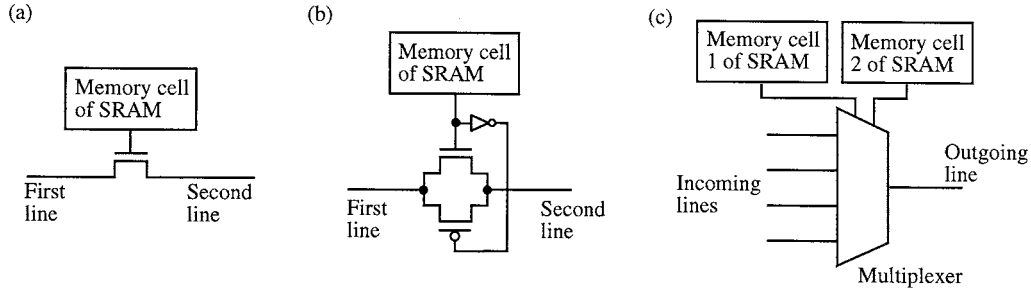

FIGURE 44.5 Connection of lines controlled by SRAM.

FPGAs based on SRAMs are available from Xilinx, Atmel (previously Concurrent Logic), and others. Lines are connected by transfer gates (or pass transistors) in Fig. 44.5(a), transmission gates in (b), or multiplexers in (c) that are controlled by ON or OFF states of memory cells of SRAM. A multiplexer is typically used to connect one of several incoming lines to one outgoing line.

FPGAs based on SRAMs were started by Xilinx.[6,10] Many logic blocks that contain SRAMs and flip-flops are provided in FPGAs of this type, along with many pre-laid connection lines, as illustrated in Fig. 44.1. Each block is connected to nearby one-line segments, as shown in Fig. 44.6. A switch matrix shown with a square is a set of multiplexers, where any one outgoing line segment can be connected to any of many incoming line segments. Besides these one-line segments, where by connecting many of them through switch matrices, long lines can be formed, there are global long lines that can be formed by

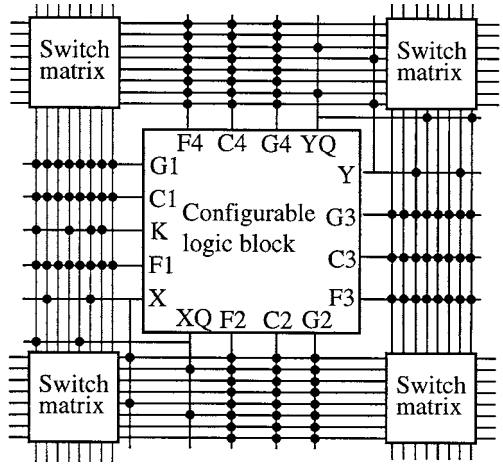

FIGURE 44.6 Typical connection of a configurable logic block to single line sections.

connecting fewer segments, each of which has longer segment length. (Note that a long line formed by connecting many one-line segments has a long delay because delays of many switch matrices are added to the delay of the lines due to parasitic capacitance.) In this sense, delay times on lines that consist of many line segments are unpredictable. Each logic block consists of a RAM along with several flip-flops, as shown in Fig. 44.7. Xilinx calls logic blocks **configurable logic block**s (**CLB**s). Users can store logic functions in these SRAMs and connect the blocks by lines as they want.

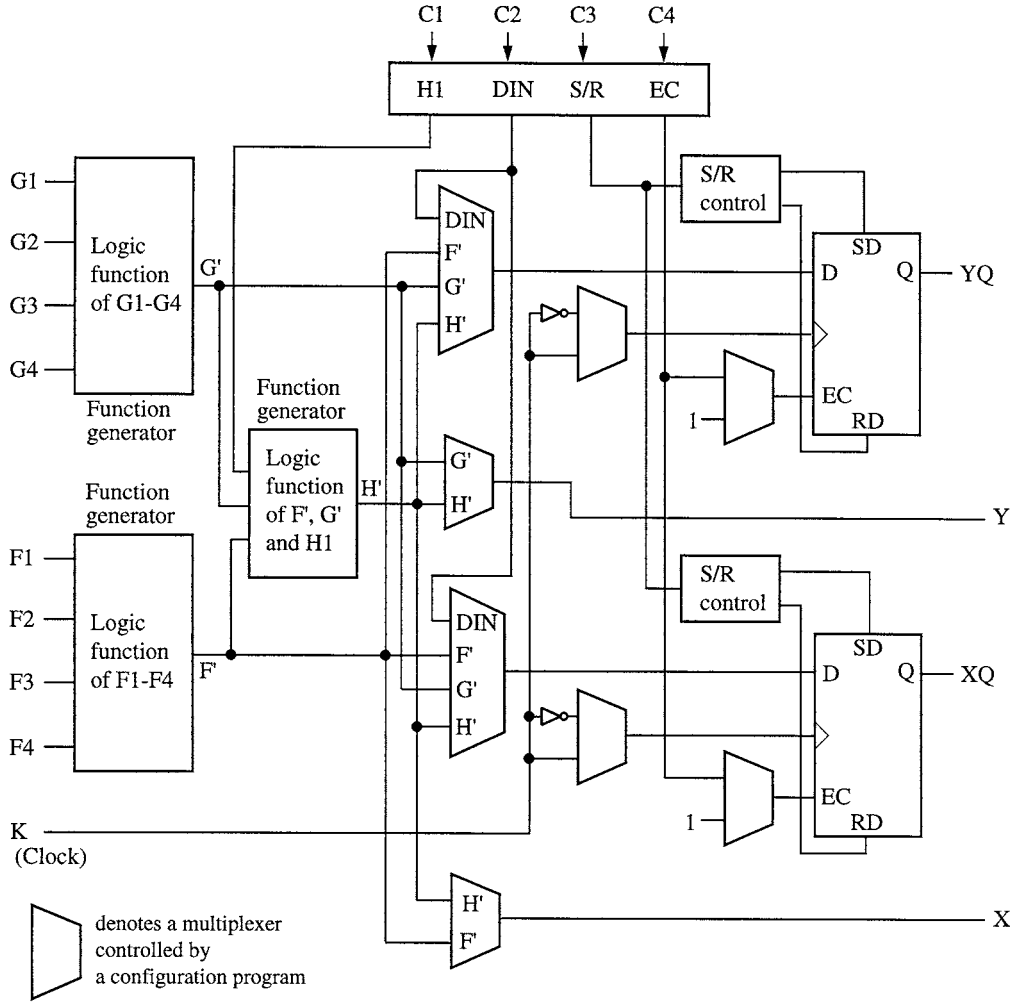

FIGURE 44.7 Simplified block diagram of configurable logic block of XC4000, FPGA of Xilinx, Inc.

Each CLB packs a pair of flip-flops and two independent four-input function generators, as illustrated in Fig. 44.7. The two function generators whose outputs are labeled F′ and G′ are realized with RAMs and are each capable of realizing any logic function of their four inputs, offering designers sufficient flexibility, because most combinational logic functions doe not need more than four inputs. Thirteen CLB inputs provide access to the function generators and flip-flops. These inputs and four CLB outputs connect to the programmable interconnect resources outside the block. Four independent inputs, F1–F4 or G1–G4, are provided to each of the two function generators. The function generators are used as look-up table memories; therefore, the propagation delay is independent of the function being realized. A third function generator, labeled H′, can realize any logic function of its three inputs, F′ and G′, and a

third input from outside the block (H1). Signals from the function generators can exit the CLB on two outputs; in other words, F′ or H′ can be connected to the X output, and G′ or H′ can be connected to the Y output. Thus, a CLB can realize any two independent functions of up to four variables, or any single function of five variables, or any function of four variables together with some functions of five variables, or it can even realize some functions of up to nine variables. Realizing a variety of functions in a single logic block reduces both the number of blocks required and the delay in the signal path, thus increasing both density and speed.

The CLB contains also edge-triggered D-type flip-flops with common clock (K) and clock enable (EC) inputs. A third common input (S/R) can be programmed as either an asynchronous set- or reset-signal independently for each of the two flip-flops; this input can also be disabled for either flip-flop. Each flip-flop can be triggered on either the rising or falling clock edge. The source of a flip-flop data input is programmable; it is driven either by the functions F′, G′, and H′, or the Direct In (DIN) block input. The flip-flops drive the CLB outputs, XQ and YQ.

In addition, each CLB function generator, F′ or G′, contains dedicated arithmetic/logic unit (not shown in Fig. 44.7) for the fast generation of carry and borrow signals, greatly increasing the efficiency and performance of adders, subtracters, accumulators, comparators, and counters. Multiplexers in the CLB map the four control inputs, labeled C1 through C4 in Fig. 44.7, into the four internal control signals (H1, DIN, S/R, and EC) in any arbitrary manner.

This FPGA has the following advantages:

- Once logic design is finished, logic functions can be realized by this FPGA in minutes by writing design information into SRAMs and flip-flops, as necessary.
- Quick realization of complex logic functions that require a large number of logic gates and therefore cannot be realized with FPLAs or PALs is the great advantage of this type of FPGA.

The disadvantages include the following:

- If the power supply to this FPGA is turned off, the information is lost and, consequently, design information must be written each time the power supply is turned on.
- Also, compared with mask-programmable gate arrays, its chip size is roughly 10 times larger and its speed is far slower. But its speed is still much faster than software run on a general-purpose computer.

If the number of CLBs is to be minimized, this type of FPGA presents a totally new type of logic design problem and there is no good design algorithm known. Traditional logic design problems are realization of given functions with a minimum number of simple logic gates of certain types (e.g., NOR gates or negative gates). But with this type of FPGA, we have to realize the given functions with logic functions that can fit in the SRAMs provided, where these functions can be far more complex than the NOR functions or negative functions that logic gates represent. But the number of CLBs is not necessarily to be minimized because after debugging logic design, final logic networks to be manufactured in large volume are usually realized with logic gates but without RAMs.

Using FPGAs of this type, the development time of mask-programmable gate arrays that are completely verified can be often shortened to less than half, and new computers can be introduced into the market quickly. In other words, when logic design is finished, computers can be shipped immediately in FPGAs to major customers for testing. After these customers find bugs, the designers fix them and the production of mask-programmable gate arrays can be started. Without FPGAs, the computers have to be shipped to customers for testing after manufacturing mask-programmable gate arrays — which takes several weeks. Then, when the customers find bugs, the designers start the production of the second mask-programmable gate arrays. Thus, when mask-programmable gate arrays are used, a new gate array must be manufactured, spending a few weeks, for each correction of bugs and testing by customers. The completion of the computer will be significantly delayed and with far greater expense. If the design is complex, the designers need repetition of tests by the customers. In contrast to this, if FPGAs are used,

the designers can send the debugged design to the customers online, and customers can start the second test instantly by revising the contents of the FPGAs.

Atmel's FPGA uses SRAMs, but logic blocks and architecture are similar to Actel's, unlike Xilinx's whose logic blocks contain SRAMs which are used as look-up tables. FPGAs of Plessey are based on SRAMs, but the architecture looks like the sea-of-gate array shown in Fig. 44.2. Altera also has FPGAs based on SRAMs, using the architecture with non-volatile memory.[10] FPGAs of Algotronix use SRAMs, but logic blocks are mostly multiplexers. AT&T Microelectronics also has FPGAs based on SRAMs similar to Xilinx's.

FPGAs Based on ROMs with Anti-fuses

There are FPGAs based on ROMs that are programmable with anti-fuses. These FPGAs are available from Actel, QuickLogic, and Crosspoint Solutions. Connection of lines in this type of FPGA can be made by the use of anti-fuses. Once an anti-fuse becomes conductive, it cannot be non-conductive again, unlike FPGAs based on SRAMs. Typical applications utilizing 85% of the available logic gates, however, need to use only 2 to 3% of these anti-fuses (i.e., to be changed to conductive state). Note that if fuses, instead of antifuses, are used, 97% or 98% of fuses need to be disconnected, requiring disconnection of a huge number of fuses.

Actel's FPGAs are of row-based structure, as illustrated in Fig. 44.3.[3–5,10] The actual logic block array of Actel is shown in Fig. 44.8 A logic block (Actel calls it a logic module) for a simple model of Actel's FPGA consists of three multiplexers and one OR gate, as shown in Fig. 44.9, where some of their inputs and outputs can be complemented. This logic module, which has eight inputs and a single output, can realize many different logic gates with some inputs inverted, as follows: four basic logic gates (i.e., NAND, AND, OR, and NOR gates with 2, 3, or 4 inputs); EXCLUSIVE-OR gates, EXCLUSIVE-OR-OR gates, EXCLUSIVE-OR-AND gates, OR-EXCLUSIVE-OR gates, AND-EXCLUSIVE-OR gates, AND-OR gates, and OR-AND gates; and a variety of D latches. Other models of Actel have more complex logic modules that contain latches.

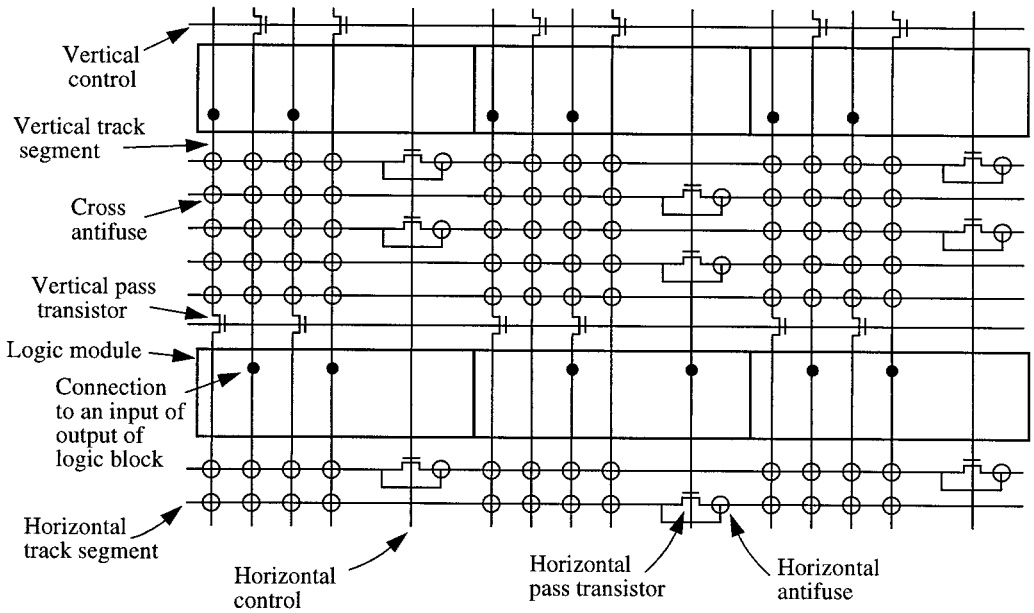

FIGURE 44.8 Logic module array of Actel.

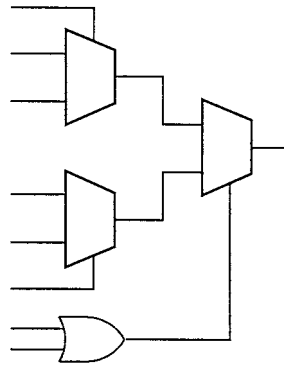

FIGURE 44.9 Logic block of Actel.

FPGAs Based on Non-volatile Memories

Altera has FPGAs that are based on non-volatile memory for connecting lines.[10] This FPGA has bus-based structure illustrated in Fig. 44.10 (i.e., Fig. 44.4). The inputs and outputs of each logic block can be connected to bus lines, as shown in Fig. 44.10. Altera calls these bus lines PIA (Programmable Interconnect Array). Altera claims that delay times on PIAs are more predictable than those on lines that consist of many line segments. A logic block contains of 16 logic macrocells, such as the one shown in Fig. 44.11.

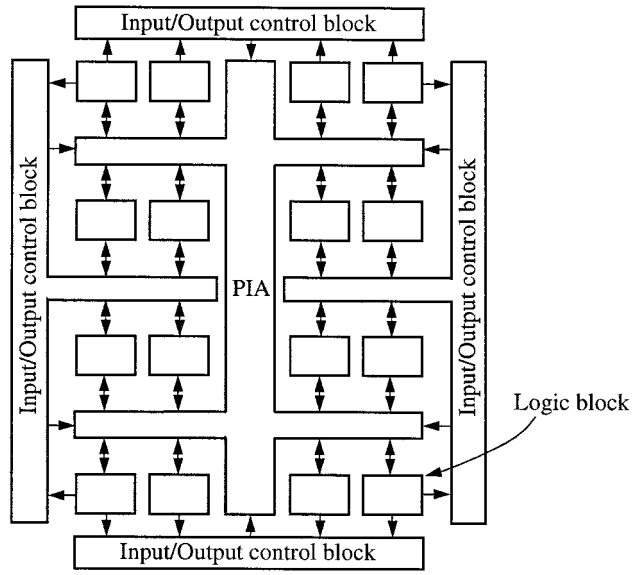

FIGURE 44.10 FPGA of Altera with non-volatile memory.

FPGAs of Advanced Micro Devices and Lattice Semiconductor Corp. are based on a different type of non-volatile memory, using PALs as logic blocks that can be connected with switch matrixes similar to Altera's.

44.4 Features of FPGAs

If we order semiconductor manufacturers to make mask-programmable gate arrays, we have to wait several weeks and pay twenty-thousand to hundreds of thousands of dollars. But with FPGAs, we can

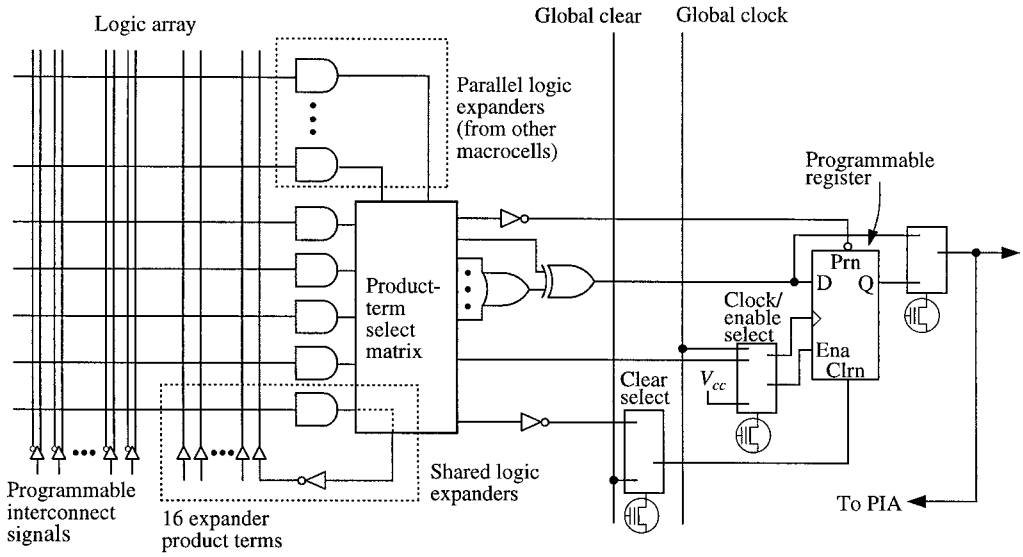

FIGURE 44.11 Macrocell of FPGA of Altera.

program FPGAs in minutes by ourselves and need to pay in the tens of dollars. But a FPGA can pack only about one-tenth the number of logic gates in a mask-programmable gate array because devices for user programmability, such as SRAMs, non-volatile memory, and anti-fuses, take up large areas. Mask-programmable gate arrays are faster by two orders of magnitude and far cheaper for large production volume. Thus, for debugging or verifying logic design that needs to be done quickly, FPGAs are used, and then mask-programmable gate arrays are used for large volume production after completing debugging or verification.

As seen already, FPGAs are classified into two types, depending on the types of devices used for programmability: rewritable FPGAs and non-rewritable FPGAs. Then, they are accordingly used for completely different purposes. Rewritable FPGAs, such as Xilinx's based on SRAMs and Altera's based on non-volatile memory, can be repeatedly rewritten in minutes. Non-rewritable FPGAs cannot be changed once programmed, but still have the advantages of realizing inexpensive logic chips with faster speed.

The area size of different devices for programmability also gives different advantages and disadvantages. A non-volatile memory cell is roughly four to five times larger than anti-fuse; a memory cell of SRAM is two times larger than a non-volatile memory cell. Anti-fuses are much smaller. So, because of smaller parasitic capacitance, FPGAs based on anti-fuses tend to be faster than those based on non-volatile memory or SRAMs.

Cell-Library Design Approach

Saburo Muroga
University of Illinois at Urbana-Champaign

45.1 Introduction

Compact layouts for basic logic gates (such as NOR gates) and small networks that are frequently used (such as flip-flops and a full adder) are designed by professional designers with time-consuming efforts and are stored in computer memories (i.e., magnetic disks). Each layout is called a **cell** and a collection of these layouts is called a **cell library**. Once a cell library is ready, any other designer can call up specific cells on the monitor of a computer. By arranging them and adding connections among them by the use of a mouse, the designer can make a layout of the entire logic network. When the layout is complete, photomasks are automatically prepared by computer. Such a design approach is called the **cell-library design approach**.[1–3]

45.2 Polycell Design Approach

When the layout of every cell has the same height, although its width may be different, this approach is called the **polycell design approach** (or **standard-cell design approach).** It is often called the cell-library design approach, but it is also called the polycell or standard-cell design approach in order to avoid confusion with the words "cell" and "library" from those which are used in the gate arrays. The height of all cells are chosen the same, even though area is wasted inside a cell, such that many cells are connected into rows, as exemplified in Fig. 45.1, which shows an example with three rows of cells.

Routing (i.e., connections among cells) is mainly done in space between adjacent rows of cells, as shown in Fig. 45.1. This space for routing is called a **routing channel**. Routing, in addition to design of logic networks, is the major task in the polycell design approach and is greatly facilitated by CAD programs.

Connections from one routing channel to others can be done through narrow passages, which are provided between cells in each row. In some cases, connections are allowed to go through cells horizontally or vertically (without going through the narrow passages provided) in order to reduce wiring areas. In this case, detailed routing rules on where in each cell connections are allowed to go through must be incorporated in the CAD programs.

The preparation of a cell library takes time (probably more than a dozen man-months for a small library), but layout time of chips, using a cell library, is greatly reduced by the polycell design approach (probably by an order of magnitude), compared with full-custom design which requires the most compact layout of gates and connections. This is a great advantage. When new fabrication technology is to be adopted, only cells have to be newly laid out; whereas in the case of full-custom design, the entire chip has to be laid out

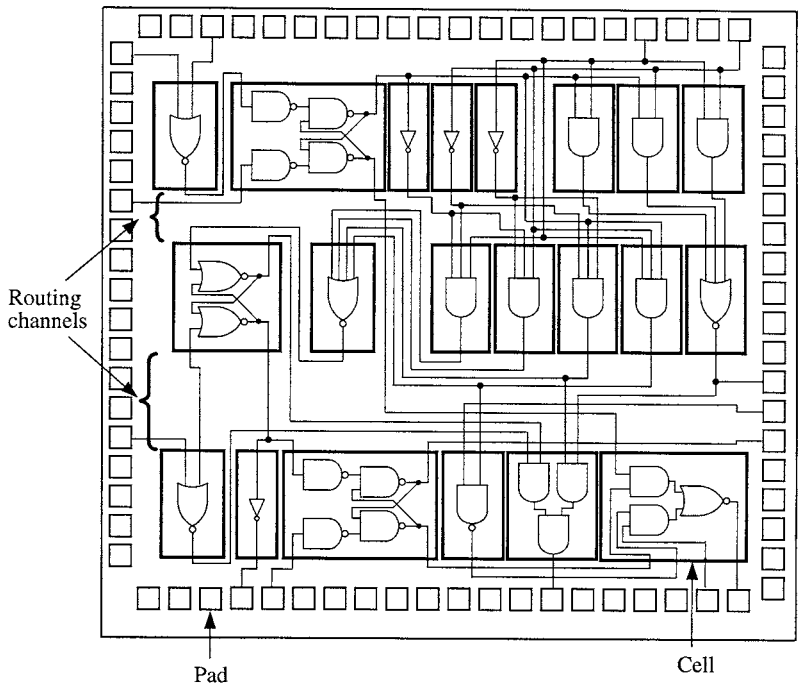

FIGURE 45.1 Polycell layout.

compactly with new technology. Thus, the cell library approach can adapt to a new technology in a shorter time than the full-custom design, but chip size and performance are sacrificed. Compared with the full-custom layout of random-logic gate networks, chip size is many times larger, although it is much smaller than the size realized with a gate array. In order to facilitate routing among cells laid out, all cells are prepared with equal height, keeping their inputs and outputs at the sides that face routing channels. Then, cells for simple functions become very thin and those for complex functions become squat. Thus, the area in each cell is not efficiently utilized. Also, interconnections among cells take up a significant share of the chip area.

Unlike gate arrays where only masks for connections and contact windows are to be custom-made, here all masks must be custom-made, so the polycell design approach needs expensive initial investment, despite its advantage of smaller chip size than gate arrays. However, since the layout is highly automated with interactive CAD programs for placement and routing, the layout of the entire chip is not as time-consuming as those by full-custom design, and consequently the polycell design approach is favored in many cases. In this sense, the polycell design approach is not as purely semi-custom design as the gate array design approach. But the approach is not purely full-custom design either, since the chips are not as compact as those by the full-custom design. Thus, it might be called a pseudo-full-custom design approach, although some people call it a full-custom design approach.

The polycell design approach is cost-effective when the production volume is in hundreds of thousands of dollars, since the initial investment costs $20,000 or more, which is much lower than tens of millions dollars for the full-custom design. The polycell design approaches have been extensively used when the chip compactness attained by the full-custom design approach is not required.

45.3 Hierarchical Design Approach

The cell library design approaches, using cells of different shapes and sizes, can reduce the chip size more than the polycell design approach, because by keeping the same height, a large portion of the area of

each cell is wasted, and by keeping all connections among cells in routing channels, the connection area may not be minimized. Moreover, by using a **hierarchical approach** based on cells of different shapes and sizes — in other words, by treating many cells as a building block in a higher level, and many such building blocks as a building block in a next higher level, and so on — we can further reduce the chip area, as illustrated in Fig. 45.2, because global area minimization can be treated better, even though this is done on the monitor. In other words, cells A, B, C, and D are assembled into a block R (shown in a dot-lined rectangle), as shown in Fig. 45.2. Then, such blocks, R, S, T and U, shown in dot-lined rectangles are assembled into a bigger block W, which is a block in a higher level than blocks R, S, T, and U, as shown in Fig. 45.2. But this is much more time-consuming than the polycell design approach, and the development of efficient CAD programs is harder. It appears to be difficult to make the difference of chip area from full-custom designed chips within about 20%, although the areas of full-custom designed chips vary greatly with designers and, accordingly, comparison is not simple.

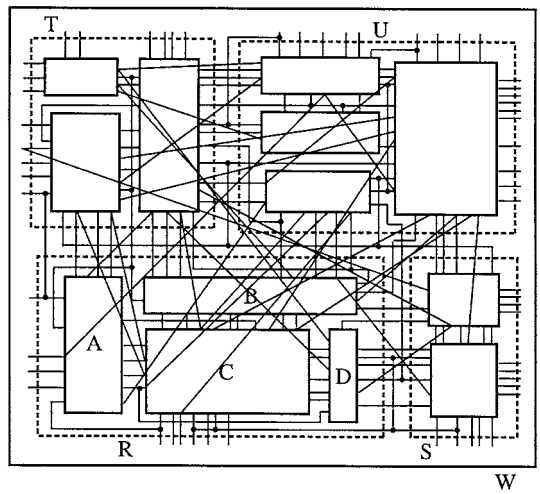

FIGURE 45.2 Hierachical design approach.

Comparison of Different Design Approaches

Saburo Muroga
University of Illinois at Urbana-Champaign

46.1 Introduction

As discussed so far, there is an almost continuous spectrum of different design approaches from design approaches with off-the-shelf packages, semi-custom design approaches, to the full-custom design approach, depending on the degree of the regularity of transistor arrangement in the layout and the simplification of realization of logic functions (i.e., whether logic functions are realized by a minimal sum or a logic network). Naturally, comparison of these approaches by many different criteria such as performance, design time, and chip size is very complex. Also, different design approaches are often mixed on the same chip, further complicating the comparison. Reliable comparison data are rarely available. But here we will try to give some idea of the advantages and disadvantages of the different design approaches.[1-4]

46.2 Design Approaches with Off-the-Shelf Packages

Here, let us compare different design approaches from the viewpoint of design of logic networks or digital systems. This comparison includes off-the-shelf packages (where a package means a component or an IC chip encased in a container). But among all off-the-shelf packages, let us compare only off-the-shelf discrete component packages and off-the-shelf IC packages (many commonly used logic functions are commercially available as off-the-shelf IC packages), excluding off-the-shelf processors that are fully programmable. We exclude off-the-shelf fully programmable processor packages, such as microprocessor or microcontroller packages, because these off-the-shelf packages are essentially general-purpose computers that are used by writing appropriate software and accordingly do not require design of logic networks.

The major advantage of the off-the-shelf packages is the ease of partial changes of the entire computer or replacement of faulty parts. But there are many disadvantages, such as low reliability (due to connections outside these packages), high cost, and bulkiness. When off-the-shelf packages are assembled on pc boards and further into cabinets, the overall system costs make a substantial difference because of additional costs. In the case of custom-designed IC packages of large integration size (the integration size of an integrated-circuit chip means the number of transistors packed in a chip), all additional costs, such as those for pc boards and fans, become zero or insignificant, but we still have to consider test costs, which are even higher because of more stringent test requirements. Thus, custom-designed IC packages of large integration size are cost-effective for high volume production, which justifies high initial investment.

46.3 Full- and Semi-Custom Design Approaches

An approximate comparison of different design approaches in terms of design time and chip area is given in Fig. 46.1 in logarithmic scale. For each design situation, designers must choose the most appropriate approach, considering tradeoffs between design time (which is closely related to design cost) and chip area (which is related to manufacturing cost and performance). In this comparison, a design approach in a higher position in Fig. 46.1 takes less time to finish the design, but the finished chip is larger and slower in speed than those in lower positions.

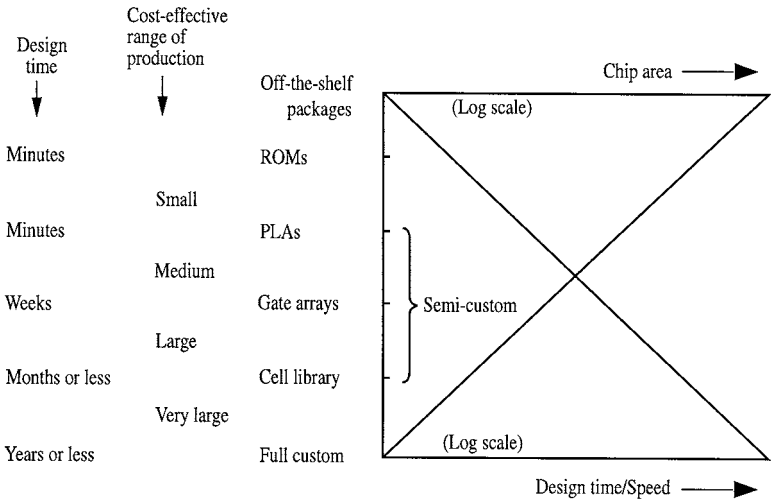

FIGURE 46.1 Chip area versus design time.

Logic functions can be realized in ROMs (read-only-memory) as a truth table. As the number of variables increases, the required memory size exponentially increases. So, its use is limited.

Among all custom (semi- and full-custom) design approaches, PLAs are the quickest to realize logic functions because we can do so simply by deriving minimum sums or minimum products with the use of CAD (computer-aided design) programs, skipping designing logic networks, and also layout and customization of many masks (where manufacturing cost is affected by how many masks need to be customized). But performance, size, and cost are sacrificed. PLAs require only one custom-made mask for connections, while the other custom design approaches require two or more custom-made masks among all of about two dozen required masks. Field-programmable PLAs have larger chip areas than mask-programmable ones, although no custom masks are required.

In using gate arrays, users need to design logic networks but can realize logic networks by the layout of connections among logic gates with CAD programs. Layout and customization of many masks can be skipped. Performance is much higher than PLAs. Gate arrays require two custom-made masks for connections among all of about two dozens masks. Field-programmable gate arrays have a variety. Among them, non-rewritable FPGAs have larger chip areas than mask-programmable ones, although no custom masks are required. Rewritable FPGAs (e.g., those with RAMs) are so different from the other custom design approaches that they cannot be properly compared in Fig. 46.1.

The cell-library design approach requires logic design and layout of connections with CAD, using a cell library which requires a one-time design effort. But the layout of logic gates and connections inside cells and layout of transistor circuits can be skipped, though all masks need to be customized. All of about two dozen masks need to be custom-made, making the cell-library design approach more expensive than gate arrays and PLAs.

The full-custom design approach requires deliberate design of all aspects of a digital system, although semi-custom design approaches along with appropriate CAD programs are used wherever speed is not critical for the speed of the entire system or frequent changes are expected, in the entire system. For example, PLAs are used in the control unit of the full-custom design system. All masks need to be custom-made. The full-custom design approach is the most expensive, taking the longest design time, but the approach yields chips with the highest performance and the lowest cost for high volume production.

A crude estimation of design time is of the order of minutes for ROMs and PLAs, weeks for gate arrays, months for cell-library approach, and years for full-custom design approaches, with the appropriate number of engineers assigned in each case, as shown in Fig. 46.1. A crude estimation of the cost-effective range of production, as shown in Fig. 46.1, is small volume production for the upper range of the cost-effective production of ROMs (i.e., the lower range of the cost-effective production of PLAs), and so on. And the full-custom design approach cannot be more cost-effective than the cell-library approach, unless the production volume is very high.

Rewritable FPGAs have a unique feature that is very different from the other custom design approaches: the ease of changing information in the memories of the FPGAs. With this feature, a designer can send new information to customers over communication lines, instead of sending hardware. So, the customers can change the information on their FPGAs instantly and very inexpensively. Thus, rewritable FPGAs are replacing other custom design approaches in many applications.

An approximate relationship between cost per package and production volume is illustrated in Fig. 46.2, although this may change depending on many factors, such as fabrication technology, logic families, system size, and performance. For each production volume, there is the most economical design approach. But the comparison is difficult and has to be done carefully in each case, because each approach has variations and it makes a difference whether or not libraries of cells or macrocells are prepared from scratch. (Notice that in Fig. 46.2, design approaches are shown in thin-line curves for the sake of simplicity, but actually they should be represented in very broad lines.) The cost per package for the off-the-shelf package design approach is fairly uniform over the entire range, but it increases for low production volumes because the development cost becomes significant as initial investment in the overall package

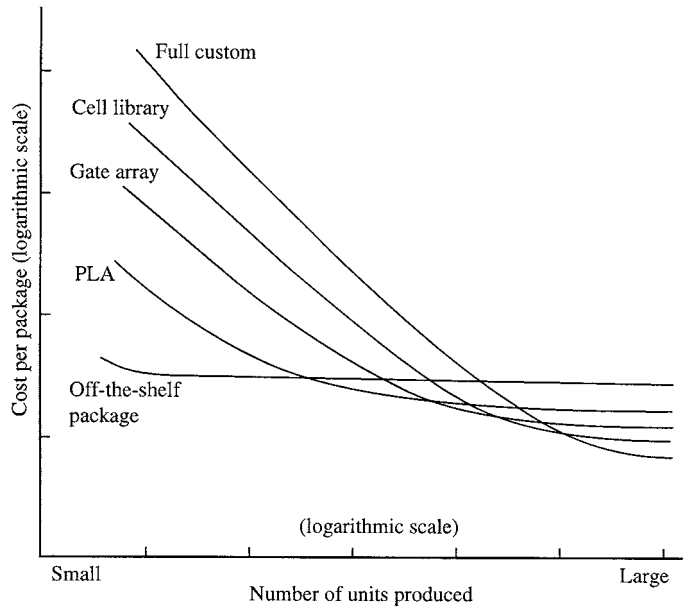

FIGURE 46.2 Package cost versus production volume.

cost. The relationship shown in this figure will change as the integration size of an IC chip increases, because the dependence on CAD will inevitably increase.

46.4 Comparison of All Different Design Approaches

As discussed so far, we have a very wide spectrum of different design approaches, from full-custom design approaches to the design approaches with off-the-shelf packages, as illustrated in Table 46.1. Digital systems can be designed by combining them. Depending upon different criteria imposed by different design motivations, such as speed, power consumption, size, design time, ease of changes, and reliability, designers can use the following approaches:

TABLE 46.1 Comparison of Different Task-Realization Approaches

	Full-Custom	Semi-Custom	Off-the-Shelf IC Package	Off-the-Shelf Microcomputer
Speed	Fastest	Fast	Medium	Slowest
Size	Smallest (chip size)	Small (chip size)	Large (many chips)	Medium (many chips)
Development time	Longest (layout)	Long (layout)	Medium (logic design)	Short (programming)
Flexibility	Lowest	Low	Medium	High
Initial investment	Highest (layout)	High (layout)	Medium (logic design)	Low (programming)
Unit Cost				
High volume	Lowest	Low	Medium	Highest
Low volume	Highest	High	Medium	Lowest
Reliability	Highest	High	Low	Medium

1. Custom-design full- and semi-custom approaches
2. Off-the-shelf discrete components and off-the-shelf IC packages, along with memory packages
3. Off-the-shelf microcomputers along with off-the-shelf IC packages

The full-custom design approaches give us the highest performance and reliability or the smallest chip size, although they are most time-consuming. (Even in the case of microcomputers, the full-custom designed microcomputers have better performance and smaller size than off-the-shelf microcomputers, by being tailored to the users' specific needs.) This is one end of the wide spectrum of different design approaches. At the other end, the off-the-shelf microcomputers give us a design approach where the development time is shortest, by programming rather than by chip design (including logic design), and the design changes are the easiest. The off-the-shelf discrete components and off-the-shelf IC packages give us logic networks tailored to specific needs with less programming than the off-the-shelf microcomputers.

Custom design approaches, in particular the full-custom design approaches, are the most economical for very high production volumes (on the order of a few hundred thousand) but the least economical for low production volumes.

When the production volume is low, the off-the-shelf discrete components and off-the-shelf IC packages give us the most economical approaches for simple tasks, but the off-the-shelf microcomputers are more economical for complex tasks, although performance is usually sacrificed.

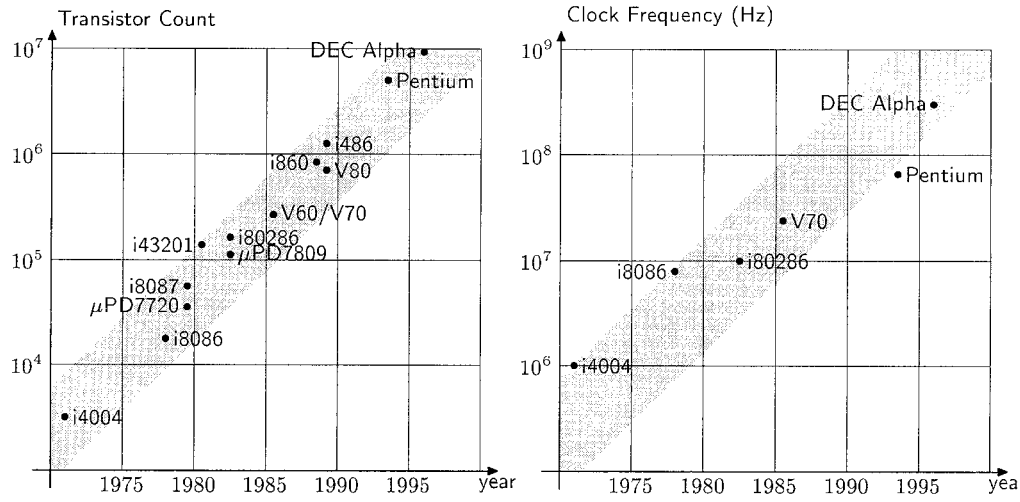
47.1 Introduction

The concept of *data* or *information processing* arises in a variety of fields. Understanding the principles behind this concept is fundamental to computer design, communications, manufacturing process control, biomedical engineering, and an increasingly large number of other areas of technology and science. It is impossible to imagine modern life without computers for generating, analyzing, and retrieving large amounts of information, as well as communicating information to end users regardless of their location.

Technologies for designing and building microelectronics-based computational equipment have been steadily advancing ever since the first commercial *discrete integrated circuits* were introduced[1] in the late 1950s.[1] As predicted by *Moore's law* in the 1960s,[2] integrated circuit (IC) density has been doubling approximately every 18 months, and this doubling in size has been accompanied by a similar exponential increase in circuit speed (or, more precisely, clock frequency). These trends of steadily increasing circuit size and clock frequency are illustrated in Fig. 47.1(a) and (b), respectively. As a result of this amazing revolution in semiconductor technology, it is not unusual for modern integrated circuits to contain over ten million switching elements (i.e., transistors) packed into a chip area as large as 500 mm^2.[3-5] This truly exceptional technological capability is due to advances in both design methodologies and physical manufacturing technologies. Research and experience demonstrate that this trend of exponentially increasing integrated circuit computational power will continue into the foreseeable future.

[1] Monolithic integrated circuits (ICs) were introduced in the 1960s.



(a) Evolution of the number of transistors per integrated circuit; and (b) Evolution of clock frequency.

FIGURE 47.1 Moore's law: exponential increase in circuit integration and clock frequency. (Ref. 2. With permission.)

Integrated circuit performance is typically characterized[6] by the *speed of operation*, the available *circuit functionality*, and the *power consumption*, and there are multiple factors which directly affect these performance characteristics. While each of these factors is significant, on the technological side, increased circuit performance has been largely achieved by the following approaches:

- Reduction in feature size (technology scaling); that is, the capability of manufacturing physically smaller and faster device structures
- Increase in chip area, permitting a larger number of circuits and therefore greater on-chip functionality
- Advances in packaging technology, permitting the increasing volume of data traffic between an integrated circuit and its environment as well as the efficient removal of heat created during circuit operation.

The most complex integrated circuits are referred to as VLSI circuits, where the term "VLSI" stands for Very Large-Scale Integration. This term describes the complexity of modern integrated circuits consisting of hundreds of thousands to many millions of active transistor elements. Presently, the leading integrated circuit manufacturers have a technological capability for the mass production of VLSI circuits with feature sizes as small as 0.12 μm.[7] These sub-1/2-micrometer technologies are identified with the term *deep submicrometer* (DSM) since the minimum feature size is well below the one micrometer mark.

As these dramatic advances in fabricating technologies take place, integrated circuit performance is often limited by effects closely related to the very reasons behind these advances, such as small geometry interconnect structures. Circuit performance has become strongly dependent and limited by electrical issues that are particularly significant in deep submicrometer integrated circuits. *Signal delay* and related *waveform effects* are among those phenomena that have a great impact on high-performance integrated circuit design methodologies and the resulting system implementation. In the case of fully synchronous VLSI systems, these effects have the potential to create catastrophic failures due to the limited time available for signal propagation among gates.

Synchronous systems in general are reviewed in Section 47.2, followed by a more detailed description of these systems and the related timing constraints in Section 47.3. The timing properties of the storage elements are discussed in Section 47.4 closing with an appendix containing a glossary of the many terms used throughout this chapter.

47.2 Synchronous VLSI Systems

General Overview

Typically, a digital VLSI system performs a complex computational algorithm, such as a Fast Fourier Transform or a RISC[2] architecture microprocessor. Although modern VLSI systems contain large number of components, these systems normally employ only a limited number of different kinds of *logic elements* or *logic gates*. Each logic element accepts certain input signals and computes an output signal to be used by other logic elements. At the logic level of abstraction, a VLSI system is a *network* of tens of thousands or more logic gates whose terminals are *interconnected* by wires in order to implement the target algorithm.

The switching variables acting as inputs and outputs of a logic gate in a VLSI system are represented by tangible physical qualities,[3] while a number of these devices are interconnected to yield the desired function of each logic gate. The specifiics of the physical characteristics are collectively summarized with the term *technology*, which encompasses such detail as the type and behavior of the devices that can be built, the number and sequence of the manufacturing steps, and the impedance of the different interconnect materials used. Today, several technologies make possible the implementation of high-performance VLSI systems — these are best exemplified by CMOS, bipolar, BiCMOS, and Gallium Arsenide.[2,8] CMOS technology in particular exhibits many desirable performance characteristics, such as low power consumption, high density, ease of design, and reasonable to excellent speed. Due to these excellent performance characteristics, CMOS technology has become the dominant VLSI technology used today.

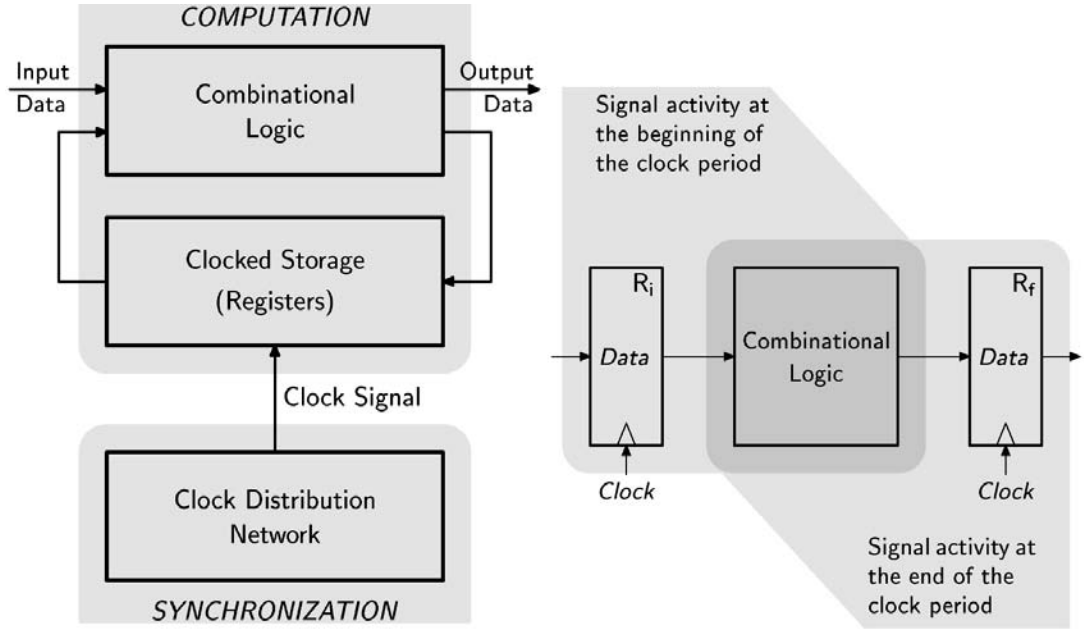
The design of a digital VLSI system may require a great deal of effort in order to consider a broad range of architectural and logic issues; that is, choosing the appropriate gates and interconnections among these gates to achieve the required circuit function. No design is complete, however, without considering the *dynamic* (or transient) characteristics of the signal propagation, or, alternatively, the changing behavior of signals within *time*. Every computation performed by a switching circuit involves multiple signal transitions between logic states and requires a *finite* amount of time to complete. The voltage at every circuit node must reach a specific value for the computation to be completed. Therefore, state-of-the-art integrated circuit design is largely centered around the difficult task of predicting and properly interpreting signal waveform shapes at various points in a circuit.

In a typical VLSI system, millions of signal transitions determine the individual gate delays and the overall speed of the system. Some of these signal transitions can be executed *concurrently,* while others must be executed in a strict *sequential* order.[9] The sequential occurence of the latter operations — or signal transition *events* — must be properly coordinated in time so that logically correct system operation is guaranteed and its results are reliable (in the sense that these results can be repeated). This coordination is known as *synchronization* and is critical to ensuring that any pair of logical operations in a circuit with a precedence relationship proceed in the proper order. In modern digital integrated circuits, synchronization is achieved at all stages of system design and system operation by a variety of techniques, known as a *timing discipline* or *timing scheme*.[8, 10-12] With few exceptions, these circuits are based on a *fully synchronous* timing scheme, specifically developed to cope with the finite speed required by the physical signals to propagate through the system.

An example of a *fully synchronous* system is shown in Fig. 47.2(a). As illustrated in Fig. 47.2(a), there are three recognizable components in this system. The first component — the logic gates, collectively referred to as the *combinational logic* — provides the range of operations that a system executes. The second component — the *clocked storage* elements or simply the *registers* — are elements that store the results of the logical operations. Together, the combinational logic and registers constitute the *computational* portion of the synchronous system and are interconnected in a way that implements the

[2] RISC = Reduced Instruction Set Computer.

[3] Such quantities as the *electical voltages* and *currents* in the electronic devices.



(a) Finite-state machine model of a sychronous system; and (b) A local data path.

FIGURE 47.2 A synchronous system.

required system function. The third component of the synchronous system — known as the *clock distribution network* — is a highly specialized circuit structure which does not perform a computational process, but rather provides an important control capability. The clock generation and distribution network controls the overall synchronization of the circuit by *generating* a time reference and properly *distributes* this time reference to every register.

The normal operation of a system, such as the example shown in Fig. 47.2(a), consists of the iterative execution of computations in the combinational logic, followed by the storage of the processed results in the registers. The actual process of storage is temporally controlled by the clock signal and occurs once the signal transients in the logic gate outputs are completed and the outputs have settled to a valid state. At the beginning of each computational cycle, the inputs of the system, together with the data stored in the registers, initiate a new switching process. As time proceeds, the signals propagate through the logic, generating results at the logic output. By the end of the clock period, these results are stored in the registers and are operated upon during the following clock cycle.

Therefore, the operation of a digital system can be thought of as the sequential execution of a large set of simple computations that occur concurrently in the combinational logic portion of the system. The concept of a *local data path* is a useful abstraction for each of these simple operations and is shown in Fig. 47.2(b). The magnitude of the delay of the combinational logic is bound by the requirement of storing data in the registers within a clock period. The initial register R_i is the storage element at the beginning of the local data path and provides some or all of the input signals for the combinational logic at the beginning of the computational cycle (defined by the beginning of the clock period). The *combinational path* ends with the data successfully latching within the final register R_f, where the results are stored at the end of the computational cycle. Each register acts as a *source* or *sink* for the data, depending upon which phase the system is currently operating in.

Advantages and Drawbacks of Synchronous Systems

The behavior of a fully synchronous system is well-defined and controllable as long as the *time window* provided by the clock period is sufficiently long to allow every signal in the circuit to propagate through

the required logic gates and interconnect wires and successfully latch within the final register. In designing the system and choosing the proper clock period, however, two contradictory requirements must be satisfied. First, the smaller the clock period, the more computational cycles can be performed by the circuit in a given amount of time. Alternatively, the time window defined by the clock period must be sufficiently long so that the slowest signals reach the destination registers before the current clock cycle is concluded and the following clock cycle is initiated.

This way of organizing computation has certain clear advantages that have made a fully synchronous timing scheme the primary choice for digital VLSI systems:

- It is easy to understand and its properties and variations are well-understood.
- It eliminates the nondeterministic behavior of the propagation delay in the combinational logic (due to environmental and process fluctuations and the unknown input signal pattern) so that the system as a whole has a completely deterministic behavior corresponding to the implemented algorithm.
- The circuit design does *not* need to be concerned with glitches in the combinational logic outputs so the only relevant dynamic characteristic of the logic is the *propagation delay*.
- The state of the system is completely defined within the storage elements; this fact greatly simplifies certain aspects of the design, debug, and test phases in developing a large system.

However, the synchronous paradigm also has certain limitations that make the design of synchronous VLSI systems increasingly challenging:

- This synchronous approach has a serious drawback in that it requires the overall circuit to operate as slow as the *slowest* register-to-register path. Thus, the global speed of a fully synchronous system depends upon those paths in the combinational logic with the largest delays; these paths are also known as the *worst-case* or *critical* paths. In a typical VLSI system, the propagation delays in the combinational paths are distributed unevenly so there may be many paths with delays much smaller than the clock period. Although these paths could take advantage of a lower clock period — higher clock frequency — it is the paths with the largest delays that bound the clock period, thereby imposing a limit on the overall system speed. This imbalance in propagation delays is sometimes so dramatic that the system speed is dictated by only a handful of very slow paths.
- The clock signal has to be distributed to tens of thousands of storage registers scattered throughout the system. Therefore, a significant portion of the system area and dissipated power is devoted to the clock distribution network — a circuit structure that does not perform any computational function.
- The reliable operation of the system depends upon the assumptions concerning the values of the propagation delays which, if not satisfied, can lead to catastrophic timing violations and render the system unusable.

47.3 Synchronous Timing and Clock Distribution Networks

Background

As described in Section 47.2, most high-performance digital integrated circuits implement data processing algorithms based on the iterative execution of basic operations. Typically, these algorithms are highly *parallelized* and *pipelined* by inserting clocked registers at specific locations throughout the circuit. The synchronization strategy for these clocked registers in the vast majority of VLSI/ULSI-based digital systems is a fully synchronous approach. It is not uncommon for the computational process in these systems to be spread over hundreds of thousands of functional logic elements and tens of thousands of registers.

For such synchronous digital systems to function properly, the many thousands of switching events require a strict temporal ordering. This strict ordering is enforced by a global synchronization signal known as the *clock signal*. For a fully synchronous system to operate correctly, the clock signal must be delivered to every register at a precise *relative* time. The delivery function is accomplished by a circuit and interconnect structure known as a *clock distribution network*.[13]

Multiple factors affect the propagation delay of the data signals through the combinational logic gates and the interconnect. Since the clock distribution network is composed of logic gates and interconnection wires, the signals in the clock distribution network are also delayed. Moreover, the dependence of the correct operation of a system on the signal delay in the clock distribution network is far greater than on the delay of the logic gates. Recall that by delivering the clock signal to registers at precise times, the clock distribution network essentially quantizes the time of a synchronous system (into clock periods), thereby permitting the simultaneous execution of operations.

The nature of the on-chip clock signal has become a primary factor limiting circuit performance, causing the clock distribution network to become a performance bottleneck for high-speed VLSI systems. The primary source of the load for the clock signals has shifted from the logic gates to the *interconnect*, thereby changing the physical nature of the load from a lumped capacitance (C) to a distributed *resistive-capacitive* (RC) load.[6,7] These interconnect impedances degrade the on-chip signal waveform shapes and increase the path delay. Furthermore, statistical variations in the parameters characterizing the circuit elements along the clock and data signal paths, caused by the imperfect control of the manufacturing process and the environment, introduce ambiguity into the signal timing that cannot be neglected. All of these changes have a profound impact on both the choice of synchronous design methodology and on the overall circuit performance. Among the most important consequences are increased power dissipated by the clock distribution network, as well as the increasingly challenging timing constraints that must be satisfied in order to avoid timing violations.[3-5,13,14] Therefore, the majority of the approaches used to design a clock distribution network attempts to simplify the performance goals by targeting minimal or zero global clock skew,[15-17] which can be achieved by different routing strategies,[18-21] buffered clock tree synthesis, symmetric n-ary trees[3] (most notably H-trees), or a distributed series of buffers connected as a mesh.[13,14]

Definitions and Notation

A synchronous digital system is a network of logic gates and registers whose input and output terminals are interconnected by wires. A sequence of connected logic gates (no registers) is called a *signal path*. Signal paths bounded by registers are called *sequentially-adjacent paths* and are defined next:

Definition 47.1: Sequentially-adjacent pair of registers. For an arbitrary ordered pair of registers $\langle R_i, R_f \rangle$ in a synchronous circuit, one of the following two situations can be observed. Either there exists at least one signal path[4] that connects some output of R_i to some input of R_f or any input of R_f cannot be reached from any output of R_i by propagating through a squence of logic elements only. In the former case — denoted by $R_1 \rightsquigarrow R_2$ — the pair of registers $\langle R_i, R_f \rangle$ is called a sequentially-adjacent pair of registers and switching events at the output of R_i can possibly affect the input of R_f during the same clock period. A sequentially-adjacent pair of registers is also referred to as a local data path.[13]

Examples of local data paths with flip-flops and latches are shown in Figs. 47.14 and 47.17, respectively. The clock signal C_i driving the initial register R_i of the local data path and the clock signal C_f driving the final register R_f are shown in Figs. 47.14 and 47.17, respectively.

A fully synchronous digital circuit is formally defined as follows:

[4] Consecutively connected logic gates.

Definition 47.2: A fully synchronous digital circuit $S = \langle G, R, C \rangle$ is an ordered triple, where:

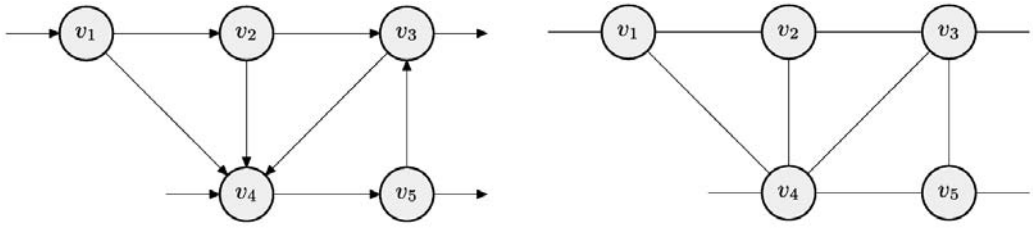
- $G = \{g_1, g_2, \ldots, g_M\}$ is the set of all combinational logic gates,
- $R = \{R_1, R_2, \ldots, R_N\}$ is the set of all registers, and
- $C = \|c_{i \times j}\|_{N \times N}$ is a matrix describing the connectivity of G where for every element $C_{i,j}$ of C

$$c_{i,j} = \begin{cases} 0, & \text{if}(R_i \rightsquigarrow R_j) \\ 1, & \text{if}(R_i \not\rightsquigarrow R_j) \end{cases}$$

Note that in a fully synchronous digital system there are no purely combinational signal *cycles*, that is, it is impossible to reach the input of any logic gate g_k by starting at the same gate and going through a sequence of combinational logic gates only.[13,22]

Graph Model of a Fully Synchronous Digital Circuit

Certain properties of a synchronous digital circuit may be better understood by analyzing a graph model of a circuit. A synchronous digital circuit can be modeled as a *directed graph*[23,24] G with a *vertex set* $V = \{v_1, \ldots, v_N\}$ and an *edge set* $E = \{e_1, \ldots, e_{N_p}\} \subseteq V \times V$. An example of a circuit graph G is illustrated in Fig. 47.3(a). The number of registers in the circuit is $|V| = N$ where the vertex v_k corresponds to the register R_k. The number of local data paths in the circuit is $|E| = N_p = 11$ for the example shown in Fig. 47.3. An edge is directed from v_i to v_j *iff* $R_i \rightsquigarrow R_j$. In the case where multiple paths between a sequentially-adjacent pair of registers $R_i \rightsquigarrow R_j$ exist, only *one* edge connects v_i to v_j. The *underlying* graph G_u of the graph G is a *non-directed* graph that has the same vertex set V, where the directions have been removed from the edges. The underlying graph G_u of the graph G depicted in Fig. 47.3(a) is shown in Fig. 47.3(b). Furthermore, an input or an output of the circuit is indicated in Fig. 47.3 by an edge incident to only one vertex.



(a) The directed graph G. (b) The underlying graph Gu of G in(a).

FIGURE 47.3 Graphs G and its underlying graph G_u of the graph $N = 5$ registers.

The timing constraints of a local data path are derived in Section 47.4 for paths consisting of flip-flops and latches. The concept of clock skew used in these timing constraints is formally defined next.

Definition 47.3: Let $S = \langle G, R, C \rangle$ be a fully synchronous digital circuit as defined in Definition 47.2. For any ordered pair of registers $\langle R_i, R_j \rangle$ driven by the clock signals C_i and C_j, respectively, the clock skew $T_{Skew}(i,j)$ is defined as the difference:

$$T_{Skew}(i,j) = t_{cd}^{i} - t_{cd}^{j} \tag{47.1}$$

where t_{cd}^{i} and t_{cd}^{j} are the clock delays of the clock signals C_i and C_j, respectively.

In Definition 47.3, the clock delays t_{cd}^{i} and t_{cd}^{j} are with respect to some reference point. A commonly used reference point is the source of the clock distribution network on the chip. Note that the clock skew $T_{Skew}(i,j)$ as defined in Definition 47.3 obeys the antisymmetric property,

$$T_{Skew}(i,j) = -T_{Skew}(j,i) \tag{47.2}$$

The clock skew $T_{Skew}(i,j)$ as defined in Definition 47.3 is a component in the timing constraints of a local data path (see inequalities 47.19, 47.24, 47.34, 47.35, and 47.40). Therefore, clock skew is defined and is only of practical use for sequentially-adjacent registers R_i and R_j[5] (i.e., only for local data paths).

The following substitutions are introduced for notational convenience:

Definition 47.4: Let $S = \langle G, R, C \rangle$ be a fully synchronous digital circuit where the registers $\mathsf{R}_i, \mathsf{R}_f \in R$ and $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$. The long path delay $\hat{D}^{i,f}_{PM}$ of the local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ is defined as

$$\hat{D}^{i,f}_{PM} = \begin{cases} (D^{Fi}_{CQM} + D^{i,f}_{PM} + \delta^{Ff}_{S} + 2\Delta^{F}_{L}), & \text{if } \mathsf{R}_i, \mathsf{R}_f \text{ are flip flops} \\ (D^{Li}_{CQM} + D^{i,f}_{PM} + \delta^{Lf}_{S} + \Delta^{L}_{L} + \Delta^{L}_{T}), & \text{if } \mathsf{R}_i, \mathsf{R}_f \text{ are latches} \end{cases} \tag{47.3}$$

Similarly, the short delay $\hat{D}^{i,f}_{Pm}$ of the local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ is defined as

$$\hat{D}^{i,f}_{Pm} = \begin{cases} (D^{i,f}_{Pm} + D^{Fi}_{CQ} - \delta^{Ff}_{H} - 2\Delta^{F}_{L}), & \text{if } \mathsf{R}_i, \mathsf{R}_f \text{ are flip flops} \\ (D^{Li}_{CQm} + D^{i,f}_{Pm} - \delta^{Lf}_{H} - \Delta^{L}_{L} - \Delta^{L}_{T}), & \text{if } \mathsf{R}_i, \mathsf{R}_f \text{ are latches} \end{cases} \tag{47.4}$$

For example, using the notations described in Definition 47.4, the timing constraints of a local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ with flip-flops (Eqs. 47.19 and 47.24) become

$$T_{Skew}(i,f) \le T_{CP} - \hat{D}^{i,f}_{PM} \tag{47.5}$$

$$-\hat{D}^{i,f}_{Pm} \le T_{Skew}(i,f) \tag{47.6}$$

For a local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ consisting of the flip-flows R_i and R_f, the setup and hold time violations are avoided if Eqs. 47.5 and 47.6, respectively, are satisfied.

The clock skew $T_{Skew}(i,f)$ for a local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ can be either *positive* or *negative*, as illustrated in Figs. 47.15 and 47.16, respectively. Negative clock skew may be used to effectively speed up a local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ by allowing an additional $T_{Skew}(i,f)$ amount of time for the signal to propagate from R_i to R_f. However excessive negative skew may create a hold time violation, thereby creating a lower bound on $T_{Skew}(i,f)$ as described by Eq. 47.6. A hold time violation is a *clock hazard* or a *race condition*, also known as *double clocking*.[13, 25] Similarly, positive clock skew effectively decreases the clock period T_{CP} by $T_{Skew}(i,f)$, thereby limiting the maximum clock frequency.[6] In this case, a clocking hazard known as *zero clocking* may be created.[13,25]

Clock Scheduling

Examining the constraints of Eqs. 47.5 and 47.6 reveals a procedure for preventing clock hazards. Assuming Eq. 47.5 is not satisfied, a suitably large value of T_{CP} can be chosen to satisfy constraint Eq. 47.5 and prevent zero clocking. Also note that, unlike Eq. 47.5, Eq. 47.6 is independent of T_{CP}. Therefore, T_{CP} cannot be varied to correct a double clocking hazard, but rather a redesign of the clock distribution network may be required.[17]

Both double and zero clocking hazards can be eliminated if two simple choices characterizing a fully synchronous digital circuit are made. Specifically, if equal values are chosen for all clock delays, then the clock skew $T_{Skew}(i,f) = 0$ for each local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$,

[5] Note that technically, however, $T_{Skew}(i,j)$ can be calculated for any ordered pair of registers $\langle \mathsf{R}_i, \mathsf{R}_j \rangle$.

[6] Positive clock skew may also be thought of as increasing the path delay. In either case, positive clock skew $T_{Skew} > 0$ makes it more difficult to satisfy Eq. 47.5.

$$\forall \langle R_i, R_f \rangle : t_{cd}^{i} = t_{cd}^{f} \Rightarrow T_{Skew}(i, f) = 0 \tag{47.7}$$

Therefore, Eqs. 47.5 and 47.6 become

$$T_{Skew}(i, f) = t_{cd}^{i} - t_{cd}^{f} = 0 \leq T_{CP} - \hat{D}_{PM}^{i,f} \tag{47.8}$$

$$-\hat{D}_{Pm}^{i,f} \leq 0 = T_{Skew}(i, f) = t_{cd}^{i} - t_{cd}^{f} \tag{47.9}$$

Note that Eq. 47.8 can be satisfied for each local data path $R_i \rightsquigarrow R_f$ in a circuit if a sufficiently large value — larger than the greatest value $\hat{D}_{PM}^{i,f}$ in a circuit — is chosen for T_{CP}. Furthermore, Eq. 47.9 can be satisfield across an entire circuit if it can be ensured that $\hat{D}_{Pm}^{i,f} \geq 0$ for each local data path $R_i \rightsquigarrow R_f$ in the circuit. The timing constraint Eqs. 47.8 and 47.9 can be satisfield since choosing a sufficiently large clock period T_{CP} is always possible and $\hat{D}_{Pm}^{i,f}$ is positive for a properly designed local data path $R_i \rightsquigarrow R_f$. The application of this zero clock skew methodology (Eqs. 47.7, 47.8, and 47.9) has been central to the design of fully synchronous digital circuits for decades.[13, 26] By requiring the clock signal to arrive at each register R_j with approximately the same delay t_{cd}^{j},[7] these design methods have become known as *zero* clock skew methods.

As shown by previous research,[13,15-17,27-29] both double and zero clocking hazards may be removed from a synchronous digital circuit even when the clock skew is *non-zero;* that is, $T_{Skew}(i, f) \neq 0$ for some (or *all*) local data paths $R_i \rightsquigarrow R_f$. As long as Eqs. 47.5 and 47.6 are satisfied, a synchronous digital system can operate reliably with *non-zero* clock skews, permitting the system to operate at higher clock frequencies while removing all race conditions.

The vector column of clock delays $\mathbf{T_{CD}} = [\, t_{cd}^{1}, t_{cd}^{2}, \ldots]^T$ is called a *clock schedule.*[13,25] If $\mathbf{T_{CD}}$ is chosen such that Eqs. 47.5 and 47.6 are satisfied for every local data path $R_i \rightsquigarrow R_f$, $\mathbf{T_{CD}}$ is called a *consistent* clock schedule. A clock schedule that satisfies Eq. 47.7 is called a *trivial* clock schedule. Note that a trivial clock schedule $\mathbf{T_{CD}}$ implies global *zero* clock skew since for any i and f, $t_{cd}^{i} = t_{cd}^{f}$, thus, $T_{Skew}(i, f) = 0$.

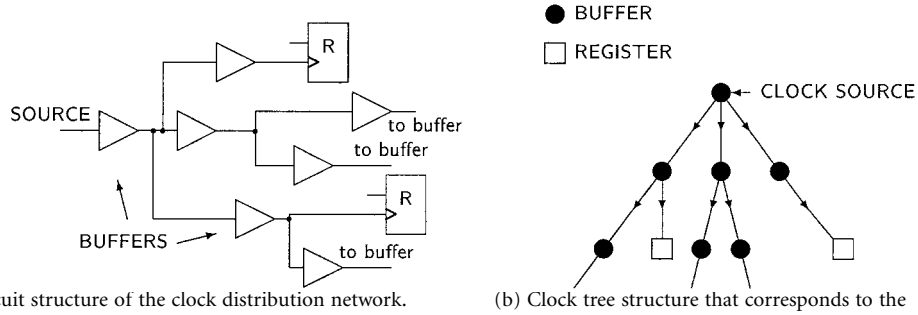
Fishburn[25] first suggested an algorithm for computing a consistent clock schedule that is *non-trivial.* Furthermore, Fishburn showed[25] that by exploiting negative and positive clock skew within the local data paths $R_i \rightsquigarrow R_f$, a circuit can operate with a clock period T_{CP} less than the clock period achievable by a trivial (or zero skew) clock schedule that satisfies the conditions specified by Eqs. 47.5 and 47.6. In fact, Fishburn[25] determined an *optimal* clock schedule by applying linear programming techniques to solve for $\mathbf{T_{CD}}$ so as to satisfy Eqs. 47.5 and 47.6 while minimizing the objective function $F_{\text{objective}} = T_{CP}$.

The process of determining a consistent clock schedule $\mathbf{T_{CD}}$ can be considered as the mathematical problem of minimizing the clock period T_{CP} under the constraints Eqs. 47.5 and 47.6. However, there are important practical issues to consider before a clock schedule can be properly implemented. A clock distribution network must be synthesized such that the clock signal is delivered to each register with the proper delay so as to satisfy the clock skew schedule $\mathbf{T_{CD}}$. Furthermore, this clock distribution network must be constructed so as to minimize the deleterious effects of *interconnect impedances* and *process parameter variations* on the implemented clock schedule. Synthesizing the clock distribution network typically consists of determining a *topology* for the network, together with the circuit design and physical layout of the *buffers* and *interconnect* within the clock distribution network.[13]

Structure of the Clock Distribution Network

The clock distribution network is typically organized as a rooted tree structure,[13,15,23] as illustrated in Fig. 47.4, and is often called a *clock tree.*[13] A circuit schematic of a clock distribution network is shown in Fig. 47.4(a). An abstract graphical representation of the tree structure depicted in Fig. 47.4(a) is shown in Fig. 47.4(b). The unique source of the clock signal is at the root of the tree. This signal is distributed

[7] Equivalently, it is required that the clock signal arrive at each register at approximately the same time.



(a) Circuit structure of the clock distribution network.

(b) Clock tree structure that corresponds to the circuit shown in (a).

FIGURE 47.4 Tree structure of a clock distribution network.

from the source to every register in the circuit through a sequence of buffers and interconnects. Typically, a buffer in the network drives a combination of other buffers and registers in the VLSI circuit. An interconnection network of wires connects the output of the driving buffer to the inputs of these driven buffers and registers. An *internal node* of the tree corresponds to a buffer, and a *leaf node* of the tree corresponds to a register. There are N leaves[8] in the clock tree labeled F_1 through F_N, where leaf F_j corresponds to register R_j. A clock tree topology that implements a given clock schedule $\mathbf{T_{CD}}$ must enforce a clock skew $T_{Skew}(i, f)$ for each local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ of the circuit in order to ensure that both Eqs. 47.5 and 47.6 are satisfied. This topology, however, can be affected by three important issues relating to the operation of a fully synchronous digital system.

Linear Dependency of the Clock Skews

An important corollary related to the *conservation property*[13] of clock skew is that there is a *linear dependency* among the clock skews of a global data path that form a cycle in the underlying graph of the circuit. Specifically, if $v_0, e_1, v_1 \neq v_0, \ldots, v_{k-1}, e_k, v_k \equiv v_0$ is a cycle in the underlying graph of the circuit, then

$$\begin{aligned} 0 &= [t_{cd}^0 - t_{cd}^1] + [t_{cd}^1 - t_{cd}^2] + \ldots \\ &= \sum_{i=0}^{k-1} T_{Skew}(i, i+1) \end{aligned} \tag{47.10}$$

The property described by 47.10 is illustrated in Fig. 47.3 for the undirected cycle v_1, v_4, v_3, v_2, v_1. Note that

$$\begin{aligned} 0 &= (t_{cd}^1 - t_{cd}^4) + (t_{cd}^4 - t_{cd}^3) + (t_{cd}^3 - t_{cd}^2) + (t_{cd}^2 - t_{cd}^1) \\ &= T_{Skew}(1, 4) + T_{Skew}(4, 3) + T_{Skew}(3, 2) + T_{Skew}(2, 1) \end{aligned} \tag{47.11}$$

The importance of this property is that Eq. 47.10 describes the inherent correlation among certain clock skews within a circuit. Therefore, these correlated clock skews *cannot* be optimized independently of each other. Returning to Fig. 47.3, note that it is not necessary that a directed cycle exists in the directed graph G of a circuit for Eq. 47.10 to hold. For example, v_2, v_3, v_4 is not a cycle in the directed circuit graph G in Fig. 47.3(a) but v_2, v_3, v_4 is a cycle in the undirected circuit graph G_u in Fig. 47.3(b). In addition, $T_{Skew}(2, 3) + T_{Skew}(3, 4) + T_{Skew}(4, 2) = 0$; that is, the skews $T_{Skew}(2, 3)$, $T_{Skew}(3, 4)$, and $T_{Skew}(4, 2)$ are linearly dependent. A maximum of $(|V| - 1) = (N - 1)$ clock skews can be chosen independently of each other in a circuit, which is easily proven by considering a spanning tree of the underlying circuit graph G_u.[23,24] Any spanning tree of G_u will contain $(N - 1)$ edges — each edge corresponding to a local

[8] The number of registers N in the circuit.

data path — and the addition of any other edge of G_u will form a cycle such that Eq. 47.10 holds for this cycle. Note, for example, that for the circuit modeled by the graph shown in Fig. 47.3, *four* independent clock skews can be chosen such that the remaining three clock skews can be expressed in terms of the independent clock skews.

Permissible Ranges

Previous research[17,29] has indicated that tight control over the clock skews rather than the clock delays is necessary for the circuit to operate reliably. The relationships in Eqs. 47.5 and 47.6 are used in Ref. 29 to determine a *permissible range* of the allowed clock skew for each local data path. The concept of a permissible range for the clock skew $T_{Skew}(i, f)$ of a local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ is illustrated in Fig. 47.5. When $T_{Skew}(i, f) \in [-\hat{D}^{i,f}_{Pm}, T_{CP} - \hat{D}^{i,f}_{PM}]$ — as shown in Fig. 47.5 — Eqs. 47.5 and 47.6 are satisfied. The clock skew $T_{Skew}(i, f)$ is *not permitted* to be in either the interval $(-\infty, -\hat{D}^{i,f}_{Pm})$ because a race condition will be created or the interval $(T_{CP} - \hat{D}^{i,f}_{PM}, +\infty)$ because the minimum clock period will be limited.

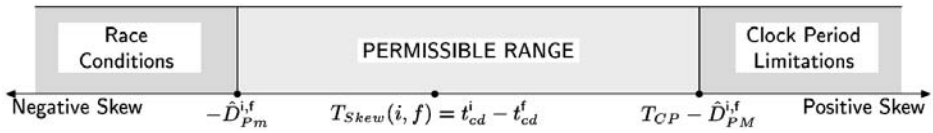


FIGURE 47.5 The permissible range of the clock skew of a local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$. A timing violation exists if $T_{Skew}(i, f) \notin [-\hat{D}^{i,f}_{Pm}, T_{CP} - \hat{D}^{i,f}_{PM}]$.

Also, note that the reliability of the circuit is related to the probability of a timing violation occurring for any local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$. Therefore, the reliability of any local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ of the circuit (and therefore of the entire circuit) is increased in two ways:

1. By choosing the clock skew $T_{Skew}(i, f)$ for a local data path as far as possible from the borders of the interval $[-\hat{D}^{i,f}_{Pm}, T_{CP} - \hat{D}^{i,f}_{PM}]$, that is, by (ideally) positioning the clock skew $T_{Skew}(i, f)$ in the middle of the permissible range, that is, $T_{Skew}(i, f) = 1/2\,[T_{CP} - (\hat{D}^{i,f}_{PM} + \hat{D}^{i,f}_{Pm})]$,
2. By increasing the width $T_{CP} - (\hat{D}^{i,f}_{PM} - \hat{D}^{i,f}_{Pm})$ of the permissible range of the local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$

Due to the linear dependence of the clock skews shown previously, however, it is *not* possible to build a typical circuit such that for each local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$, the clock skew $T_{Skew}(i, f)$ is in the middle of the permissible range.

Differential Character of the Clock Tree

In a given circuit, the clock signal delay t^j_{cd} from the clock source to the register R_j is equal to the sum of the propagation delays of the buffers on the unique path that exists between the root of the clock tree and the leaf F_j corresponding to the j-th register. Furthermore, if $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ is a sequentially-adjacent pair of registers, there is a portion of the two paths — denoted P^*_{if} — between the root of the clock tree and R_i and R_f, respectively, that is common to both paths. This concept is illustrated in Fig. 47.6. A portion of a clock tree is shown in Fig. 47.6 where each of the vertices 1 through 10 corresponds to a buffer in the clock tree. The vertices 4, 5, and 9 are leaves of the tree and correspond to the registers R_4, R_5, and R_9, respectively.[9] The local data paths $\mathsf{R}_4 \rightsquigarrow \mathsf{R}_5$ and $\mathsf{R}_5 \rightsquigarrow \mathsf{R}_9$ are indicated with arrows in Fig. 47.6, while the paths of the clock signals to each of the registers R_4, R_5, and R_9 are shown in Fig. 47.6 lightly shaded. The portion of the clock signal paths common to both registers of a local data path is shaded darker in Fig. 47.6; note the segments $1 \rightarrow 2 \rightarrow 3$ for $\mathsf{R}_4 \rightsquigarrow \mathsf{R}_5$ and $1 \rightarrow 2$ for $\mathsf{R}_5 \rightsquigarrow \mathsf{R}_9$.

Similarly, there is a portion of the clock signal path to any of the registers R_i and R_f in a sequentially-adjacent pair of registers $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$, denoted by P^i_{if} and P^f_{if}, respectively, that is unique to this register.

[9] Note that *not* all of the vertices correspond to registers.

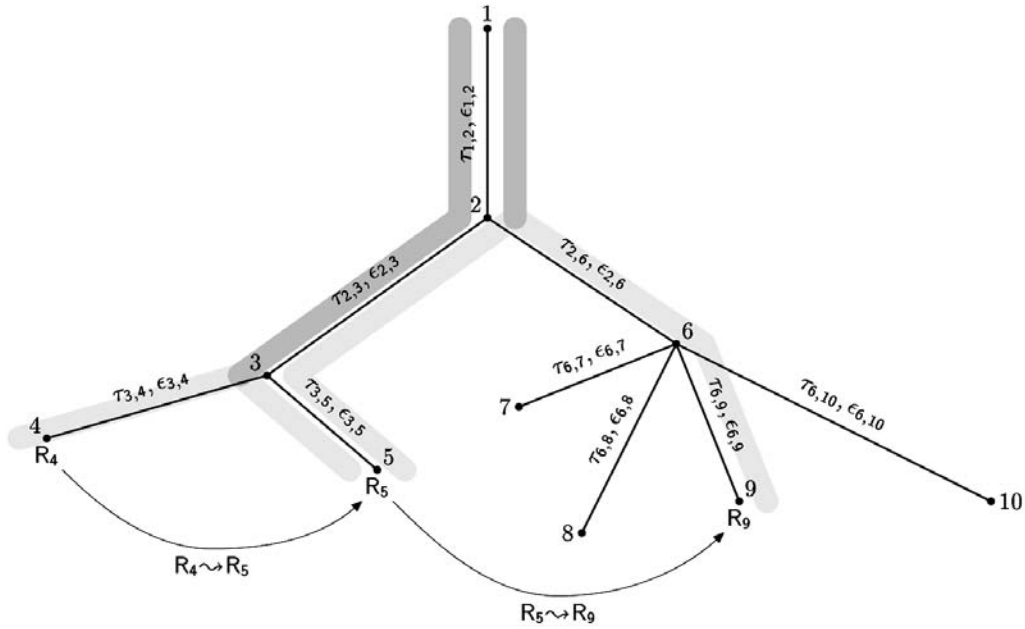

FIGURE 47.6 Illustration of the differential nature of the clock tree.

Returning to Fig. 47.6, the segments $3 \rightarrow 4$ and $3 \rightarrow 5$ are unique to the clock signal paths to the registers R_4 and R_5, while the segments $2 \rightarrow 3 \rightarrow 5$ and $2 \rightarrow 6 \rightarrow 9$ are unique to the clock signal paths to the registers R_5, and R_9, respectively.

Note that the clock skew $T_{Skew}(i, f)$ between the sequentially adjusted pair of registers $R_i \rightsquigarrow R_f$ is equal to the difference between the accumulated buffer propagation delays between P^i_{if} and P^f_{if}, that is, $T_{Skew}(i, f)$ = Delay (P^i_{if}) − Delay (P^f_{if}). Therefore, any variations of circuit parameters over P^*_{if} will not affect the value of the clock skew $T_{Skew}(i, f)$. For the example shown in Fig. 47.6, $T_{Skew}(4,5)$ = Delay $(P^4_{4,5})$ − Delay $(P^5_{4,5})$ and $T_{Skew}(5,9)$ = Delay $(P^5_{5,9})$ − Delay $(P^9_{5,9})$.

The differential feature of the clock tree suggests an approach for minimizing the effects of process parameter variations on the correct operation of the circuit. To illustrate this approach, each branch $p \rightarrow q$ of the clock tree shown in Fig. 47.6 is labeled with two numbers: $\tau_{p,q} > 0$ is the intended delay of the branch and $\varepsilon_{p,q} \geq 3\ 0$ is the maximum error (deviation) of this delay.[10] In other words, the actual delay of the branch $p \rightarrow q$ is in the interval $[\tau_{p,q} - \varepsilon_{p,q}, \tau_{p,q} + \varepsilon_{p,q}]$. With this notation, the *target* clock skew values for the local data paths $R_4 \rightsquigarrow R_5$ and $R_5 \rightsquigarrow R_9$ are shown in the middle column in Table 47.1. The bounds of the actual clock skew values for the local data paths $R_4 \rightsquigarrow R_5$ and $R_5 \rightsquigarrow R_9$ (considering the ε variations) are shown in the right-most column in Table 47.1.

TABLE 47.1 Target and Actual Values of the Clock Skews for the Local Data Paths $R_4 \rightsquigarrow R_5$ and $R_5 \rightsquigarrow R_9$ Shown in Fig. 47.6

	Target Skew	Actual Skew Bounds
$T_{Skew}(4, 5)$	$\tau_{3,4} - \tau_{3,5}$	$\tau_{3,4} - \tau_{3,5} \pm (\varepsilon_{3,4} + \varepsilon_{3,4})$
$T_{Skew}(5, 9)$	$\tau_{2,3} + \tau_{3,5} - \tau_{2,6} - \tau_{6,9}$	$\tau_{2,3} + \tau_{3,5} - \tau_{2,6} - \tau_{6,9} \pm (\varepsilon_{2,3} + \varepsilon_{3,5} + \varepsilon_{2,6} + \varepsilon_{6,9})$

[10] The deviation ε is due to parameter variations during circuit manufacturing as well as to environmnetal conditions during operation of the circuit.

As the results in Table 47.1 demonstrate, it is advantageous to maximize P^*_{if} for any local data path $R_i \rightsquigarrow R_f$ with a relatively narrow permissible range, such that the parameter variations on P^*_{if} do not affect $T_{Skew}(i, f)$ Similarly, when the permissible range $[-\hat{D}^{i,f}_{Pm}, T_{CP} - \hat{D}^{i,f}_{PM}]$ is wider, P^*_{if} may be permitted to be only a small franction of the total path from the root to R_i and R_f, respectively. Future research work will explore this approach of synthesizing a clock tree based on choosing a tree structure which restricts the possible variations of those local data paths with narrow permissible ranges, and tolerates larger delay variations for those local data paths with wider permissible ranges.

47.4 Timing Properties of Synchronous Storage Elements

Common Storage Elements

The general structure and principles of operation of a fully synchronous digital VLSI system were described in Section 47.2. In this section, the timing constraints due to the combinational logic and the storage elements within a synchronous system are reviewed. The clock distribution network provides the time reference for the storage elements — or registers — thereby enforcing the required logical order of operations. This time reference consists of one or more *clock signals* that are delivered to each and every register within the integrated circuit. These clock signals control the order of computational events by controlling the exact times the register data inputs are sampled.

The data signals are inevitably delayed as these signals propagate through the logic gates and along interconnections within the local data paths. These propagation delays can be evaluated within a certain accuracy and used to derive timing relationships among signals in a circuit. In this section, the properties of commonly used types of registers and their local timing relationships for different types of local data paths are described. After discussing registers in general in the next subsection, the properties of level-sensitive registers (latches) and the significant timing parameters of these registers are reviewed. Edge-sensitive registers (flip-flops) and their timing parameters are also analyzed. Properties and definitions related to the clock distribution network are reviewed, and finally, the mathematical foundation for analyzing timing violations in both flip-flops and latches is discussed.

Storage Elements

The storage elements (registers) encountered throughout VLSI systems vary widely in their function and temporal relationships. Independent of these differences, however, all storage elements share a common feature — the existence of two groups of signals with largely different purposes. A generalized view of a register is depicted in Fig. 47.7. The I/O signals of a register can be divided into two groups as shown in Fig. 47.7. One group of signals — called the *data signals* — consists of input and output signals of

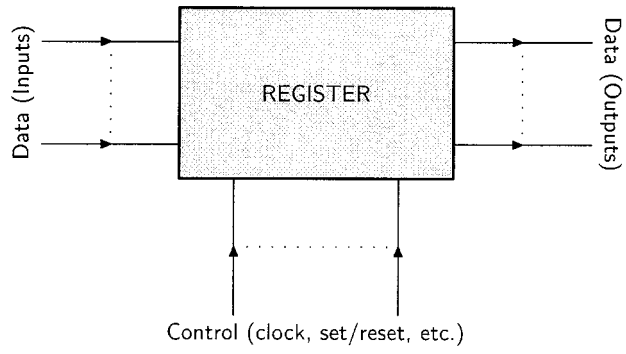

FIGURE 47.7 A general view of a register.

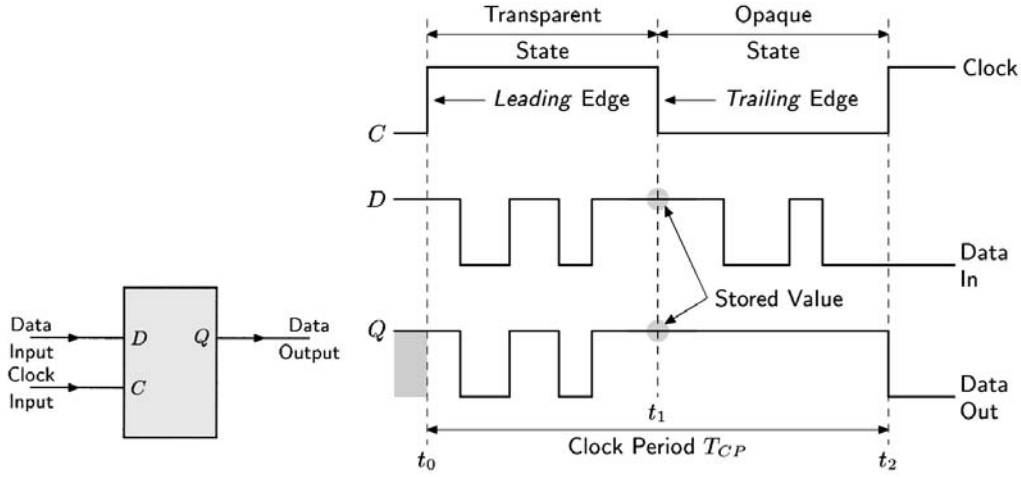
the storage element. These input and output signals are connected to the *data* signal terminals of other storage elements as well as to the terminals of ordinary logic gates. Another group of signals — identified by the name *control* signals — are those signals that control the storage of the data signals in the registers but do not participate in the logical computation process.

Certain control signals enable the storage of a data signal in a register independently of the values of any data signals. These control signals are typically used to initialize the data in a register to a specific well-known value. Other control signals — such as a *clock* signal — control the process of storing a data signal within a register. In a synchronous circuit, each register has at least one clock (or control) signal input.

The two major groups of storage elements (registers) are considered in the following sections based on the type of relationship that exists among the data and clock signals of these elements. In *latches*, it is the specific value or level of a control signal[11] that determines the data storage process. Therefore, latches are also called *level-sensitive registers*. In contrast to latches, a data signal is stored in *flip-flops* as controlled by an *edge* of a control signal. For that reason, flip-flops are also called *edge-triggered registers*. The timing properties of latches and flip-flops are described in detail in the following two sections.

Latches

A *latch* is a register whose behavior depends upon the value or level of the clock signal.[8,30-36] Therefore, a latch is often referred to as a *transparent* latch, a *level-sensitive* register, or a *polarity hold* latch. A simple type of latch with a clock signal C and an input signal D is depicted in Fig. 47.8(a)—the output of the latch is typically labeled Q. This type of latch is also known as a D latch and its operation is illustrated in Fig. 47.8(b).



(a) A level-sensitive register or latch. (b) Idealized operation of the latch shown in (a).

FIGURE 47.8 Schematic representation and principle of operation of a level-sensitive register (latch).

The register illustrated in Fig. 47.8 is a *positive-polarity*[12] latch since it is transparent during that portion of the clock period for which C is high. The operation of this positive latch is summarized in Table 47.2.

As described in Table 47.2 and illustrated in Fig. 47.8(b), the output signal of the latch follows the data input signal while the clock signal remains high, that is, $C = 1 \Rightarrow Q = D$. Therefore, the latch is said

[11] This signal is most frequently the clock signal.

[12] Or simply a *positive* latch.

TABLE 47.2 Operation of the Positive-Polarity D Latch

Clock	Output	State
High	Passes input	Transparent
Low	Maintains output	Opaque

to be in a *transparent* state during the interval $t_0 < t < t_1$ shown in Fig. 47.8(b). When the clock signal C changes from 1 to 0, the current value of D is stored in the register and the output Q remains fixed to that value regardless of whether the data input D changes. The latch does *not* pass the input data signal to the output, but rather holds onto the last value of the data signal when the clock signal made the high-to-low transition. By analogy with the term *transparent* introduced above, this state of the latch is called *opaque* and corresponds to the interval $t_1 < t < t_2$ shown in Fig. 47.8(b) where the input data signal is isolated from the output port. As shown in Fig. 47.8(b), the clock period is $T_{CP} = t_2 - t_0$.

The edge of the clock signal that causes the latch to switch to its transparent state is identified as the *leading edge* of the clock pulse. In the case of the positive latch shown in Fig. 47.8(a), the leading edge of the clock signal occurs at time t_0. The opposite direction edge of the clock signal is identified as the *trailing edge* — the falling edge at time t_1 shown in Fig. 47.8(b). Note that for a negative latch, the leading edge is a high-to-low transition and the trailing edge is a low-to-high transition.

Parameters of Latches

Registers such as the D latch illustrated in Fig. 47.8 and the flip-flops described later are built of discrete transistors. The exact relationships among signals on the terminals of a register can be presented and evaluated in analytical form.[37–39] In this section, however, registers are considered at a higher level of abstraction in order to hide the details of the specific electrical implementation. The latch parameters are briefly introduced next.

Note: The remaining portion of this section uses an extensive notation for various parameters of signals and storage elements. A glossary of terms used throughout this chapter is listed in the appendix.

Minimum Width of the Clock Pulse

The *minimum width of the clock pulse* C^L_{Wm} is the *minimum* permissible width of this portion of the clock signal during which the latch is transparent. In other words, C^L_{Wm} is the length of the time interval between the leading and the trailing edge of the clock signal such that the latch will operate properly. Increasing the value of C^L_{Wm} any further will *not* affect the values of D^L_{DQ}, δ^L_S, and δ^L_H (defined later). The minimum width of the clock pulse, $C^L_{Wm} = t_6 - t_1$, is illustrated in Fig. 47.9. The clock period is $T_{CP} = t_8 - t_1$.

Latch Clock-to-Output Delay

The *clock-to-output delay* D^L_{CQ} (typically called the clock-to-Q delay) is the propagation delay of the latch from the *clock* signal terminal to the output terminal. The value of $D^L_{CQ} = t_2 - t_1$ is depicted in Fig. 47.9 and is defined assuming that the data input signal has settled to a stable value sufficiently early, that is, setting the data input signal earlier with respect to the leading clock edge will not affect the value of D^L_{CQ}.

Latch Data-to-Output Delay

The *data-to-output delay* D^L_{DQ} (typically called the data-to-Q delay) is the propagation delay of the latch from the data signal terminal to the output terminal. The value of D^L_{DQ} is defined assuming that the clock signal has set the latch to its transparent state sufficiently early, that is, making the leading edge of the clock signal occur earlier will not change the value of D^L_{DQ}. The data-to-output delay $D^L_{DQ} = t_4 - t_3$ is illustrated in Fig. 47.9.

Latch Setup Time

The *latch setup time* $\delta^L_S = t_6 - t_5$, shown in Fig. 47.9, is the *minimum* time between a change in the data signal and the trailing edge of the clock signal such that the new value of D would propagate to the output Q of the latch and be stored within the latch during its opaque state.

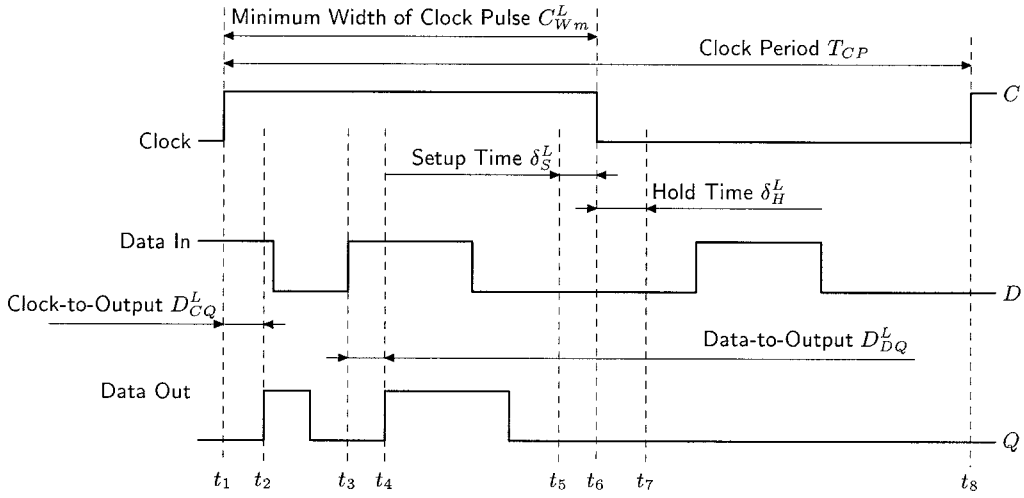


FIGURE 47.9 Parameters of a level-sensitive register.

Latch Hold Time

The *latch hold time* δ^L_H is the minimum time after the trailing clock edge that the data signal must remain constant so that this value of D is successfully stored in the latch during the opaque state. This definition of δ^L_H assumes that the last change of the value of D has occurred to later than δ^L_S before the trailing edge of the clock signal. The term $\delta^L_H = t_7 - t_6$ is shown in Fig. 47.9.

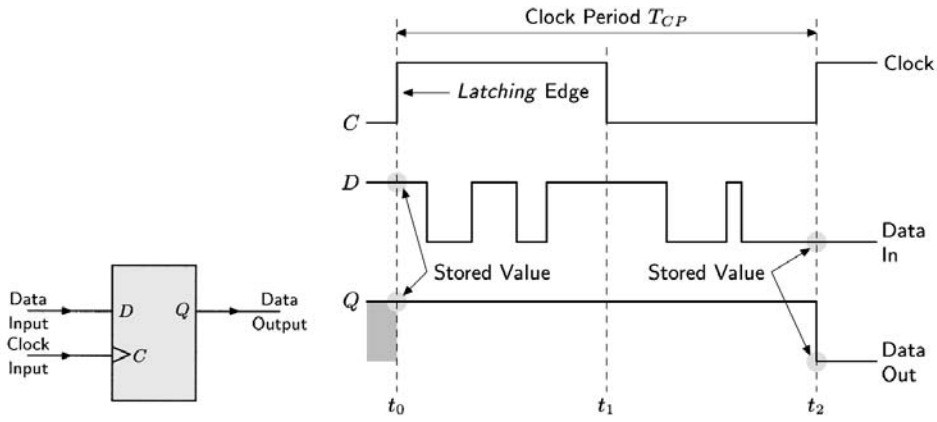
Note: The latch parameters previously introduced are used to refer to any latch in general, or to a specific instance of a latch when this instance can be unambiguously identified. To refer to a specific instance i of a latch explicitly, the parameters are additionally shown with a superscript. For example, D^{Li}_{CQ} refers to the clock-to-output delay of latch i. Also, adding m and M to the subscript of D^L_{CQ} and D^L_{DQ} can be used to refer to the *minimum* and *maximum* values of D^L_{CQ} and D^L_{DQ}, respectively.

Flip-Flops

An *edge-triggered register* or *flip-flop* is a type of register which, unlike the latches described previously, is never transparent with respect to the input data signal.[8, 30-36] The output of a flip-flop normally does not follow the input data signal at any time during the register operation, but rather holds onto a previously stored data value until a new data signal is stored in the flip-flop. A simple type of flip-flop with a clock signal C and an input signal D is shown in Fig. 47.10(a); similar to latches, the output of a flip-flop is usually labeled Q. This specific type of register, shown in Fig. 47.10(a), is called a D flip-flop and its operation is illustrated in Fig. 47.10(b).

In typical flip-flops, data is stored either on the rising edge (low-to-high transition) or on the falling edge (high-to-low transition) of the clock signal. The flip-flops are known as *positive-edge-triggered* and *negative-edge-triggered* flip-flops, respectively. The terms *latching, storing,* or *positive* edge is used to identify the edge of the clock signal on which storage in the flip-flop occurs. For the sake of clarity, the latching edge of the clock signal for flip-flops will also be called the *leading edge* (compare with the previous discusion of latches). Also, note that certain flip-flops — known as *double-edged-triggered* (DET) flip-flops[40-44] — can store data at either edge of the clock signal. The complexity of these flip-flops, however, is significantly higher and these registers are therefore rarely used.

As shown in the timing diagram in Fig. 47.10(b), the output of the flip-flop remains unchanged most of the time, regardless of the transitions in the data signal. Only values of the data signal in the vicinity of the storing edge of the clock signal can affect the output of the flip-flop. Therefore, changes in the



(a) An edge-triggered register or flip-flop. (b) Idealized operation of the flip-flop shown in (a).

FIGURE 47.10 Schematic representation and principle of operation of an edge-triggered register (flip-flop).

output will only be observed when the currently stored data has a logic value x, and the storing edge of the clock signal occurs while the input data signal has a logic value of $\bar{x}$.

Parameters of Flip-Flops

The significant timing parameters of an edge-triggered register are similar to those of latches and are presented next. These parameters are illustrated in Fig. 47.11.

Minimum Width of the Clock Pulse

The *minimum width of the clock pulse* C^F_{Wm} is the *minimum* permissible width of the time interval between the latching edge and the non-latching edge of the clock signal. The minimum width of the clock pulse $C^F_{Wm} = t_6 - t_3$ is shown in Fig. 47.11 and is defined as the minimum interval between the latching and non-latching edges of the clock pulse such that the flip-flop will operate correctly. Further increasing C^F_{Wm} will *not* affect the values of the setup time δ^F_S and hold time δ^F_H (defined later). The clock period $T_{CP} = t_6 - t_1$ is also shown in Fig. 47.11.

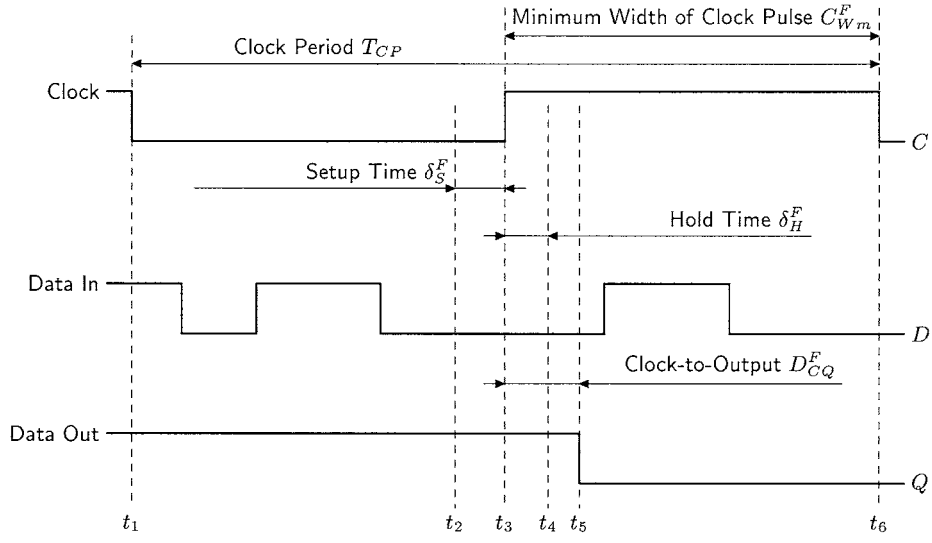


FIGURE 47.11 Parameters of an edge-triggered register.

Flip-Flop Clock-to-Output Delay

As shown in Fig. 47.11, the *clock-to-output delay* D^F_{CQ} of the flip-flop is $D^F_{CQ} = t_5 - t_3$. This propagation delay parameter — typically called the clock-to-Q delay — is the propagation delay from the clock signal terminal to the output terminal. The value of D^F_{CQ} is defined assuming that the data input signal has settled to a stable value sufficiently early, that is, setting the data input any earlier with respect to the latching clock edge will not affect the value of D^F_{CQ}.

Flip-Flop Setup Time

The flip-flop *setup time* δ^F_S is shown in Fig. 47.11 — $\delta^F_S = t_3 - t_2$. The parameter δ^F_S is defined as the *minimum* time between a change in the data signal and the latching edge of the clock signal such that the new value of D propagates to the output Q of the flip-flop and is successfully latched within the flip-flop.

Flip-Flop Hold Time

The flip-flop *hold time* δ^F_H is the minimum time after the arrival of the latching clock edge in which the data signal must remain constant in order to successfully store the D signal within the flip-flop. The hold time $\delta^F_H = t_4 - t_3$ is illustrated in Fig. 47.11. This definition of the hold time assumes that the last change of D has occurred no later than δ^F_S before the arrival of the latching edge of the clock signal.

Note: Similar to latches, the parameters of these edge-triggered registers refer to any flip-flop in general, or to a specific instance of a flip-flop when this instance is uniquely identified. To refer to a specific instance i of a flip-flop explicitly, the flip-flop parameters are additonally shown with a superscript. For example, δ^{Fi}_S refers to the setup time parameter flip-flop i. Also, adding m and M to the subscript of D^F_{CQ} can be used to refer to the *minimum* and *maximum* values of D^F_{CQ}, respectively.

The Clock Signal

The clock signal is typically delivered to each storage element within a circuit. This signal is crucial to the correct operation of a fully synchronous digital system.The storage elements serve to establish the relative sequence of events within a system so that those operations that cannot be executed concurrently operate on the proper data signals.

A typical clock signal $c(t)$ in a synchronous digital system is shown in Fig. 47.12. The *clock period* T_{CP} of $c(t)$ is indicated in Fig. 47.12. In order to provide the highest possible clock frequency, the objective is for T_{CP} to be the smallest number such that

$$\forall t: c(t) = c(t + nT_{CP}) \tag{47.12}$$

where n is an integer. The width of the clock pulse C_W is shown in Fig. 47.12 where the meaning of C_W has been previously explained.

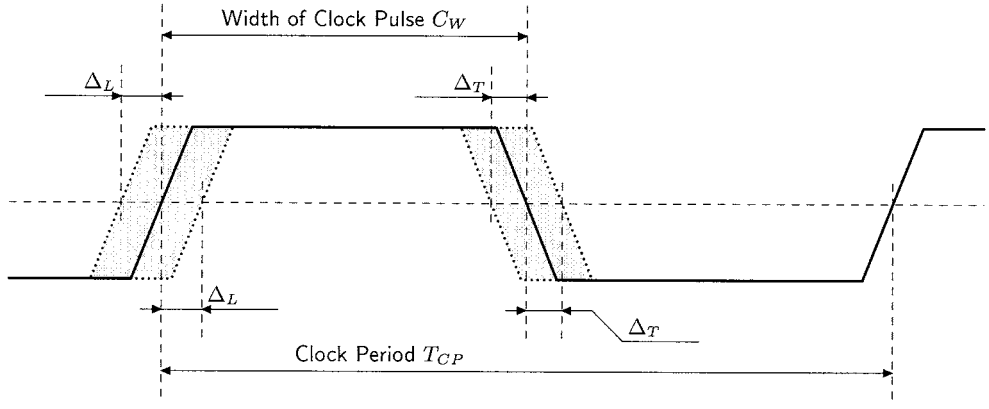

FIGURE 47.12 A typical clock signal.

Typically, the period of the clock signal T_{CP} is a constant,that is, $\partial T_{CP}/\partial t = 0$. If the clock signal $c(t)$ has a delay τ from some reference point, then the leading edges of $c(t)$ occur at times

$$\tau + mT_{CP} \qquad \text{for} \qquad m \in \{\ldots, -2, -1, 0, 1, 2, \ldots\} \tag{47.13}$$

and the trailing edges of c(t) occur at times

$$\tau + C_W + mT_{CP} \qquad \text{for} \qquad m \in \{\ldots, -2, -1, 0, 1, 2, \ldots\} \tag{47.14}$$

In practice, however, it is possible for the edges of a clock signal to fluctuate in time, that is, *not* to occur precisely at the times described by Eqs. 47.13 and 47.14 for the leading and trailing edges, respectively. This phenomenon is known as *clock jitter* and may be due to various causes, such as variations in the manufacturing process, ambient temperature, power supply noise, and oscillator characteristics.

To account for this clock jitter, the following parameters are introduced:

- The maximum deviation $\triangle_L$ of the leading edge of the clock signal: that is, the leading edge is guaranteed to occur anywhere in an interval $(\tau + kT_{CP} - \triangle_L, \tau + kT_{CP} + \triangle_L)$
- The maximum deviation $\triangle_T$ of the trailing edge of the clock signal: that is, the trailing edge is guaranteed to occur anywhere in the interval $(\tau + C_W + kT_{CP} - \triangle_T, \tau + C_W + kT_{CP} + \triangle_T)$,

Clock Skew

Consider a local data path such as the path shown in Fig. 47.2(b). Without loss of generality, assume that the registers shown in Fig. 47.2(b) are flip-flops. The clock signal with period T_{CP} is delivered to each of the registers R_i and R_f. Let the clock signal driving the register R_i be denoted as C_i. and the clock signal driving the registerR_f be denoted by C_f. Also, let t^{i}_{cd} and t^{f}_{cd} be the delays of C_i and C_f to the registers R_i and R_f, respectivly.[13] As described by Eq. 47.13, the latching or leading edges of C_i. occur at times

$$\ldots, \tau + t^{\mathsf{i}}_{cd} - T_{CP}, \tau + t^{\mathsf{i}}_{cd}, \tau + t^{\mathsf{i}}_{cd} + T_{CP}, \ldots$$

Similarly, the latching or leading edges of C_f. occur at times

$$\ldots, \tau + t^{\mathsf{f}}_{cd} - T_{CP}, \tau + t^{\mathsf{f}}_{cd}, \tau + t^{\mathsf{f}}_{cd} + T_{CP}, \ldots$$

as described by Eq. 47.14.

The *clock skew* $T_{Skew}(i, f) = t^{\mathsf{i}}_{cd} - t^{\mathsf{f}}_{cd}$ between $C_i$and C_f is introduced next as the difference of the arrival times of $C_i$and C_f.[13] This concept is illustrated by Fig. 47.13. Note that depending on the values of t^{i}_{cd}

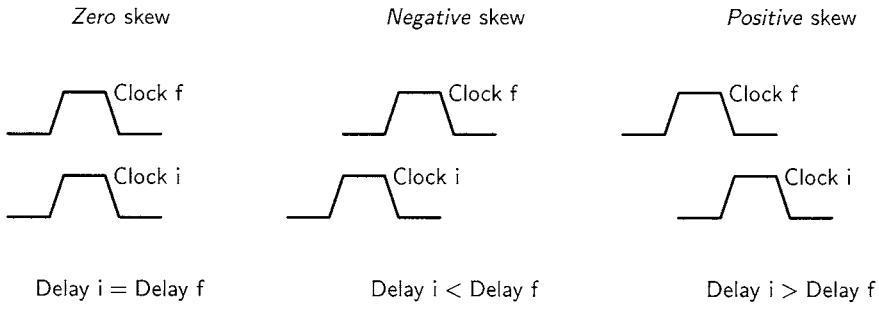

FIGURE 47.13 Lead/lag relationships causing clock skew to be zero, negative, or positive.

[13] Note that these delays t^{i}_{cd} and t^{f}_{cd} are measured with respect to the same reference point.

and t_{cd}^{f}, the skew can be *zero* ($t_{cd}^{i} = t_{cd}^{f}$), *negative* ($t_{cd}^{i} < t_{cd}^{f}$), or *positive* ($t_{cd}^{i} > t_{cd}^{f}$). Furthermore, note that the clock skew as defined above is only defined for sequentially-adjacent registers, that is, a local data path (such as the path shown in Fig. 47.2(b)).

Analysis of a Single-Phase Local Data Path with Flip-Flops

A local data path composed of two flip-flops and combinational logic between the flip-flops is shown in Fig. 47.14. Note the initial flip-flop R_i, which is the origin of the data signal, and the final flip-flop R_f, which is the destination of the data signal. The combinational logic block L_{if} between R_i and R_f accepts the input data signals supplied by R_i and other registers and logic gates and transmits the operated upon data signals to R_f. The period of the clock signal is denoted by T_{CP} and the delays of the clock signal C_i and C_f to the flip-flops R_i and R_f are denoted by t_{cd}^{i} and t_{cd}^{f}, respectively. The input and output data signals to R_i and R_f are denoted by D_i, Q_i, D_f, and Q_f, respectively.

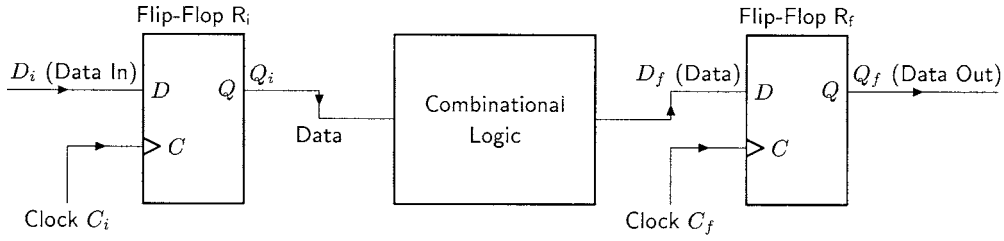

FIGURE 47.14 A single-phase local data path.

An analysis of the timing properties of the local data path shown in Fig. 47.14 is offered in the following sections. First, the timing relationships to prevent the late arrival of data signals to R_f are examined in the next subsection. The timing relationships to prevent the early arrival of signals to the register R_f are then described followed by analyses that borrow some notation from Refs. 11 and 12. Similar analyses of synchronous circuits from the timing perspective can be found in Refs. 45 through 49.

Preventing the Late Arrival of the Data Signal in a Local Data Path with Flip-Flops

The operation of the local data path $R_i \rightsquigarrow R_f$ shown in Fig. 47.14 requires that any data signal that is being stored in R_f arrives at the data input D_f of R_f no later than δ_S^{Ff} before the latching edge of the clock signal C_f. It is possible for the opposite event to occur, that is, for the data signal D_f not to arrive at the register R_f sufficiently early in order to be stored successfully within R_f. If this situation occurs, the local data path shown in Fig. 47.14 fails to perform as expected and it is said that a *timing failure* or *violation* has been created. This form of timing violation is typically called a *setup* (or *long path*) *violation*. A setup violation is depicted in Fig. 47.15 and is used in the following discussion.

The identical clock periods of the clock signals C_i and C_f are shaded for identification in Fig. 47.15. Also shaded in Fig. 47.15 are those portions of the data signals D_i, Q_i, and D_f that are relevant to the operation of the local data path shown in Fig. 47.14. Specifically, the shaded portion of D_i corresponds to the data to be stored in R_i at the beginning of the k-th clock period. This data signal propagates to the output of the register R_i and is illustrated by the shaded portion of Q_i shown in Fig. 47.15. The combinational logic operates on Q_i during the k-th clock period. The result of this operation is the shaded portion of the signal D_f which must be stored in R_f during the next $(k+1)$-st clock period.

Observe that, as illustrated in Fig. 47.15, the leading edge of C_i that initiates the k-th clock period occurs at time $t_{cd}^{i} + kT_{CP}$. Similarly, the leading edge of C_f that initiates the $(k+1)$-th clock period occurs at time $t_{cd}^{f} + (k+1)\,T_{CP}$. Therefore, the *latest arrival time* t_{AM}^{Ff} of D_f at R_f must satisfy.

$$t_{AM}^{Ff} \leq [\,t_{cd}^{f} + (k+1)\,T_{CP} - \Delta_L^{F}] - \delta_S^{Ff} \tag{47.15}$$

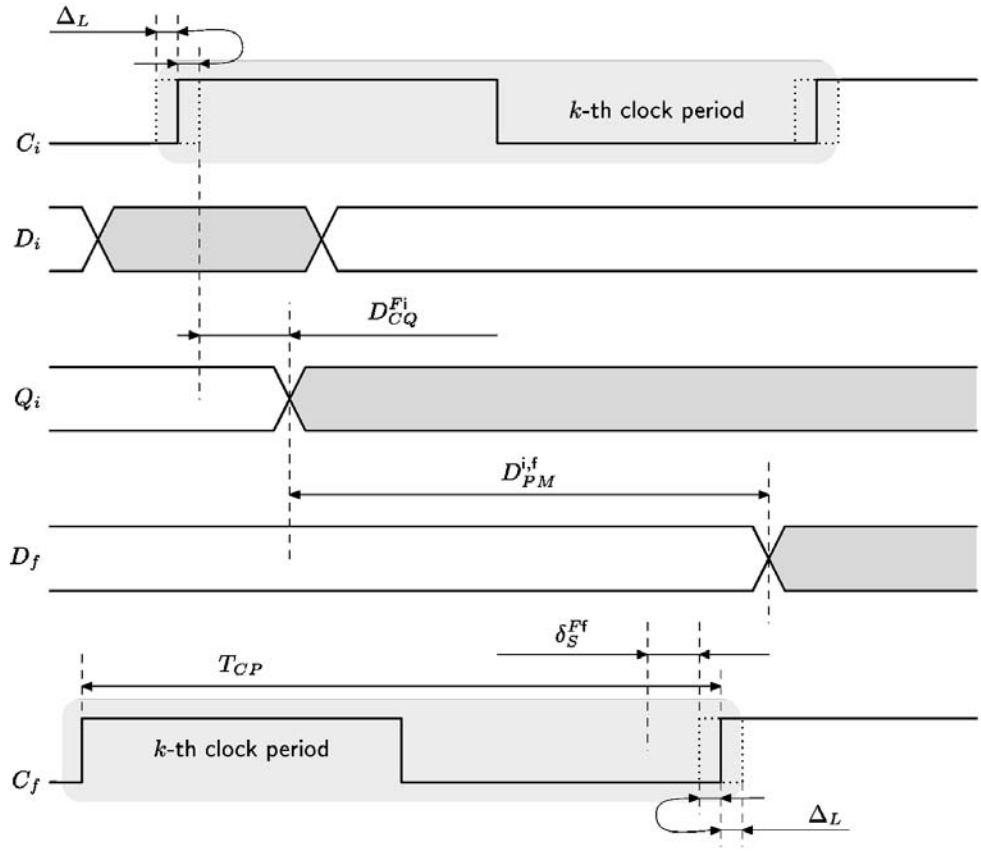

FIGURE 47.15 Timing diagram of a local data path with flip-flops with violation of the setup constraint.

The term $[\,t_{cd}^{f} + (k+1)T_{CP} - \Delta_L^F\,]$ on the right-hand side of Eq. 47.15 corresponds to the critical situation of the leading edge of C_f arriving earlier by the maximum possible deviation Δ_L^F. The $-\delta_S^{Ff}$ term on the right-hand side of Eq. 47.15 accounts for the setup time of R_f (recall the definition of δ_s^F). Note that the value of t_{AM}^{Ff} in Eq. 47.15 consists of two components:

1. The latest arrival time t_{QM}^{Fi} that a valid data signal Q_i appears at the output of R_i: that is, the sum $t_{QM}^{Fi} = t_{cd}^{i} + kT_{CP} + \Delta_L^F + D_{CQM}^{Fi}$ of the latest possible arrival time of the leading edge of C_i and the maximum clock-to-Q delay of R_i,
2. The maximum propagation delay $D_{PM}^{i,f}$ of the data signals through the combinational logic block L_{if} and interconnect along the path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$.

Therefore, t_{AM}^{Ff} can be described as

$$t_{AM}^{Ff} = t_{QM}^{Fi} + D_{PM}^{i,f} = (t_{cd}^{i} + kT_{CP} + \Delta_L^F + D_{CQM}^{Fi}) + D_{PM}^{i,f}. \tag{47.16}$$

By substituting Eq. 47.16 into Eq. 47.15, the timing condition guaranteeing correct signal arrival at the data input D of R_f is

$$(t_{cd}^{i} + kT_{CP} + \Delta_L^F + D_{CQM}^{Fi}) + D_{PM}^{i,f} \le [\,t_{cd}^{f} + (k+1)T_{CP} - \Delta_L^F\,] - \delta_S^{Ff}. \tag{47.17}$$

The above inequality can be transformed by subtracting the kT_{CP} terms from both sides of Eq. 47.17. Furthermore, certain terms in Eq. 47.17 can be grouped together and, by noting that $t_{cd}^{i} - t_{cd}^{f} = T_{Skew}(i, f)$ is the clock skew between the registers R_i and R_f,

$$T_{Skew}(i, f) + 2\Delta_L^F \leq T_{CP} - (D_{CQM}^{Fi} + D_{PM}^{i,f} + \delta_S^{Ff}) \tag{47.18}$$

Note that a violation of Eq. 47.18 is illustrated in Fig. 47.15.

The timing relationship Eq. 47.18 represents three important results describing the late arrival of the signal D_f at the data input of the final register R_f in a local data path $R_i \rightsquigarrow R_f$:

1. Given *any* values of $T_{Skew}(i, f)$ Δ_L^F, $D_{PM}^{i,f}$, δ_S^{Ff}, and D_{CQM}^{Fi}, the late arrival of the data signal at R_f can be prevented by controlling the value of the clock period T_{CP}. A sufficiently large value of T_{CP} can always be chosen to relax Eq. 47.18 by increasing the upper bound described by the right-hand side of Eq. 47.18.
2. For correct operation, the clock period T_{CP} does *not* necessarily have to be larger than the term $(D_{CQM}^{Fi} + D_{PM}^{i,f} + \delta_S^{Ff})$. If the clock skew $T_{Skew}(i, f)$ is properly controlled, choosing a particular negative value for the clock skew will relax the left side of Eq. 47.18, thereby permitting Eq. 47.18 to be satisfied despite $T_{CP} - (D_{CQM}^{Fi} + \hat{D}_{PM}^{i,f} + \delta_S^{Ff}) < 0$.
3. Both the term $2\Delta_L^F$ and the term $(D_{CQM}^{Fi} + \hat{D}_{PM}^{i,f} + \delta_S^{Ff})$ are harmful in the sense that these terms impose a *lower bound* on the clock period T_{CP} (as expected). Although negative skew can be used to relax the inequality of Eq. 47.18, these two terms work against relaxing the values of T_{CP} and $T_{Skew}(i, f)$

Finally, the relationship in Eq. 47.18 can be rewritten in a form that clarifies the upper bound on the clock skew $T_{Skew}(i, f)$ imposed by Eq. 47.18:

$$T_{Skew}(i, f) \leq T_{CP} - (D_{CQM}^{Fi} + D_{PM}^{i,f} + \delta_S^{Ff}) - 2\Delta_L^F \tag{47.19}$$

Preventing the Early Arrival of the Data Signal in a Local Data Path with Flip-Flops

Late arrival of the signal D_f at the data input of R_f (see Fig. 47.14) was analyzed in the previous subsection. In this section, the analysis of the timing relationships of the local data path $R_i \rightsquigarrow R_f$ to prevent early data arrival of D_f is presented. To this end, recall from previous discussion that any data signal D_f being stored in R_f must lag the arrival of the leading edge of C_f by at least δ_H^{Ff}. It is possible for the opposite event to occur, that is, for a new data D_f^{new} to overwrite the value of D_f and be stored within the register R_f. If this situation occurs, the local data path shown in Fig. 47.14 will not perform as desired because of a catastrophic timing violation known as a *hold* (or *short path*) violation.

In this section, hold timing violations are analyzed. It is shown that a hold violation is more dangerous than a setup violation since a hold violation cannot be removed by simply adjusting the clock period T_{CP} (unlike the case of a data signal arriving late where T_{CP} can be increased to satisfy Eq. 47.18). A hold violation is depicted in Fig. 47.16, which is used in the following discussion.

The situation depicted in Fig. 47.16 is different from the situation depicted in Fig. 47.15 in the following sense. In Fig. 47.15, a data signal stored in R_i during the k-th clock period arrives too late to be stored in R_f during the $(k + 1)$-th clock period. In Fig. 47.16, however, the data stored in R_i during the k-th clock period arrives at R_f too early and *destroys* the data that had to be stored in R_f during the same k-th clock period. To clarify this concept, certain portions of the data signals are shaded for easy identification in Fig. 47.16. The data D_i being stored in R_i at the beginning of the k-th clock period is shaded. This data signal propagates to the output of the register R_i and is illustrated by the shaded portion of Q_i shown in Fig. 47.16. The output of the logic (left unshaded in Fig. 47.16) is being stored within the register R_f at the beginning of the $(k + 1)$-th clock period. Finally, the shaded portion of D_f corresponds to the data that must be stored in R_f at the beginning of the k-th clock period.

Note that, as illustrated in Fig. 47.16, the leading (or latching) edge of C_i that initiates the k-th clock period occurs at time $t_{cd}^{i} + kT_{CP}$. Similarly, the leading (or latching) edge of C_f that initiates the k-th clock period occurs at time $t_{cd}^{f} + kT_{CP}$. Therefore, the earliest arrival time t_{Am}^{Ff} of the data signal D_f at the register R_f must satisfy the following condition:

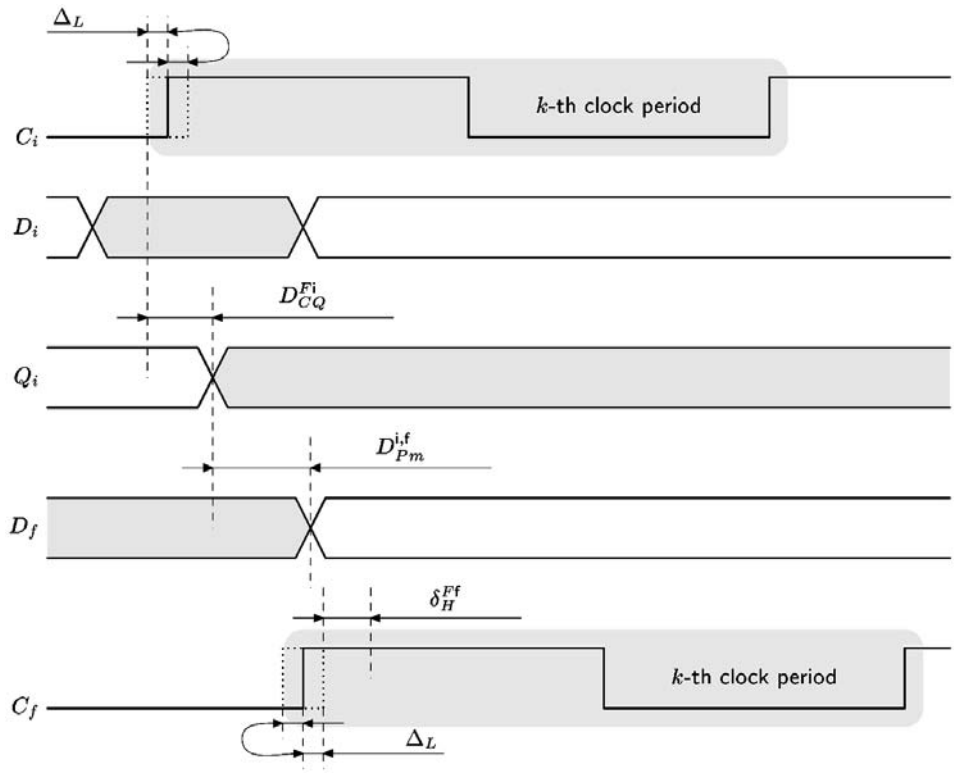

FIGURE 47.16 Timing diagram of a local data path with flip-flops with a violation of the hold constraint.

$$t_{Am}^{Ff} \geq (t_{cd}^{f} + kT_{CP} + \Delta_L^F) + \delta_H^{Ff} \tag{47.20}$$

The term $(t_{cd}^{f} + kT_{CP} + \Delta_L^F)$ on the right-hand side of Eq. 47.20 corresponds to the critical situation of the leading edge of the k-th clock period of C_f arriving late by the maximum possible deviation Δ_L^F. Note that the value of t_{Am}^{Ff} in Eq. 47.20 has two components:

1. The earliest arrival time t_{Qm}^{Fi} that a valid data signal Q_i appears at the output of $\mathsf{R_i}$: that is, the sum $t_{Qm}^{Fi} = t_{cd}^{i} + kT_{CP} - \Delta_L^F + D_{CQm}^{Fi}$ of the earliest arrival time of the leading edge of C_i and the minimum clock-to-Q delay of $\mathsf{R_i}$
2. The minimum propagation delay $D_{Pm}^{i,f}$ of the signals through the combinational logic block $\mathsf{L_{if}}$ and interconnect wires along the path $\mathsf{R_i} \rightsquigarrow \mathsf{R_f}$

Therefore, t_{Am}^{Ff} can be described as

$$t_{Am}^{Ff} = t_{Qm}^{Ff} + D_{Pm}^{i,f} = (t_{cd}^{i} + kT_{CP} - \Delta_L^F + D_{CQM}^{Fi}) + D_{Pm}^{i,f} \tag{47.21}$$

By substituting Eq. 47.21 into Eq. 47.20, the timing condition that guarantees that D_f does *not* arrive too early at $\mathsf{R_f}$ is

$$(t_{cd}^{i} + kT_{CP} - \Delta_L^F + D_{CQm}^{Fi}) + D_{Pm}^{i,f} \geq (t_{cd}^{f} + kT_{CP} + \Delta_L^F) + \delta_H^{Ff} \tag{47.22}$$

The inequality Eq. 47.22 can be further simplified by regrouping terms and noting that $t_{cd}^{i} - t_{cd}^{f} = T_{Skew}(i, f)$ is the clock skew between the registers $\mathsf{R_i}$ and $\mathsf{R_f}$:

$$T_{Skew}(i, f) - 2\Delta_L^F \geq -(D_{CQm}^{Fi} + D_{Pm}^{i,f}) + \delta_H^{Ff} \tag{47.23}$$

Recall that a violation of Eq. 47.23 is illustrated in Fig. 47.16.

The timing relationship described by Eq. 47.23 provides certain important facts describing the early arrival of the signal D_f at the data input of the final register R_f of a local data path:

1. Unlike Eq. 47.18, the inequality Eq. 47.23 does not depend on the clock period T_{CP}. Therefore, a violation of Eq. 47.23 *cannot* be corrected by simply manipulating the value of T_{CP}. A synchronous digital system with hold violations is non-functional, while a system with setup violations will still operate correctly at a reduced speed.[14] For this reason, hold violations result in catastrophic timing failure and are considered significantly more dangerous than the setup violations previously described.
2. The relationship in Eq. 47.23 can be satisfied with a sufficiently large value of the clock skew $T_{Skew}(i, f)$. However, both the term $2\Delta_L^F$ and the term δ_H^{Ff} are harmful in the sense that these terms impose a lower bound on the clock skew $T_{Skew}(i, f)$ between the register R_i and R_f. Although positive skew may be used to relax Eq. 47.23, these two terms work against relaxing the values of $T_{Skew}(i, f)$ and $(D_{CQm}^{Fi} + D_{Pm}^{i,f})$.

Finally, the relationship in Eq. 47.23 can be rewritten to stress the lower bound imposed on the clock skew $T_{Skew}(i, f)$ by Eq. 47.23:

$$T_{Skew}(i, f) \geq -(D_{Pm}^{i,f} + D_{CQ}^{Fi}) + \delta_H^{Ff} + 2\Delta_L^F \tag{47.24}$$

Analysis of a Single-Phase Local Data Path with Latches

A local data path consisting of two level-sensitive registers (or latches) and the combinational logic between these registers (or latches) is shown in Fig. 47.17. Note the initial latch R_i, which is the origin of the data signal, and the final latch R_f, which is the destination of the data signal. The combinational logic block L_if between R_i and R_f accepts the input data signals sourced by R_i and other registers and logic gates and transmits the data signals that have been operated on to R_f . The period of the clock signal is denoted by T_{CP} and the delays of the clock signals C_i and C_f to the latches R_i and R_f are denoted by t_{cd}^{i} and t_{cd}^{f}, respectively. The input and output data signals to R_i and R_f are denoted by D_i, Q_i, D_f, and Q_f, respectively.

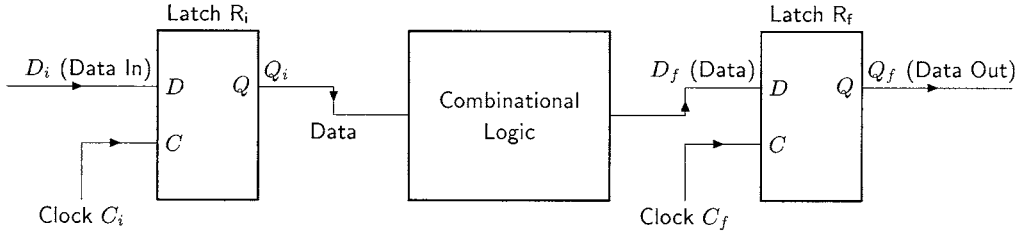

FIGURE 47.17 A single-phase local data path with latches.

An analysis of the timing properties of the local data path shown in Fig. 47.17 is offered in the following sections. The timing relationships to prevent the late arrival of the data signal at the latch R_f are examined, as well as the timing relationships to prevent the early arrival of the data signal at the latch R_f.

[14] Increasing the clock period T_{CP} in order to satisfy Eq. 47.18 is equivalent to reducing the frequency of the clock signal.

The analyses presented in this section build on assumptions regarding the timing relationships among the signals of a latch similar to those assumptions used in the previous chapter section. Specifically, it is guaranteed that every data signal arrives at the data input of a latch no later than δ_S^L time before the trailing clock edge. Also, this data signal must remain stable at least δ_H^L time after the trailing edge, that is, no new data signal should arrive at a latch δ_H^L time after the latch has become opaque.

Observe the differences between a latch and a flip-flop.[45,50] In flip-flops, the setup and hold requirements described in the previous paragraph are relative to the *leading* — not to the trailing — *edge* of the clock signal. Similar to in flip-flops, the late and early arrival of the data signal to a latch give rise to timing violations known as setup and hold violations, respectively.

Preventing the Late Arrival of the Data Signal in a Local Data Path with Latches

A similar signal setup to the example illustrated in Fig. 47.15 is assumed in the following discussion. A data signal D_i, is stored in the latch $\mathsf{R_i}$ during the k-th clock period. The data Q_i, stored in $\mathsf{R_i}$ propagates through the combinational logic $\mathsf{L_{if}}$ and the interconnect along the path $\mathsf{R_i} \rightsquigarrow \mathsf{R_f}$. In the $(k+1)$-th clock period, the result D_f of the computation in $\mathsf{L_{if}}$ is stored within the latch $\mathsf{R_f}$. The signal D_f must arrive at least δ_S^L time before the trailing edge of C_f in the $(k+1)$-th clock period.

Similar to the discussion presented in the previous section, the *latest arrival time* $t_{AM}^{L\mathsf{f}}$ of D_f at the D input of $\mathsf{R_f}$ must satisfy

$$t_{AM}^{L\mathsf{f}} \leq [\, t_{cd}^{\mathsf{f}} + (k+1)\, T_{CP} + C_{Wm}^{L} - \Delta_T^L] - \delta_S^{L\mathsf{f}} \tag{47.25}$$

Note the difference between Eqs. 47.25 and 47.15. In Eq. 47.15, the first term on the right-hand side is $[\, t_{cd}^{\mathsf{f}} + (k+1)\, T_{CP} - \Delta_L^F\,]$, while in Eq. 47.25, the first term on the right-hand side has an additional term C_{Wm}^L. The addition of C_{Wm}^L corresponds to the concept that, unlike flip-flops, a data signal is stored in a latch, shown in Fig. 47.17, at the trailing edge of the clock signal (the C_{Wm}^L term). Similar to the case of flip-flops, the term $[\, t_{cd}^{\mathsf{f}} + (k+1)\, T_{CP} + C_{Wm}^L - \Delta_T^L\,]$ in the right-hand side of Eq. 47.25 corresponds to the critical situation of the trailing edge of the clock signal C_f arriving earlier by the maximum possible deviation Δ_T^L.

Observe that the value of $t_{AM}^{L\mathsf{f}}$ in Eq. 47.25 consists of two components:

1. The latest arrival time $t_{QM}^{L\mathsf{i}}$ when a valid data signal Q_i appears at the output of the latch $\mathsf{R_i}$,
2. The maximum signal propagation delay through the combinational logic block $\mathsf{L_{if}}$ and the interconnect along the path $\mathsf{R_i} \rightsquigarrow \mathsf{R_f}$

Therefore, $t_{AM}^{L\mathsf{f}}$ can be described as

$$t_{AM}^{L\mathsf{f}} \;=\; D_{PM}^{\mathsf{i},\,\mathsf{f}} + t_{QM}^{L\mathsf{i}} \tag{47.26}$$

However, unlike the situation of flip-flops discussed previously, the term $t_{Qm}^{L\mathsf{i}}$ on the right-hand side of Eq. 47.26 is not the sum of the delays through the register $\mathsf{R_i}$. The reason is that the value of $t_{QM}^{L\mathsf{i}}$ depends on whether the signal D_i arrived *before* or *during* the transparent state of $\mathsf{R_i}$ in the k-th clock period. Therefore, the value of $t_{Qm}^{L\mathsf{i}}$ in Eq. 47.26 is the greater of the following two quantities:

$$t_{QM}^{L\mathsf{i}} \;=\; \max[(t_{AM}^{L\mathsf{i}} + D_{DQM}^{L\mathsf{i}}),\, (t_{cd}^{\mathsf{i}} + kT_{CP} + \Delta_L^L + D_{CQM}^{L\mathsf{i}})] \tag{47.27}$$

There are two terms in the right-hand side of Eq. 47.27:

1. The term $(\, t_{AM}^{L\mathsf{i}} + D_{DQM}^{L\mathsf{i}}\,)$ corresponds to the situation in which D_i arrives at $\mathsf{R_i}$ after the leading edge of the k-th clock period
2. The term $(\, t_{cd}^{\mathsf{i}} + kT_{CP} + \Delta_L^L + D_{CQM}^{L\mathsf{i}}\,)$ corresponds to the situation in which D_i arrives at $\mathsf{R_i}$ before the leading edge of the k-th clock pulse arrives

By substituting Eq. 47.27 into Eq. 47.26, the latest time of arrival t_{AM}^{Lf} is:

$$t_{AM}^{Lf} = D_{PM}^{i,f} + \max[(t_{AM}^{Li} + D_{DQM}^{Li}), (t_{cd}^{i} + kT_{CP} + \Delta_L^L + D_{CQM}^{Li})] \tag{47.28}$$

which is in turn substituted into Eq. 47.25 to obtain

$$\begin{aligned} &D_{PM}^{i,f} + \max[(t_{AM}^{Li} + D_{DQM}^{Li}), (t_{cd}^{i} + kT_{CP} + \Delta_L^L + D_{CQM}^{Li})] \\ &\leq [t_{cd}^{f} + (k+1)T_{CP} + C_{Wm}^{L} - \Delta_T^L] - \delta_S^{Lf} \end{aligned} \tag{47.29}$$

Equation Eq. 47.29 is an expression for the inequality that must be satisfied in order to prevent the late arrival of a data signal at the data input D of the register R_f. By satisfying Eq. 47.29, setup violations in the local data path with latches shown in Fig. 47.17 are avoided. For a circuit to operate correctly, Eq. 47.29 must be enforced for any local data path $\mathsf{R}_i \rightsquigarrow \mathsf{R}_f$ consisting of the latches R_i and R_f.

The max operation in Eq. 47.29 creates a mathematically difficult situation since it is unknown which of the quantities under the max operation is greater. To overcome this obstacle, this max operation can be split into two conditions:

$$D_{PM}^{i,f} + (t_{AM}^{Li} + D_{DQM}^{Li}) \leq [t_{cd}^{f} + (k+1)T_{CP} + C_{Wm}^{L} - \Delta_T^L] - \delta_S^{Lf} \tag{47.30}$$

$$D_{PM}^{i,f} + (t_{cd}^{i} + kT_{CP} + \Delta_L^L + D_{CQM}^{Li}) \leq [t_{cd}^{f} + (k+1)T_{CP} + C_{Wm}^{L} - \Delta_T^L] - \delta_S^{Lf} \tag{47.31}$$

Taking into account that the clock skew $T_{Skew}(i,f) = t_{cd}^{i} - t_{cd}^{f}$, Eqs. 47.30 and 47.31 can be rewritten as

$$D_{PM}^{i,f} + (t_{AM}^{Li} + D_{DQM}^{Li}) \leq [t_{cd}^{f} + (k+1)T_{CP} + C_{Wm}^{L} - \Delta_T^L] - \delta_S^{Lf} \tag{47.32}$$

$$T_{Skew}(i,f) + (\Delta_L^L + \Delta_T^L) \leq (T_{CP} + C_{Wm}^{L}) - (D_{CQM}^{Li} + D_{PM}^{i,f} + \delta_S^{Lf}) \tag{47.33}$$

Equation 47.33 can be rewritten in a form that clarifies the upper bound on the clock skew $T_{Skew}(i,f)$ imposed by Eq. 47.33:

$$D_{PM}^{i,f} + (t_{AM}^{Li} + D_{DQM}^{Li}) \leq [t_{cd}^{f} + (k+1)T_{CP} + C_{Wm}^{L} - \Delta_T^L] - \delta_S^{Lf} \tag{47.34}$$

$$T_{Skew}(i,f) \leq (T_{CP} + C_{Wm}^{L} - \Delta_L^L - \Delta_T^L) - (D_{CQM}^{Li} + D_{PM}^{i,f} + \delta_S^{Lf}) \tag{47.35}$$

Preventing the Early Arrival of the Data Signal in a Local Data Path with Latches

A similar signal setup to the example illustrated in Fig. 47.16 is assumed in the discussion presented in this section. Recall the difference between the late arrival of a data signal at R_f and the early arrival of a data signal at R_f. In the former case, the data signal stored in the latch R_i during the k-th clock period arrives too late to be stored in the latch R_f during the $(k+1)$-th clock period. In the latter case, the data signal stored in the latch R_i during the k-th clock period propagates to the latch R_f too early and overwrites the data signal that was already stored in the latch R_f during the same k-th clock period.

In order for the proper data signal to be successfully latched within R_f during the k-th clock period, there should not be any changes in the signal D_f until at least the hold time after the arrival of the storing (trailing) edge of the clock signal C_f. Therefore, the earliest arrival time t_{Am}^{Lf} of the data signal D_f at the register R_f must satisfy the following condition:

$$t_{Am}^{Lf} \geq (t_{cd}^{f} + kT_{CP} + C_{Wm}^{L} + \Delta_T^L) + \delta_H^{Lf} \tag{47.36}$$

The term $(t_{cd}^{\mathrm{f}} + \mathrm{k}T_{CP} + C_{Wm}^{L} + \Delta_{T}^{L})$ on the right-hand side of Eq. 47.36 corresponds to the critical situation of the trailing edge of the k-th clock period of the clock signal C_f arriving late by the maxiumum possible deviation Δ_{T}^{L}. Note that the value of t_{Am}^{Lf} in Eq. 47.36 consists of two components:

1. The earliest arrival time t_{Qm}^{Li} that a valid data signal Q_i appears at the output of the latch R_{i}: that is, the sum $t_{Qm}^{Li} = t_{cd}^{\mathrm{i}} + \mathrm{k}T_{CP} - \Delta_{L}^{L} + D_{CQm}^{Li}$ of the earliest arrival time of the leading edge of the clock signal C_i and the minimum clock-to-Q delay D_{CQm}^{Li} of R_{f},
2. The minimum propagation delay $D_{Pm}^{\mathrm{i,f}}$ of the signal through the combinational logic L_{if} and the interconnect along the path $\mathsf{R}_{\mathsf{i}} \rightsquigarrow \mathsf{R}_{\mathsf{f}}$.

Therefore, t_{Am}^{Lf} can be described as

$$t_{Am}^{Lf} = t_{Qm}^{Li} + D_{Pm}^{\mathrm{i,f}} = (t_{cd}^{\mathrm{i}} + kT_{CP} - \Delta_{L}^{L} + D_{CQm}^{Li}) + D_{Pm}^{\mathrm{i,f}} \tag{47.37}$$

By substituting Eq. 47.37 into Eq. 47.36, the timing condition guaranteeing that D_f does *not* arrive too early at the latch R_{f} is

$$(t_{cd}^{\mathrm{i}} + kT_{CP} - \Delta_{L}^{L} + D_{CQm}^{Li}) + D_{Pm}^{\mathrm{i,f}} \geq (t_{cd}^{\mathrm{f}} + kT_{CP} + C_{Wm}^{L} + \Delta_{T}^{L}) + \delta_{H}^{Lf} \tag{47.38}$$

The inequality Eq. 47.38 can be further simplified by reorganizing the terms and noting that $t_{cd}^{\mathrm{i}} - t_{cd}^{\mathrm{f}} = T_{Skew}(i, f)$ is the clock skew between the registers R_{i} and R_{f}:

$$T_{Skew}(i, f) - (\Delta_{L}^{L} + \Delta_{T}^{L}) \geq -(D_{CQm}^{Li} + D_{Pm}^{\mathrm{i,f}}) + \delta_{H}^{Lf} \tag{47.39}$$

The timing relationship described by Eq. 47.39 represents two important results describing the early arrival of the signal D_f at the data input of the final latch R_{f} of a local data path:

1. The relationship in Eq. 47.39 does not depend on the value of the clock period T_{CP}. Therefore, if a hold timing violation in a synchronous system has occurred,[15] this timing violation is catastrophic.
2. The relationship in Eq. 47.39 can be satisfied with a sufficiently large value of the clock skew $T_{Skew}(i, f)$. Furthermore, both the term $(\Delta_{L}^{L} + \Delta_{T}^{L})$ and the term δ_{H}^{Lf} are harmful in the sense that these terms impose a lower bound on the clock skew $T_{Skew}(i, f)$ between the latches R_{i} and R_{f}. Although positive skew $T_{Skew}(i, f) > 0$ can be used to relax Eq. 47.39, these two terms make it difficult to satisfy the inequality in Eq. 47.39 for specific values of $T_{Skew}(i, f)$ and $(D_{CQm}^{Li} + D_{Pm}^{\mathrm{i,f}})$.

Furthermore, Eq. 47.39 can be rewritten to emphasize the lower bound on the clock skew $T_{Skew}(i, f)$ imposed by Eq. 47.39:

$$T_{Skew}(i, f) \geq (\Delta_{L}^{L} + \Delta_{T}^{L}) - (D_{CQm}^{Li} + D_{Pm}^{\mathrm{i,f}}) + \delta_{H}^{Lf} \tag{47.40}$$

47.5 A Final Note

The properties of registers and local data paths were described in this chapter. Specifically, the timing relationships to prevent setup and hold timing violations in a local data path consisting of two positive edge-triggered flip-flops were analyzed. The timing relationships to prevent setup and hold timing violations in a local data path consisting of two positive-polarity latches were also analyzed.

In a fully synchronous digital VLSI system, however, it is possible to encounter types of local data paths different from those circuits analyzed in this chapter. For example, a local data path may begin

[15] As described by the inequality Eq. 47.39 not being satisfied.

with a *positive*-polarity, edge-sensitive register R_i, and end with a *negative*-polarity, edge-sensitive register R_f. It is also possible that different types of registers are used, for example, a register with more than one data input. In each individual case, the analyses described in this chapter illustrate the general methodology used to derive the proper timing relationships specific to that system. Furthermore, note that for a given system, the timing relationships that must be satisfied for the system to operate correctly — such as Eqs. 47.19, 47.24, 47.34, 47.35, and 47.40 — are collectively referred to as the overall *timing constraints* of the synchronous digital system.[13,51–55]

Appendix

Glossary of Terms

The following notations are used in this section.

1. Clock Signal Parameters
   - T_{CP}: The clock period of a circuit
   - Δ_L: The tolerance of the leading edge of any clock signal
   - Δ_T: The tolerance of the trailing edge of any clock signal
   - Δ_L^L: The tolerance of the leading edge of a clock signal driving a latch
   - Δ_T^L: The tolerance of the trailing edge of a clock signal driving a latch
   - Δ_L^F: The tolerance of the leading edge of a clock signal driving a flip-flop
   - Δ_T^F: The tolerance of the trailing edge of a clock signal driving a flip-flop
   - C_{Wm}^L: The minimum width of the clock signal in a circuit with latches
   - C_{Wm}^F: The minimum width of the clock signal in a circuit with flip-flops
2. Latch Parameters
   - D_{CQ}^L: The clock-to-output delay of a latch
   - D_{CQ}^{Li}: The clock-to-output delay of the latch R_i
   - D_{CQm}^L: The minimum clock-to-output delay of a latch
   - D_{CQm}^{Li}: The minimum clock-to-output delay of the latch R_i
   - D_{CQM}^L: The maximum clock-to-output delay of a latch
   - D_{CQM}^{Li}: The maximum clock-to-output delay of the latch R_i
   - D_{DQ}^L: The data-to-output delay of a latch
   - D_{DQ}^{Li}: The data-to-output delay of the latch R_i
   - D_{DQm}^L: The minimum data-to-output delay of a latch
   - D_{DQm}^{Li}: The minimum data-to-output delay of the latch R_i
   - D_{DQM}^L: The maximum data-to-output delay of a latch
   - D_{DQM}^{Li}: The maximum data-to-output delay of the latch R_i
   - δ_S^L: The setup time of a latch
   - δ_S^{Li}: The setup time of the latch R_i
   - δ_H^L: The hold time of a latch
   - δ_H^{Li}: The hold time of the latch R_i
   - t_{AM}^L: The latest arrival time of the data signal at the data input of a latch
   - t_{AM}^{Li}: The latest arrival time of the data signal at the data input of the latch R_i
   - t_{Am}^L: The earliest arrival time of the data signal at the data input of a latch
   - t_{Am}^{Li}: The earliest arrival time of the data signal at the data input of the latch R_i
   - t_{QM}^L: The latest arrival time of the data signal at the data output of a latch

$t_{QM}^{L\mathrm{i}}$: The latest arrival time of the data signal at the data output of the latch R_i

t_{Qm}^{L}: The earliest arrival time of the data signal at the data output of a latch

$t_{Qm}^{L\mathrm{i}}$: The earliest arrival time of the data signal at the data output of the latch R_i

3. Flip-flop Parameters

D_{CQ}^{F}: The clock-to-output delay of a latch

$D_{CQ}^{F\mathrm{i}}$: The clock-to-output delay of the latch R_i

D_{CQm}^{F}: The minimum clock-to-output delay of a flip-flop

$D_{CQm}^{F\mathrm{i}}$: The minimum clock-to-output delay of the flip-flop R_i

D_{CQM}^{F}: The maximum clock-to-output delay of a flip-flop

$D_{CQM}^{F\mathrm{i}}$: The maximum clock-to-output delay of the flip-flop R_i

δ_{S}^{F}: The setup time of a flip-flop

$\delta_{S}^{F\mathrm{i}}$: The setup time of the flip-flop R_i

δ_{H}^{F}: The hold time of a flip-flop

$\delta_{H}^{F\mathrm{i}}$: The hold time of the flip-flop R_i

t_{AM}^{F}: The latest arrival time of the data signal at the data input of a flip-flop

$t_{AM}^{F\mathrm{i}}$: The latest arrival time of the data signal at the data input of the flip-flop R_i

t_{Am}^{F}: The earliest arival time of the data signal at the data input of a flip-flop

$t_{Am}^{F\mathrm{i}}$: The earliest arrival time of the data signal at the data input of the flip-flop R_i

t_{QM}^{F}: The latest arrival time of the data signal at the data output of a flip-flop

$t_{QM}^{F\mathrm{i}}$: The latest arival time of the data signal at the data output of the flip-flop R_i

t_{Qm}^{F}: The earliest arrival time of the data signal at the data output of a flip-flop

$t_{Qm}^{F\mathrm{i}}$: The earliest arrival time of the data signal at the data output of the flip-flop R_i

4. Local Data Path Parameters

$\mathsf{R}_\mathsf{i} \rightsquigarrow \mathsf{R}_\mathsf{f}$: A local data path from register R_i to register R_f exists

$\mathsf{R}_\mathsf{i} \not\rightsquigarrow \mathsf{R}_\mathsf{f}$: A local data path from register R_i to register R_f does not exist

ROM/PROM/EPROM

Jen-Sheng Hwang
National Science Council

48.1 Introduction

Read-only memory (ROM) is the densest form of semiconductor memory, which is used for the applications such as video game software, laser printer fonts, dictionary data in word processors, and sound-source data in electronic musical instruments.

The ROM market segment grew well through the first half of the 1990s, closely coinciding with a jump in personal computer (PC) sales and other consumer-oriented electronic systems, as shown in Fig. 48.1.[1] Because a very large ROM application base (video games) moved toward compact disc ROM-based systems (CD-ROM), the ROM market segment declined. However, greater functionality memory products have become relatively cost-competitive with ROM. It is believed that the ROM market will continue to grow moderately through the year 2003.

48.2 ROM

Read-only memories (ROMs) consist of an array of core cells whose contents or state is preprogrammed by using the presence or absence of a single transistor as the storage mechanism during the fabrication process. The contents of the memory are therefore maintained indefinitely regardless of the previous history of the device and/or the previous state of the power supply.

Core Cells

A binary core cell stores binary information through the presence or absenc of a single transistor at the intersection of the wordline and bitline. ROM core cells can be connected in two possible ways: a parallel NOR array of cells or a series NAND array of cells each requiring one transistor per storage cell. In this case, either connecting or disconnecting the drain connection from the bitline programs the ROM cell. The NOR array is larger as there is potentially one drain contact per transistor (or per cell) made to each bitline. Potentially, the NOR array is faster as there are no serially connected transistors as in the NAND array approach. However, the NAND array is much more compact as no contacts are required within the array itself. However, the serially connected pull-down transistors that comprise the bitline are potentially very slow.[2]

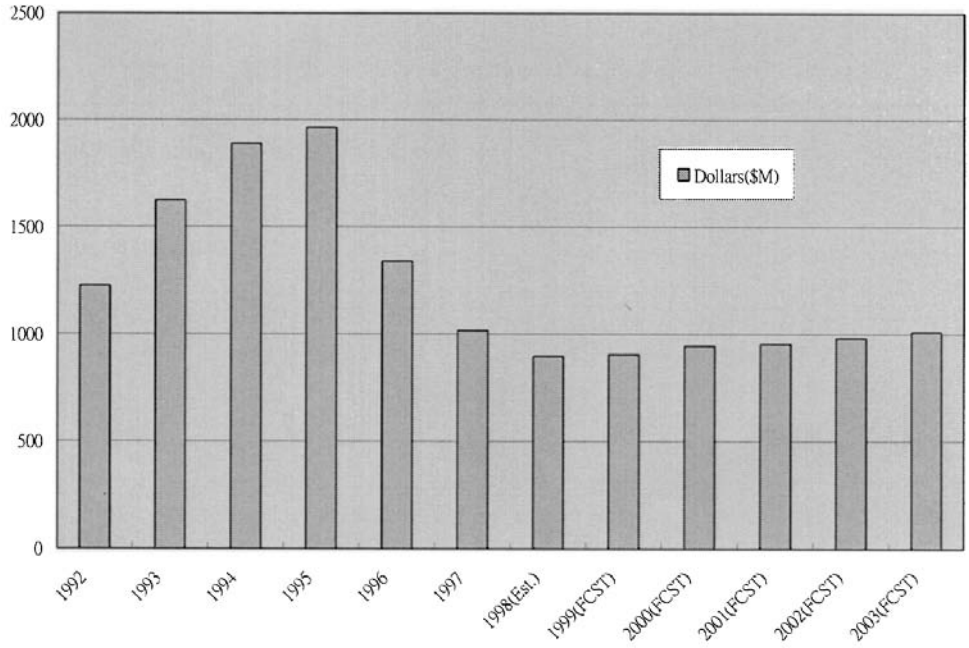

FIGURE 48.1 The ROM market growth and forecast.

Encoding multiple-valued data in the memory array involves a one-to-one mapping of logic value to transistor characteristics at each memory location and can be implemented in two ways:

(i) adjust the width-to-length (W/L) ratios of the transistors in the core cells of the memory array; or
(ii) adjust the threshold voltage of the transistors in the core cells of the memory array.[3]

The first technique works on the principle that W/L ratio of a transistor determines the amount of current that can flow through the device (i.e., the transconductance). This current can be measured to determine the size of the device at the selected location and hence the logic value stored at this location. In order to store 2 bits per cell, one would use one of four discrete transistor sizes. Intel Corp. used this technique in the early 1980s to implement high-density look-up tables in its i8087 math co-processor. Motorola Inc. also introduced a four-state ROM cell with an unusual transistor geometry that had variable W/L devices. The conceptual electrical schematic of the memory cell along with the surrounding peripheral circuitry is shown in Fig. 48.2.[2]

Peripheral Circuitry

The four states in a two-bit per cell ROM are four distinct current levels. There are two primary techniques to determine which of the four possible current levels an addressed cell generates. One technique compares the current generated by a selected memory cell against three reference cells using three separate sense amplifiers. The reference cells are transistors with W/L ratios that fall in between the four possible standard transistor sizes found in the memory array as illustrated in Fig. 48.3.[2]

The approach is essentially a two-bit flash analog-to-digital (A/D) converter. An alternate method for reading a two-bit per cell device is to compute the time it takes for a linearly rising voltage to match the output voltage of the cell. This time interval then can be mapped to the equivalent two-bit binary code corresponding the memory contents.

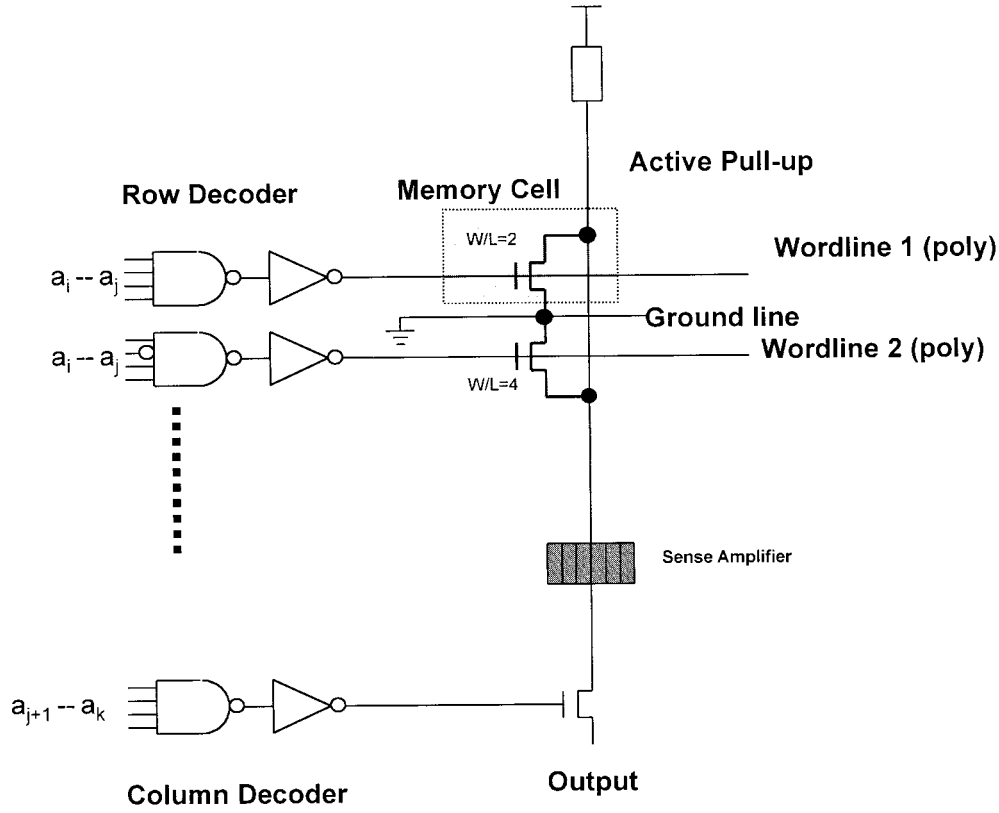

FIGURE 48.2 Geometry-variable multiple-valued NOR ROM.

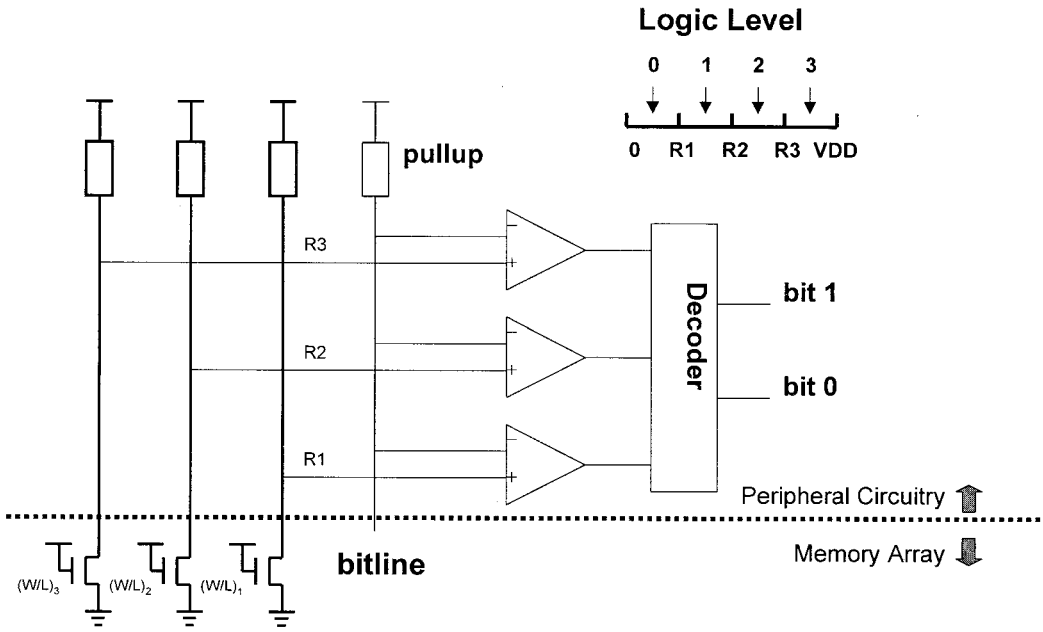

FIGURE 48.3 ROM sense amplifier.

Architecture

Constructing large ROMs with fast access times requires the memory array to be divided into smaller memory banks. This gives rise to the concept of divided wordlines and divided bitlines that reduces the capacitance of these structures allowing for faster signal dynamics. Typically, memory blocks would be no larger than 256 rows by 256 columns. In order to quantitatively compare the area advantage of the multiple-valued approach, one can calculate the area per bit of a two-bit per cell ROM divided by the area per bit of a one-bit per cell ROM. Ideally, one would expect this ratio to be 0.5. In the case of a practical two-bit per cell ROM,[4] the ratio is 0.6 since the cell is larger than a regular ROM cell in order to accommodate any one of the four possible size transistors. ROM density in the Mb capacity range is in general very comparable to that of DRAM density despite the differences in fabrication technology.[2]

In user-programmable or field-programmable ROMs, the customer can program the contents of the memory array by blowing selected fuses (i.e., physically altering them) on the silicon substrate. This allows for a "one-time" customization after the ICs have been fabricated. The quest for a memory that is nonvolatile and electrically alterable has led to the development of EPROMs, EEPROMs, and flash memories.[2]

48.3 PROM

Since process technology has shifted to QLM or PLM to achieve better device performance, it is important to develop a ROM technology that offers short TAT, high density, high speed, and low power. There are many types of ROM each with merits and demerits:[5]

- The diffusion programming ROM has excellent density but has a very long process cycle time.
- The conventional VIA-2 contact programming ROM has better cycle time, but it has poor density.
- An architecture VIA-2 contact programming ROM for QLM and PLM processes has simple processing with high density which obtains excellent results targeting 2.5 V and 2.0 V supply voltage.

Read Only Memory Module Architecture

The details of the ROM module configuration are shown in Fig. 48.4. This ROM has a single access mode (16-bit data read from half of ROM array) and a dual access mode (32-bit data read from both

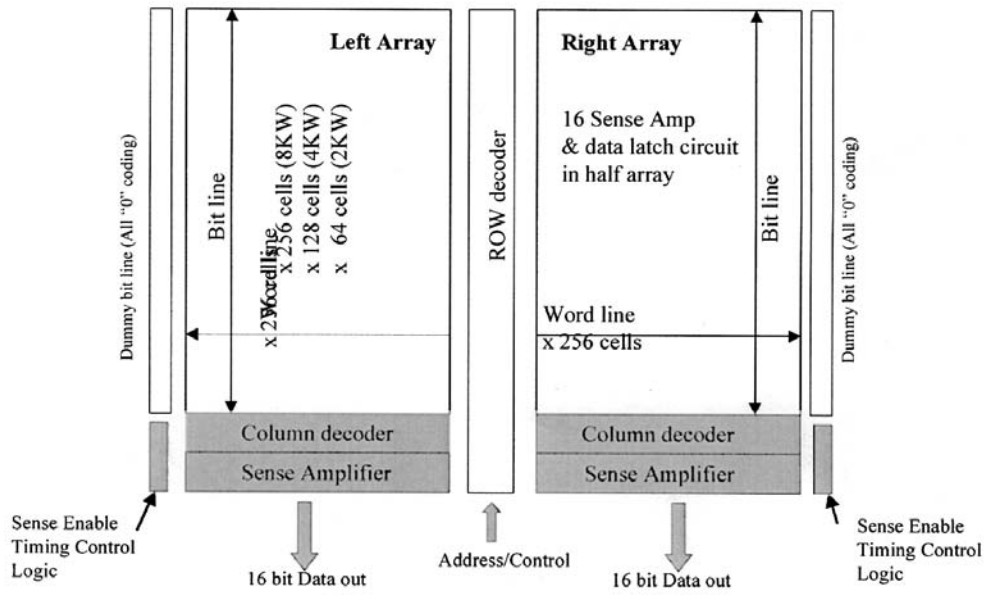

FIGURE 48.4 ROM module array configuration.

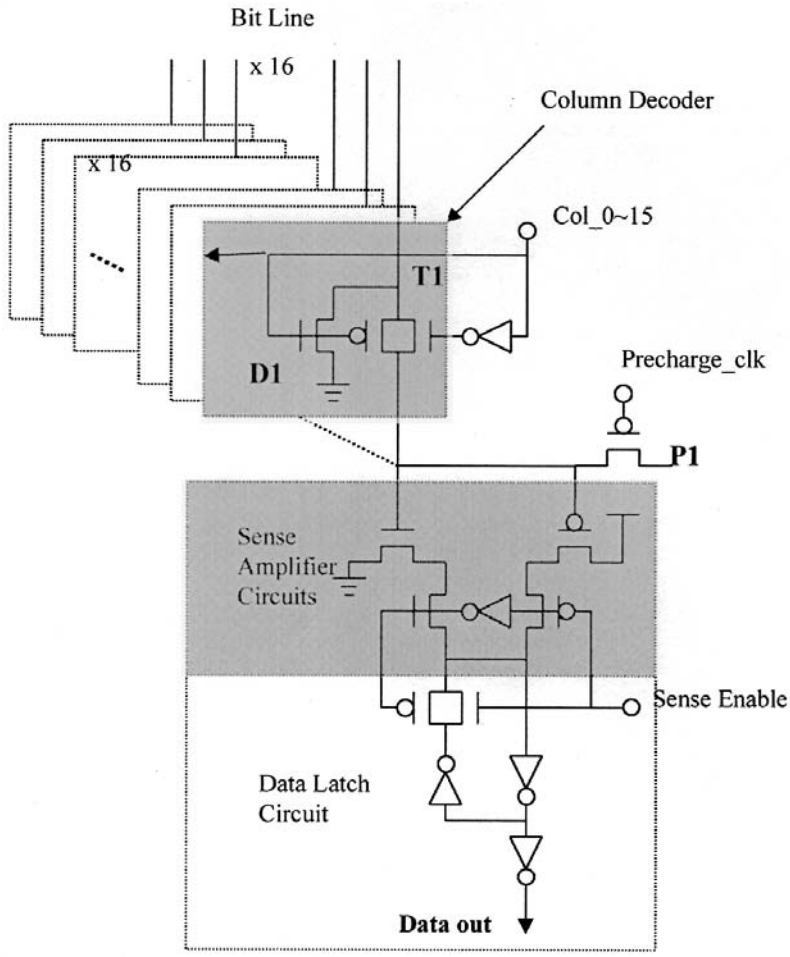

FIGURE 48.5 Detail of low power selective bit line precharge and sense amplifier circuits.

ROM array) with external address and control signals. One block in the array contains 16-bit lines and is connected to a sense amplifier circuit as shown in Fig. 48.5. In the decoder, only one bit line in 16 bits is selected and precharged by P1 and T1.[5]

16 bits in half array at a single access mode or 32 bits in a dual access mode are dynamically precharged to VDD level. Dl is a pull down transistor to keep unselected bit lines at ground level. The speed of the ROM will be limited by bit line discharge time in the worst case ROM coding. When connection exists on all of bit lines vertically, total parasitic capacitance Cbs on the bit line by N-diffusions and Cbg will be a maximum. Tills situation is shown in Fig. 48.6a. In the 8KW ROM, 256 bit cells are in the vertical direction, resulting in 256 times of cell bit line capacitance. In this case, discharge time from VDD to GND level is about 6 – 8ns at VDD = 1.66 V and depends on ROM programming type such as diffusion or VIA-2. Short circuit currents in the sense amplifier circuits arc avoided by using a delayed enable signal (Sense Enable). There are dummy bit lines on both sides of the array as indicated in Fig 48.4. This line contains "0" s on all 256 cells and has the longest discharge time. It is used to generate timing for a delayed enable signal that activates the sense amplifier circuits. These circuits were used for all types of ROM to provide a fair comparison of the performance of each type of ROM.[5]

Conventional Diffusion Programming ROM

Diffusion programmed ROM is shown in Fig. 48.6. This ROM has the highest density because bit line contact to discharge transistor can be shared by two-bit cells (as shown in Fig. 48.6). Cell-A in Fig. 48.6a is coding "0" adding diffusion which constructs transistor, but Cell-B is coding "1" which does not have diffusion and resulted in field oxide without transistor as shown in Fig. 48.6c. This ROM requires very long fabrication cycle time since process steps for the diffusion programming are required.[5]

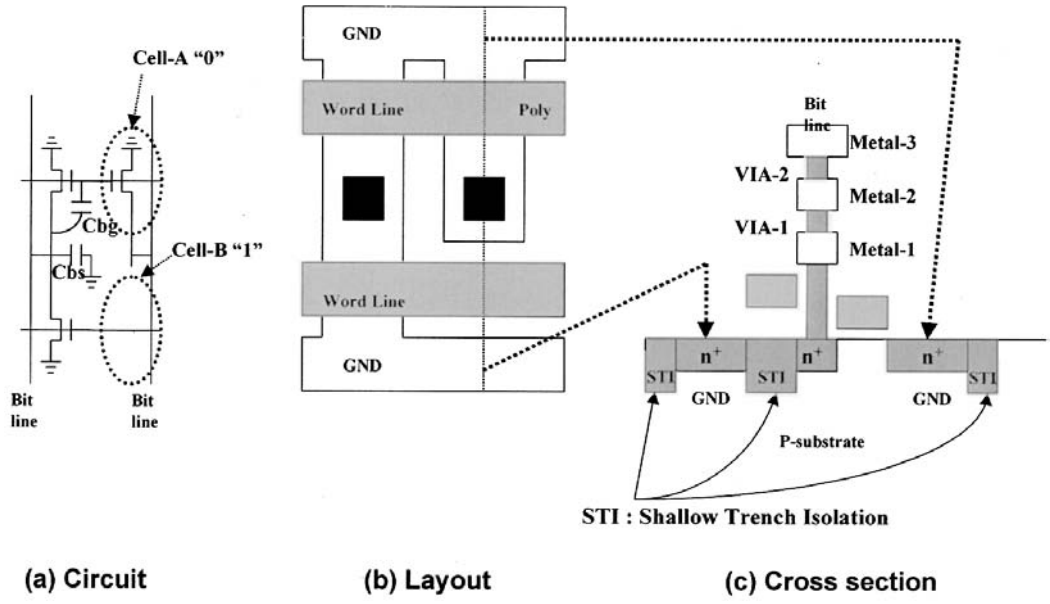

FIGURE 48.6 Diffusion programming ROM.

Conventional VIA-2 Contact Programming ROM

In order to obtain better fabrication cycle time, conventional VIA-2 contact programming ROM was used as shown in Fig. 48.7, Cell-C in Fig. 48.7a is coding "1" Cell-D is coding "1". There are determined by VIA-2 code existence on bit cells. The VIA-2 is final stage of process and base process can be completed just before VIA-2 etching and remaining process steps are quite few. So, VIA-2 ROM fabrication cycle time is about 1/5 of the diffusion ROM. The demerit of VIA-2 contact and other type of contact programming ROM was poor density. Because diffusion area and contact must be separated in each ROM bit cell as shown in Fig. 48.7c, this results in reduced density, speed, and increased power. Metal-4 and VIA-3 at QLM process were used for word line strap in the ROM since RC delay time on these nobles is critical for 100MIPS DSP.[5]

New VIA-2 Contact Programming ROM

The new architecture VIA-2 programming ROM is shown in Fig. 48.8. A complex matrix constructs each 8-bit block with GND on each side. Cell-E in Fig. 48.8a is coding "0". Bit4 and N4 are connected by VIA-2. Cell-F is coding "1" since Bit5 and N5 are disconnected. Coding other bit lines (Bit 0, 1, 2, 3,5, 6, and 7) follow the same procedure. This is one of the coding examples to discuss worst case operating speed. In the layout shown in Fig. 48.8b, the word line transistor is used not only in the active mode but also to isolate each bit line in the inactive mode. When the word line goes high, all transistors are turned on.

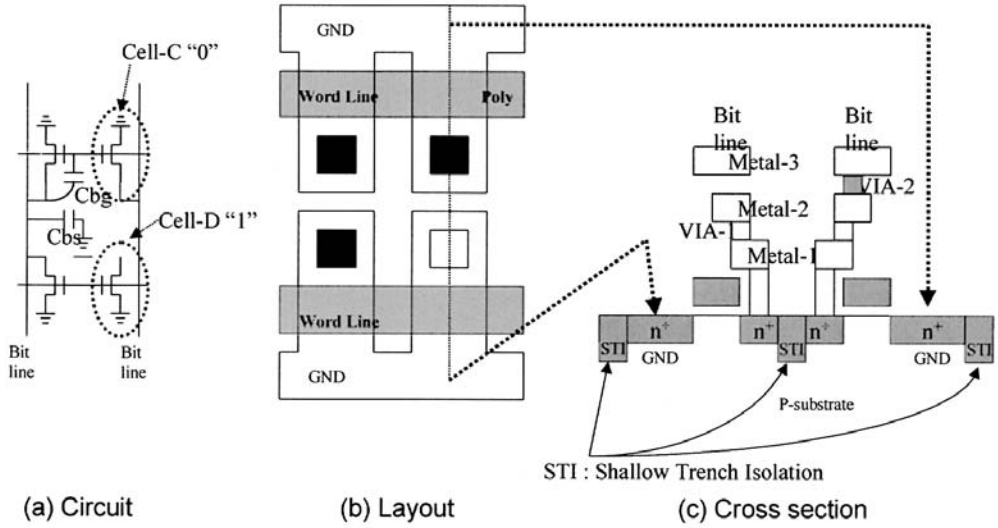

FIGURE 48.7 Conventional VIA-2 programming ROM.

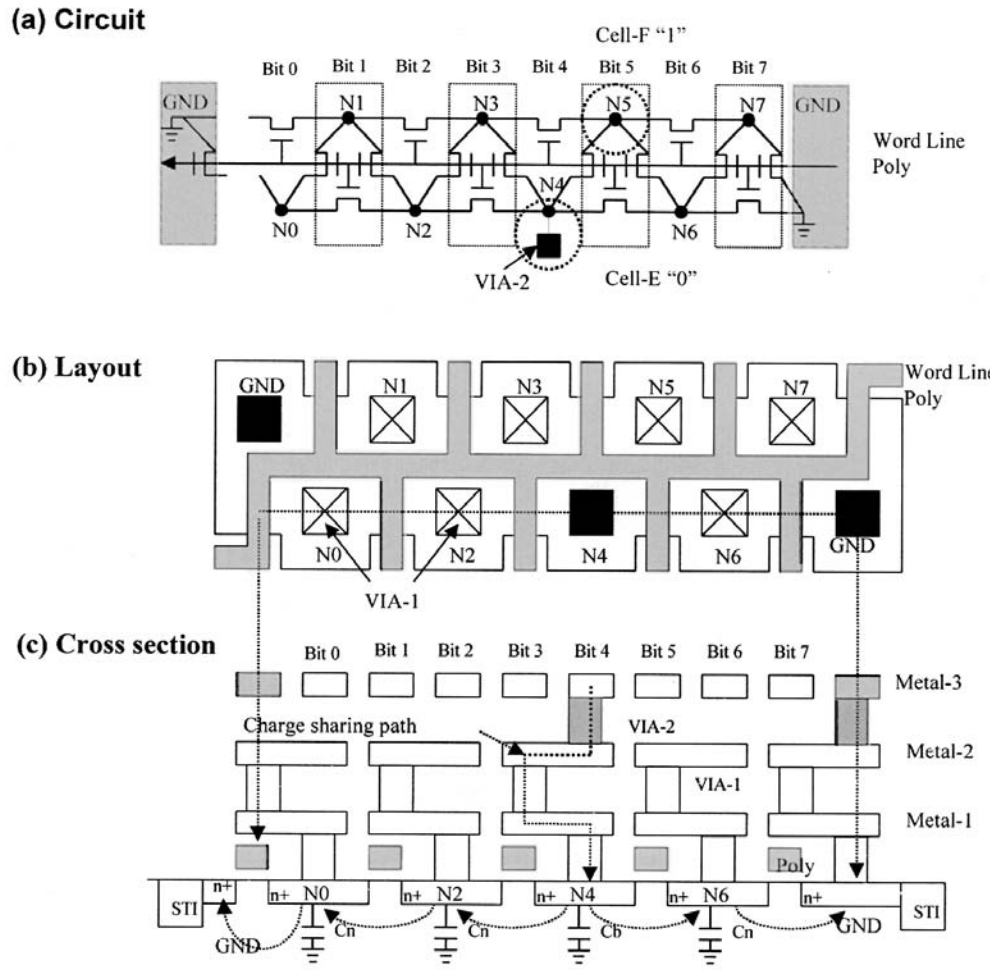

FIGURE 48.8 New VIA-2 programming ROM.

All nodes (N0 - N7) are horizontally connected with respect to GND. If VIA-2 code exists on all or some of nodes (N0 - N7) in the horizontal direction, the discharge time of bit lines is very short since this ROM uses a selective bit fine precharge method.[5]

Figure 48.9 shows timing chart of each key signal and when Bit4 is accessed, for example, only this line will be precharged during precharge phase. However, all other bit lines are pulled down to GND by Dl transistors as shown in Fig. 48.4. When VIA-2 code exists like N4 and Bit4, this line will be discharged. But if it does not exist, this line will stay at VDD level dynamically as described during word line active phase, which is shown in Fig. 48.9. After this operation, valid data appears on data out node of data latch circuits.[5]

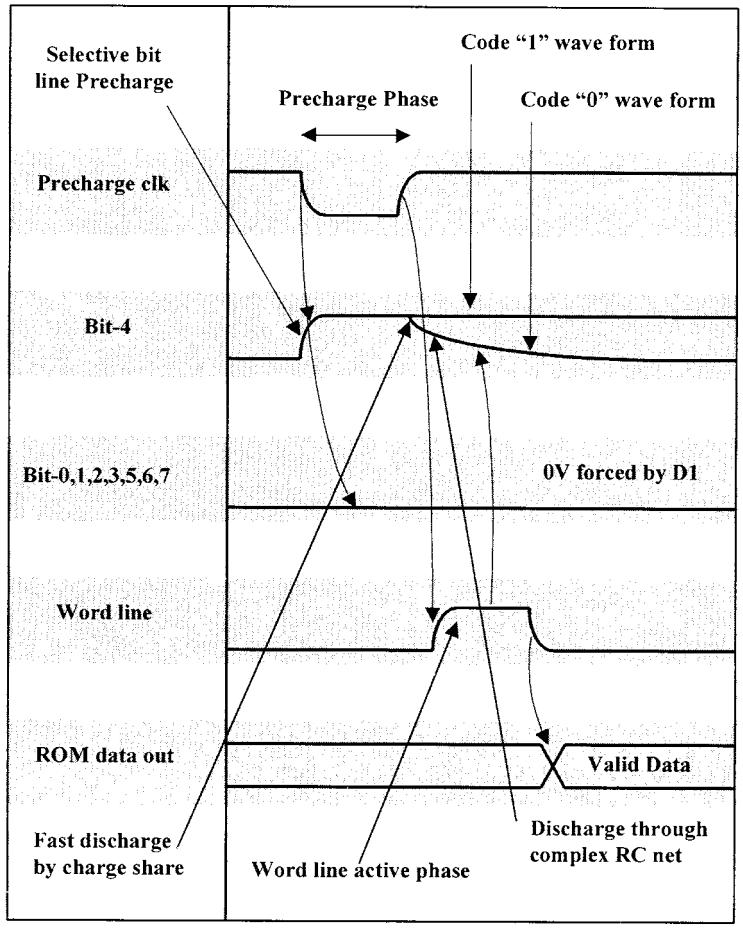

FIGURE 48.9 Timing chart of new VIA-2 programming ROM.

In order to evaluate worst case speed, no VIA-2 coding on horizontal bit cell was used since transistor series resistance at active mode will be maximum with respect to GND. However, in this situation, charge sharing effects and lower transistor resistance during the word line active mode allow fast discharge of bit lines despite the increased parasitic capacitance on bit line to 1.9 times. This is because all other nodes (N0-N7) will stay at GND dynamically. The capacitance ratio between bit line (Cb) and all nodes except N4 (Cn) was about 20:1. Fast voltage drop could be obtained by charge sharing at the initial stage of bit line discharging. About five voltage drop could be obtained on 8KW configuration through the charge-sharing path shown in Fig. 48.8c. With this phenomenon, the full level discharging was mainly determined by complex transistor RC network connected to GND as shown in Fig. 48.8a. This new ROM has much

wider transistor width than conventional ROMs and much smaller speed degradation due to process deviations, because conventional ROMs typically use the minimum allowable transistor size to achieve higher density and are more sensitive due to process variations.[5]

Comparison of ROM Performance

The performance comparison of each type of ROM are listed in Table 48.1. 8KW ROM module area ratio was indicated using same array configuration, and peripheral circuits with layout optimization to achieve fair comparison. The conventional VIA-2 ROM was 20% bigger than diffusion ROM, but new VIA-2 ROM was only 4% bigger. TAT ratio (days for processing) was reduced to 0.2 due to final stage of process steps. SPICE simulations were performed to evaluate each ROM performance considering low voltage applications. The DSP targets 2.5 V and 2.0 V supply voltage as chip specification with low voltage comer at 2.3 V and 1.8 V, respectively. However, a lower voltage was used in SPICE simulations for speed evaluation to account for the expected 7.5 supply voltage reduction due to the IR drop from the external supply voltage on the DSP chip. Based on this assumption, VDD = 2.13 V and VDD = 1.66 V were used for speed evaluation. The speed of new VIA-2 ROM was optimized at 1.66V to get over 100 MHz and demonstrated 106 MHz operation atVDD = 1.66 V, 125dc, (based on typical process models). Additionally, 149 MHz at VDD = 2.13 V, 125dc was demonstrated with the typical model and 123 MHz using the slow model. This is a relatively small deviation induced by changes in process parameters such as width reduction of the transistors. By using the fast model, operation at 294 MHz was demonstrated without any timing problems. This means the new ROM has very high productivity with even three sigma of process deviation and wide range of voltages and temperatures.[5]

TABLE 48.1 Comparison of ROM Performance

Comparison Item	Diffusion ROM	Conventional VIA-2 ROM	New VIA-2 ROM
8KW (Area ratio)	1.0	1.2	1.04
TAT (Day ratio)	1.0	0.2	0.2
Speed @ 2,13 V, 125dc. Weak.	83 MHz	86 MHz	123 MHz
Speed @ 2.13 V, 125dc. Typical.	166 MHz	98M Hz	149 MHz
Speed @ 2.81 V, -40dc. Strong.	277 MHz	179 MHz	294 MHz
Speed @ 1.66 V. 125dc, Typical.	103 MHz	75 MHz	106 MHz
Power@2.81 V,-40dc. Strong. 100 MHz. (16-bit single access)	15.6 mW	19.3 mW	2 UrnW
Power@2.81 V@40dc. Strong. 100 MHz. (32-bit dual access)	29.6 mW	37.1 mW	401 mW

Performance was measured with worst coding (all coding "1").

49.1 Read/Write Operation

Figure 49.1 shows a simplified readout circuit for an SRAM. The circuit has static bit-line loads composed of pull-up PMOS devices M1 and M2. The bit-lines are pulled up to VDD by bit-line load transistors M1 and M2. During the read cycle, one word-line is selected. The bit line BL is discharged to a level determined by the bit-line load transistor M1, the accessed transistor N1, and the driver transistor N2 as shown in Fig. 49.1(b). At this time, all selected memory cells consume a dc column current flowing through the bit-line load transistors, accessed transistors, and driver transistors. This current flow increases the operating power and decreases the access speed of the memory.

Figure 49.2 shows a simplified circuit diagram for SRAM write operation. During the write cycle, the input data and its complement are placed on the bit-lines. Then the word-line is activated. This will force the memory cell to flip into the state represented on the bit-lines, whereas the new data is stored in the memory cell. The write operation can be described as follows. Consider a high voltage level and a low voltage level are stored in both node 1 and node 2, respectively. If the data is to be written into the cell, then node 1 becomes low and node 2 becomes high. During this write cycle, a dc current will flow from VDD through bit-line load transistor M1 and write circuits to ground. This extra dc current flow in write cycle increases the power consumption and degrades the write speed performance. Moreover, in the tail portion of write cycle, if data 0 has been written into node 1 as shown in Fig. 49.2, the turn-on word-line transistor N1 and driver transistor N2 form a discharge circuit path to discharge the bit-line voltage. Thus, the write recovery time is increased. In high-speed SRAM, write recovery time is an important component of the write cycle time. It is defined as the time necessary to recover from the write cycle to the read state after the WE signal is disabled.[1] During the write recovery period, the selected cell is in the quasi-read condition,[2] which consumes dc current as in the case of read cycle.

Based on the above discussion, the dc current problems that occur in the read and write cycles should be overcome to reduce power dissipation and improve speed performance. Some solutions for the dc current problems of conventional SRAM will be described. During the active mode (read cycle or write cycle), the word-line is activated, and all selected columns consume a dc current. Thus, the word-line activation duration should be shortened to reduce the power consumption and improve speed performance during the active mode. This is possible by using the Address Transition Detection (ATD) technique[3] to generate the pulsed word-line signal with enough time to achieve the read and write operation, as shown in Fig. 49.3.

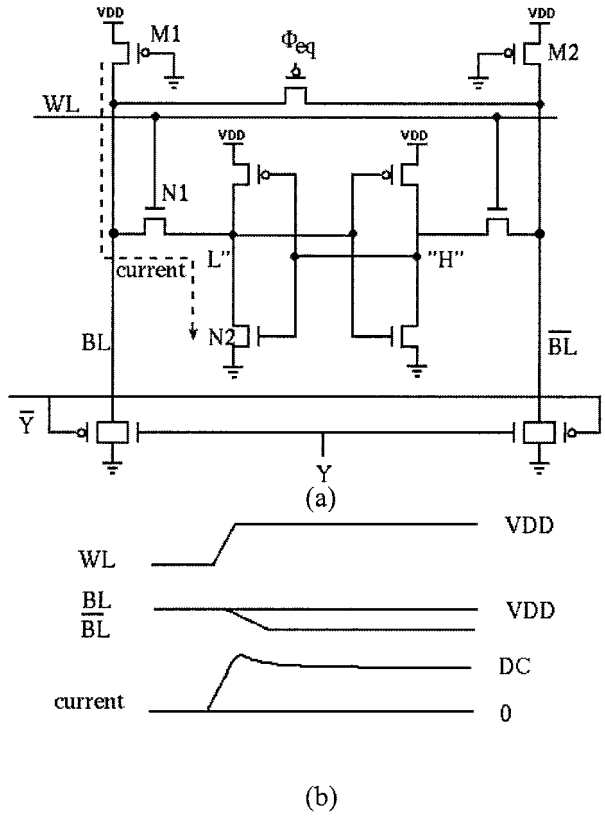

FIGURE 49.1 (a) Simplified readout circuit for an SRAM, (b) signal waveform.

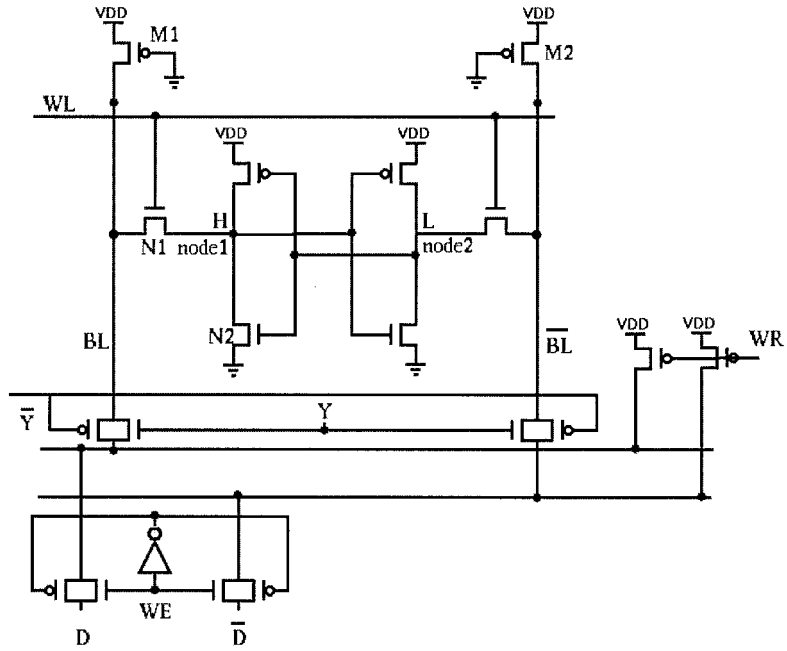

FIGURE 49.2 Simplified circuit diagram for SRAM write operation

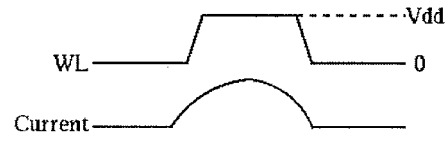

FIGURE 49.3 Word-line signal and current reduction by pulsing the word line

However, the memory cells asserted by the pulsed word-line signal still consume dc current from VDD through bit-line load transistors, accessed transistors, and driver transistors or write circuits to the ground during the word-line activation period. A dynamic bit-line loads circuit technique[2,4-6] can be used to eliminate the dc power consumption during operation period.

Figure 49.4 shows a simplified circuit configuration and time diagram for read and write operation. In the read cycle, the bit-line load transistors are turned off because the Φ_{LD} signal is in the high state. The bit-line load consists of only the stray capacitance. Therefore, the selected memory cell can rapidly drive the bit-line load, resulting in a fast access time. Moreover, the dc column current consumed by the other activated memory cells can be eliminated. Similarly, the dc current consumption in the write cycle can be eliminated.

A memory cell's readout current I_{cell} depends on the channel conductance of the transfer gates in a memory cell. As the supply voltage is scaled down, the speed performance of SRAM is decreased, significantly, due to small cell's readout current. To increase the channel conductance, widening the channel width and/or boosting word-line voltage are used. For low-voltage operation, boosting the word-line voltage is effective in shortening the delay time, in contrast to widening the channel width. However, this causes an increased power dissipation and a large transition time due to enhanced bit-line swing. To solve these problems, a step-down boosted-word-line scheme that shortens the readout time with little power dissipation penalty was reported by Morimura and Shibata in 1998.[7]

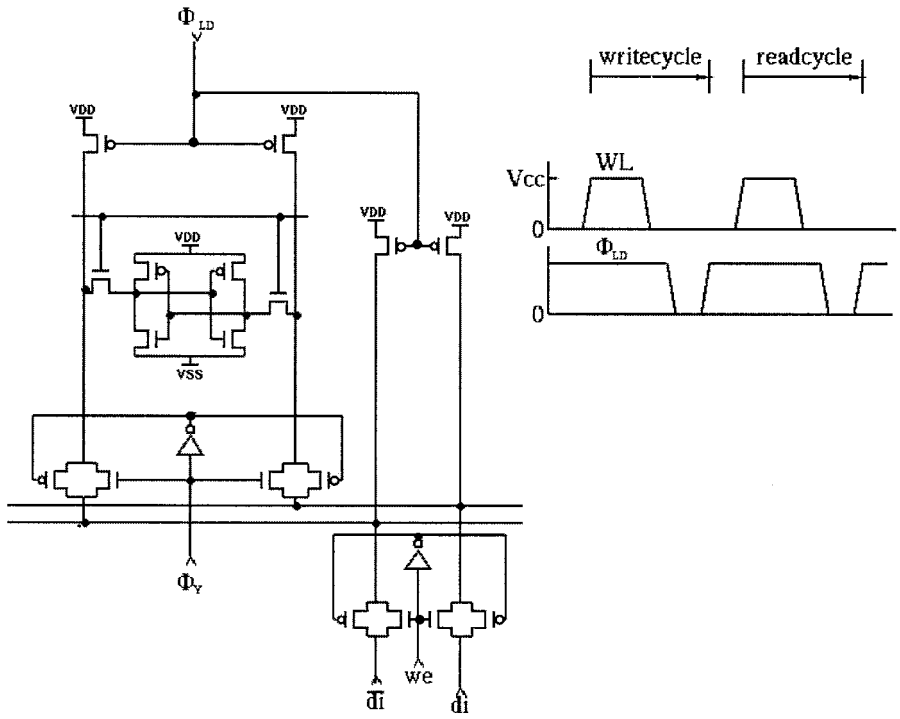

FIGURE 49.4 Simplified circuit configuration and time diagram for read and write operation.

The concept of this scheme is shown in Fig. 49.5(b), in contrast to the conventional full-bootsted-word-line scheme in Fig. 49.5(a). The step-down boosted-word-line scheme also boosts the selected word-line, but the boosted period is restricted only at the beginning of memory cell access. This enables the sensing operation to start early, by fast bit-line transition. During the sensing period of bit-line signals, the word-line potential is stepped down to the supply voltage to suppress the power dissipation; the reduced bit-line signals are sufficient to read out data by current sensing, and the reduced bit-line swing is effective in shortening the bit-line transition time in the next read cycle (Fig. 49.5(c)). As a result, fast readout is accomplished with little dissipation penalty (Fig. 49.5(d)).

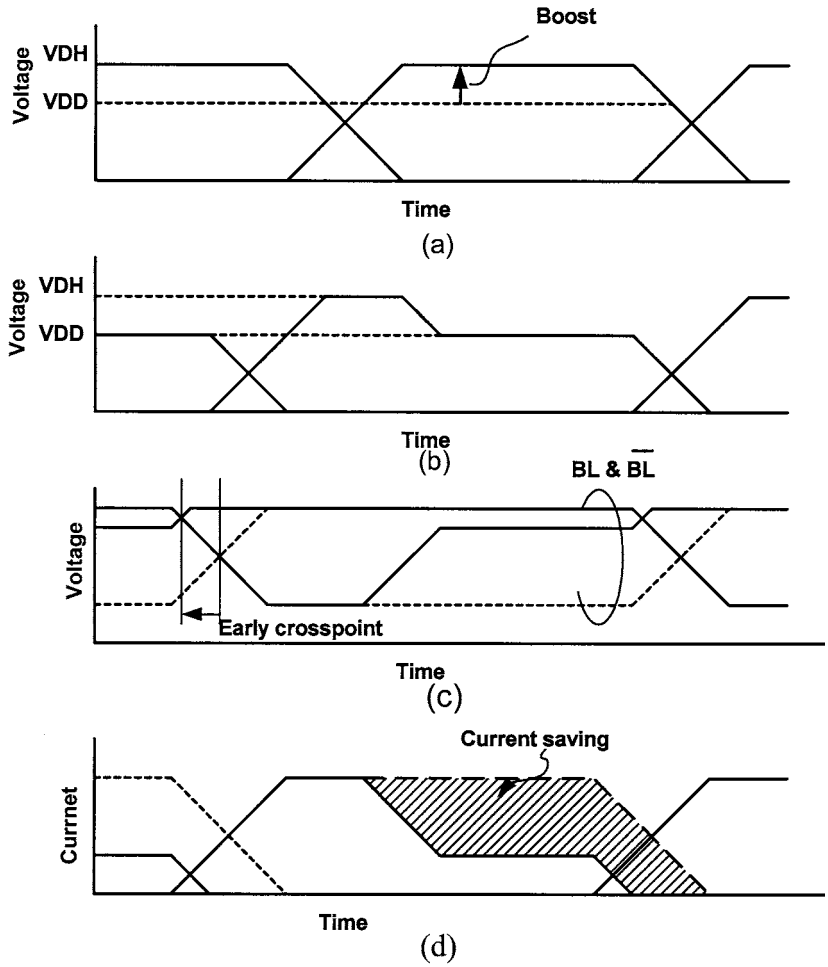

FIGURE 49.5 Step-down boosted-word-line scheme: (a) conventional boosted word-line, (b) step-down boosted word-line, (c) bit-line transition, and (d) current consumption of a selected memory cell. (From Ref. 7.)

The step-down boosted-word-line scheme is also used in data writing. In the writing cycle, the proposed scheme is just as effective in reducing the memory-cell current because the memory cells unselected by column-address signals consume the same power as in the read cycle. The boosted word-line voltage shortens the time for writing data because it increases the channel conductance of the access transistor in the selected memory cells. The writing recovery operation starts after the word-line voltage is stepped down. Reducing the memory cell's current accelerates the recovery operation of lower bit-lines. So, a shorter recovery time than that of the conventional full-boosted-word-line scheme is obtained.

Other circuit techniques for dc column current reduction, such as divided word-line (DWL)[8] and hierarchical word decoding (HWD)[9] structures will be described in the following sections.

49.2 Address Transition Detection (ATD) Circuit for Synchronous Internal Operation[1,10]

The address transition detection (ATD) circuit plays an important role in achieving internal synchronization of operation in SRAM. ATD pulses can be used to generate the different time signals for pulsing word-lines, sensing amplifier, and bit-line equalization. The ATD pulse activating $\phi_{(ai)}$ is generated with XOR circuits by detecting "L" to "H" or "H" to "L" transitions of any input address signal a_i, as shown in Fig. 49.6. All the ATD pulses generated from all the address input transitions are summed up to one pulse, ϕ_{ATD} as shown in Fig. 49.6. The pulse width of ϕ_{ATD}, is controlled by the delay element τ. The pulse width is usually stretched out with a delay circuit and used to reduce or speed up signal propagation in the SRAM.

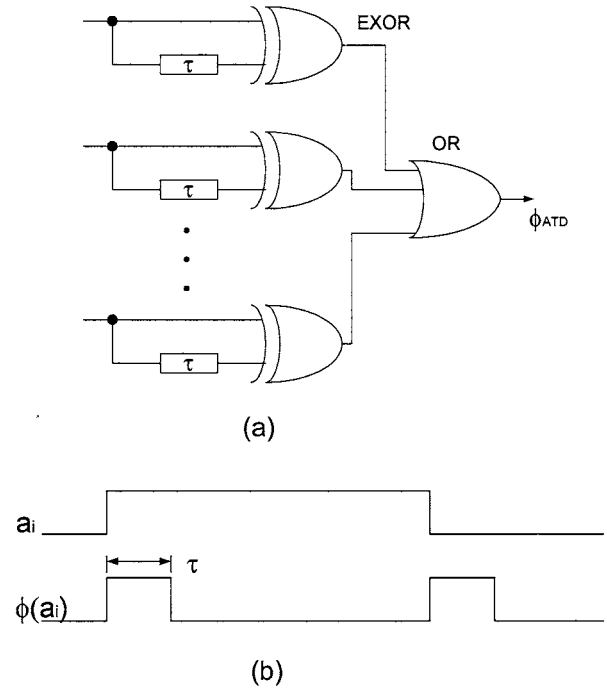

FIGURE 49.6 (a) Summation circuit of all ATD pulses generated from all address transitions (b) ATD pulse waveform. (From Ref. 10.)

49.3 Decoder and Word-Line Decoding Circuit[10-13]

Two kinds of decoders are used in SRAM: the row decoder and the column decoder. Row decoders are needed to select one row of word-lines out of a set of rows in the array. A fast decoder can be implemented by using AND/NAND and OR/NOR gates. Figure 49.7 shows the schematic diagrams of static and dynamic AND gate decoders. The static NAND-type structure is chosen due to its low power consumption, that is, only the decoded row transitions. The dynamic structure is chosen due to its speed and power improvement over conventional static NAND gates.

From a low-voltage operation standpoint, a dynamic NOR-base decoding would provide lower delay times through the decoder due to the limited amount of stacking of devices. Figure 49.8 shows circuit

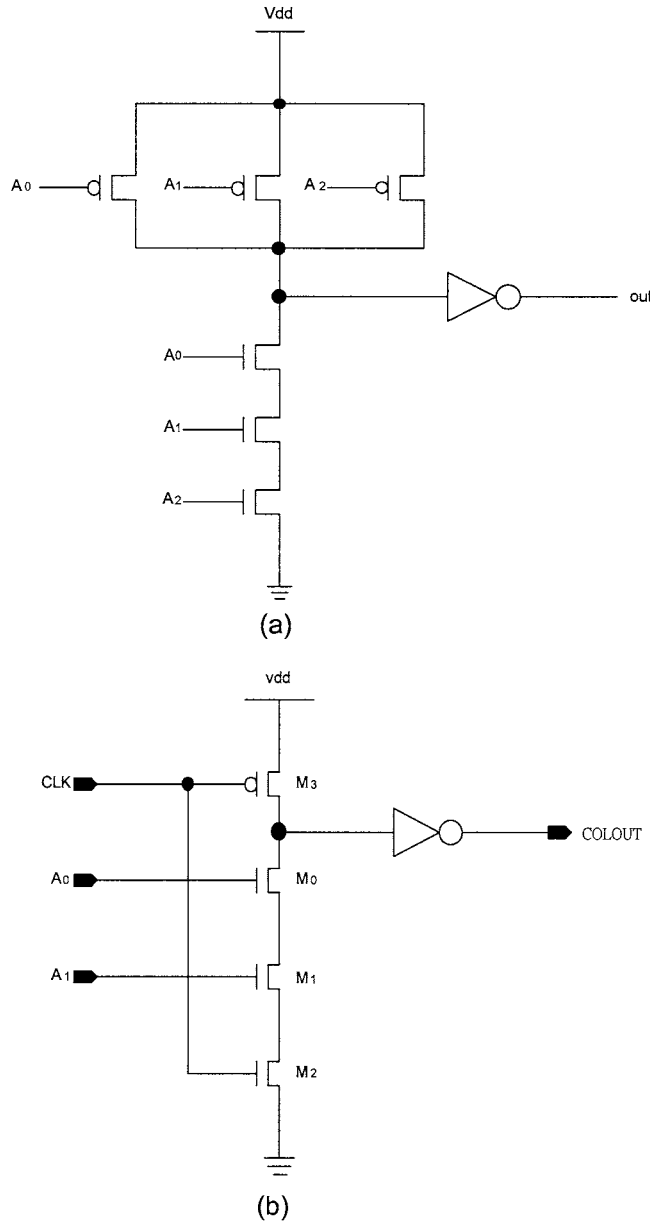

FIGURE 49.7 Circuit diagrams of a three-input AND gate: (a) static CMOS, (b) dynamic CMOS.

diagrams of dynamic NOR gates. The dynamic CMOS gate as shown in Fig. 49.8(a) consists of input-NMOSs whose drain nodes are precharged to a high level by a PMOS when a clock signal Φ is at a low level, and conditionally discharged by the input-NMOSs when a clock signal Φ is at a high level. The delay time of the dynamic NOR/OR gate does not increase when the number of input signals increases. This is because only one PMOS and two NMOSs are connected in series, even if the number of input signals is large. However, the output of the OR signal is slower than that of the NOR signal because the OR signal is generated from the inverter driven by the NOR signal.

Figure 49.8 (b) shows the source-coupled-logic (SCL)[11] NOR/OR circuit. When a clock signal Φ is at a low level, the drain nodes of the NMOS (N1, N2) are precharged to a high level in the circuit. If at

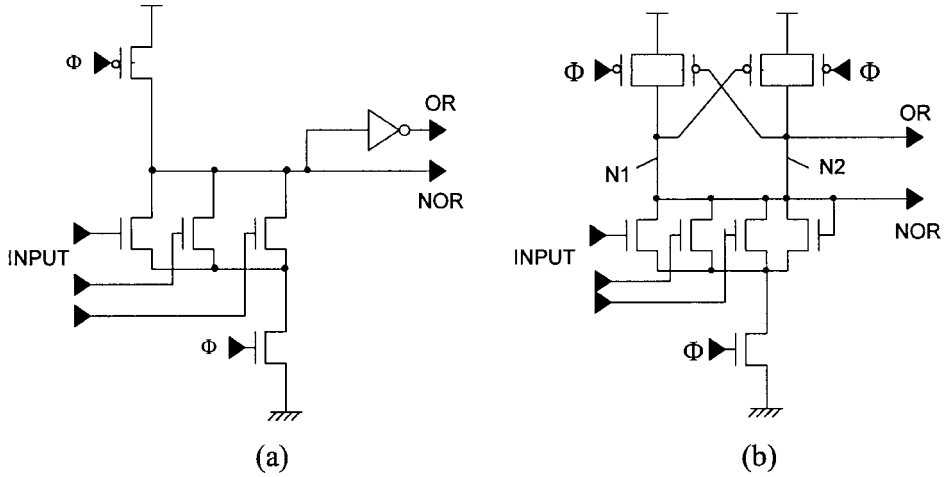

FIGURE 49.8 Circuit diagrams of three-input NOR/OR gates: (a) dynamic CMOS, (b) SCL> (From Ref. 11)

least one of input signals of the circuit is at a high level and the clock Φ then turns to a high level, node N1 is discharged to a low level and node N2 remains at a high level. On the other hand, if all the input signals are at a low level and Φ then turns to a high level, node N2 is discharged and node N1 remains at a high level. The SCL circuit can produce an OR signal and a NOR signal simultaneously. Thus, the SCL circuit is suitable for predecoders that have a large number of input signals and for address buffers that need to produce OR and NOR signals simultaneously.

Column decoders select the desired bit pairs out of the sets of bit pairs in the selected row. A typical dynamic AND gate decoder as shown in Fig. 49.7(b) can be used for column decoding because the AND structure meets the delay requirements (column decode is not in the worst-case delay path) and does so at a much lower power consumption.

A highly integrated SRAM adopts a multi-divided memory cell array structure to achieve high-speed word decoding and reduce column power dissipation. For this purpose, many high-speed word-decoding circuit architectures have been proposed, such as divided word-line (DWL)[8] and hierarchical word decoding (HWD)[9] structures. The multi-stage decoder circuit technique is adopted in both word-decoding circuit structures to achieve high-speed and low-power operation. The multi-stage decoder circuit has advantages over the one-stage decoder in reducing the number of transistors and fanin. Also, it reduces the loading on the address input buffers. Figure 49.9 shows the decoder structure for a typical partitioned memory array with divided word-line (DWL). The cell array is divided into N_B blocks. If the SRAM has N_C columns, each block contains N_C/N_B columns. The divided word-line in each block is activated by the global word-line and the vertical block select line. Consequently, only the memory cells connected to one divided word-line within a selected block are accessed in a cycle. Hence, the column current is reduced because only the selected columns switch. Moreover, the word-line selection delay, which is the sum of the global word-line delay and the divided word-line delay, is reduced. This is because the total capacitance of the global word-line is smaller than that of a conventional word-line. The delay time of each divided word-line is small due to the short length. In the block decoder, an additional signal Φ, which is generated from an ATD pulse generator, can be adopted to enable the decoder and ensure the pulse activated word-line.

However, in high-density SRAM, with a capacity of more than 4 Mb, the number of blocks in the DWL structure will have to increase. Therefore, the capacitance of the global word-line will increase and that causes the delay and power to increase. To solve this problem, the hierarchical word decoding (HWD)[9] circuit structure, as shown in Fig. 49.10, was proposed. The word-line is divided into multi-levels. The number of levels is determined by the total capacitance of the word select line to efficiently distribute it.

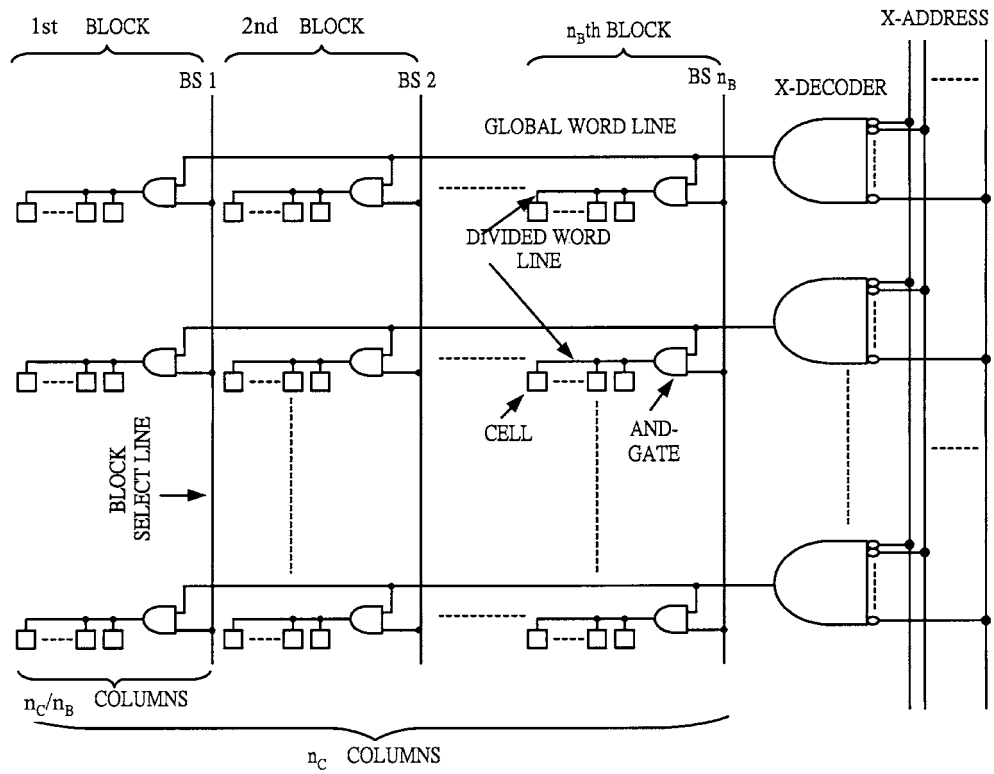

FIGURE 49.9 Divided word-line (DWL) structure. (From Ref. 8.)

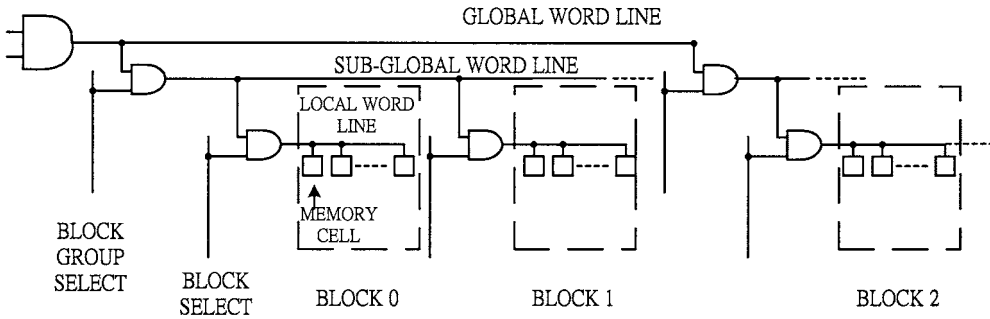

FIGURE 49.10 Hierarchical word decoding structure.

Hence, the delay and power are reduced. Figure 49.11 shows the delay time and the total capacitance of the word decoding path comparison for the optimized DWL and HWD structures of 256-Kb, 1-Mb, and 4-Mb SRAMs.

49.4 Sense Amplifier[10]

During the read cycle, the bit-lines are initially precharged by bit-line load transistors. When the selected word-line is activated, one of the two bit-lines is pulled low by driver transistor, while the other stays high. The bit-line pull-down speed is very slow due to the small cell size and large bit-line load capacitance. Differential sense amplifiers are used for speed purposes because they can detect and amplify a very small

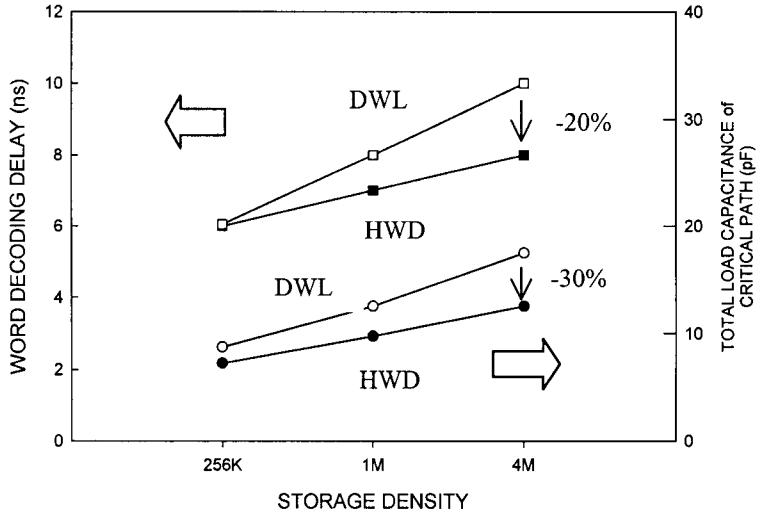

FIGURE 49.11 Comparison of DWL and HWD. (From Ref. 9. With permission.)

level difference between two bit-lines. Thus, a fast sense amplifier is an important factor in realizing fast access time.

Figure 49.12 shows a switching scheme of well-known current-mirror sense amplifiers.[14] Two amplifiers are serially connected to obtain a full supply voltage swing output because one stage of the amplifier

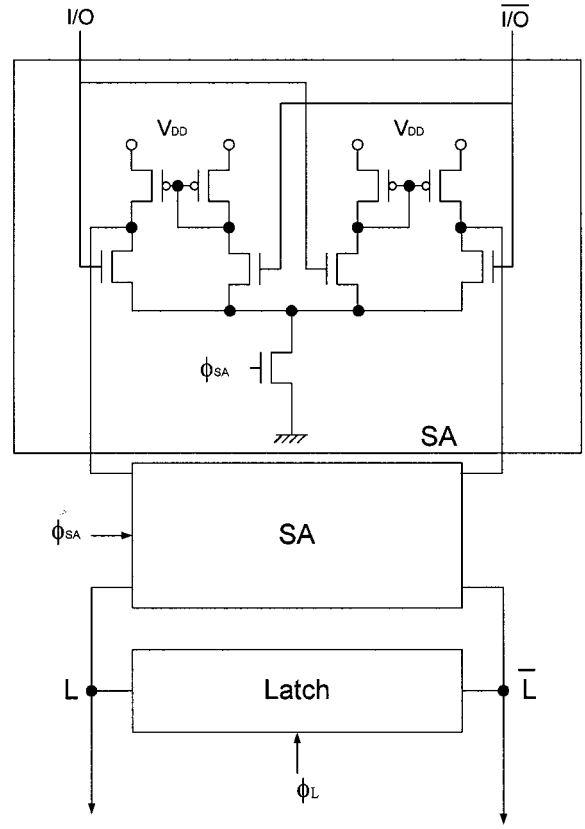

FIGURE 49.12 Two-stage current-mirror sense amplifier. (From Refs. 10 and 14. With permission.)

does not provide enough gain for a full swing. The signal Φ_{SA} is generated with an ATD pulse. It is asserted for a period of time, enough to amplify the small difference on data lines; then it is deactivated and the amplified output is latched. Hence, the switch reduces the power consumption, especially at relatively low frequencies.

A latch-type sense amplifier such as a PMOS cross-coupled amplifier,[15] as shown in Fig. 49.13, greatly reduces the dc current after amplification and latching, because the amplifier provides a nearly full supply voltage swing with positive feedback of outputs to PMOSFETs. As a result, the current in the PMOS cross-coupled sense amplifier is less than one fifth of that in a current-mirror amplifier. Moreover, this positive feedback effect gives much faster sensing speed than the conventional amplifier. To obtain correct and fast operation, the equalization element EQL is connected between the output terminals and are turned on with pulse signals Φ_S and its complement during the transition period of the input signals.

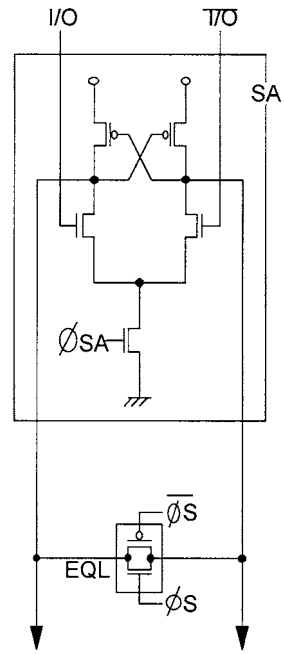

FIGURE 49.13 PMOS cross-coupled amplifier. (From Ref. 15. With permission.)

However, the latch-type sense amplifier has a large dependence on the input voltage swing, especially at low current operation conditions. An NMOS source-controlled latched sense amplifier[16] as shown in Fig. 49.14 is able to quickly amplify an input voltage swing as small as 10 mV. The sense amplifier consists of two PMOS loads, two NMOS drivers, and two feedback inverters. The sense amplifier control (SAC) signal is driven by the CS input buffer, and Φ_S is a sense-amplifier equalizing pulse generated by the ATD pulse. The gate terminal of the NMOS driver is connected to the local data bus (LD1 and LD2), and the source terminal of the NMOS driver is controlled by the feedback inverter connected to the opposite output node of sense amplifier. Thus, the NMOS driver connected to the high-going output node turns off immediately. Therefore, the charge-up time of that node can be reduced because no current is wasted in the NMOS driver.

A bidirectional sense amplifier, called a bidirectional read/write shared sense amplifier (BSA),[17] is shown in Fig. 49.15. The BSA plays three roles. It functions as a sense amplifier for read operations, and it serves as a write circuit and a data input buffer for write operations. It consists of an 8-to-1 column selector and bit-line precharger, a CMOS dynamic sense amplifier, an SR flip-flop, and an I/O circuit.

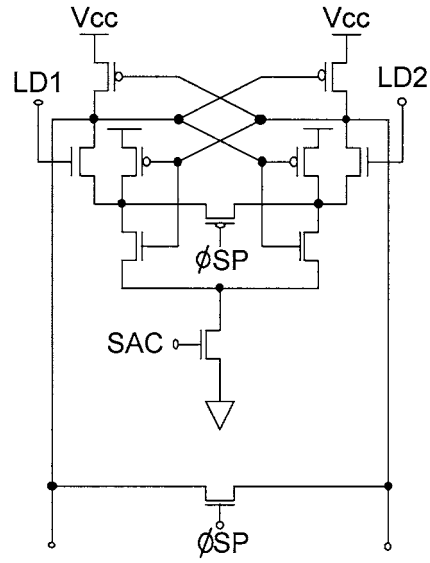

FIGURE 49.14 NMOS source-controlled latched sense amplifier. (From Ref. 16. With permission.)

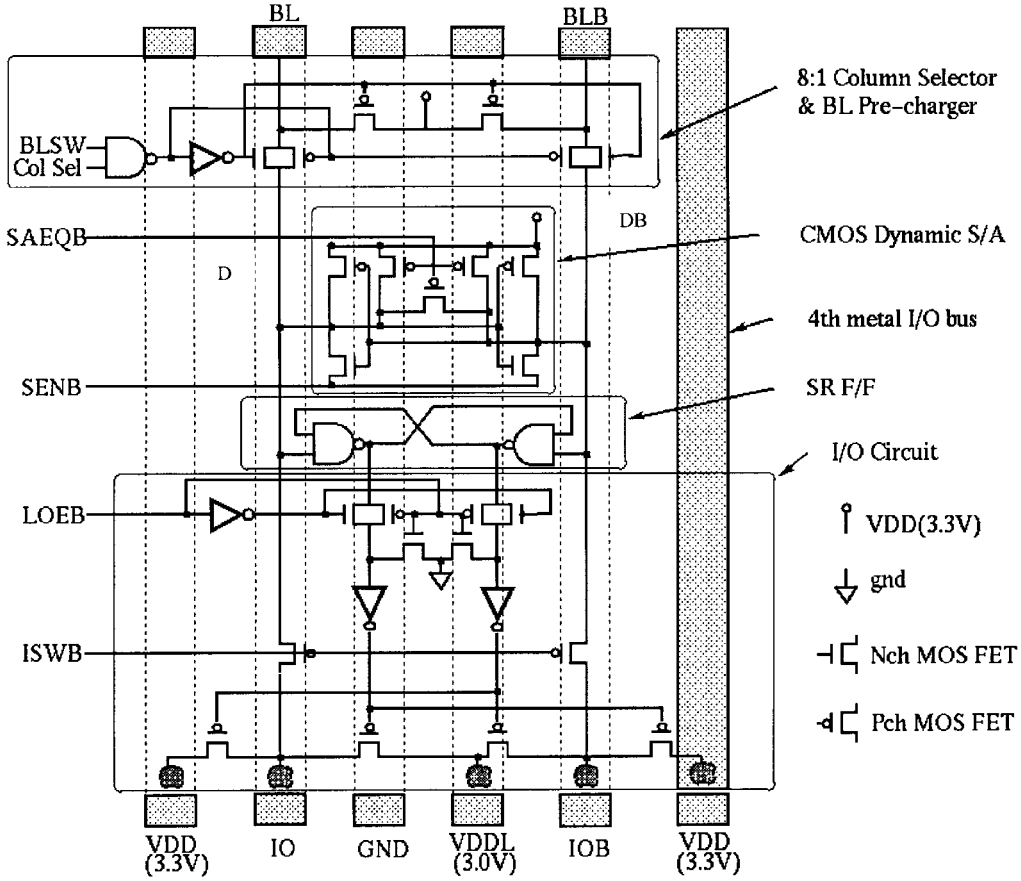

FIGURE 49.15 Schematic diagram of BSA. (From Ref. 17. With permission.)

Eight bit-line pairs are connected to a CMOS dynamic sense amplifier through CMOS transfer gates. The BLSW signal is used to select a column and to precharge bit-lines. When the BLSW signal is high, one of eight bit-line pairs is connected to the sense amplifier. When the BLSW signal is low, all bit-line pairs are precharged to VDD level. The SAEQB signal controls the sense amplifier equalization. When the SAEQB signal is low, sense nodes D and DB are equalized and precharged to the VDD level. The SENB signal activates the CMOS dynamic sense amplifier. The SR flip-flop holds the result. The output circuit consists of four p-channel transistors. If the result is high, I/O is connected to VDD (3.3 V) and IOB is connected to VDD (3 V) through p-channel devices. VDDL is a 3-V power supply provided externally. The I/O pair is connected to the sense amplifier through p-channel transfer gates controlled by ISWB. During write operations, ISWB falls to connect the I/O pair to the sense amplifier.

Figure 49.16 shows operational waveforms of the BSA. At the beginning of the read operations, after some intrinsic delay from the rising edge of the SACLK, data from the selected cell is read onto the bit-line pair. At the same time, the BLSW and the SAEQB rise. One of the eight CMOS transfer gates is turned on, the bit-line pair is connected to sense nodes D and DB, and precharging of the CMOS sense amplifier and bit-line pair is terminated. After the signal on the bit-line pair signal is sufficiently developed, the BLSW falls to disconnect the bit-line pair from the sense nodes D and DB. At the same time, the SENB falls to activate the sense amplifier. After the differential output data is latched onto the SR flip-flop, the SAEQB falls to start the equalization of the bit-line pair and the CMOS sense amplifier.

At the beginning of the write operations, after some delay from the rising edge of SACLK, the ISWB signal falls, and the differential I/O pair is directly connected to the sense amplifier through p-channel

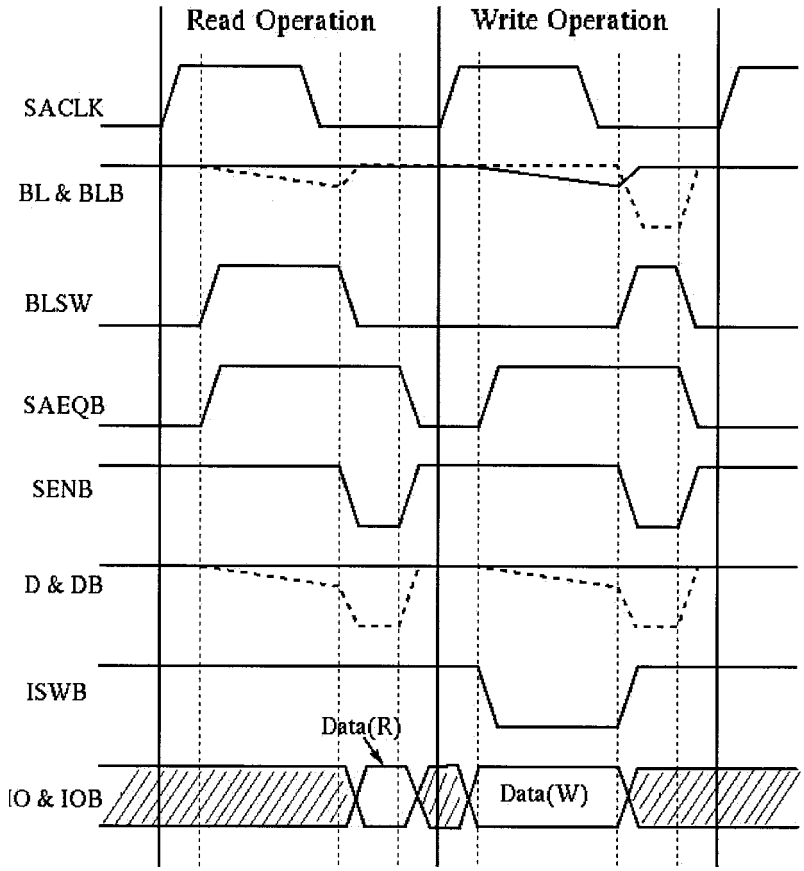

FIGURE 49.16 Operational waveforms of the BSA. (From Ref. 17. With permission.)

transfer gates. After the signals D and DB are sufficiently developed, ISWB turns off the p-channel transfer gates to disconnect the sense amplifier from the I/O pair. At the same time, the SENB falls to sense the data, and BLSW rise to connect the sense amplifier to the bit-line pair. After the data is written into the selected memory cell, SAEQB and BLSW fall to start equalization of the bit-line pair and the CMOS sense amplifier.

Conventional sense amplifiers operate incorrectly when threshold voltage deviation is larger than bit-line swing, a current-sensing sense amplifier proposed by Izumikawa et al. in 1997 can continue to operate normally.[18] Figure 49.17 illustrates the sense amplifier operations. Bit-lines are always charged up to VDD through load PMOSFETs. When memory-cells are selected with a word-line, the voltage difference in a bit-line pair appears (Fig. 49.17(a)). During this period, all column-select PMOSFETs are off, and no dc current flows in the sense amplifier. The sense amplifier differential outputs, referred to as ReadData, are equalized at ground level through pull-down NMOSFETs M7 and M8.

After a 40-mV difference appears in a bit-line pair, power switch M9 of the sense amplifier and one column-select pair of PMOSFETs are set to on (Fig. 49.17(b)). The difference in bit-line voltages causes

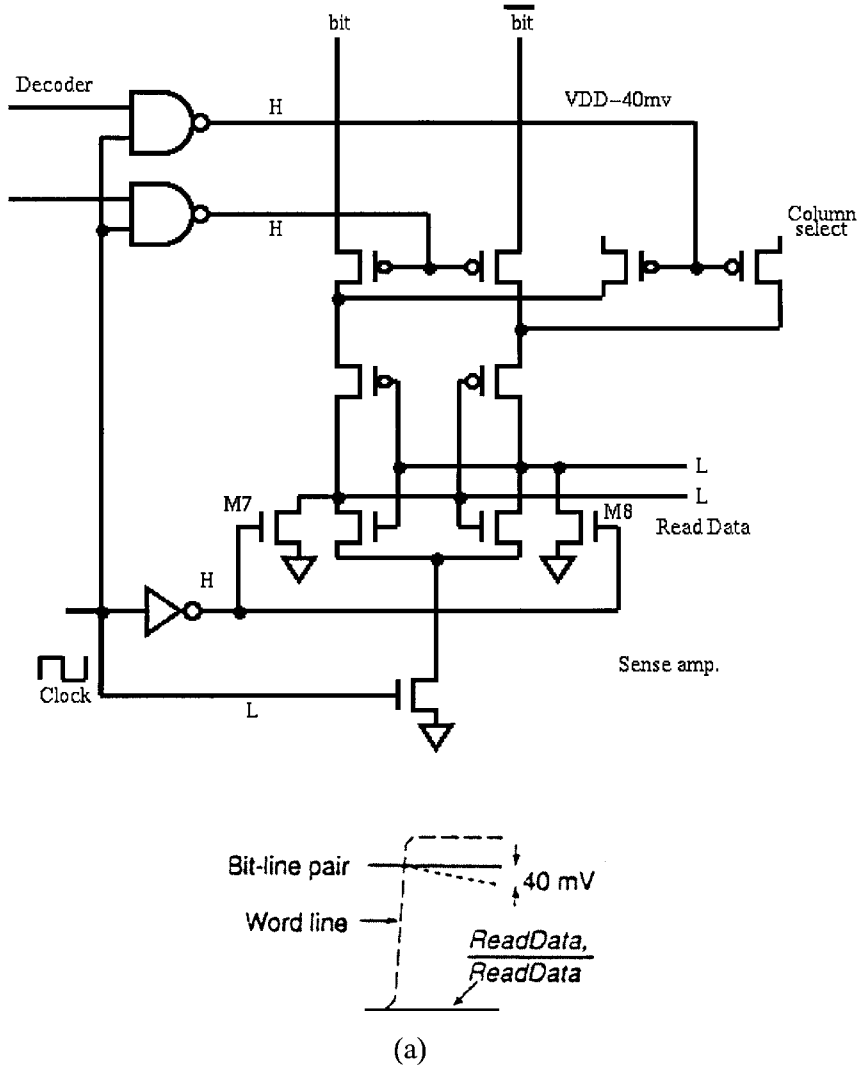

FIGURE 49.17(a) Sense amplifier operation: (a) before sensing. (From Ref. 18. With permission.)

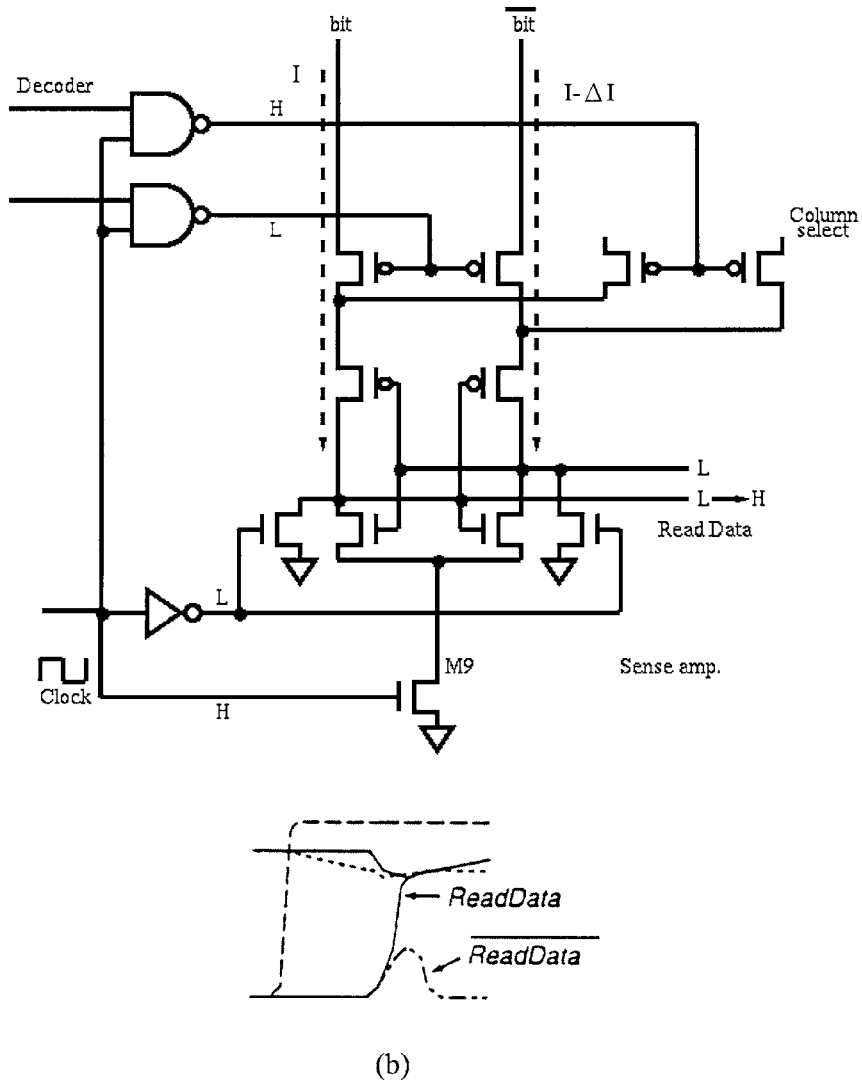

FIGURE 49.17(b) Sense amplifier operation: (b) sensing. (From Ref. 18. With permission.)

a current difference between the differential pair PMOS in the sense amplifier, which appears as an output voltage difference. This voltage difference is amplified, and the read operation is accomplished. The current is automatically cut off because of the CMOS inverter. Consequently, the small bit-line swing is sensed without dc current consumption.

49.5 Output Circuit[4]

The key issue for designing the high-speed SRAM with byte-wide organization is noise reduction. There are two kinds of noise: VDD noise and GND noise. In the high-speed SRAM with byte-wide organization, when the output transistors drive a large load capacitance, the noise is generated and multiplied by 8 because eight outputs may change simultaneously. It is a fundamentally serious problem for the data zero output. That is to say, when the output NMOS transistor drives the large load capacitance, the GND potential of the chip goes up because of the peak current and the parasitic inductance of the GND line. Therefore, the address buffer and the ATD circuit are influenced by the GND bounce, and unnecessary signals are generated.

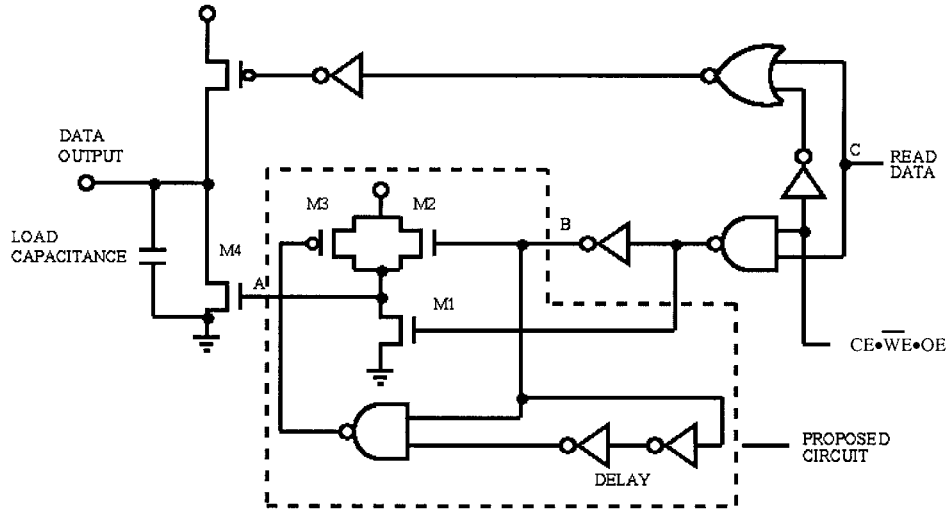

FIGURE 49.18 Noise-reduction output circuit. (From Ref. 4. With permission.)

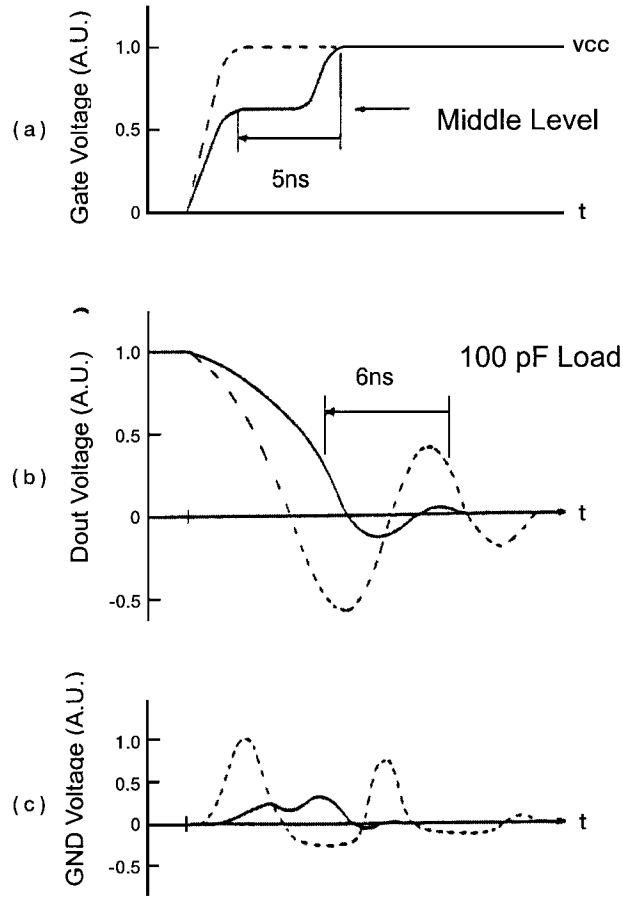

FIGURE 49.19 Waveforms of noise-reduction output circuit (solid line) and conventional output circuit: (a) gate bias, (b) data output, and (c) GND bounce. (From Ref. 4. With permission.)

Figure 49.18 shows a noise-reduction output circuit. The waveforms of the noise-reduction output circuit and conventional output circuit are shown in Fig. 49.19. In the conventional circuit, nodes A and B are connected directly as shown in Fig. 49.18. Its operation and characteristics are shown by the dotted lines in Fig. 49.18. Due to the high-speed driving of transistor M4, the GND potential goes up, and the valid data are delayed by the output ringing. A new noise-reduction output circuit consists of one PMOS transistor, two NMOS transistors, one NAND gate, and the delay part (its characteristics are shown by the solid lines in Fig. 49.19). The operation of this circuit is explained as follows. The control signals CE and OE are at high level and signal WE is at low level in the read operation. When the data zero output of logical high level is transferred to node C, transistor M1 is cut off, and M2 raises node A to the middle level. Therefore, the peak current that flows into the GND line through transistor M4 is reduced to less than one half that of the conventional circuit because M4 is driven by the middle level. After a 5-ns delay from the beginning of the middle level, transistor M3 raises node A to the VDD level. As a result, the conductance of M4 becomes maximum, but the peak current is small because of the low output voltage. Therefore, the increase of GND potential is small, and the output ringing does not appear.

Embedded Memory

Chung-Yu Wu
National Chiao Tung University

50.1 Introduction

As CMOS technology progresses rapidly toward the deep submicron regime, the integration level, performance, and fabrication cost increase tremendously. Thus, low-integration low-performance small circuits or systems chips designed using deep submicron CMOS technology are not cost-effective. Only high-performance system chips that integrate CPU (central processing unit), DSP (digital signal processing) processors or multimedia processors, memories, logic circuits, analog circuits, etc. can afford the deep submicron technology. Such system chips are called system-on-a-chip (SOC) or system-on-silicon (SOS).[1,2] A typical example of SOC chips is shown in Fig. 50.1.

Embedded memory has become a key component of SOC and more practical than ever for at least two reasons:[3]

1. Deep submicron CMOS technology affords a reasonable tradeoff for large memory integration in other circuits. It can afford ULSI (ultra large-scale integration) chips with over 10^9 elements on a single chip. This scale of integration is large enough to build an SOC system. This size of circuitry inevitably contains different kinds of circuits and technologies. Data processing and storage are the most primitive and basic components of digital circuits, so that the memory implementation on logic chip has the highest priority. Currently in quarter-micron CMOS technology, chips with up to 128 Mbits of DRAM and 500 Kgates of logic circuit, or 64 Mbits of DRAM and 1 Mgates of logic circuit, are feasible.
2. Memory bandwidth is now one of the most serious bottlenecks to system performance. The memory bandwidth is one of the performance determinants of current von Neuman-type MPU (microprocessing unit) systems. The speed gap between MPUs and memory devices has been increased in the past decade. As shown in Fig. 50.1, the MPU speed has improved by a factor of 4 to 20 in the past decade. On the other hand, in spite of exponential progress in storage capacity, minimum access times for each quadrupled storage capacity have improved only by a factor of two, as shown in Fig. 50.2. This is partly due to the I/O speed limitation and to the fact that major

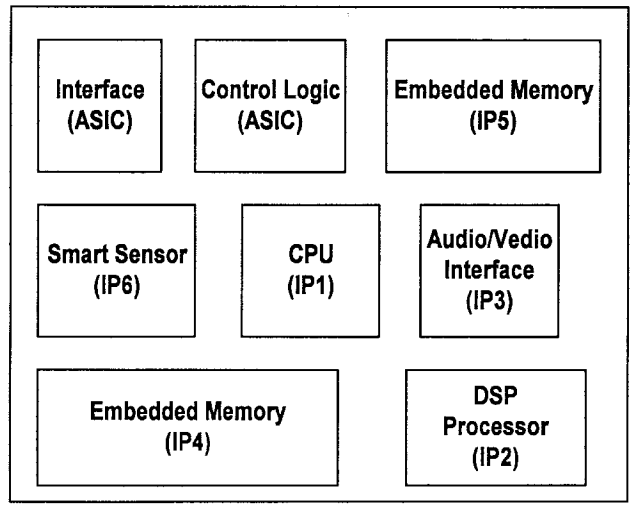

FIGURE 50.1 An example of system-on-a-chip (SOC).

efforts in semiconductor memory development have focused on density and bit cost improvements. This speed gap creates a strong demand for memory integration with MPU on the same chip. In fact, many MPUs with cycle times better than 60 ns have on-chip memories. The new trend in MPUs, (i.e., RISC architecture) is another driving force for embedded memory, especially for cache applications.[4] RISC architecture is strongly dependent on memory bandwidth, so that high-performance, non-ECL-based RISC MPUs with more than 25 to 50 MHz operation must be equipped with embedded cache on the chip.

50.2 Merits and Challenges

The main characteristics of embedded memories can be summarized as follows.[5]

On-chip Memory Interface

Advantages include:

1. Replacing off-chip drivers with smaller on-chip drivers can reduce power consumption significantly, as large board wire capacitive loads are avoided. For instance, consider a system which needs a 4-Gbyte/s bandwidth and a bus width of 256 bits. A memory system built with discrete SDRAMs (16-bit interface at 100 MHz) would require about 10 times the power of an embedded DRAM with an internal 256-bit interface.
2. Embedded memories can achieve much higher fill frequencies,[6] which is defined as the bandwidth (in Mbit/s) divided by the memory size in Mbit (i.e., the fill frequency is the number of times per second a given memory can be completely filled with new data), than discrete memories. This is because the on-chip interface can be up to 512 bits wide, whereas discrete memories are limited to 16 to 64 bits. Continuing the above example, it is possible to make a 4-Mbit embedded DRAM with a 256-bit interface. In contrast, it would take 16 discrete 4-Mbit chips (256 K×16) to achieve the same width, so the granularity of such a discrete system is 64 Mbits. But the application may only call for, say, 8 Mbits of memory.
3. As interface wire lengths can be optimized for application in embedded memories, lower propagation times and thus higher speeds are possible. In addition, noise immunity is enhanced.

Challenges and disadvantages include:

1. Although the power consumption per system decreases, the power consumption per chip may increase. Therefore, junction temperature may increase and memory retention time may decrease. However, it should be noted that memories are usually low-power devices.
2. Some sort of minimal external interface is still needed in order to test the embedded memory. The hybrid chip is neither a memory nor a logic chip. Should it be tested on a memory or logic tester, or on both?

System Integration

Advantages include:

1. Higher system integration saves board space, packages, and pins, and yields better form factors.
2. Pad-limited design may be transformed into non-pad-limited by choosing an embedded solution.
3. Better speed scalability, along with CMOS technology scaling.

Challenges and disadvantages include:

1. More expensive packages may be needed. Also, memories and logic circuits require different power supplies. Currently, the DRAM power supply (2.5 V) is less than the logic power supply (3.3 V); but this situation will reverse in the future due to the back-biasing problem in DRAMs.
2. The embedded memory process adds another technology for which libraries must be developed and characterized, macros must be ported, and design flows must be tuned.
3. Memory transistors are optimized for low leakage currents, yielding low transistor performance, whereas logic transistors are optimized for high saturation currents, yielding high leakage currents. If a compromise is not acceptable, expensive extra manufacturing steps must be added.
4. Memory processes have fewer layers of metal than do logic circuit processes. Layers can be added at the expense of fabrication cost.
5. Memory fabs are optimized for large-volume production of identical products, for high-capacity utilization and for high yield. Logic fabs, while sharing these goals, are slanted toward lower batch sizes and faster turnaround time.

Memory Size

The advantage is that:

1. Memory size can be customized and memory architecture can be optimized for dedicated applications.

Challenges and disadvantages include:

1. On the other hand, the system designer must know the exact memory requirement at the time of design. Later extensions are not possible, as there is no external memory interface. From the customer's point of view, the memory component goes from a commodity to a highly specialized part that may command premium pricing. As memory fabrication processes are quite different, second-sourcing problems abound.

50.3 Technology Integration and Applications[3,5]

The memory technologies for embedded memories have a wide variation—from ROM to RAM—as listed in Table 50.1.[3] In choosing these technologies, one of the most important figure of merits is the compatibility to logic process.

TABLE 50.1 Embedded Memory Technologies and Applications

Embedded Memory Technology	Compatibility to Logic Process	Applications
ROM	Diffusion, Vt, Contact programming High compatibility to logic process	Microcode, program storage PAL, ROM-based logic
E/E^{2}prom	High-voltage device, tunneling insulator required	Program, parameter storage, sequencer, learning machine
SRAM	6-Tr/4-Tr single/double poly load cells. Wide range of compatibility	High-speed buffers, cache memory
DRAM	Gate capacitor /4-T /planar /stacked / trench cells. Wide range of compatibility	High-density, high bit rate storage

Source: From Ref. 3.

1. Embedded ROM: ROM technology has the highest compatibility to logic process. However, its application is rather limited. PLA, or ROM-based logic design, is a well-used but rather special case of embedded ROM category. Other applications are limited to storage for microcode or well-debugged control code. A large size ROM for tables or dictionary applications may be implemented in generic ROM chips with lower bit cost.
2. Embedded EPROM/E^{2}ROM: EPROM/E^{2}PROM technology includes high-voltage devices and/or thin tunneling insulators, which require two to three additional mask steps and processing steps to logic process. Due to its unique functionality, PROM-embedded MPUs[7] are well used. To minimize process overhead, single poly E^{2}PROM cell has been developed.[8] Counterparts to this approach are piggy-back packaged EPROM/MPUs or battery-backed SRAM/MPUs. However, considering process technology innovation, on-chip PROM implementation is winning the game.
3. Embedded SRAM is one of the most frequently used memory embedded in logic chips. Major applications are high-speed on-chip buffers such as TLB, cache, register file, etc. Table 50.2 gives a comparison of some approaches for SRAM integration. A six-transistor cell approach may be the most highly compatible process, unless any special structures used in standard 6-Tr SRAMs are employed. The bit density is not very high. Polysilicon resistor load 4-Tr cells provide higher bit density with the cost of process complexity associated with additional polysilicon-layer resistors. The process complexity and storage density may be compromised to some extent using a single layer of polysilicon. In the case of a polysilicon resistor load SRAM, which may have relaxed specifications with respect to data holding current, the requirement for substrate structure to achieve good soft error immunity is more relaxed as compared to low stand-by generic SRAMs. Therefore, the TFT (thin-film transistor) load cell may not be required for several generations due to its complexity.

TABLE 50.2 Embedded SRAM Options

SRAM Cell Type	Features
CMOS 6-Tr cell	No extra process steps to logic Lower bit density (Cell size, Acell=2.0 a.u.) Wide operational margin Low data-load current
NMOS 4-Tr Polysilicon Load Cell	
-Single Poly:	1 additional step to logic process Higher density (Acell=1.25 a.u.)
-Double Poly:	3 addititional steps to logic process Higher density (Acell=1 a.u.)

Source: From Ref. 3.

4. Embedded DRAM (eDRAM) is not as widely used as SRAMs. Its high density features, however, are very attractive. Several different embedded DRAM approaches are listed in Table 50.3. A trench or stacked cell used in commodity DRAMs has the highest density, but the complexity is also high.

TABLE 50.3 Embedded DRAM Technology Options

Technology	Features
Standard DRAM Trench/Stacked Cell	High density (cell size A_{cell} = 1 a.u.)
	Large process overhead,>45% additional to logic
Planar C-plate poly-Si Cell	High density ($A_{cell>}$ = 1.3 a.u.)
	Process overhead >35% additional to logic
Gate capacitor +	Relatively high density (A_{cell} = 2.5 a.u.)
1-Tr Cell	No additional process to logic
4-Tr Cell	High speed, short cycle time
	Density is equivalent to 2-poly SRAM cell
	(equiv. to SRAM excpt refresh. A_{cell} = 5 a.u.)

Source: From Ref. 3.

The cost is seldom attractive when compared to a multi-chip approach using standard DRAM, which is the ultimate in achieving low bit cost. This type of cell is well suited for ASM (application specific memory), which will be described in the next section. A planar cell with multiple (double) polysilicon structures is also suitable for memory-rich applications.[9] A gate capacitor storage cell approach can be fully compatible to logic process providing relatively high density.[10] The four-Tr cell (4-Tr SRAM cell minus resistive load) provides the same speed and density as SRAM, but full compatibility to logic process and requires refresh operation.[11]

50.4 Design Methodology and Design Space[3,5]

Design Methodology

The design style of embedded memory should be selected according to applications. This choice is critically important for the best performance and cost balancing. Figure 50.2 shows the various design styles to implement embedded memories.

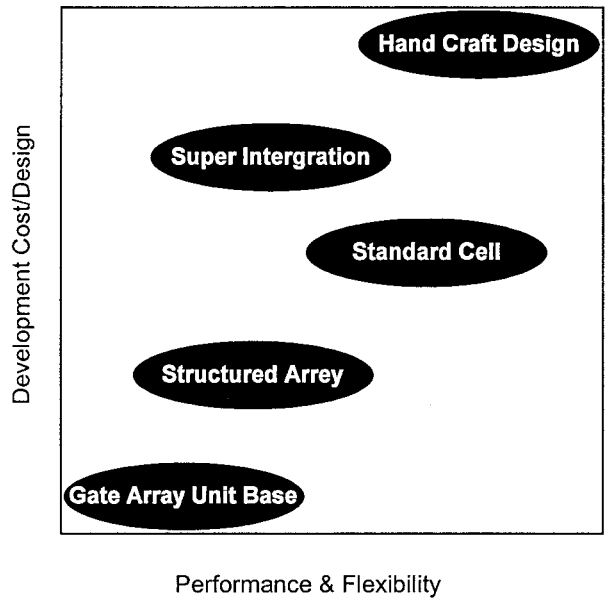

FIGURE 50.2 Various design styles for embedded memories. (From Ref. 3.)

The most primitive semi-custom design style is based on unit the memory cell. It provides high flexibility in memory architecture and short design TAT (turn around time). However, the memory density is the lowest among various approaches.

The structured array is a kind of gate array that has a dedicated memory array region in the master chip that is configurable to several variations of memory organizations by metal layer customization. Therefore, it provides relatively high density and short TAT. Configurability and fixed maximum memory area are the limitations to this approach.

The standard cell design has high flexibility to the extent that the cell library has a variety of embedded memory designs. But in many cases, new system design requires new memory architectures. The memory performance and density is high, but the mask-to-chip TAT tends to be long.

Super integration is an approach that integrates existing chip design, including I/O pads, so the design TAT is short and proven designs can be used. However, availability of memory architecture is limited and the mask-to-chip TAT is long.

Hand-craft design (does not necessarily mean the literal use of human hands, but heavy interactive design) provides the most flexibility, high performance, and high density; but design TAT is the longest. Thus, design cost is the highest so that the applications are limited to high-volume and/or high-end systems. Standard memories, well-defined ASMs, such as video memories,[12] integrated cache memories,[13] and high-performance MPU-embedded memories, are good examples.

An eDRAM (embedded DRAM) designer faces a design space that contains a number of dimensions not found in standard ASICs, some of which we will subsequently review. The designer has to choose from a wide variety of memory cell technologies which differ in the number of transistors and in performance.

Also, both DRAM technology and logic technology can serve as a starting point for embedding DRAM. Choosing a DRAM technology as the base technology will result in high memory densities but suboptimal logic performance. On the other hand, starting with logic technology will result in poor memory densities, but fast logic circuits. To some extent, one can therefore trade logic speed against logic area. Finally, it is also possible to develop a process that gives the best of both worlds—most likely at higher expense. Furthermore, the designer can trade logic area for memory area in a way heretofore impossible.

Large memories can be organized in very different ways. Free parameters include the number of memory banks, which allow the opening of different pages at the same time, the length of a single page, the word width, and the interface organization. Since eDRAM allows one to integrate SRAMs and DRAMs, the decision between on/off-chip DRAM-and SRAM/DRAM-partitioning must be made.

In particular, the following problems must be solved at the system level:

- Optimizing the memory allocation
- Optimizing the mapping of the data into memory such that the sustainable memory bandwidth approaches the peak bandwidth
- Optimizing the access scheme to minimize the latency for the memory clients and thus minimize the necessary FIFO depth

The goals are to some extent independent of whether or not the memory is embedded. However, the number of free parameters available to the system designer is much larger in an embedded solution, and the possibility of approaching the optimal solution is thus correspondingly greater. On the other hand, the complexity is also increased. It is therefore incumbent upon eDRAM suppliers to make the tradeoffs transparent and to quantize the design space into a set of understandable if slightly suboptimal solutions.

50.5 Testing and Yield[3,5]

Although embedded memory occupies a minor portion of the total chip area, the device density in the embedded memory area is generally overwhelming. Failure distribution is naturally localized at memory areas. In other words, embedded memory is a determinant of total chip yield to the extent that the memory portion has higher device density weighted by its silicon area.

For a large memory-embedded VLSI, memory redundancy is helpful to enhance the chip yield. Therefore, the embedded-memory testing, combined with the redundancy scheme, is an important issue. The implementation of means for direct measurement of embedded memory on wafer as well as in assembled samples is necessary.

In addition to off-chip measurement, on-chip measurement circuitry is essential for accurate AC evaluation and debugging. Testing DRAMs is very different from testing logic. In the following, the main points of notice are discussed.

- The fault models of DRAMs explicitly tested for are much richer. They include bit-line and word-line failures, crosstalk, retention time failures, etc.
- The test patterns and test equipment are highly specialized and complex. As DRAM test programs include a lot of waiting, DRAM test times are quite high, and test costs are a significant fraction of total cost.
- As DRAMs include redundancy, the order of testing is: (1) pre-fuse testing, (2) fuse blowing, (3) post-fuse testing. There are thus two wafer-level tests.

The implication on eDRAMs is that a high degree of parallelism is required in order to reduce test costs. This necessitates on-chip manipulation and compression of test data in order to reduce the off-chip interface width. For instance, Siemens Corp. offers a synthesizable test controller supporting algorithmic test pattern generation (ATPG) and expected-value comparison [partial built-in self test (BIST)].

Another important aspect of eDRAM testing is the target quality and reliability. If eDRAM is used for graphics applications, occasional "soft" problems, such as too short retention time of a few cells, are much more acceptable than if eDRAM is used for program data. The test concept should take this cost-reduction potential into account, ideally in conjunction with the redundancy concept.

A final aspect is that a number of business models are common in eDRAM, from foundry business to ASIC-type business. The test concept should thus support testing the memory, either from a logic tester or a memory tester, so that the customer can do memory testing on his logic tester if required.

50.6 Design Examples

Three examples of embedded memory designs are described. The first one is a flexible embedded DRAM design from Siemens Corp.[5] The second one is the embedded memories in MPEG environment from Toshiba Corp.[14] The last one is the embedded memory design for a 64-bit superscaler RISC microprocessor from Toshiba Corp. and Silicon Graphics, Inc.[15]

A Flexible Embedded DRAM Design[5]

There is an increasing gap between processor and DRAM speed: processor performance increases by 60% per year in contrast to only a 10% improvement in the DRAM core. Deep cache structures are used to alleviate this problem, albeit at the cost of increased latency, which limits the performance of many applications. Merging a microprocessor with DRAM can reduce the latency by a factor of 5 to 10, increase the bandwidth by a factor of 50 to 100, and improve the energy efficiency by a factor of 2 to 4.[16]

Developing memory is a time-consuming task and cannot be compared with a high-level based logic design methodology which allows fast design cycles. Thus, a flexible memory concept is a prerequisite for a successful application of eDRAM. Its purpose is to allow fast construction of application-specific memory blocks that are customized in terms of bandwidth, word width, memory size, and the number of memory banks, while guaranteeing first-time-right designs accompanied by all views, test programs, etc.

A powerful eDRAM approach that permits fast and safe development of embedded memory modules is described. The concept, developed by Siemens Corp. for its customers, uses a 0.24-μm technology based on its 64/256 Mbit SDRAM process.[5] Key features of the approach include:

- Two building-block sizes, 256 Kbit and 1 Mbit; memory modules with these granularities can be constructed
- Large memory modules, from 8 to 16 Mbit upwards, achieving an area efficiency of about 1 Mbit/mm^2
- Embedded memory sizes up to at least 128 Mbits
- Interface widths ranging from 16 to 512 bits per module
- Flexibility in the number of banks as well as the page length
- Different redundancy levels, in order to optimize the yield of the memory module to the specific chip
- Cycle times better than 7 ns, corresponding to clock frequencies better than 143 MHz.
- A maximum bandwidth per module of about 9 Gbyte/s
- A small, synthesizable BIST controller for the memory (see next section)
- Test programs, generated in a modular fashion

Siemens Corp. has made eDRAM since 1989 and has a number of possible applications of its eDRAM approach in the pipeline, including TV scan-rate converters, TV picture-in-picture chips, modems, speech-processing chips, hard-disk drive controllers, graphics controllers, and networking switches. These applications cover the full range of memory sizes (from a few Mbits to 128 Mbits), interface widths (from 32 to 512 bits), and clock frequencies (from 50 to 150 MHz), which demonstrates the versatility of the concept.

Embedded Memories in MPEG Environment[14]

Recently, multimedia LSIs, including MPEG decoders, have been drawing attention. The key requirements in realizing multimedia LSIs are their low-power and low-cost features. This example presents embedded memory-related techniques to achieve these requirements, which can be considered as a review of the state-of-the-art embedded memory macro techniques applicable to other logic LSIs.

Figure 50.3 shows embedded memory macros associated with the MPEG2 decoder. Most of the functional blocks use their own dedicated memory blocks and, consequently, memory macros are rather

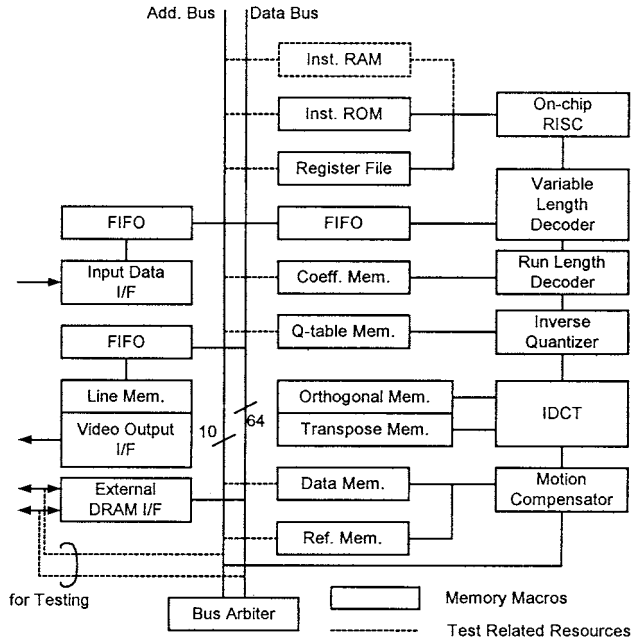

FIGURE 50.3 Block diagram of MPEG2 decoder LSI. (From Ref. 14.)

small and distributed on a chip. Memory blocks are also connected to a central address/data bus for implementing direct test mode.

An input buffer for the IDCT is shown in Fig. 50.4. Eight 16-bit data from D0 to D7 come from the inverse quantization block sequentially. The stored data should then be read out as 4-bit chunks orthogonal to the input sequence. The 4-bit data is used to address a ROM in the IDCT to realize a distributed arithmetic algorithm.

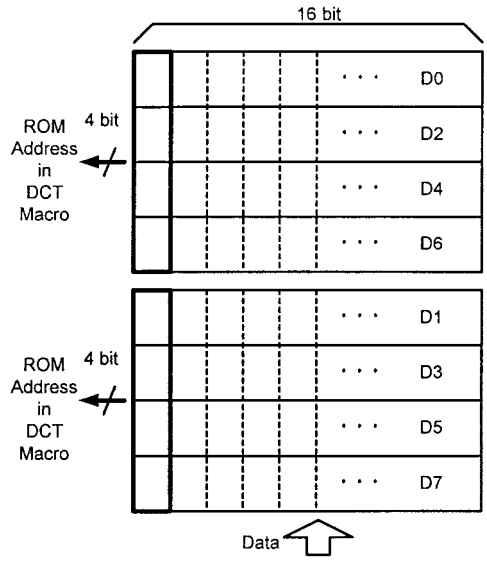

FIGURE 50.4 Input buffer structure for IDCT. (From Ref. 14.)

The circuit diagram of an orthogonal memory whose circuit diagram is shown in Fig. 50.5. It realizes the above-mentioned functionality with 50% of the area and the power that would be needed if the IDCT input buffer were built with flip-flops. In the orthogonal memory, word-lines and bit-lines run both vertically and horizontally to achieve the functionality. The macro size of the orthogonal memory is 420 μm × 760 μm, with a memory cell size of 10.8 μm × 32.0 μm.

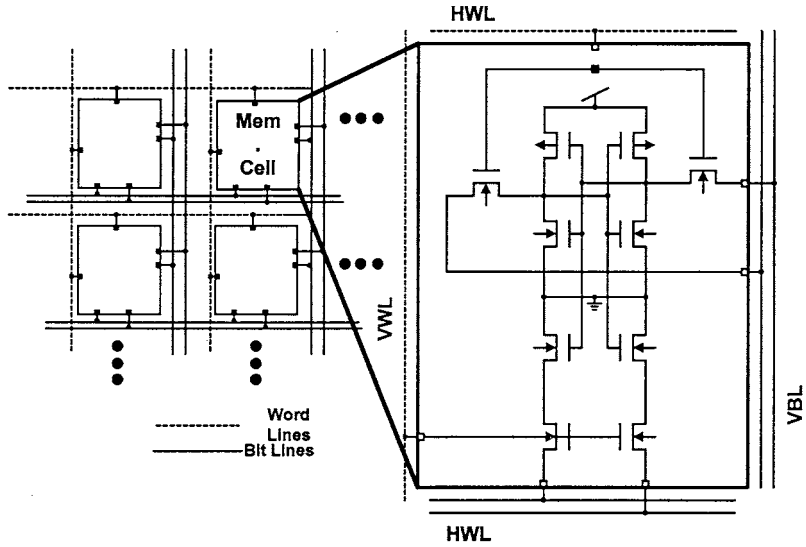

FIGURE 50.5 Circuit diagram of orthogonal memory.(From Ref. 14.)

FIFOs and other dual-port memories are designed using a single-port RAM operated twice in one clock cycle to reduce area, as shown in Fig. 50.6. A dual-port memory cell is twice as large as a single-port memory cell.

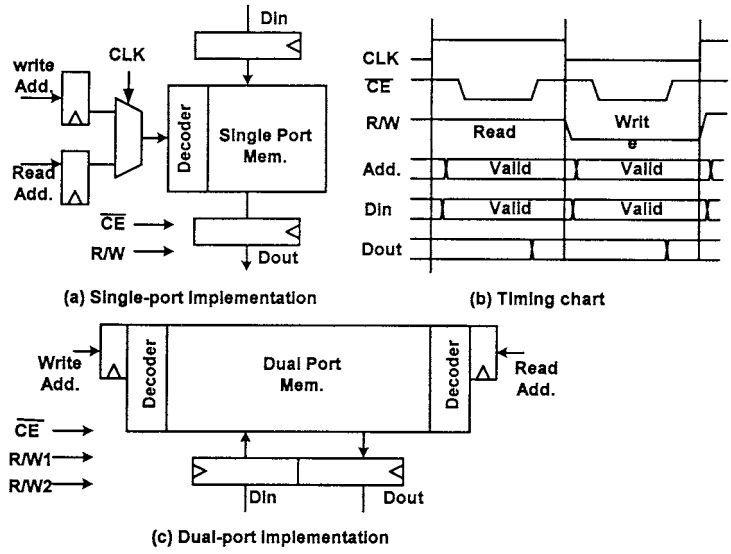

FIGURE 50.6 Realizing dual-port memory with a single-port memory (FIFO case). (From Ref. 14.)

All memory blocks are synchronous self-timed macros and contain address pipeline latches. Otherwise, the timing design needs more time, since the lengths of the interconnections between latches and a decoder vary from bit to bit. Memory power management is carried out using a Memory Macro Enable signal when a memory macro is not accessed, which reduces the total memory power to 60%.

Flip-flop (F/F) is one of the memory elements in logic LSIs. Since digital video LSIs tend to employ several thousand F/Fs on a chip, the design of the F/F is crucial for small area and low power. The optimized F/F with hold capability is shown in Fig. 50.7. Due to the optimized smaller transistor sizes, especially for clock input transistors, and a minimized layout accomodating a multiplexer and a D-F/F in one cell, 40% smaller power and area are realized compared with a normal ASIC F/F.

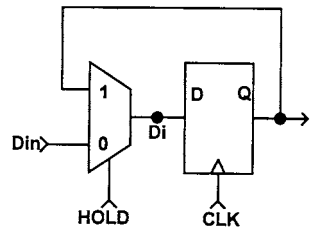

FIGURE 50.7 Optimized flip-flop. (From Ref. 14.)

Establishing full testability of on-chip memories without much overhead is another important issue. Table 50.4 compares three on-chip memory test strategies: a BIST (Built-In Self Test), a scan test, and a direct test. The direct test mode, where all memories can be directly accessed from outside in a test mode, is implemented because of its inherent small area. In a test mode, DRAM interface pads are turned into test pins and can access to each memory block through internal buses, as shown in Figs. 50.3 and 50.8.

TABLE 50.4 Comparison of Various Memory Test Strategies

Items	Direct	Scan	BIST
Area	○	Δ	X
Test time	○	X	○
Pattern control	○	○	X
Bus capacitance	Δ	○	○
At-speed test	○	X	○

The present MPEG2 decoder contains a RISC whose firmware is stored in an on-chip ROM. In order to make the debugging easy and extensive, an instruction RAM is put outside the pads in parallel to the instruction ROM and activated by an Al-masterslice in an initial debugging stage as shown in Fig. 50.9. For a sample chip mounted in a plastic package, the instruction RAM is cut out by a scribe line. This scheme enables extensive debugging and early sampling at the same time for firmware-ROM embedded LSIs.

Embedded Memory Design for a 64-bit Superscaler RISC Microprocessor[15]

High-performance embedded memory is a key component in VLSI systems because of the high-speed and wide bus width capability eliminating inter-chip communication. In addition, multi-ported buffer memories are often demanded on a chip. Furthermore, a dedicated memory architecture that meets the special constraint of the system can neatly reduce the system critical path.

On the other hand, there are several issues in embedded RAM implementation. The specialty or variety of the memories could increase design cost and chip cost. Reading very wide data causes large power dissipation. Test time of the chip could be increased because of the large memory. Therefore, design efficiency, careful power bus design, and careful design for testability are necessary.

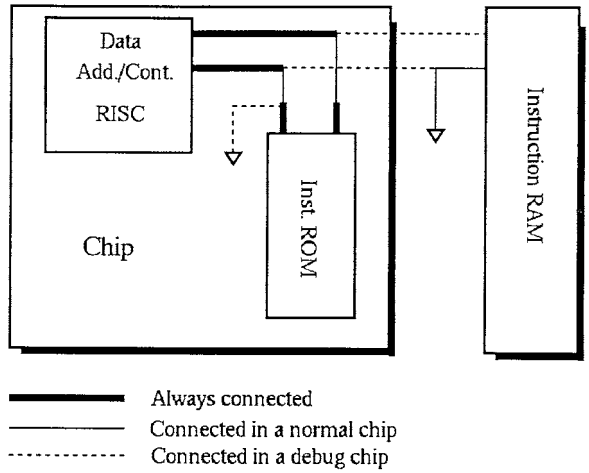

FIGURE 50.9 Instruction RAM masterslice for code debugging. (From Ref. 14.)

TFP is a high-speed and highly concurrent 64-bit superscaler RISC microprocessor, which can issue up to four instructions per cycle.[17,18] Very wide bandwidth of on-chip caches is vital in this architecture. The design of the embedded RAMs, especially on caches and TLB, is reported.

The TFP integer unit (IU) chip implements two integer ALU pipelines and two load/store pipelines. The block diagram is shown in Fig. 50.10. A five-stage pipeline is shown in Fig. 50.11. In the TFP IU chip, RAM blocks occupy a dominant part of the real estate. The die size is 17.3 mm × 17.3 mm. In addition to other caches, TLB, and register file, the chip also includes two buffer queues: SAQ (store address queue) and FPQ (floating point queue). Seventy-one percent of all overall 2.6 million transistors are used for memory cells. Transistor counts of each block are listed in Table 50.5.

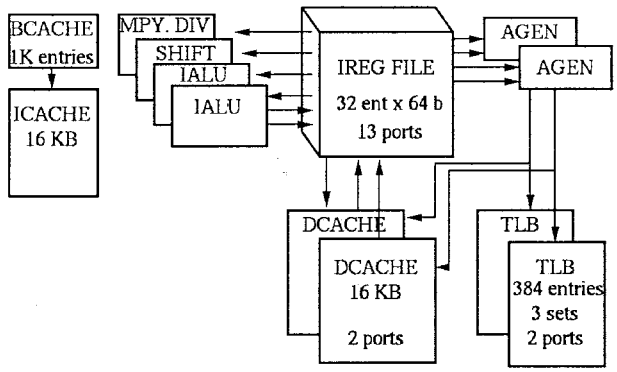

FIGURE 50.10 Block diagram of TFP IU. (From Ref. 15.)

The first generation of TFP chip was fabricated using Toshiba's high-speed 0.8 μm CMOS technology: double poly-Si, triple metal, and triple well. A deep n-well was used in PLL and cache cell arrays in order to decouple these circuits from the noisy substrate or power line of the CMOS logic part. The chip operates up to 75 MHz at 3.1 V and 70°C, and the peak performance reaches 300 MIPS.

Features of each embedded memory are summarized in Table 50.6. Instruction, branch, and data caches are direct mapped because of the faster access time. High-resistive poly-Si load cells are used for these caches since the packing density is crucial for the performance.

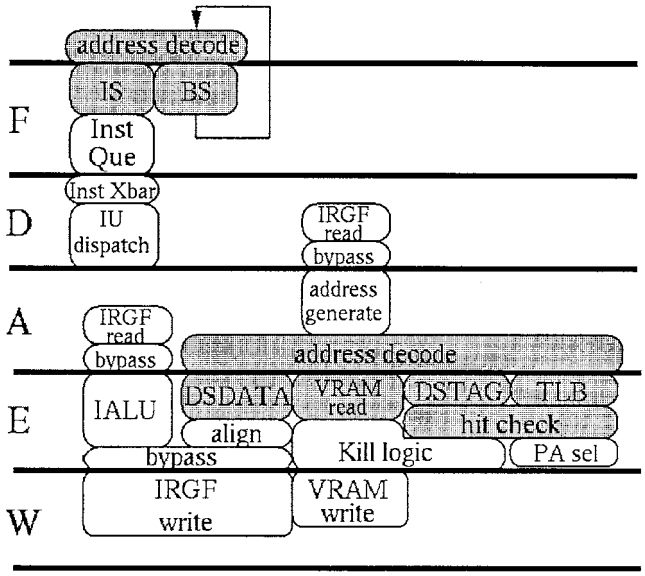

FIGURE 50.11 TFP IU pipelining. (From Ref. 15.)

TABLE 50.5 Transistor Counts

Block	Transistor Count	Ratio (%)
Cache, TLB memory cell	1,761,040	67.02%
RegFile, FPQ, SAQ memory cells	106,624	4.06%
Custom block without memory cell	209,218	19.38%
Random blocks	250,621	9.54%
Total	2,627,503	100.00%

Source: Ref. 15.

Instruction cache (ICACHE) is 16 KB of virtual address memory. It provides four instructions (128 bit wide) per cycle. Branch cache (BCACHE) contains branch target address with one flag bit to indicate a predicted branch. BCACHE contains 1-K entries and is virtually indexed in parallel with ICACHE.

Data cache (DCACHE) is 16 KB, dual ported, and supports two independent memory instructions (two loads, or one load and one store) per cycle. Total memory bandwidth of ICACHE and DCACHE reaches 2.4 GB/s at 75 MHz. Floating point load/store data bypass DCACHE and go directly to bigger external global cache.[17,19] DCACHE is virtually indexed and physically tagged.

TLB is dual ported, three-set-associative memory containing 384 entries. A unique address comparison scheme is employed here, which will be described in the following section. It supports several different page sizes, ranging from 4 KB to 16 MB. TLB is indexed by low-order 7 bits of virtual page number (VPN). The index is hashed by exclusive-OR with a low-order ASID (address space identifier) so that many processes can co-exist in TLB at one time.

Since several different RAMs are used in TFP chip, the design efficiency is important. Consistent circuit schemes are used for each of the caches and TLB RAMs. Layout is started from the block that has the tightest area restriction, and the created layout modules are exported to other blocks with small modification.

The basic block diagram of cache blocks is shown in Fig. 50.12, and timing diagram is shown in Fig. 50.13. Unlike a register file or other smaller queue buffers, these blocks employ dual-railed bit-lines. To achieve 75-MHz operation in the worst-case condition, it should operate at 110 MHz under typical conditions. In this targeted 9-ns cycle time, address generation is done about 3 ns before the end of the

TABLE 50.6 Summary of Embedded RAM Features

Block	Feature	Cell Size
Instruction cache	16 KB, direct mapped	Hi-R cell
(ICACHE)	32 B line size Vitually addressed 4 instructions per cycle	6.75 μm × 9 μm
Branch Cache (BCACHE)	1 K entries, direct mapped	Hi-R cell 6.75 μm × 9 μm
Data cache	2-ported, 16 KB, direct mapped 32 B line size Virtually indexed and physically tagged Write through	Hi-R cell 12.6 μm × 9.45 μm
Valid RAM (VRAM)	One valid bit for 32 b word 4-ported (2 read, 2 write) 34.3μm × 18.9μm	CMOS cell
TLB	3 sets, 384 entries 2-ported Index is hashed by ASID Supported page size: 4K,8K,16K,64K,1M,4,16M	CMOS cell 21.2 μm ×13.7 μm
Register file	64 b × 32 entries 13-ported (9 read, 4 write)	CMOS cell 59.5 μm × 42.8 μm
Floating point queue (FPQ)	Dispatches 4 floating-point instructions per cycle 3-ported (2 read, 1 write) 16 entries	16.1 μm × 40.7 μm
Store address queue (SAQ)	Content addressable 3-ported (1 read, 1 write, 1 compare) 32 entries, 2 banked	CMOS cell 35.1 μm × 17.1 μm

Source: Ref. 15.

cycle, as shown in Fig. 50.11. To take advantage of this big address set-up time, address is received by transparent latch: TLAT_N (transparent while clock is low) instead of flip-flop. Thus, decode is started as soon as address generation is done and is finished before the end of the cycle. Another transparent latch—TLAT_P (transparent while clock is high)—is placed after the sense amplifier and it holds read data while the clock is low.

Word-line (WL) is enabled while clock is high. Since the decode is already finished, WL can be driven to "high" as fast as possible. The sense amplifier is enabled (SAE) with a certain delay after the word-line. The paired current-mirror sense amplifier is chosen since it provides good performance without overly strict SAE timing. Bit-line is precharged and equalized while the clock is low. The clock-to-data delay of DCACHE, which is the biggest array, is 3.7 ns under typical conditions: clock-to-WL is 0.9 ns and WL-to-data is 2.8 ns. Since on-chip PLL provides 50% duty clock, timing pulses such as SAE or WE (write enable) are created from system clock by delaying the positive edge and negative edge appropriately.

As both word-line and sense amplifier are enabled in just half the time of one cycle, the current dissipation is reduced by half. However, the power dissipation and current spike are still an issue because the read/write data width is extremely large. Robust power bus matrix is applied in the cache and TLB blocks so that the dc voltage drop at the worst place is limited to 60 mV inside the block.

From a minimum cycle time viewpoint, write is more critical than read because write needs bigger bit-line swing, and the bit-line must be precharged before the next read. To speed up precharge time,

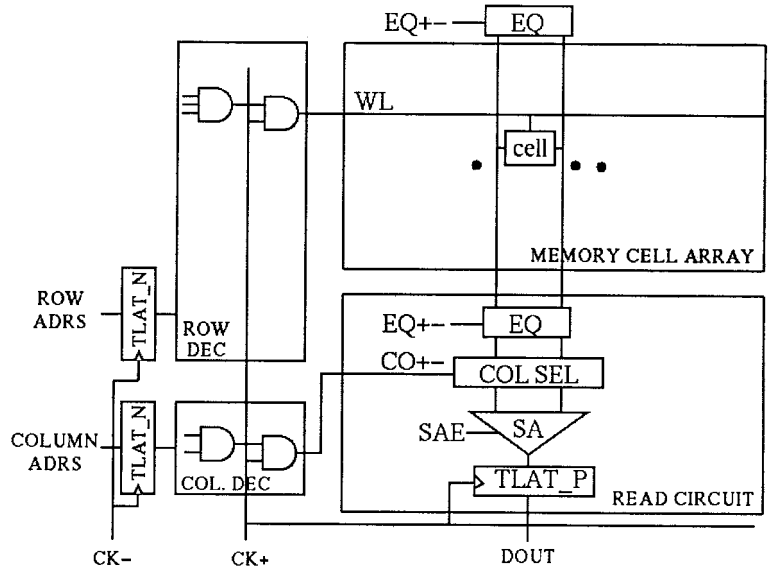

FIGURE 50.12 Basic RAM block diagram. (From Ref. 15)

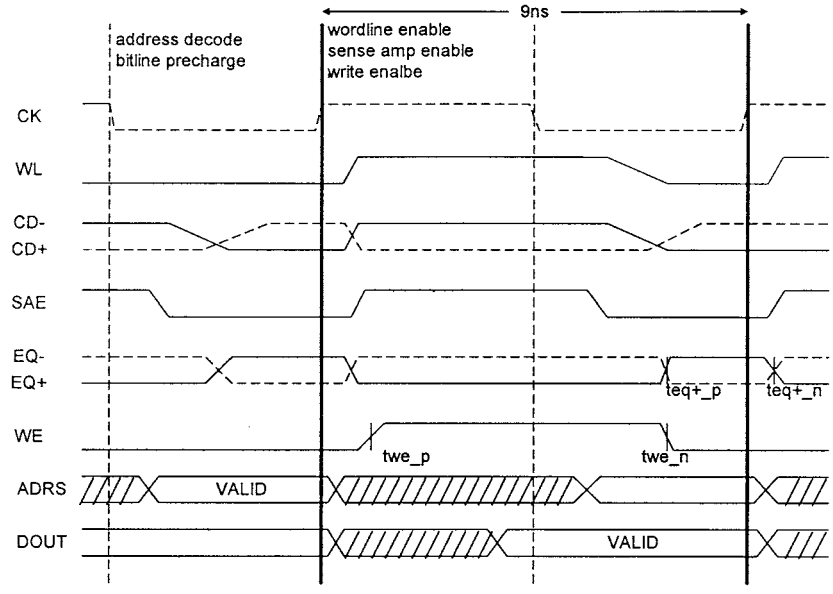

FIGURE 50.13 RAM timing diagram. (From Ref. 15)

precharge circuitry is placed on both the top and bottom of the bit-line. In addition, the write circuitry dedicated to cache-refill is placed on the top side of DCACHE and ICACHE to minimize the wire delay of the write data from input pad. Write data bypass selector is implemented so that the write data is available as read data in the same cycle with no timing penalty.

Virtual to physical address translation and following cache hit check are almost always one of the critical paths in a microprocessor. This is because the cache tag comparison has to wait for the VTLB (RAM that contains virtual address tag) search operation and the following physical address selection from PTLB (RAM that contains physical address).[20] A timing example of the conventional scheme is

shown in Fig. 50.14. In TFP, the DCACHE tag is directly compared with all the three sets of PTLB data in parallel—which are merely candidates of physical address at this stage—without waiting for the VTLB hit results. The block diagram and timing are shown in Figs. 50.15 and 50.16. By the time this hit check of the cache tag is done, VTLB hit results are just ready and they select the PTLB hit result immediately. The "ePmatch" signal in Fig. 50.16 is the overall cache hit result. Although three times more comparators are needed, this scheme saves about 2.8 ns as compared to the conventional one.

In TLB, sense amplifiers of each port are separately placed on the top and bottom of the array to mitigate the tight layout pitch of the circuit. A large amount of wire creates problems around VTLB,

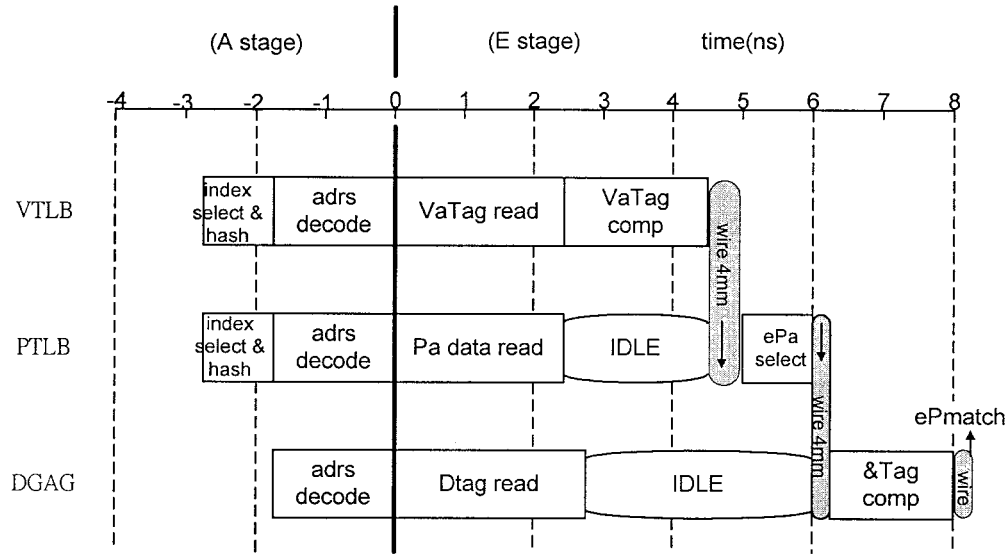

FIGURE 50.14 Conventional physical cache hit check. (From Ref. 15.)

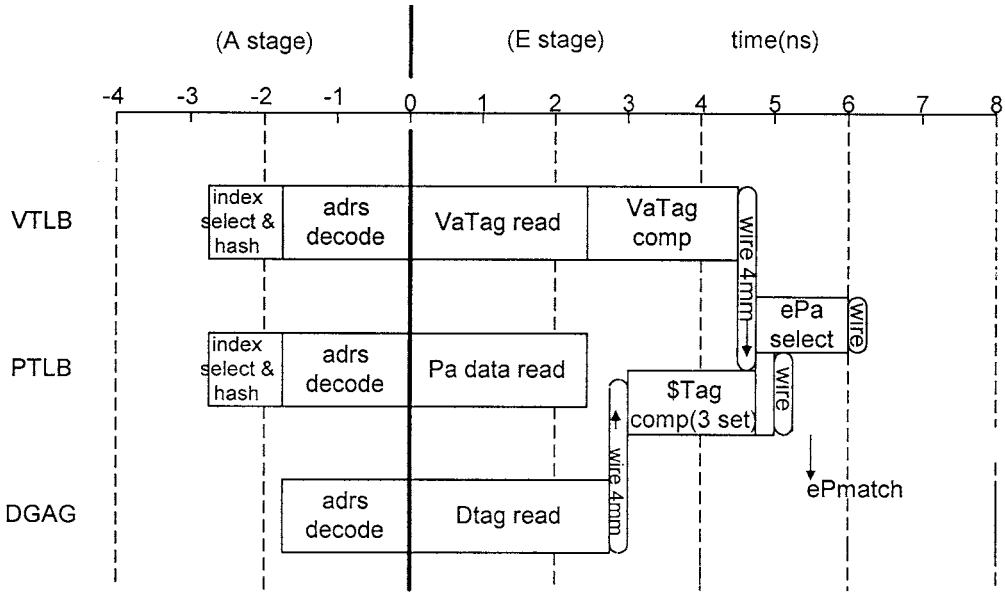

FIGURE 50.15 TFP physical cache hit check. (From Ref. 15.)

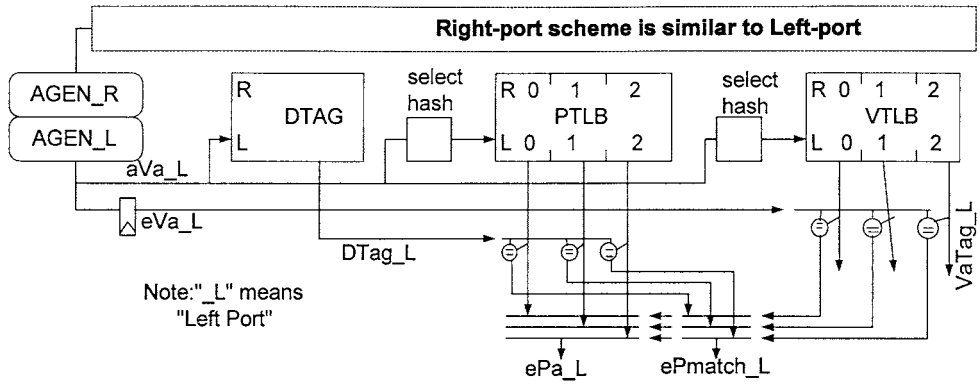

FIGURE 50.16 Block diagram of TLB and DTAG. (From Ref. 15.)

PTLB, and DTAG (DCACHE tag RAM) from both layout and critical path viewpoints. This was solved by piling them to build a data path (APATH: Address Data Path) by making the most of the metal-3 vertical interconnection. Although this metal-3 signal line runs over TLB arrays in parallel with the metal-1 bit-line, the TLB access time is not degraded since horizontal metal-2 word-line shields the bit-line from the coupling noise. The data fields of three sets are scrambled to make the data path design tidy; 39-bit (in VTLB) and 28-bit (in PTLB) comparators of each set consist of optimized AND-tree. Wired-OR type comparators are rejected because a longer wired-OR node in this array configuration would have a speed penalty.

As TFP supports different page sizes, VPN and PFN (page frame number) fields change, depending on the page size. The index and comparison field of TLB are thus made selectable by control signals.

32-bit DCACHE data are qualified by one valid bit. A valid bit needs the read-modify-write operation based on the cache hit results. However, this is not realized in one cycle access because of tight timing. Therefore, two write ports are added to valid bit and write access is moved to the next cycle: the W-stage. The write data bypass selector is essential here to avoid data hazard.

To minimize the hardware overhead of the VRAM (valid bit RAM) row decoder, two schemes are applied. First, row decoders of read ports are shared with DCACHE by pitch-matching one VRAM cell height with two DCACHE cells. Second, write word-line drivers are made of shift registers that have read word-lines as inputs. The schematic is shown in Fig. 50.17.

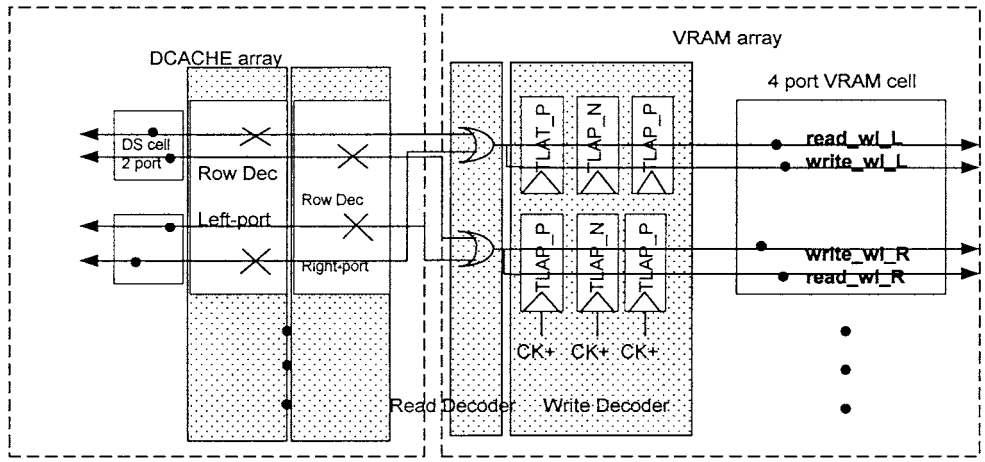

FIGURE 50.17 VRAM row decoder. (From Ref. 15.)

Although the best way to verify the whole chip layout is to do DRC (design rule check) and LVS (layout versus schematic) check that includes all sections and the chip, it was not possible in TFP since the transistor count is too large for CAD tools to handle. Thus, it was necessary to exclude a large part of the memory cells from the verification flow. To avoid possible mistakes around the boundary of the memory cell array, a few rows and columns were sometimes retained on each of the four sides of a cell array. In the case when this breaks signal continuity, text is added on the top level of the layout to make a virtual connection, as shown in Fig. 50.18. These works are basically handled by CAD software plus small programming without editing the layout by hand.

Direct testing of large on-chip memory is highly preferable in VLSI because of faster test time and complete test coverage. TFP IU defines cache direct test in JTAG test mode, in which cache address, data, write enable, and select signals are directly controlled from the outside. Thus, very straightforward evaluation is possible. Utilizing 64-bit, general-purpose bus that runs across the chip, the additional hardware for the data transfer is minimized.

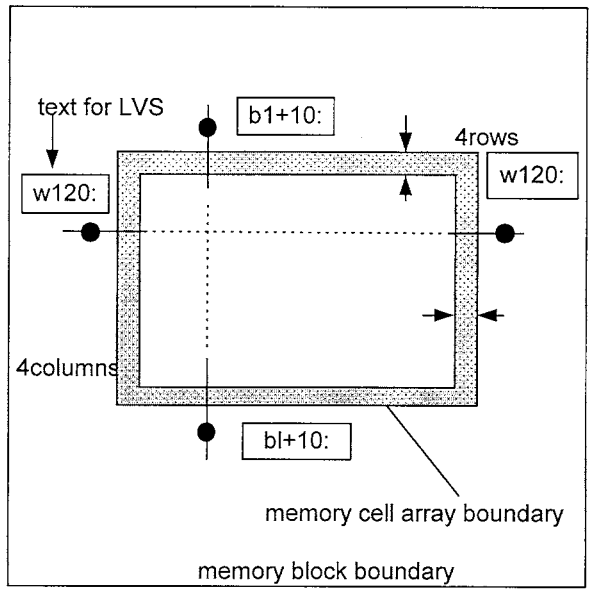

FIGURE 50.18 RAM layout verification. (From Ref. 15.)

Since defect density is a function of device density and device area, large on-chip memory can be a determinant of total chip yield. Raising embedded memory yield can directly lead to the rise of the chip yield. Failure symptoms of the caches have been analyzed by making a fail-bit-map, and this has been fed back to the fabrication process.

51.1 Introduction

In past decades, owing to process simplicity, stacked-gate memory devices have become the mainstream in the non-volatile memory market. This chapter is divided into seven sections to review the evolution of stacked-gate memory, device operation, device structures, memory array architectures, and flash memory system. In Section 51.2, a short historical review of stacked-gate memory device and the current flash device are described. Following this, the current–voltage characteristics, charge injection/ejection mechanisms, and the write/erase configurations are mentioned in detail. Based on the descriptions of device operation, some modifications in the memory device structure to improve performance are addressed in Section 51.4. Following the introductions of single memory device cells, descriptions of the memory array architectures are employed in Section 51.6 to facilitate the understanding of device operation. In Section 51.7, a table lists the history of flash memory development over the past decade. Finally, Section 51.8 is dedicated to the issues related to implementation of a flash memory system.

51.2 Review of Stacked-Gate Non-Volatile Memory

The concept of a memory device with a floating gate was first proposed by Kahng and Sze in 1967.[1] The suggested device structure was started from a basic MOS structure. As shown in Fig. 51.1, the insulator in the conventional MOS structure was replaced with a thin oxide layer (I1), an isolated metal layer (M1), and a thick oxide layer (I2). These stacked oxide and metal layers led to the so-called MIMIS structure. In this

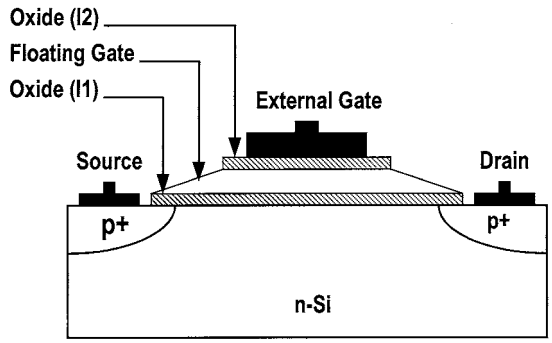

FIGURE 51.1 Schematic cross-section of MIMIS structure.

device structure, the first insulator layer I1 had to be thin enough to allow electrons injected into the floating gate M1. Besides, the second insulator layer I2 is required to be thick enough to avoid the loss of stored charge during charge injection operation. During electron injection operation, a high electric field (~10 MV/cm) enables the electron tunneling through I1 directly, and the injected electrons are captured in the floating gate and thus change the I–V characteristics. On the other hand, a negative voltage is applied at the external gate to remove the stored electrons during the discharge operation by the same direct tunneling mechanism. Owing to the very thin oxide layer I1, the defects in the oxide and the back tunneling phenomena lead to a poor charge retention capability. However, this MIMIS structure demonstrated, for the first time, the possibility of implementation of non-volatile memory device based on the MOS structure.

After MIMIS was invented, several improvements were proposed to enhance the performance of MIMIS. One was the utilization of dielectric material with a large amount of electron-trapping centers as a replacement of the floating metal gate.[2,3] The injected electrons would be trapped in the bulk and also at the interface traps in the dielectric material, such as silicon nitride (Si_3N_4), Al_2O_3, Ta_2O_5. The device structure with these insulating layers as electron storage node was referred as a *charge trapping device*. Another solution to improve the oxide quality and charge retention capability was the increase of the thickness of the tunnel dielectric I1. This device structure based on the MIMIS structure but with a thicker insulating layer was also referred as *floating gate device*.

In the initial development period, the charge trapping devices had several advantages compared with floating gate devices. They allowed high density, good write/erase endurance capability, and fast programming/erase time. However, the main obstacle for the wide application in charge trapping devices was the poorer charge retention capability than in floating gate devices. On the other hand, the floating gate devices showed a major drawback of not being electrically erasable. Therefore, the erase operation had to be preceded by the time-consuming UV-irradiation process. However, the floating gate devices had been applied successfully because of the following advantages and improvements. First, the floating gate devices were compatible with the standard double polysilicon NMOS process and then became compatible with CMOS process after minor modification. Second, an excellent charge retention capability was obtained because of the thicker gate oxide. Besides, the thicker oxide leads to a relieved gate disturbance issue. Furthermore, the development of electrical erase operation technique during the 1980s made the write/erase operation easier and more efficient. Based on these reasons, most commercial non-volatile memory companies focused their research efforts on the floating gate devices. Therefore, floating gate devices have become the mainstream product in the non-volatile market.

A high operation voltage is unavoidable when the thickness of oxide I1 increases in MIMIS structure. Thus, another way to achieve electron injection was necessary to make the injection operation more efficient. In 1971, the introduction of a memory element with avalanche injection scheme was demonstrated.[4] This first operating floating gate device — named Floating gate Avalanche injection MOS (FAMOS), as shown in Fig. 51.2 — was a p-channel MOSFET in which no electrical contact was made

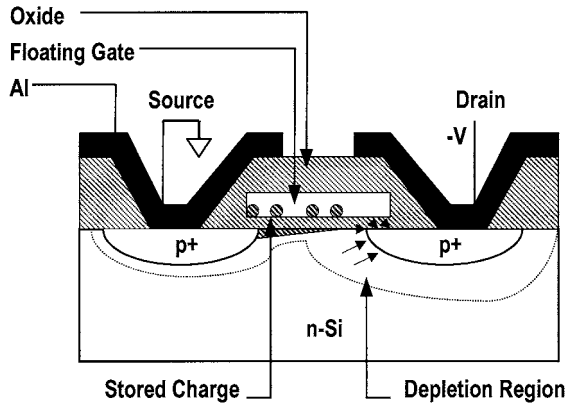

FIGURE 51.2 Schematic cross-section of FAMOS structure.

to the silicon gate. The injection operation of the FAMOS memory structure is initiated by avalanche phenomena in the drain region underneath the gate. The electron-hole pair generation is caused by applying a high reversed bias at the drain/substrate junction. Some of generated electrons drift toward the floating gate by the positive oxide field which is induced by the capacitive coupling between floating gate and drain. However, the inefficient injection process was the major drawback in this device structure.

In order to improve the injection efficiency, the Stacked-gate Avalanche injection MOS (SAMOS) with an external gate was proposed, as shown in Fig. 51.3. Owing to the additional gate bias, the programming speed was improved by an increased drift velocity of electrons in the oxide and the field induced energy barrier lowering at the Si–SiO_2, interface. Besides, by employing this control gate, the electrical erase operation became possible by building up a high electric field across the inter-polysilicon dielectric.

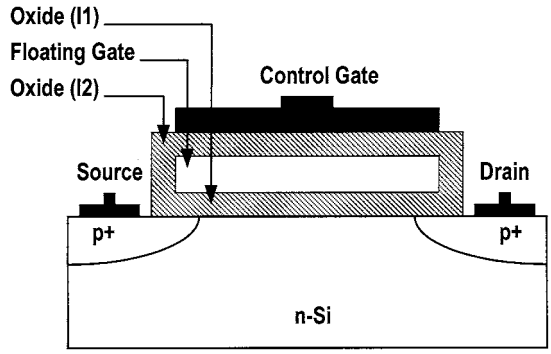

FIGURE 51.3 Schematic cross-section of p-channel SAMOS structure.

All the stacked-gate devices mentioned above are p-channel devices, which utilize avalanche injection scheme. However, if a smaller access time is required for the read operation, n-channel devices are necessary because of higher channel carrier mobility. Since the avalanche injection in an n-channel device is based on the hole injection, other injection mechanisms are required for n-channel stacked-gate memory cells. There are two major injection schemes for the n-channel memory cell. One is the channel hot electron injection (CHEI) and the other one is high electric field (Fowler-Nordheim, FN) tunneling mechanism. These two operation schemes lead to different device structures. The memory devices using

the CHEI scheme allow a thicker gate oxide, whereas the memory devices using FN tunneling scheme require thinner oxide. In 1980, researches at Intel Corp. proposed the FLOTOX (FLOating gate Tunnel OXide) device, as shown in Fig. 51.4, in which the electrons are injected into and ejected from the floating gate through a high-quality thin oxide region outside the channel region.[5] The FLOTOX cell must be isolated by a select transistor to avoid the over-erase issue and therefore it consists of two transistors. Although this limits the density of such memory in comparison with EPROM and the Flash cell, it enables the byte-by-byte erase and reprogramming operation without having to erase the entire chip or sector. Based on this, the FLOTOX cell is suitable for the applications in which low density, high reliability, and non-volatile memory are required.

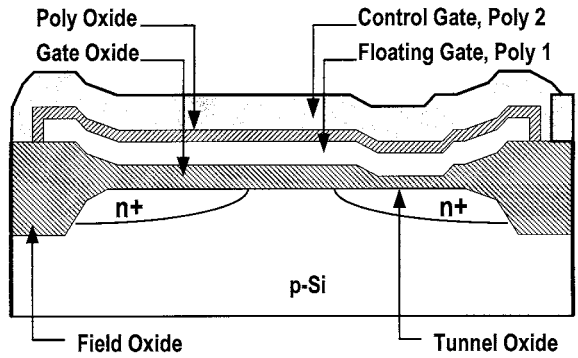

FIGURE 51.4 Schematic cross-section of FLOTOX structure.

Another modification of operation from EEPROM is the erase of the whole memory chip instead of erasing a byte. By using an electrical erase signal, all cells in the memory chip, which is called a Flash device, are erased simultaneously. The first Flash memory cell was proposed and realized in a three-layer polysilicon technology by Toshiba Corp.[6] The first polysilicon is used as the erase gate, the second polysilicon as the floating gate, and the third polysilicon as the control gate, as shown in Fig. 51.5(c). In this device, programming operation is performed by channel hot electron injection and erase operation is carried out by extracting the stored electron from the floating gate to erase gate for all the bits at the same time.

51.3 Basic Flash Memory Device Structures

n-Channel Flash Cell

Based on the concept proposed by researchers at Toshiba Corp., the developments in Flash memory have burgeoned since the end of 1980s. There are three categories of device structures based on the n-channel MOS structure. Besides the triple polysilicon Flash cell, the most popular Flash cell structures are the ETOX cell and the split-gate cell.

In 1985, Mukherjee et. al.[7,9] proposed a source-erase Flash cell called the ETOX (EPROM with Tunnel OXide). This cell structure is the same as that of the UV-EPROM, as shown in Fig. 51.6, but with a thin tunnel oxide layer. The cell is programmed by CHEI and erased by applying a high voltage at the source terminal.

A split-gate memory cell was proposed by Samachisa et. al. in 1987.[8] This split-gate Flash cell with a drain-erase type has two polysilicon layers, as shown in Fig. 51.7. The cell can be regarded as two transistors in series. One is a floating gate memory, which is similar to an EPROM cell; the other, which is used as a select transistor, is an enhancement transistor controlled by the control gate.

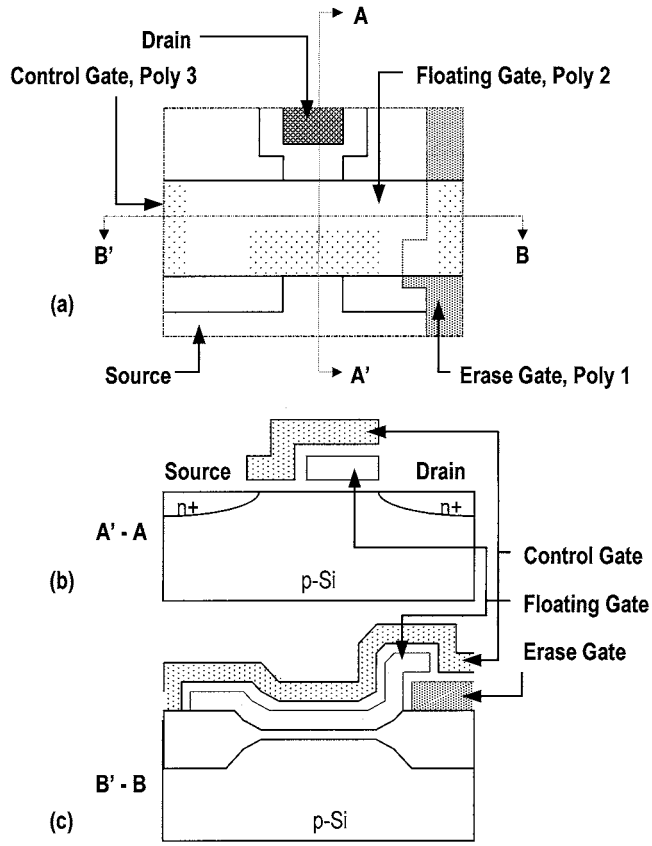

FIGURE 51.5 Tripe-gate Flash memory structure proposed by Toshiba: (a) layout of the cell; (b) cross-section along the channel length, and (c) cross-section along the channel width.

p-Channel Flash Cell

The p-channel Flash memory cell was first proposed by Hsu et. al. in 1992.[9] Recently, several studies have been done on this device structure.[10–13] This Flash cell structure is similar to the ETOX cell but with p-channel. The erase mechanism is still by FN tunneling. As to the electron injection, there are two injection schemes that can be employed: CHEI and BBHE (Band-to-Band tunneling induced Hot Electron injection).[11] The p-channel Flash cell features high electron injection efficiency, scalability, immunity to the hot hole injection and reduced oxide field during programming. Based on these advantages, the p-channel Flash memory cell seems to reveal a high potential for future low-power Flash applications.

51.4 Device Operations

Device Characteristics

Capacitive Coupling Effects and Coupling Ratios

The I–V characteristics of stacked gate can be derived from the MOSFET characteristics accompanying with the capacitive-coupling factors. For a stacked-gate device, the device structure can be depicted as an equivalent capacitive circuit, as shown in Fig. 51.8. Owing to being isolated from other terminals, the potential of floating gate, V_{FG}, can be expressed as not only the total contributions from four terminals of the device, but also from the contribution of the stored charge in the floating gate:

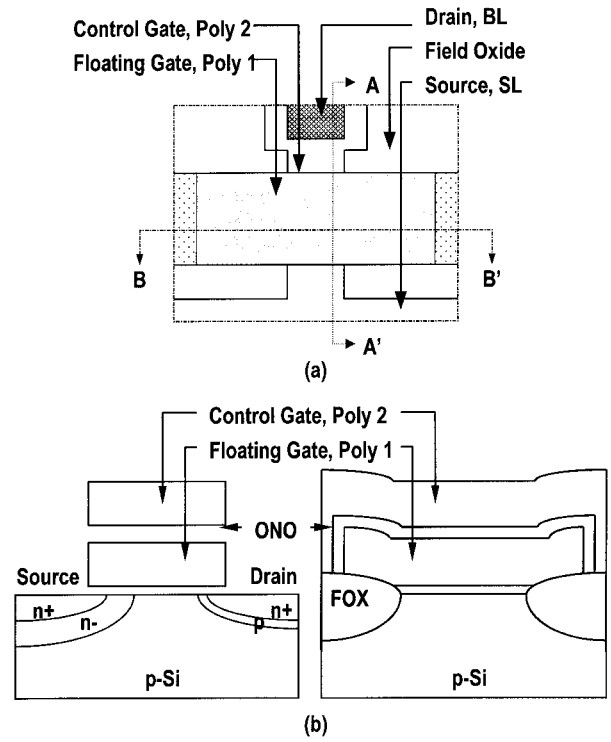

FIGURE 51.6 Schematic cross-section of ETOX-type Flash memory cell: (a) the top view of the cell, and (b) the cross-section along the channel length and channel width.

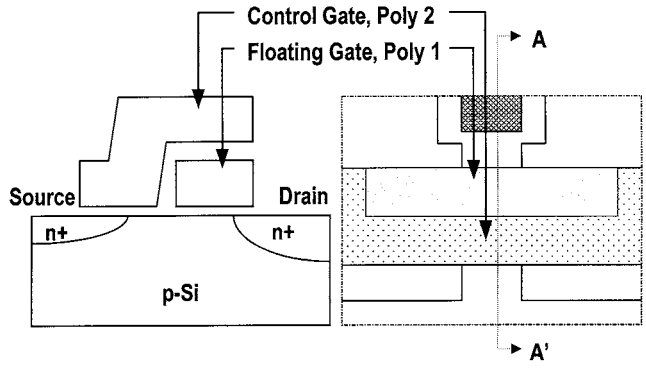

FIGURE 51.7 Schematic cross-section of split-gate Flash memory cell.

$$V_{FG} = \frac{C_{FG}}{C_{TOTAL}} V_G + \frac{C_B}{C_{TOTAL}} V_{WELL} + \frac{C_D}{C_{TOTAL}} V_D + \frac{C_S}{C_{TOTAL}} V_S - \frac{Q}{C_{TOTAL}} \tag{51.1}$$

$$C_{TOTAL} = C_{FG} + C_B + C_D + C_S \tag{51.2}$$

and

$$\alpha_{FG} = \frac{C_{FG}}{C_{TOTAL}}, \alpha_B = \frac{C_B}{C_{TOTAL}}, \alpha_D = \frac{C_D}{C_{TOTAL}}, \alpha_S = \frac{C_S}{C_{TOTAL}} \tag{51.3}$$

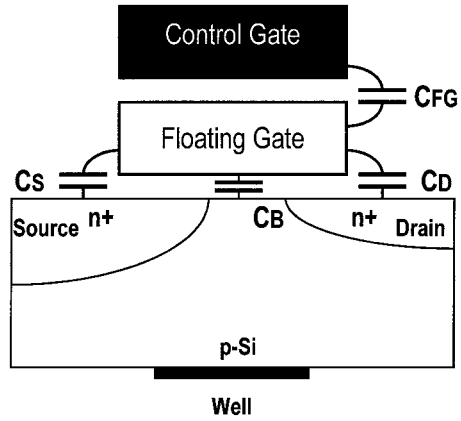

FIGURE 51.8 Schematic cross-section of stacked-gate device and its equivalent capacitive model.

where C_{FG}, C_B, C_D, and C_S are the capacitances between floating gate and control gate, well terminal, drain terminal, and source terminal, respectively. Q is the charge stored on the floating gate, and α_{FG}, α_B, α_D, α_S are the gate, well, drain, and source coupling ratios, respectively.

Current–Voltage Characteristics

The current–voltage relationship in a stacked-gate device has been studied and modeled in detail.[14,15] By employing Eq. 51.1 for general I–V characteristics in MOSFETs, a simplified I-V relationship in stacked gate devices can be obtained:

$$\begin{aligned} V_{FG} &= \frac{C_{FG}}{C_{TOTAL}} V_G + \frac{C_D}{C_{TOTAL}} V_D - \frac{Q}{C_{TOTAL}} \\ &= \alpha_{FG}\left(V_G + \frac{C_D}{C_{FG}} V_D - \frac{Q}{C_{FG}} \right) \\ \text{for } V_S &= V_{WELL} = 0\,V \end{aligned} \tag{51.4}$$

In the linear region,

$$\begin{aligned} I_D &= \frac{\mu n \cdot C_{ox} \cdot W}{L}\left(V_{FG} - V_{TH} - \frac{V_D}{2} \right) \cdot V_D \\ &= \frac{\alpha_{FG} \cdot \mu n \cdot C_{ox} \cdot W}{L}\left[V_G + \left(\frac{C_D}{C_{FG}} - \frac{1}{2} \right) V_D - \frac{Q}{C_{FG}} - \frac{V_{TH}}{\alpha_{FG}} \right] V_D \end{aligned} \tag{51.5}$$

And also in saturation region,

$$\begin{aligned} I_D &= \frac{\mu n \cdot C_{ox} \cdot W}{2L} (V_{FG} - V_{TH})^2 \\ &= \frac{\alpha_{FG}{}^2 \cdot \mu n \cdot C_{ox} \cdot W}{2L}\left(V_G + \frac{C_D}{C_{FG}} V_D - \frac{Q}{C_{FG}} - \frac{V_{TH}}{\alpha_{FG}} \right)^2 \end{aligned} \tag{51.6}$$

From Eqs. 51.5 and 51.6, it is clearly demonstrated that the stacked-gate device suffers from drain bias coupling during operation. An increase of drain current can be observed, both in output characteristics and transfer characteristics. Fig. 51.9 shows the subthreshold characteristics of both the n-channel and p-channel Flash devices. An obvious increase of the subthreshold current can be observed while the drain

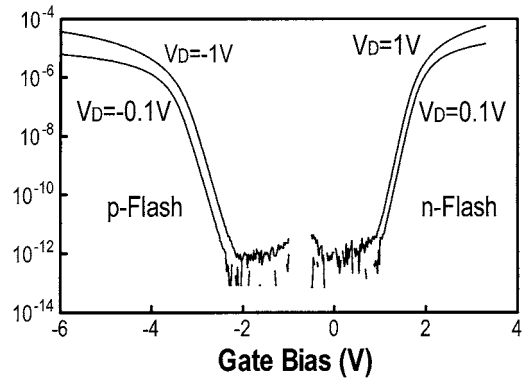

FIGURE 51.9 The subthreshold characteristics of n- and p-channel Flash memory cells.

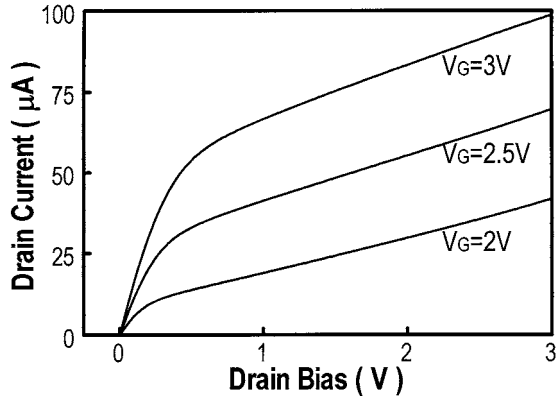

FIGURE 51.10 The output characteristics of stacked-gate memory cells.

bias increases. In addition, the increased drain current characteristics in the saturation region are shown in Fig. 51.10.

Threshold Voltage of Flash Memory Devices

Threshold voltage is defined as the minimum voltage needed to turn on the device. For a stacked-gate device, the threshold voltage measured from the control gate is an indicator of charge storage condition. From Eq. 51.4, we can obtain

$$V_{FGTH} = \alpha_{FG}\left(V_{GTH} + \frac{C_D}{C_{FG}}V_D - \frac{Q}{C_{FG}}\right) \tag{51.7}$$

According to this equation, there exists a linear relationship between threshold voltage measured from floating gate and control gate, drain bias, and stored charge amount. The threshold voltage measured from the floating gate is only determined by the process procedures and device structures. Therefore, the change of the threshold voltage measured from control gate linearly depends on the change of the stored charge amount under a fixed drain bias in a specific stacked-gate device. Thus, this can be expressed as

$$\Delta V_{GTH} = \frac{\Delta Q}{C_{FG}} \tag{51.8}$$

Based on this relationship, the amount of charge storage in stacked-gate memory cell can be monitored by the measured threshold voltage. As shown in Fig. 51.11, the transfer characteristic shifts toward a higher gate bias region, while the increasing amount of electrons are stored in the floating gate for both n- and p-channel Flash memory cells. Thus, device conduction during read operation determines the stored information of the stacked-gate devices. At a specific gate bias condition for reading, as shown in Fig. 51.11, the memory with/without stored charge would lead to different amounts of drain current. The stored electron in the floating gate leads no current flow through the channel at the "READ" bias in the n-channel Flash cell, whereas the channel would conduct at the read operation for the p-channel cell with the electron stored in the floating gate. The sense amplifier in the peripheral circuit can detect the drain current and provide the stored information for external applications.

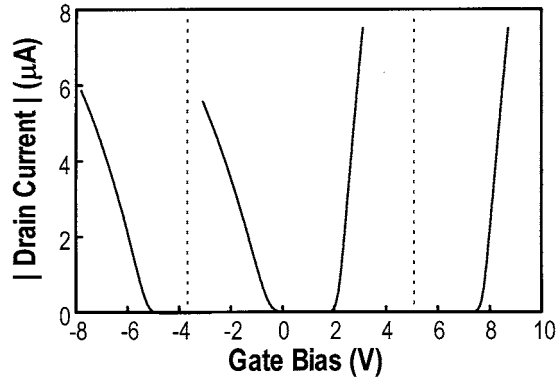

FIGURE 51.11 The transfer characteristics of n- and p-channel Flash memory cells.

Carrier Transport Schemes

Transport of charge through the oxide layer is the basic mechanism that permits operation of stacked-gate memory devices. It makes possible charging and discharging of the floating gate. In order to achieve the write/erase operations, the charge must move across the potential barrier built by the insulating layers between floating gate and other terminals of the memory device. There are different charge transport mechanisms and they can be categorized by the charge energy:[16]

1. Charges with sufficiently high energy can surmount the Si–SiO_2 potential barrier, including:
   a. Hot electrons initiated from substrate avalanche
   b. Hot electrons in a junction (initiated from p-n junction avalanche)
   c. Thermally excited electrons (thermionic emissions and Schottky effect)
   d. "Lucky" electrons at the drain side (Auger scattering)
2. Charges with lower energy can cross the barrier by quantum mechanical tunneling effects:
   a. Trap-assisted tunneling through sites located within the barrier
   b. Direct tunneling when the tunneling distance is equal to the thickness of the oxide
   c. Fowler-Nordheim (FN) tunneling

Hot carrier injection and FN tunneling injection are the common charge injection mechanisms in Flash memory cells. In this section, these charge injection mechanisms will be described in more detail.

Channel Hot Electron Injection (CHEI)

Figure 51.12 shows the schematic diagram of the CHEI for n- and p-channel MOSFET. When applying a high voltage at the drain terminal of an on-state device, electrons moving from the source terminal to the drain side are accelerated by the high lateral channel electric field near the drain terminal. Figure

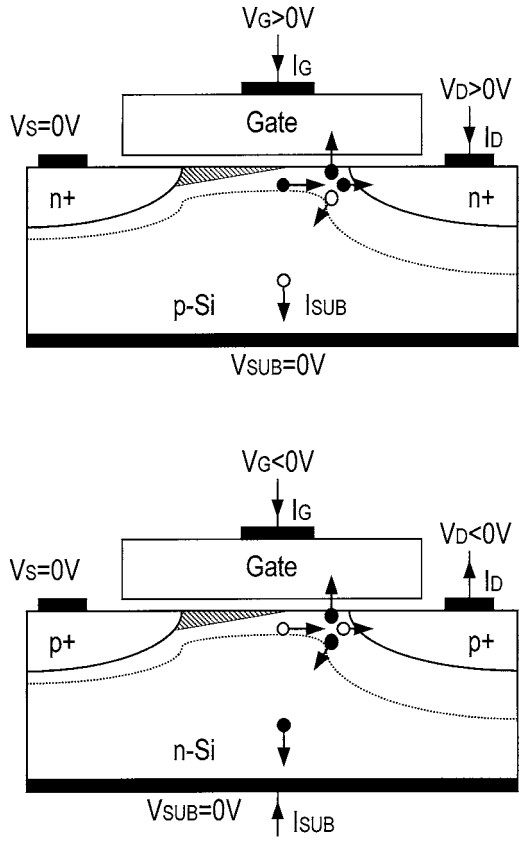

FIGURE 51.12 Schematic illustration of the channel hot carrier effect in (a) n-channel MOSFET, and (b) p-channel MOSFET.

51.13 shows the plots of simulated electric field along the channel region. Notice that the electric field increases abruptly in the pinch-off region when the location approaches the drain terminal. Under the oxide field, which is favorable for attracting electrons, part of the heated electrons gain enough energy to surmount the Si–SiO_2 potential barrier and inject into the gate terminal.

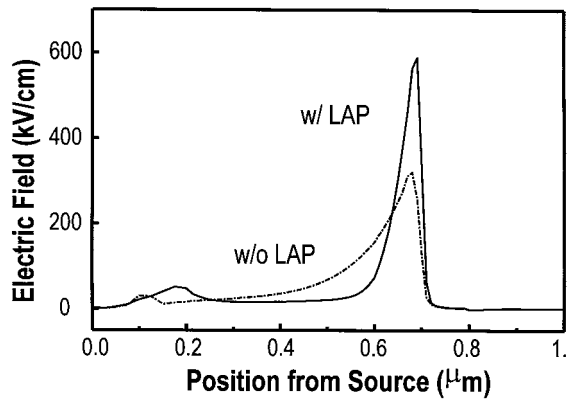

FIGURE 51.13 Simulated electric field along the channel in the n-channel MOSFET.

Figure 51.14 shows the qualitative plot of gate current characteristic for n-channel MOSFETs. For the gate bias in the region "I", a quite small gate current can be characterized. In this subthreshold region, the carrier injection mainly originates from the avalanche injection, which will be discussed in the next section. In region II, the channel conducts and the channel current increases as the gate bias increases and thus the gate current induced by CHEI increases. As the gate bias increases further, the gate current peaks at a high gate bias. Following the peak value of the gate current, the decreasing gate current is mainly caused by the decrease of the lateral electric field, as illustrated in region III.

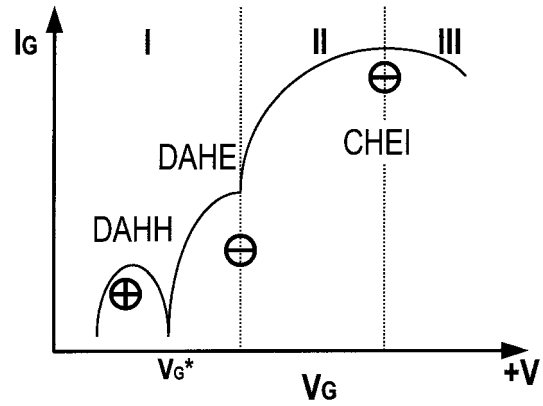

FIGURE 51.14 Schematic gate current behavior in n-channel MOSFET.

On the other hand, the measured gate current characteristic in p-channel MOSFETs is shown in Fig. 51.15. Owing to the large potential barrier and short mean free path, the hot hole generated and accelerated in the channel cannot gain enough energy to surmount the oxide barrier. Thus, electron current initiated by channel hot electrons is still the dominant component of gate current in the p-channel MOSFET.[17,18] Besides, the gate current peaks at a lower gate bias in a p-channel MOSFET and has a larger peak value than that in an n-channel MOSFET. In larger gate bias regions, the gate current is dominated by hole injection, which may be caused by the oxide field favoring the injection of the conducting holes into the gate terminal.[19]

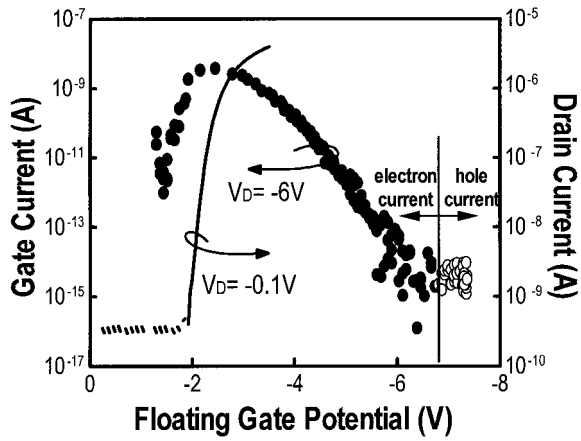

FIGURE 51.15 The gate current behavior of p-channel MOSFET measured from the threshold voltage shift of the stacked-gate structure.

In the 1980s, there were several approaches to describe the channel hot electron injection into the gate terminal. Takeda, et al.[20] modeled the gate current in n-channel MOSFETs as thermionic emission from the heated electron gas over the Si–SiO_2 potential barrier. This thermionic gate current model, referred as the "effective electron temperature model," assumes that the heated electrons become an electron gas with a Maxwellian distribution with an effective temperature $T_e(x)$. The temperature $T_e(x)$ depends on the electric field and the location in the channel. The gate current is given by

$$J_G = q \cdot n_S \cdot \left(\frac{kT_e}{2\pi m^*}\right)^{1/2} \cdot \exp\left(-\frac{\Phi_B}{k \cdot T_e}\right) \cdot \exp\left(-\frac{d}{l}\right) \tag{51.9}$$

where n_s is the surface electron density, k is the Boltzmann constant, m^* is the effective electron mass, Φ_B is the Si–SiO_2 potential barrier, d is the distance of the electron from the interface at $T_e(x)$, and the λ is the mean free path. The last term in Eq. 51.9 accounts for the probability of energy loss due to the collision while the electron moves toward the Si–SiO_2 interface.

Another gate current model, the lucky electron model, is based on the assumption that an electron is injected into oxide by obtaining enough energy from the lateral channel electric field without suffering any collision. The lucky electron approach for hot electron injection was originated by Shockley[21] and Verway et. al.,[22] who applied it in the study of substrate hot electron injection in MOSFETs and subsequently refined and verified by Ning et. al.[23] Hu modified the substrate lucky electron injection model and applied it to CHEI in MOSFETs.[24] In this model, there are three probabilities to describe the physical mechanism responsible for CHEI gate current.[25] They are (1) the probability of a hot electron to gain enough kinetic energy and normal momentum, (2) the probability of not suffering any inelastic collision during transport to the Si–SiO_2 interface, and (3) the probability of not suffering collision in oxide image-potential well. Thus, the gate current originated from CHEI is given by

$$I_G = \int_0^L I_D \frac{(P_1 \cdot P_2 \cdot P_3)}{\lambda r} dx \tag{51.10}$$

where I_D is the channel current, L is the channel length, and λ_r is the redirection scattering mean free path. P_1 is the probability that an electron can gain the energy equals the energy barrier under the channel electric field E without suffering optical phonon scattering and can be expressed as

$$P_1 = \exp\left(-\frac{\Phi_B}{E\lambda}\right) \tag{51.11}$$

where λ is the mean free path for optical phonon scattering. P_2 is the probability of not suffering any inelastic collision during transport to the Si–SiO_2 interface and can be expressed as

$$P_2 = \frac{\int_{y=0}^{\infty} n(y) \cdot \exp\left(-\frac{y}{\lambda}\right) dy}{\int_{y=0}^{\infty} n(y)\, dy} \tag{51.12}$$

The last probability factor is the scattering in the oxide image-potential well. P_3 can be expressed as[26]:

$$P_3 = \exp\left(-\frac{y_o}{\lambda_{ox}}\right) \tag{51.13}$$

Ong et al. modified the lucky electron model to analyze the hot electron injection effects in p-channel MOSFETs.[27,28] Based on Eq. 51.10 and substituting substrate current (I_{SUB}) for drain current (I_D), the gate current in p-channel MOSFETs can be expressed as:

$$I_G = \int_{y=0}^{y=L} I_{SUB} \frac{(P_1 \cdot P_2 \cdot P_3)}{\lambda r} dy \tag{51.14}$$

After describing the channel hot electron injection mechanisms, the charge injection characteristics based on the CHEI scheme are discussed. First, the output characteristics (I_D–V_D) of a memory cell are taken into account. The output characteristic of a stacked-gate device can be regarded as an injection indicator to examine the effects of channel hot electron injection under different device operation conditions and device structures. The output characteristics of the n-channel Flash memory under a high gate bias are shown in Fig. 51.16(a). The drain current rolls off at a lower drain bias as the channel length of the device decreases. This indicates obviously that the channel length reduction results in the increase of the lateral channel electric field and therefore the enhancement of hot electron injection. As the electron injection initiates, the stored electrons retard the conduction of the channel and the device is gradually turned off owing to the continuous electron injection. On the contrary, the output characteristics in the p-channel Flash memory, as shown in Fig. 51.16(b), reveal a quite different I–V behavior after electron injection. Owing to the reduction of threshold voltage after electron injection, the enhancement of further channel conduction can be observed as the drain bias increases.

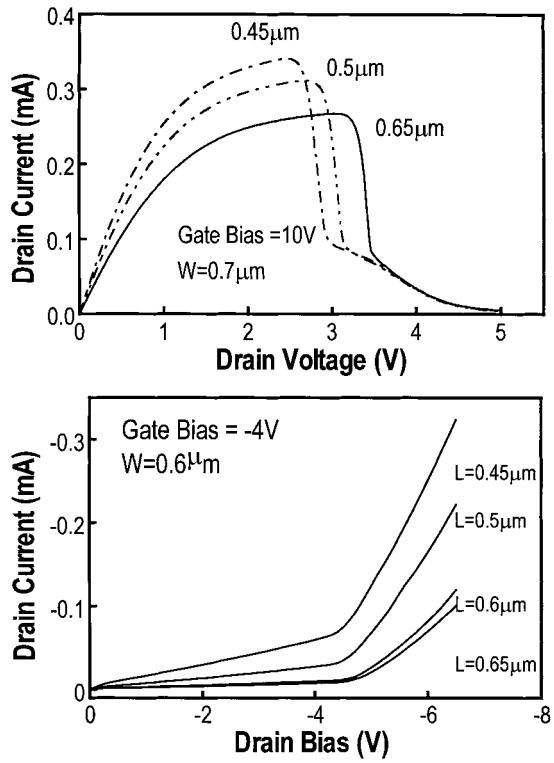

FIGURE 51.16 (a) The output characteristics of the n-channel Flash memory at high gate bias, and (b) the output characteristics of the p-channel Flash memory at high gate bias.

Second, the programming characteristics of the n- and p-channel Flash memory are demonstrated. Figure 51.17(a) shows the gate bias effects on the CHEI programming characteristics in an n-channel Flash memory cell. The threshold voltage increases as the electron injection process prolongs and then saturates at different values for different gate biases. On the other hand, Fig. 51.17(b) shows the CHEI programming characteristics in a p-channel Flash memory cell. Compared with the n-channel cell, the programming characteristic in the p-channel Flash cell reveals a large dependence on the gate bias condition. This is mainly caused by the CHEI that distributes within a narrower gate bias condition. The gate current in the p-MOSFET peaks at lower gate bias and decreases steeply when the gate bias becomes more negative. Therefore, the injected electrons during programming accompanied by the control gate bias lead to a more negative floating gate potential and the programming behavior is quite different at different gate bias conditions.

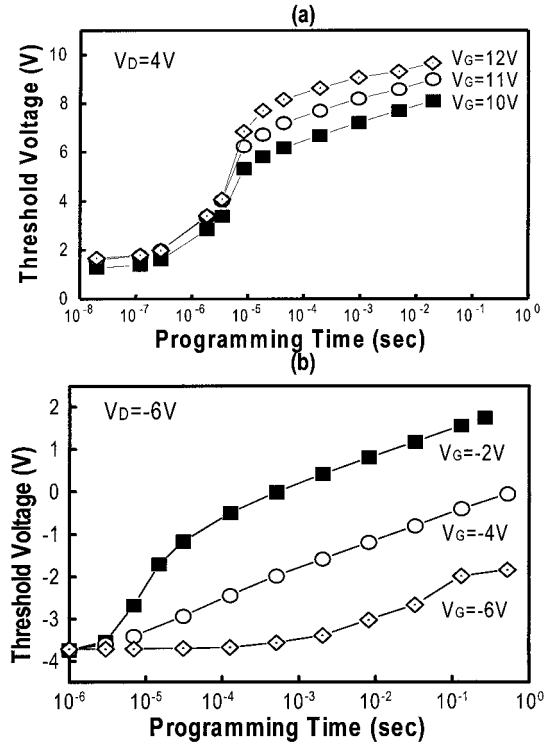

FIGURE 51.17 (a) The programming characteristics of the n-channel Flash memory using channel hot electron injection scheme; (b) the programming characteristics of the p-channel Flash memory using channel hot electron injection.

Drain Avalanche Hot Carrier (DAHC) Injection

As shown in the region I of Fig. 51.14, the characteristic of the gate current is still a function of the gate voltage in n-channel MOSFETs. When V_G is smaller than V_G^*, drain avalanche hot hole (DAHH) is the dominant carrier injected into the gate. On the other hand, when V_G is larger than V_G^*, drain avalanche hot electron (DAHE) is the dominant carrier injected into the gate terminal. V_G^* is the point at which the amounts of the injected hot hole and injected hot electron are in balance. At this gate bias condition, the gate current is not observed.

Conceptually, the existence of hot hole injection seems questionable because of the high barrier (3.8 eV) for hole injection at the Si–SiO_2 interface. However, hot hole gate currents have been experimentally identified and modeled.[29,32] Hofmann et. al.[30] employed the effective electron temperature model[20] and

the concept of oxide scattering effects[25] based on the two-dimensional distribution of electric field, charge carrier, and current density calculated by computer simulator. The hot hole injection and hot electron injection initiated by the avalanche generation were manifested qualitatively. Saks et al.[32] proposed a modified floating gate technique to characterize these extremely small gate currents. It showed that a small positive gate current exists for gate bias near the threshold voltage. They also suggested that the hole current increases with increasing drain bias and decreasing effective channel length, which is analogous to the dependencies for channel hot electron injection. Comparison of hot hole and hot electron gate current as a function of the effective channel length also suggested that the lateral electric field near the drain plays an important role in the hole injection.

In the stacked-gate devices, in the DAHH region, holes are injected into the floating gate, which increases the floating gate voltage gradually, and finally the floating gate voltage reaches the point V_G^*. On the contrary, in the DAHE region, electrons are injected into the floating gate, which decreases the floating gate, and the floating gate voltage also reaches the point V_G^*. Thus, the threshold voltage of the stacked-gate device would distribute at a specific value after the DAHC injection operation. As shown in Fig. 51.18, the threshold voltage of the flash cell after a period of DAHC operation time can converge to a specific value. For the cell with a threshold voltage larger than the converged value, the floating gate voltage is more negative than V_G^*, the hole injection occurs and makes the threshold voltage decrease. On the other hand, for the cell with a threshold voltage smaller than the converged value, it reveals a more positive potential in the floating gate, the electron injection occurs and increases the threshold voltage. In the Flash application, the DAHC injection is usually applied to the convergent operation.[33] Owing to the process-induced device variations, the electron ejection operation usually causes a wide threshold distribution. Additionally, a trapped hole in the oxide enhances the FN tunneling current and generates the erratic erased cell.[34] By employing the DAHC operation, a tighter threshold voltage distribution can be obtained.[35]

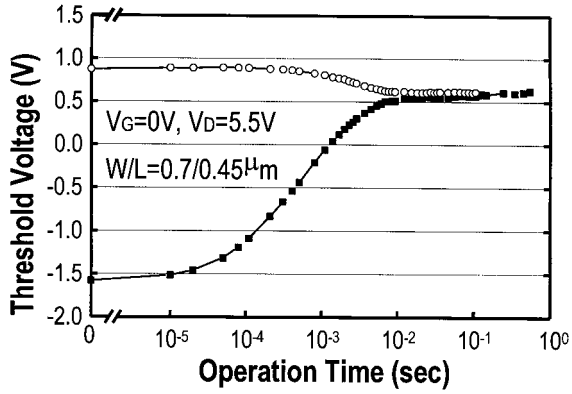

FIGURE 51.18 The convergetn characteristics of the n-channel Flash memory cell with DAHC operation.

Band-to-Band Tunneling Induced Hot Carrier Injection (BBHC)

Carrier injection initiated by band-to-band tunneling accompanied by lateral junction electric field is also an important charge transport mechanism in Flash memory. As shown in Fig. 51.19, the BBHC operation conditions for n- and p-channel lead to different charge injection behaviors. For n-channel MOSFETs, the negative gate bias and positive drain bias lead to the possible hole injection toward the gate terminal. For p-channel MOSFETs, the operation conditions lead to the possible electron injection toward the gate terminal. The initiation of the BBHC injection can be divided into two procedures. One is the band-to-band tunneling, and the other is the acceleration due to lateral electric field and injection due to favorable oxide field.

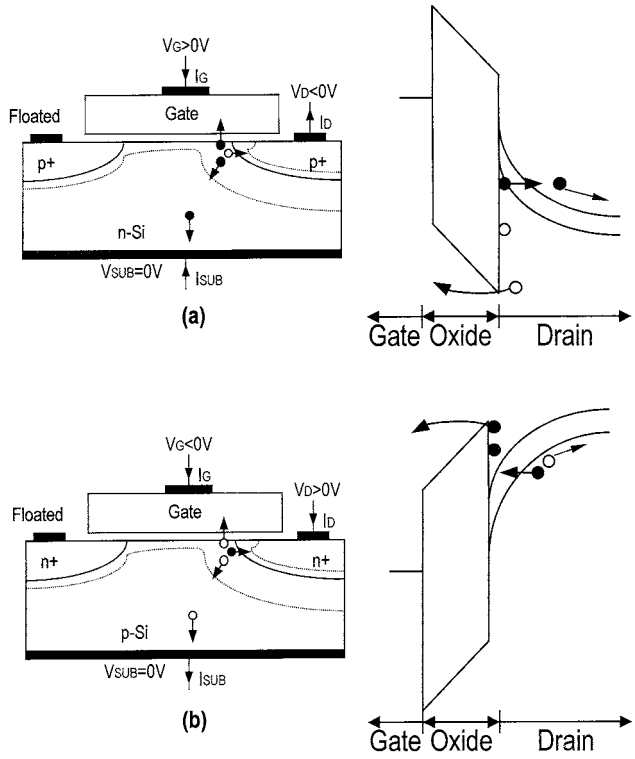

FIGURE 51.19 The schematic illustration for BBHC injection for: (a) n-channel MOSFET, and (b) p-channel MOSFET.

The band-to-band tunneling phenomenon is usually referred as gate-induced drain leakage current.[36] When a high drain voltage is applied with a grounded gate terminal, a deep depletion region is formed underneath the gate-to-drain overlap region. Electron-hole pairs are generated by the tunneling of valence band electrons into the conduction band and then collected by the drain and substrate terminals, separately. Since the minority carriers (hole in n-MOSFET and electron in p-MOSFET) generated by band-to-band tunneling in the drain region flow to the substrate due to the lateral electric field, the deep depletion region is always present and the band-to-band tunneling process proceeds without forming an inversion layer. The band-to-band tunneling characteristic can be estimated by the calculation of electric field distribution and the tunneling probability.[37,38] Based on the depletion approximation and the assumption of uniform impurity distribution, the electric field $E(x)$ in the depletion region is given by

$$E(x) = \frac{Q \cdot N_o}{\varepsilon_{si}} \sqrt{\frac{2 \cdot \varepsilon_{si} \cdot V_{bend}}{q \cdot N_o}} \left(1 - x \sqrt{\frac{q \cdot N_o}{2 \cdot \varepsilon_{si} \cdot V_{bend}}}\right) \tag{51.15}$$

where V_{bend} is the value of the band bending, N_o is the impurity density, and x is the coordinate normal to the Si–SiO_2 interface. The continuity equation at the Si–SiO_2 interface can be expressed as

$$\varepsilon_{si} \cdot E(x = 0) = \varepsilon_{ox} \cdot E_{ox} = \varepsilon_{ox} \frac{V_D - V_{bend}}{T_{ox}} \tag{51.16}$$

The tunneling characteristics are usually approximated by the relationship derived from the reverse biased p-n junction tunnel diode:[39]

$$J = B_1 \cdot E^2 \exp\left(-\frac{B_2}{E}\right) \tag{51.17}$$

where B_1 and B_2 are physical constants. Most of the generated minority carriers are drained away from the substrate terminal. However, owing to the sufficient lateral electric field across the depletion region, these hot carriers may encounter Auger scattering and generate another electron-hole pair.[40] When the drain bias is higher than Si–SiO_2 barrier, the top barrier position seen by the cold generated minority carriers is lower at the depletion edge in the channel. Thus, the injection probability of the minority carrier becomes much higher. The probability of the generated minority carrier injection is given by.[41]

$$\begin{aligned} P_{inject} &= \int \exp\left(-\frac{d(V)}{\lambda}\right) dW(V) \\ &\approx \left(\frac{2V_D}{\Phi_B} - 1\right) \cdot \exp\left(-\frac{\Phi_B}{q \cdot E_m \cdot \lambda}\right) \end{aligned} \tag{51.18}$$

Thus, the injected current accompanied with Eq. 51.17 and oxide scattering factor P expressed in Eq. 51.13 can be given by

$$J_{inject} = P \cdot P_{inject} \cdot J \tag{51.19}$$

In the n-channel MOSFET, the BBHC injection process leads to a significant amount of hot hole injection.[42,43] This situation is mostly encountered in the electron ejection operation of a Flash memory device with "edge" Fowler-Nordheim tunneling. The hole injection into the gate terminal would result in not only the deviation of the memory state, but also severe long-term device instability issues. However, on the contrary, the BBHC injection process leads to the electron injection in the p-channel MOSFET and has been employed in the programming scheme for p-channel Flash memory cell.[10,11] Figure 51.20(a) shows the BBHE characteristics of the p-channel MOSFET. The drain and gate currents monotonically increase with respect to the gate bias because of the increase of the band-to-band tunneling efficiency and the more favorable oxide field for electron injection. Owing to operating in the off state, the electron injection efficiency of the BBHE scheme is much larger than that in the CHEI operation. The BBHE injection reveals a rather high injection efficiency (I_G/I_D) up to 10^{-2}, which provides a quite efficient programming operation for the p-channel Flash cell.[10] Figure 51.20(b) shows the programming characteristics based on the BBHE injection mechanism. The programming time is greatly shortened as the control gate voltage increases. As compared with the CHEI scheme shown in Fig. 51.17(b), the BBHE approach indeed reveals a faster programming speed.

Fowler-Nordheim (FN) Tunneling

The FN tunneling formula proposed by Fowler and Nordheim in 1928 can be described as

$$J_{tunnel} = Co \cdot E^2 \cdot \exp\left(-\frac{4\sqrt{2m^* \cdot \Phi_B^{\,3}}}{3 \cdot q \cdot \hbar \cdot E}\right) \tag{51.20}$$

where J_{tunnel} and E are the tunneling current density and electric field across the oxide layer, respectively. Besides, C_o is a material-dependent constant and m^* is the carrier effective mass. The tunneling theory is developed using the semi-classical independent electron model. For a carrier with energy qU_o, the general expression for the transmission coefficient T_c through on energy barrier depends on the barrier shape $U(x)$, as shown in Fig. 51.21. The value of T_c is derived using the WKB (Wentzel-Kramers-Brillouin) approximation.[44,46]

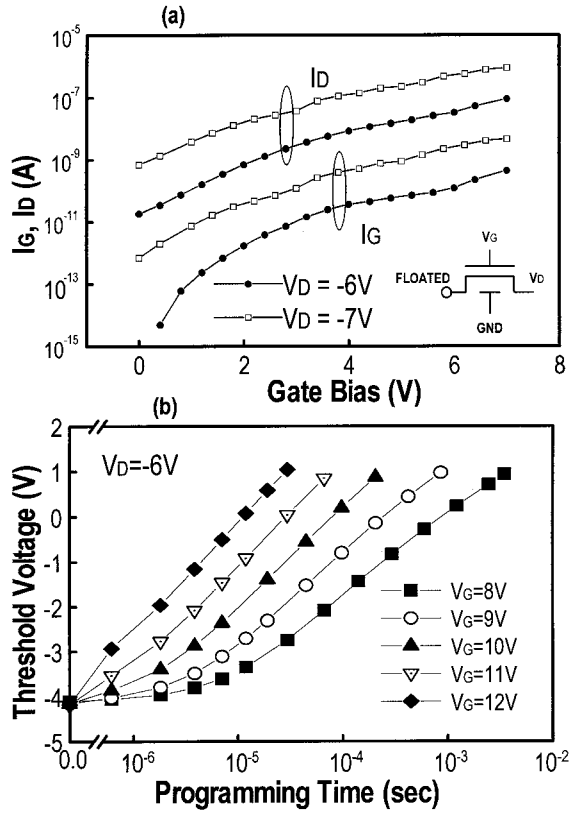

FIGURE 51.20 (a) The BBHE behavior in p-channel MOSFET with different bias conditions; and (b) the programming characteristics in p-channel Flash memory cell with BBHE injection scheme.

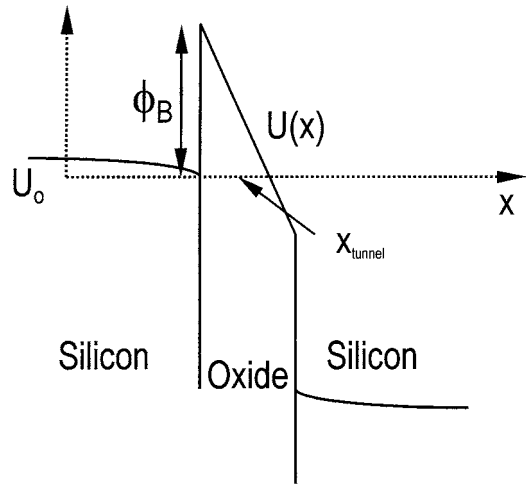

FIGURE 51.21 Schematic diagram of the potential barrier in the polysilicon-oxide-silicon system under applied high voltage.

(51.21)

$$\ln Tc = -\sqrt{\frac{8 \cdot m^* \cdot q}{\hbar}} \cdot \int_0^{X_{tunnel}} \sqrt{U(x) - U_o}\, dx$$

The tunneling current is obtained by integrating the product of the density of states $N_c(W)$ and the transmission coefficient from lowest occupied energy W_G to infinity,

$$J_{tunnel} = \int_{WG}^{\infty} Nc(W)\, Tc(W)\, dW \tag{51.22}$$

This expression is valid for any barrier shape. Under a strong oxide field E, the effective barrier is triangular and the coefficient can be obtained by integrating,

$$U(x) = \phi_B - E \cdot x \tag{51.23}$$

$$\ln Tc = \frac{-4\sqrt{2 \cdot m^* \cdot \Phi_B^{\,3}}}{3 \cdot \hbar \cdot q \cdot |E|} \tag{51.24}$$

where Φ_B is the barrier height, $\Phi_B = q\phi_B$.

Solving Eqs. 51.22 and 51.24 with the assumption that only electrons at the Fermi level contribute to the current yields the Fowler-Nordheim formula for the tunneling current density J_{tunnel} at high electric field:

$$J_{tunnel} = \frac{q^3 \cdot E^2}{16 \cdot \pi^2 \cdot \hbar \cdot \Phi_B} \cdot \exp\left(-\frac{4\sqrt{2 \cdot m^* \cdot \Phi_B^{\,3}}}{3 \cdot \hbar \cdot q \cdot E}\right) \tag{51.25}$$

This equation can also be expressed as

$$J_{tunnel} = \alpha \cdot E^2 \exp\left(-\frac{\beta}{E}\right) \tag{51.26}$$

where α and β are Fowler-Nordheim constants. The value of α is in the range of 4.7×10^{-5} to 6.32×10^{-7} A/V^2 and β is in the range of 2.2×10^8 to 3.2×10^8 V/cm.[47]

The barrier height and tunneling distance determine the tunneling efficiency. Generally, the barrier height at the Si–SiO_2 interface is about 3.1 eV, which is material dependent. This parameter is determined by the electron affinity and work function of the gate material. On the other hand, the tunneling distance depends on the oxide thickness and the voltage drop across the oxide. As indicated in Eq. 51.26, the tunneling current is exponentially proportional to the oxide field. Thus, a small variation in the oxide thickness or voltage drop would lead to a significant tunneling current change. Figure 51.22 shows the Fowler-Nordheim plot which can manifest the Fowler-Nordheim constants α and β. The Si–SiO_2 barrier height can be determined based on this F-N plot by quantum-mechanical (QM) modeling.[48]

Comparisons of Electron Injection Operations

As mentioned in the above section, there are several operation schemes that can be employed for electron injection, whereas only FN tunneling can be employed for ejecting electrons out of the floating gate. Owing to the specific features of the electron injection mechanism, the utilization of an electron injection scheme thereby determines the device structure design, process technology, and circuit design. The main features of CHEI and FN tunneling for n-channel Flash memory cell and also CHEI and BBHE injection for p-channel Flash memory cell are compared in Tables 51.1 and 51.2.

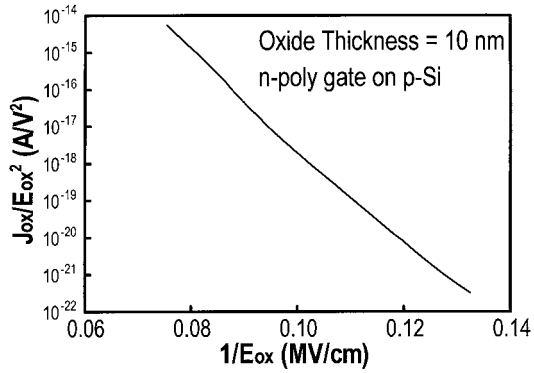

FIGURE 51.22 Fowler-Nordheim plot of the thin oxide.

TABLE 51.1 Comparisons of Fowler-Nordheim Tunneling and Channel Hot Electron Injection as Programming Scheme for Stacked-Gate Devices

FN Tunneling Injection Scheme	CHEI Scheme
Low power consumption	High power consumption
• Single external power supply	• Complicated circuitry technique
High oxide field	Low oxide field
• Thinner oxide thickness required	• Oxide can be thicker
• Higher trap generation rate	• Higher oxide integrity
• More severe read disturbance issue	• Low read disturbance issue
• Highly technological problem	
Slower programming speed	Faster programming speed

TABLE 51.2 Comparisons of Band-to-Band Tunneling Induced Hot Electron Injection and Channel Hot Electron Injection as Programming Scheme for Stacked-Gate Devices

	BBHE Injection Scheme	CHEI Scheme
Power consumption	Lower	Higher
Injection efficiency	Higher	Lower
Programming speed	Faster	Slower
Electron injection window	Wider	Narrower
Oxide field	Higher	Lower

List of Operation Modes

The employment of different electron transport mechanisms to achieve the programming and erase operations can lead to different device operation modes. Typically, in commercial applications, there are three different operation modes for n-channel Flash cells and two different operation modes for p-channel Flash cells. In the n-channel cell, as shown in Fig. 51.23, the write/erase operation modes include: (1) programming operation with CHEI and erase operation with FN tunneling ejection at source or drain side,[6–8,49–61] as shown in Fig. 51.23(a), usually referred as NOR-type operation mode; (2) programming operation with FN tunneling ejection at drain side and erase operation with FN tunneling injection through channel region,[62–70] as shown in Fig. 51.23(b), usually referred as AND-type operation mode; and (3) programming and erase operations with FN tunneling injection/ejection through channel region,[71–78] usually referred as NAND-type operation mode. As to the p-channel cell, as shown in Fig. 51.24, the write/erase operation modes include: (1) programming operation with CHEI at drain side and erase operation with FN tunneling ejection through channel region,[9] as shown in Fig. 51.24(a); (2) programming operation with BBHE at drain side and erase operation with FN tunneling injection through channel region,[10,11] as shown in Fig. 51.24(b).

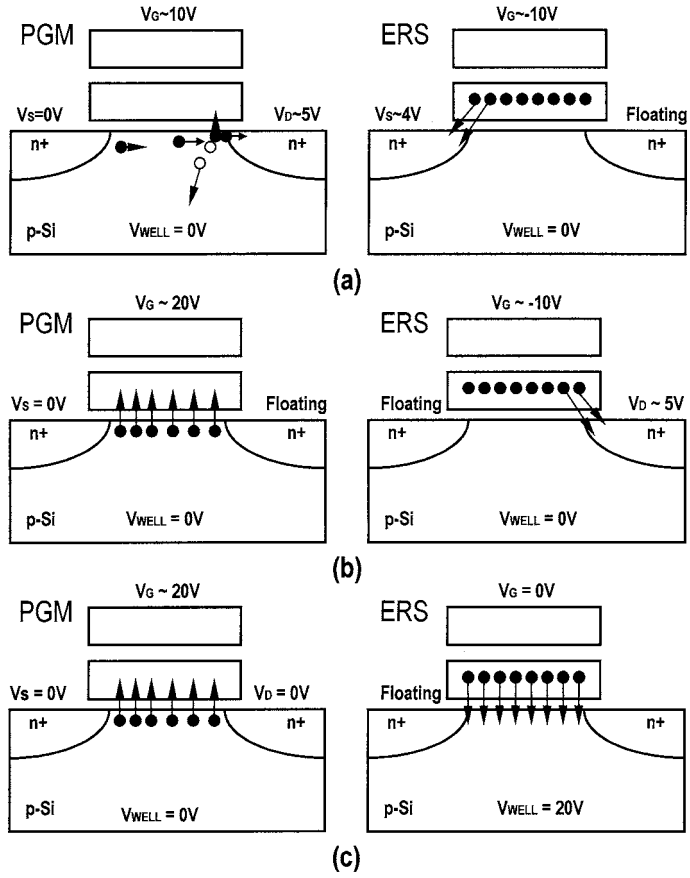

FIGURE 51.23 Different n-channel Flash write/erase operations: (a) programmming operation with CHEI at drain side and erase operation with FN tunneling ejection at source side; (b) programming operation with FN tunneling ejection at drain side and erase operation with tunneling injection through channel region; and (c) programming and erase operations with FN tunneling injection/ejection through channel region.

These operation modes not only lead to different device structures but also different memory array architectures. The main purpose of utilizing various device structures for different operation modes is based on the consideration of the operation efficiency, reliability requirements, and fabrication procedures. In addition, the operation modes and device structures determine, and also are determined by, the memory array architectures. In the following sections, the general improvements of the Flash device structures and the array architectures for specific operation modes are described.

51.5 Variations of Device Structure

CHEI Enhancement

As mentioned above, alternative operation modes are proposed to achieve pervasive purposes and various features, which are approached either by CHEI or FN tunneling injection. Furthermore, it is indicated that the over 90% of the Flash memory product ever shipped is the CHEI-based Flash memory device.[79] With the major manufacturers' competition, many innovations and efforts are dedicated to improve the performance and reliability of CHEI schemes.[50,53,56,57,61,80–83] As described in Eq. 51.11, an increase in the

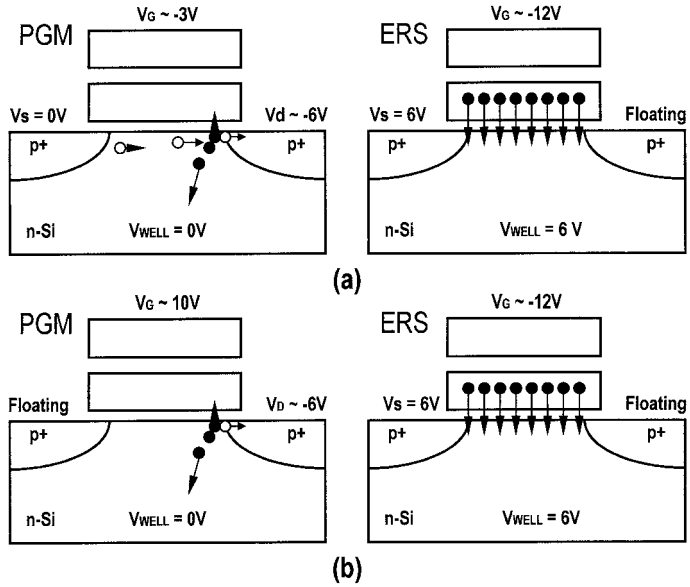

FIGURE 51.24 Different p-channel Flash write/erase operations: (a) programming operation with CHEI at drain side and erase operation with FN tunneling ejection through channel region; and (b) programming operation with BBHE at drain side and erase operation with FN tunneling injection through channel region.

electric field can enhance the probability of the electrons gaining enough energy. Therefore, the major approach to improve the channel hot electron injection efficiency is to enhance the electric field near the drain side. One of the structure modifications is utilizing the large-angle implanted p-pocket (LAP) around the drain to improve the programming speed.[56,57,60,83] LAP has also been used to enhance the punch-through immunity for scaling down capability.[50,53] As demonstrated in Fig. 51.13, the device with LAP has a twofold maximum electric field of that in the device without LAP structure. According to our previous report,[83] additionally, the LAP cell with proper process design can satisfy the cell performance requirements such as read current and punch-through resistance and also reliable long-term charge retention. Besides, the utilization of the p-pocket implantation can achieve the low-voltage operation and feasible scaling down capability simultaneously.

FN Tunneling Enhancement

From the standpoint of power consumption, the programming/erase operation based on the FN tunneling mechanism is unavoidable because of the low current during operation. As the dimension of Flash memory continues scaling down, in order to lower the operation voltage, a thinner tunnel oxide is needed. However, it is difficult to scale down the oxide thickness further due to reliability concerns. There are two ways to overcome this issue. One method is to raise the tunneling efficiency by employing a layer of electron injector on top of the tunnel oxide. Another method is to improve the gate coupling ratio of the memory cell without changing the properties of the insulator between the floating gate and well.

The electron injectors on the top of the tunnel oxide enhance the electric field locally and thus the tunneling efficiency is improved. Therefore, the onset of tunneling behavior takes place at a lower operation voltage. There are two materials used as electron injectors: polyoxide layer[84] and silicon-rich oxide (SRO) layer.[85] The surface roughness of the polyoxide is the main feature for electron injectors. However, owing to the properties of the polyoxide, the electron trapping during write/erase operation limits the application for Flash memory cells. On the other hand, the oxide layer containing excess silicon exhibits lower charge trapping and larger charge-to-breakdown characteristics. These silicon components

in the SRO layer form tiny silicon islands. The high tunneling efficiency is caused by the electric field enhancement of these silicon islands. Lin et al.[47] reported that the Flash cell with SRO layer can achieve the write/erase capability up to 10^6 cycles. However, the charge retentivity of the Flash memory cell with electron injector layers would be poorer than the conventional memory cell because the charge loss is also aggravated by the enhancement of the SRO layer. Thus, the stacked-gate device with SRO layer was also proposed as a volatile memory cell which can feature a longer refresh time than that in the conventional DRAM cell.[86]

Improvement of Gate Coupling Ratio

Another way to reduce the operation voltage is to increase the gate coupling ratio of the memory cell. From the description in the Section 51.4, the floating gate potential can be increased with an increased gate coupling ratio, through an enlarged inter-polysilicon capacitance. For the sake of obtaining a large interpoly capacitance, it is indispensable to reduce the interpoly dielectric thickness or increase the interpoly capacitor area. However, the reduced interpoly dielectric thickness would lead to charge loss during long-term operation. Therefore, a proper structure modification without increasing the effective cell size is necessary to increase the interpoly capacitance. It was proposed to put an extended floating gate layer over the bit-line region by employing two steps of polysilicon layer deposition.[68,87] Such device structure with memory array modifications would achieve a smaller effective cell size and a high coupling ratio (up to 0.8). Shirai et al.[88] proposed the process modification the increase to effective area on the top surface of the floating gate layer. This modified process, which forms a hemispherical-grained (HSG) polysilicon layer, can achieve a high capacitive coupling ratio (up to 0.8). However, the charge retentivity would be a major concern in considering the material as the electric injector.

51.6 Flash Memory Array Structures

NOR Type Array

In general, most of the Flash memory array, as shown in Fig. 51.25(a), is the NOR-type array.[49–61] In this array structure, two neighboring memory cells share a bit-line contact and a common source line. Therefore, a half the drain contact size and half the source line width is occupied in the unit memory cell. Since the memory cell is connected to the bit-line directly, the NOR-type array features random access and lower series resistance characteristics. The NOR-type array can be operated in a larger read current and thus a faster read operation speed. However, the drawback of the NOR-type array is the large cell area per unit cell. In order to maintain the advantages in NOR-type array and also reduce the cell size, there were several efforts to improve the array architectures. The major improvement in the NOR-type array is the elimination of bit-line contacts — the employment of buried bit-line configuration.[52] This concept evolves from the contactless EPROM proposed by Texas Instruments Inc. in 1986.[89] By using this contactless bit-line concept, the memory cell has a 34% size reduction.

AND Type Families

Another modification of the NOR-type array accompanied by a different operation mode is the AND-type array. In the NOR-type array, the CHEI is used as the electron injection scheme. However, owing to the considerations of power consumption and series resistance contributed by the buried bit-line/source, both the programming and erase operations utilize FN tunneling to eliminate the above concerns. Some improvements and modifications based on the NOR-type array have been proposed, including DIvided-bitline NOR (DINOR) proposed by Mitsubishi Corp.,[65,68] Contactless NOR (AND) proposed by Hitachi Corp.,[64,66] Asymmetrical Contactless Transistor (ACT) cell by Sharp Corp.,[69] and Dual String NOR (DuSNOR) by Samsung Corp.[70] and Macronix, Inc.[67] The DINOR architecture employs the main bit-line and sub-bit-line configuration to reduce the disturbance issue during FN programming. The AND and DuSNOR structures

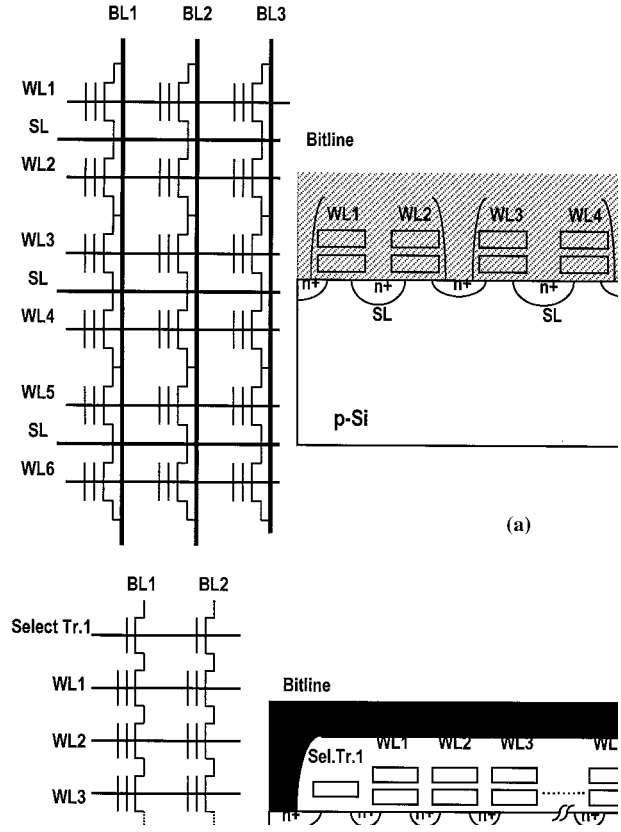

FIGURE 51.25 (a) Schematic top view and cross-section of the NOR-type Flash memory array; and (b) schematic top view and cross-section of the NAND-type Flash memory array.

consist of strings of memory cells with n^+ buried source and bit-lines. String-select and ground-select transistors are attached to the bit and source line, respectively. In DuSNOR structure, a smaller cell size can be realized because every two adjacent cell strings share a source line. Although a smaller cell size can be obtained utilizing the buried bit-line and source line, the resistance of the buried diffusion line would degrade the read performance. The read operation consideration will be the dominant factor in determining the size of a memory string in the AND and DuSNOR structures.

NAND Type Array

In order to realize a smaller Flash memory cell, the NAND structure was proposed in 1987.[90] As shown in Fig. 51.25(b), the memory cells are arranged in series. It was reported that the cell size of the NAND structure is only 44% of that in the NOR-type array under the same design rules. The operation mechanisms of a single memory cell in the NAND architecture is the same as NOR and AND architectures. However, the programming and read operations are more complex. Besides, the read operation speed is lower than that in the NOR-type structure because a number of memory cells are connected in series.

Originally, the NAND structure was operated with CHEI programming an FN tunneling through the channel region.[90] Later on, edge FN ejection at drain side was employed.[62,63] However, owing to reliability concerns, operations utilizing the bi-polarity write/erase scheme were then proposed to reduce the oxide damage.[71–78] Owing to the memory cells in the NAND structure being operated by FN write and erase, in order to improve the FN operation efficiency and reduce the operation voltage, the booster plate technology on the NAND structure was proposed by Samsung Corp.[77]

51.7 Evolution of Flash Memory Technology

In this section, as in Table 51.3, the development of device structures, process technology, and array architectures for Flash memory are listed by date. The burgeoning development in Flash memory devices reveals a prospective future.

TABLE 51.3 The Development of the Flash Memory

Year	Technology	Affiliation	Ref.
1984	Flash memory (2 μm, 64 μm^2)	Toshiba (Japan)	6
1985	Source-side erase type Flash (1.5 μm, 25 μm^2, 512 Kb)	EXCL (USA)	7
1986	Source-side injection (SI-EPROM)	UC Berkley (USA)	49
1987	Drain-erase type Flash, split gate device (128 Kb)	Seeq, UC Berkley (USA)	8
1987	NAND structure EEPROM (1 μm, 6.43 μm^2, 512 Kb)	Toshiba (Japan)	90
1987	Source-side erase Flash (0.8 μm, 9.3 μm^2)	Hitachi (Japan)	50
1988	ETOX-type Flash (1.5 μm, 36 μm^2, 256 Kb)	Intel (USA)	91
1988	NAND EEPROM (1 μm, 9.3 μm^2, 4 Mb)	Toshiba (Japan)	62
1988	NAND EEPROM (1 μm, 12.9 μm^2, 4 Mb)	Toshiba (Japan)	63
1988	Poly-poly erase Flash (1.2 μm, 18 μm^2)	WSI (USA)	92
1988	Contactless Flash (1.5 μm, 40.5 μm^2)	TI (USA)	93
1989	Negative gate erase	AMD (USA)	94
1989	ETOX-type Flash (1 μm, 15.2 μm^2, 1 Mb)	Intel (USA)	95
1989	Sidewall Flash (1 μm, 14 μm^2)	Toshiba (Japan)	51
1989	Punch-through-erase	Toshiba (Japan)	96
1990	Well-erase, bi-polarity W/E operation	Toshiba (Japan)	71, 72
1990	NAND, new self-aligned patterning (0.6 μm, 2.3 μm^2)	Toshiba (Japan)	97
1990	Contactless Flash, ACEE (0.8 μm, 8.6 μm^2, 4 Mb)	TI (USA)	98
1990	FACE cell (0.8 μm, 4.48 μm^2)	Intel (USA)	52
1990	Negative gate erase (0.6 μm, 3.6 μm^2, 16 Mb)	Mitsubishi (Japan)	54
1990	Tunnel diode-based contactless Flash	TI (USA)	99
1990	p-Pocket EPROM cell (0.6 μm, 16 Mb)	Toshiba (Japan)	53
1991	SAS process	Intel (USA)	100
1991	PB-FACE cell (0.8 μm, 4.16 μm^2)	Intel (USA)	101
1991	Burst-pulse erase (0.6 μm, 3.6 μm^2)	NEC (Japan)	56
1991	SSW-DSA cell (0.4 μm, 1.5 μm^2, 64 Mb)	NEC (Japan)	57
1991	Sector erase (0.6 μm, 3.42 μm^2, 16 Mb)	Hitachi (Japan)	64
1991	Self-convergence erase	Toshiba (Japan)	33, 35
1991	Virtual ground, auxiliary gate (0.5 μm, 2.59 μm^2)	Sharp (Japan)	59
1992	AND cell (0.4 μm, 1.28 μm^2, 64 Mb)	Hitachi (Japan)	66
1992	DINOR array (0.5 μm, 2.88 μm^2, 16 Mb)	Mitsubishi (Japan)	65
1992	2-Step erase method	NEC (Japan)	102
1992	Buried source side injection	TI (USA)	60
1992	p-Channel Flash Cell with SRO layer	IBM (USA)	9
1993	HiCR cell (0.4 μm, 1.5 μm^2, 64 Mb)	NEC (Japan)	87
1993	3-D sidewall Flash	Philip, Stanford (USA)	103
1993	Asymmetrical offset S/D DINOR (0.5 μm, 1.0 μm^2)	Mitsubishi (Japan)	68
1993	NAND EEPROM (0.4 μm, 1.13 μm^2, 64 Mb)	Toshiba (Japan)	74
1994	Self-convergent method	Motorola (USA)	104
1994	Substrate hot electron (SHE) erase	Mitsubishi (Japan)	105
1994	Dual-bit Split-Gate (DSG) cell (multi-level cell)	Hyundai (Korea)	106
1994	SA-STI NAND EEPROM (0.35 μm, 0.67 μm^2, 256 Mb)	Toshiba (Japan)	75
1994	SST cell	SST (USA)	124
1994	AND cell (0.25 μm, 0.4 μm^2, 256 Mb)	Hitachi (Japan)	107
1995	Multi-level NAND EEPROM	Toshiba (Japan)	108
1995	Convergence erase scheme	UT, AMD (USA)	109
1995	DuSNOR array (0.5 μm, 1.6 μm^2)	Samsung (Korea)	70
1995	CISEI programming scheme	AT&T, Lucent (USA)	110
1995	SAHF cell (0.3 μm, 0.54 μm^2, 256 Mb)	NEC (Japan)	88
1995	P-Flash with BBHE scheme (0.4 μm)	Mitsubishi (Japan)	10

51.8 Flash Memory System

Applications and Configurations

Flash memory is a single-transistor memory with floating gate for storing charges. Since 1985, the mass production of Flash memory has shared the market of non-volatile memory. The advantages of high density and electrical erasable operation make Flash memory an indispensable memory in the applications of programmable systems, such as network hubs, modems, PC BIOS, microprocessor-based systems, etc. Recently, image cameras and voice recorders have adopted Flash memory as the storage media. These applications require battery operation, which cannot afford large power consumption. Flash memory, a true non-volatile memory, is very suitable for these portable applications because stand-by power is not necessary.

In the interest of portable systems, the specification requirements of Flash memory include some special features that other memories (e.g., DRAM, SRAM) do not have. For example, multiple internal voltages with single external power supply, power-down during stand-by, direct execution, simultaneous erase of multiple blocks, simultaneous re-program/erase of different blocks, precise regulation of internal voltage, embedded program/erase algorithms to control threshold voltage. Since 1995, an emerging need of Flash memory is to increase the density by doubling the number of bits per cell. The charge stored in the floating gate is controlled precisely to provide multi-level threshold voltage. The information stored in each cell can be 00, 01, 10, or 11. Using multi-level storage can decrease the cost per bit tremendously. The multi-level Flash memories have two additional requirements: (1) fast sensing of multi-level information, and (2) high-speed multi-level programming. Since the memory cell characteristics would be degraded after cycling, which leads to fluctuation of programmed states, fast sensing and fast programming are challenged by the variation of threshold voltage in each level.

Another development is analog storage of Flash memory, which is feasible for image storage and voice record. The threshold voltage can be varied continuously between the maximum and minimum values to meet the analog requirements. Analog storage is suitable for recording the information that can tolerate distortion between the storing information and the restored information (e.g., image and speech data).

Before exploring the system design of Flash memory, the major differences between Flash memory and other digital memory, such as SRAM and DRAM, should be clarified. First, multiple sets of voltages are required in Flash memory for programming, erase, and read operations. The high-voltage related circuit is a unique feature that differs from other memories (e.g., DRAM, SRAM). Second, the charac-

teristics of Flash memory cell are degrading because of stress by programming and erasing. The controlling of an accurate threshold voltage by an internal finite state machine is the special function that Flash memory must have. In addition to the mentioned features, address decoding, sense amplifier, and I/O driver are all required in Flash memory. The system of Flash memory, as a result, can be regarded as a simplified mixed-signal product that employs digital and analog design concepts.

Figure 51.26 shows the block diagram of Flash memory. The word-line driver, bit-line driver, and source-line driver control the memory array. The word-line driver is high-voltage circuitry, which includes a logic X-decoder and level shifter. The interface between the bit-line driver and the memory array is the Y-gating. Along the bit-line direction, the sense amplifier and data input/output buffer are in charge of reading and temporary storage of data. The high-voltage parts include charge-pumping and voltage regulation circuitry. The generated high voltage is used to proceed programming and erasing operations. Behind the X-decoder, the address buffer catches the address. Finally, a finite state machine, which executes the operation code, dictates the operations of the system. The heart of the finite state machine is the clocking circuit, which also feeds the clock to a two-phase generator for charge-pumping circuits. In the following sections, the functions of each block will be discussed in detail.

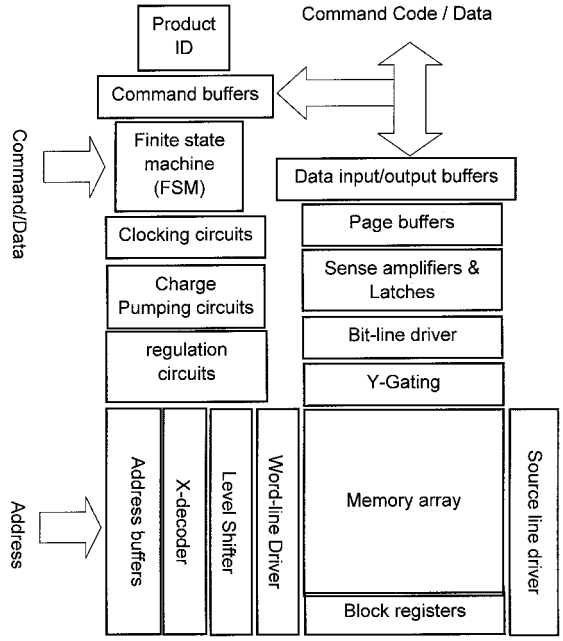

FIGURE 51.26 The block diagram of Flash memory system.

Finite State Machine

A finite state machine (FSM) is a control unit that processes commands and operation algorithms. Figure 51.27(a) demonstrates an example of an FSM. Figure 51.27(b) shows the details of an FSM. The command logic unit is an AND-OR-based logic unit that generates next state codes, while the state register latches the current state. The current state is related to the previous state and input state. State transitions follow the designated state diagram or state table that describe the functionality to translate state codes into controlling signals that are required by other circuits in the memory. The tendency to develop Flash memories goes in the direction of simultaneous program, erase, and read in different blocks. The global FSM takes charge of command distribution, address transition detection (ATD), and data input/output. The address command and data are queued when the selected FSM is busy. The local FSM deals with

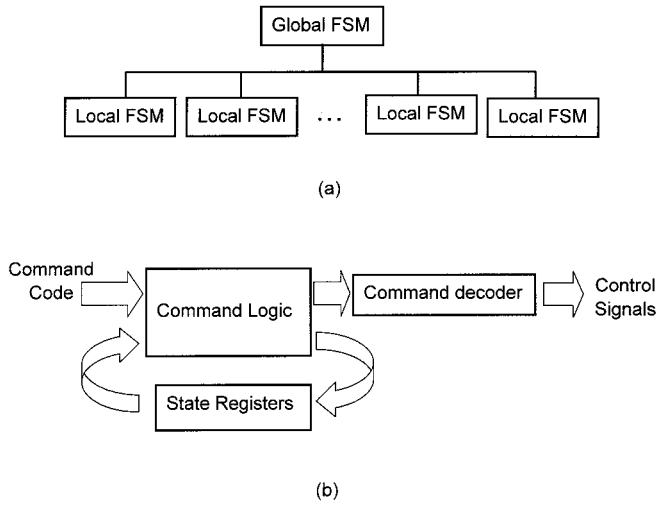

FIGURE 51.27 (a) The hierarchical architecture of a finite state machine; and (b) the block diagram of a finite state machine.

operations, including read, program, and erase, within the local block. The local FSM is activated and completes an operation independently when a command is issued. The global FSM manages the tasks distributing among local FSMs according to the address. The hierarchical local and global FSM can provide parallel processing; for instance, one block is being programmed while the other block is being erased. This feature of simultaneous read/write reduces the system overhead and speeds up the Flash memory. One example of the algorithm used in the FSM is shown in Fig. 51.28. The global FSM loads operating code (OP code) first, then the address transition detection (ATD) enables latch of the address when a different but valid address is observed. The status of the selected block is checked if the command can be executed right away, whereas the command, address, and/or data input are stored in the queues. The queue will be read when the local FSM is ready for excuting the next command. The operation code and address are decoded. Sense amplifiers are activated if a read command is issued. Charge-pumping circuits are back to work if a write command is issued. After all preparations are made, the process routine begins, which will be explained later. Following the completion of the process routine, the FSM checks its queues. If there is any command queued for delayed operation, the local FSM reads the queued data and continues the described procedures. Since these operations are invisible to the external systems, the system overhead is reduced.

The process routine is shown in Fig. 51.29. The read procedure waits for the completion signal of the sense amplifier, and then the valid data is sent immediately. The programming and erasing operations require a verification procedure to ascertain completion of the operation. The iteration of program-verification and erase-verification proceeds to fine-tune the threshold voltage. However, if the verification time exceeds the predetermined value, the block will be identified as a failure block. Further operation to this block is inhibited. Since the FSM controls the operations of the whole chip, a good design of the FSM can improve the operational speed.

Level Shifter

The level shifter is an interface between low-voltage and high-voltage circuits. Flash memory requires high voltage on the word-line and bit-line during programming and erasing operations. The high voltage appearing in a short time is regarded as a pulse. Figure 51.30 shows an example of a level shifter. The input signal is a pulse in V_{cc}/ground level, which controls the duration of a high-voltage pulse. The supply

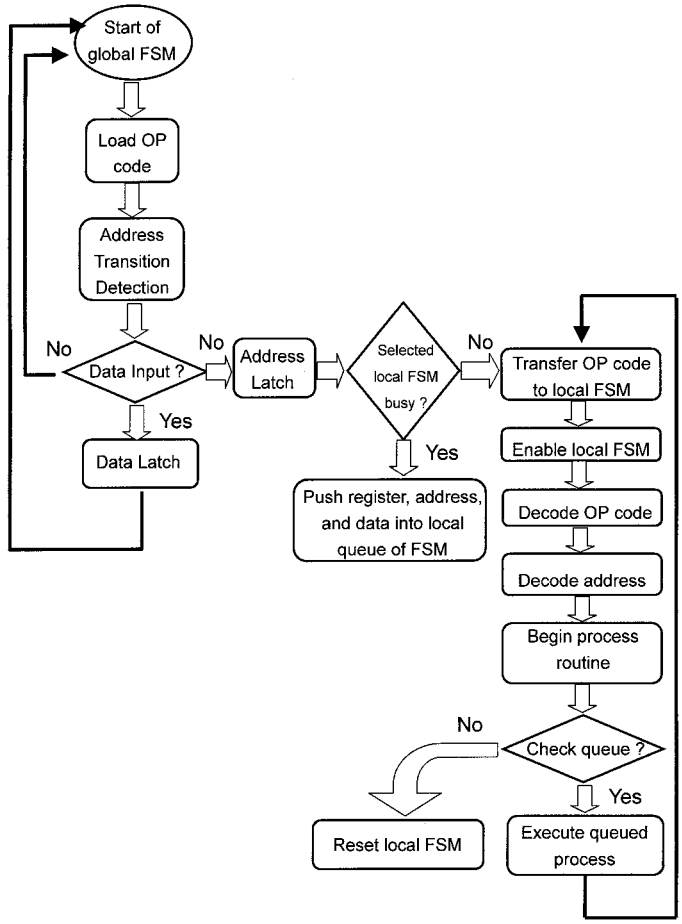

FIGURE 51.28 The algorithims of a finite state machine for simultaneous read-write feature.

of the level shifter determines the output voltage level of the high-voltage pulse. The level shifter is a positive feedback circuit, which turns stable at the ground level and supply voltage level (high voltage is generated from charge-pumping circuits). The operation of the level shifter can be realized as follows. The low-voltage input can only turn off the NMOS transistor but cannot turn off the PMOS parts. On the other hand, high voltage can only turn off the PMOS transistor. Therefore, generation of two mutually inverted signals can turn off the individual loading path and provide no leakage current during stand-by. The challenges of the design are the transition power consumption and the possibility of latch-up. The delay of the feedback loop will result in large leakage current flowing from the high-voltage supply to ground. The leakage current is similar to the transition current of conventional CMOS circuits, but larger due to the delay of the feedback loop. As the large leakage current occurs due to generated substrate current by hot carriers, the level shifter is susceptible to latch-up. The design of the level shifter should focus on speeding up the feedback loop and employing a latch-up-free apparatus. More sophisticated level shifters should be designed to provide tradeoff between switching power and the switching speed.

The level shifter is used in the word-line driver and the bit-line driver if the bit-line requires a voltage larger than the external power supply. The driver is expected to be small because the word-line pitch is nearly minimum feature size. Thus, the major challenges are to simplify the level shifter and to provide a high-performance switch.

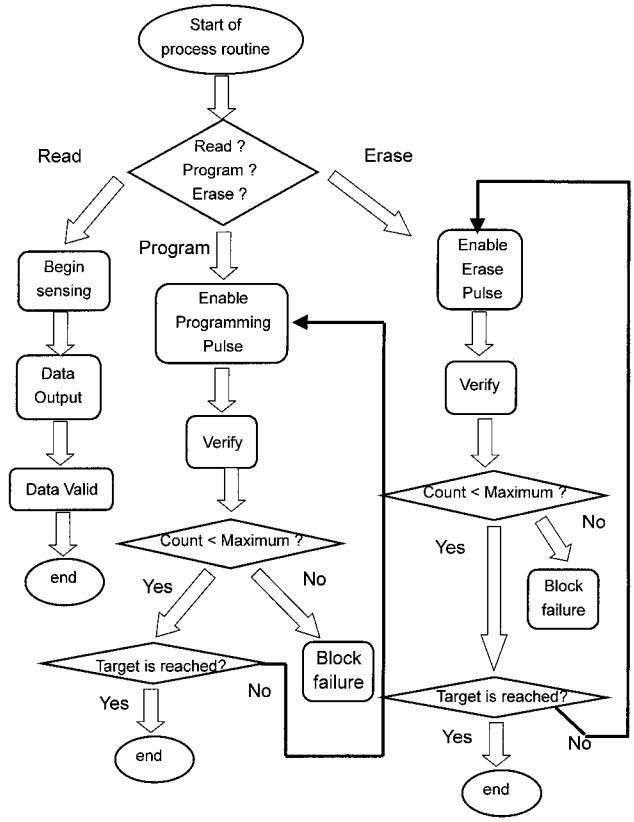

FIGURE 51.29 The algorithm of the process routine in Fig. 51.28.

Charge-Pumping Circuit

The charge-pumping circuit is a high-voltage generator that supplies high voltage for programming and erasing operations. This kind of circuit is well-known in power equipment, such as power supplies, high-voltage switches, etc. A conventional voltage generator requires a power transformer, which transforms input power to output power without loss. In other words, low voltage and large current is transformed to high voltage and low current. The transformer uses the inductance and magnetic flux to generate high voltage very efficiently. However, in the VLSI arena, it is difficult to produce inductors and the charge-pumping method is used instead. Figure 51.31 shows an example of a charge-pumping circuit that consists of multiple-stage pumping units. Each unit is composed of a one-way switch and a capacitor. The one-way switch is a high-voltage switch that does not allow charge to flow back to the input. The capacitor stores the transferred charge and gradually produces high voltage. No two consecutive stages operate at the same time. In other words, when one stage is transferring the charge, the next stage and the previous stage should serve as an isolation switch, which eliminates charge loss. Therefore, a two-phase clocking signal is required to proceed with the charge-pumping operation, producing no voltage drop between the input and output of the switch and large current drivability of the output. In addition, the voltage level must be higher than the previous stage. Therefore, the two-phase clocking signal must be level-shifted to individual high voltages to turn on and off the one-way switch in each pumping unit. A smaller charge-pumping or a more sophisticated level-shift circuit can be employed as self-boosted parts. The generated high voltage, in most cases, is higher than the required voltage. A regulation circuit, which can generate stable voltage and is immune to the fluctuation of external supply voltage and the operating temperature, is used to regulate the voltage and will be described later.

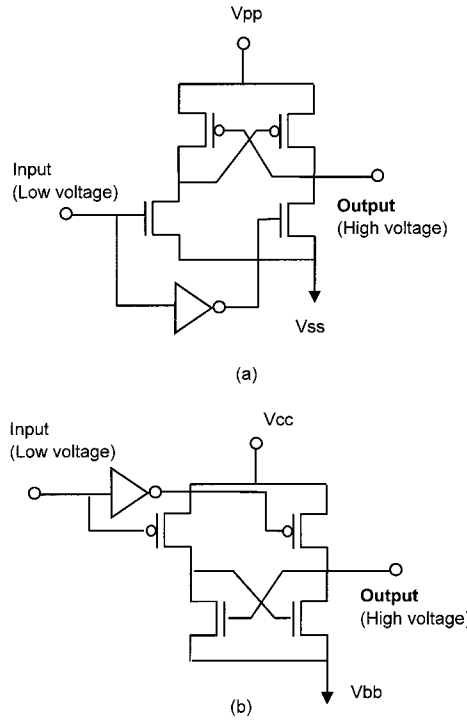

FIGURE 51.30 Level shifter: (a) positive polarity pulse, and (b) negative polarity pulse.

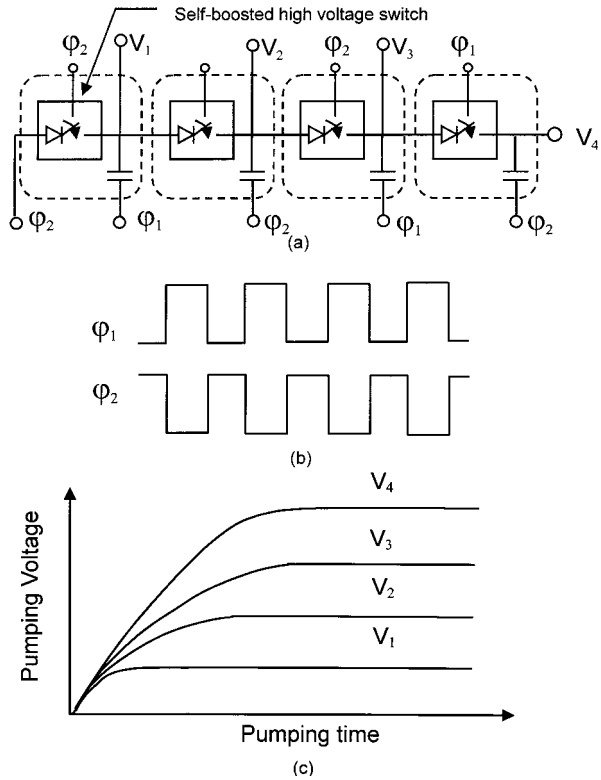

FIGURE 51.31 (a) Charge-pumping circuit; (b) two-phase clock; and (c) pumping voltage.

Sense Amplifier

The sense amplifier is an analog circuit that amplifies small voltage differences. Many circuits can be employed — from the simplest two-transistor cross-coupled latches to the complicated cascaded current-mirrors sense amplifiers. Here, a symbolic diagram is used to represent the sense amplifier in the following discussion. The focus of the sensing circuit is on multi-level sensing, which is currently the engineering issue in Flash memory. Figures 51.32(a) and (b) show the schemes of parallel sensing and consecutive sensing, respectively. These two schemes are based on analog-to-digital conversion (ADC). Information stored in the Flash memory can be read simultaneously with multiple comparators working at the same time. The outputs of the comparators are encoded into N digits for 2^N levels. Figure 51.32(b) shows the consecutive sensing scheme. The sensing time will be N times longer than the parallel sensing for 2^N levels. The sensing algorithm is a conventional binary search that compares the middle values in the consecutive range of interest. Only one sense amplifier is required for a cell. In the example, the additional sense amplifier is used for speeding up the sensing process. The second-stage sense amplifier can be pre-charged and prepared while the first-stage sense amplifier is amplifying the signal. Thus, the sensing time overhead is reduced.

When a multi-level scheme is used, the threshold voltage should be as tight as possible for each level. The depletion of unselected cells is strictly inhibited because the leakage current from unselected cells will destroy

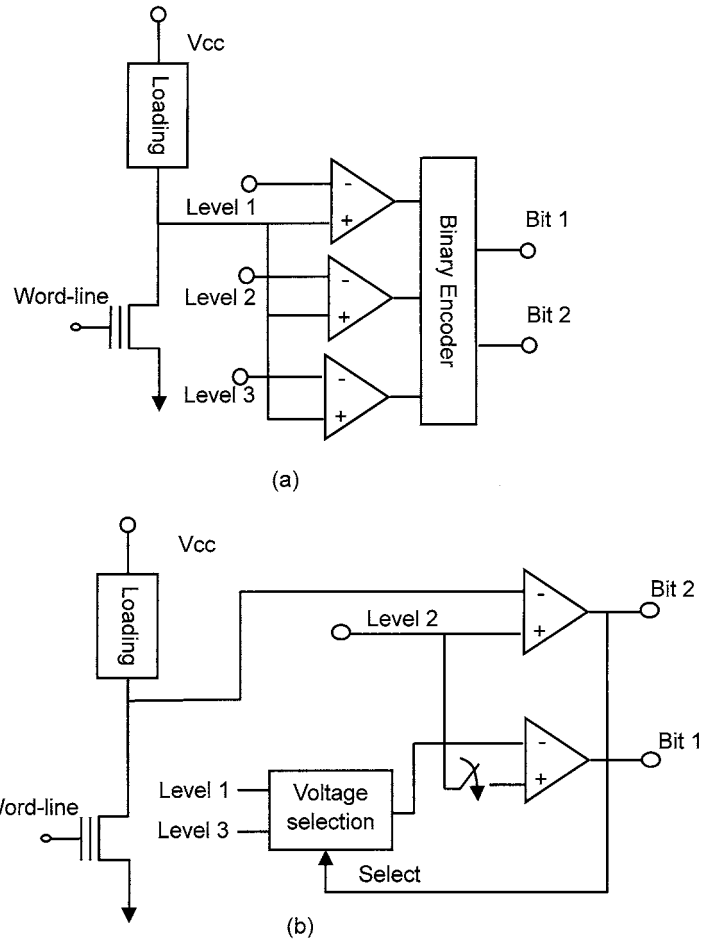

FIGURE 51.32 (a) Parallel sensing scheme, and (b) consecutive sensing scheme.

the true signal, which leads to error during sensing. Another challenge in multi-level sensing is the generation of reference voltages. Since the reference voltages are generated from the power supply, the leakage along the voltage divider path is unavoidable. Besides, the generated voltages are susceptible to the temperature variation and process-related resistance variation. If the variation of reference voltages cannot be minimized to a certain value, the ambiguous decision would be made for multi-level sensing due to unavoidable threshold spread for each level. Therefore, to provide high-sensitivity sense amplifier and to generate precise and robust reference voltages are the major developing goals for more than four-level Flash memory.

Voltage Regulator

A voltage regulator is an accurate voltage generator that is immune to temperature variation, process-related variation, and parasitic component effects. The concept of voltage regulation arises from the temperature-compensated device and the negative feedback circuits. Semiconductor carrier concentration and mobility are all dependent on the ambient temperature. Some devices have positive temperature coefficients, while others have negative coefficients. We can use both kinds of devices to produce a composite device for complete compensation. Figure 51.33 shows two back-to-back connected diodes that can be insensitive to the temperature over the temperature range of interest, if the doping concentration is properly designed. The forward-bias diode is negatively sensitive to temperature: the higher the temperature, the lower the cut-in voltage. On the other hand, the reverse-bias diode shows a reverse characteristic in the breakdown voltage. When connecting the two diodes and optimizing the diode characteristics, the regulated voltage can be insensitive to temperature. Nevertheless, the generated voltage is usually not what we want. A feedback loop, as shown in Fig. 51.34, is needed to generate precise

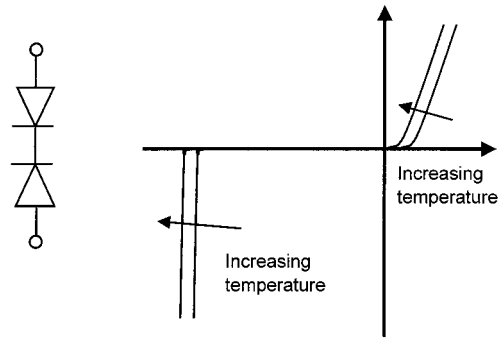

FIGURE 51.33 (a) Back-to-back connected temperature-compensated dual diodes; and (b) the characteristics of a diode as a function of temperature.

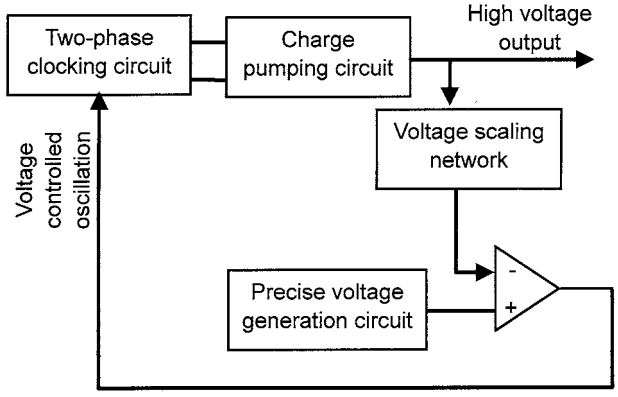

FIGURE 51.34 Voltage regulation block diagram.

programming and erasing voltage. The charge-pumping output voltage and drivability are functions of the two-phase clocking frequency. The pumping voltage can be scaled to be compared with the precise voltage generator to provide a feedback signal for the clocking circuit whose frequency can be varied. With the feedback loop, the generated voltage can be insensitive to temperature. Whatever the desired output voltage is, the structure can be applied in general to produce temperature-insensitive voltage.

Y-Gating

Y-gating is the decoding path of bit-lines. The bit-line pitch is as small as the minimum feature size. One register and one sense amplifier per bit-line is difficult to achieve. Y-gating serves as a switch that makes multiple bit-lines share one latch and one sense amplifier. Two approaches — indirect decoding and direct decoding — used as the Y-gating are shown in Figs. 51.35(a) and (b), respectively. Regarding the indirect decoding, if 2^N bit-lines are decoded using one-to-two decoding unit, the cascaded stages are required with N decoding control lines. However, when the direct decoding schemes is used, 2^N bit-lines require 2^N decoding lines to establish a one-to-2N decoding network, and the pre-decoder is required to generate the decoding signal. The area penalty of indirect decoding is reduced but the voltage drop along

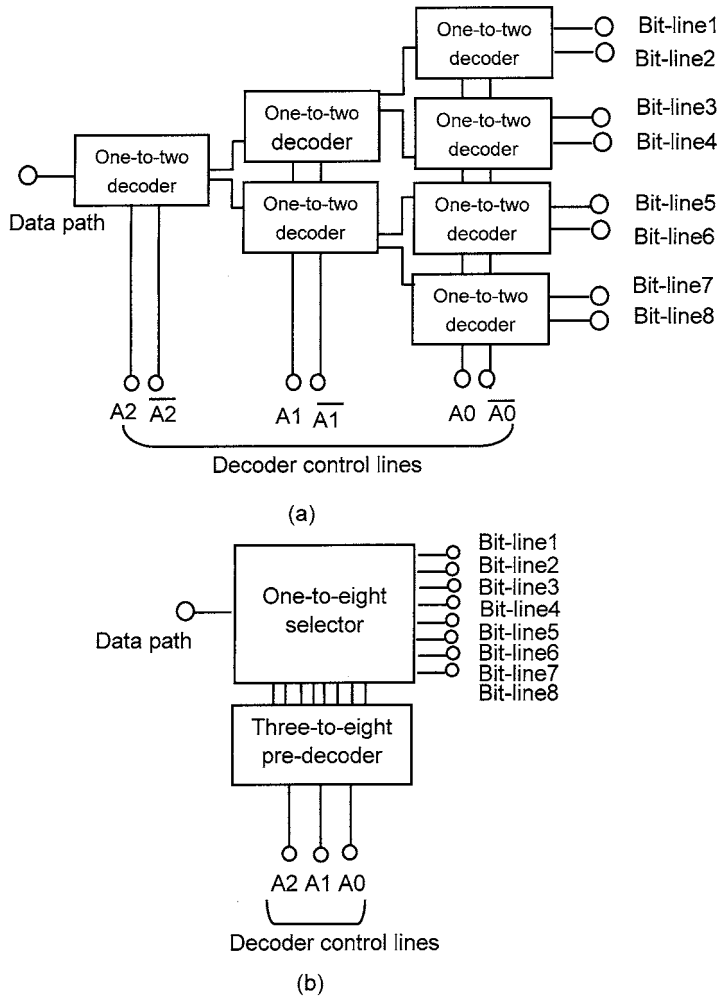

FIGURE 51.35 (a) Indirect decoding, and (b) direct decoding.

the decoding path is of concern. To avoid the voltage drop, a boosted decoding line should be used to overcome the threshold voltage of the passing transistor. Another approach to eliminate voltage drop is the employment of a CMOS transfer gate. However, the area penalty arises again due to well-to-well isolation. Since Flash memory is very sensitive to the drain voltage, the boosted decoding control lines, together with the indirect decoding scheme, are suggested.

Page Buffer

A page buffer is static memory (SRAM-like memory) that serves as a temporary storage of input data. The page buffer also serves as temporary storage of read data. With the page buffer, Flash memory can increase its throughput or bandwidth during programming and read, because external devices can talk to the page buffer in a very short time without waiting for the slow programming of Flash memory. After the input data is transferred to the page buffer, the Flash memory begins programming and external devices can do other tasks. The page size should be carefully designed according to the applications. The larger the page size, the more data can be transferred into Flash memory without having to wait for the completion of programming. However, the area penalty limits the page size. There exists a proper design of page buffer for the application of interest.

Block Register

The block register stores the information about the individual block. The information includes failure of the block, write inhibit, read inhibit, executable operation, etc., according to the applications of interest. Some blocks, especially the boot block, are write-inhibited after first programming. This prevents virus injection in some applications, such as PC BIOS. The block registers are also Flash memory cells for storing block information, which will not disappear after power-off. When the local FSM is working on a certain block, the first thing is to check the status of the block by reading the register. If the block is identified as a failure block, no further operation can be made in this block.

Summary

Flash memory is a system with mixed analog and digital systems. The analog circuits include voltage-generation circuits, analog-to-digital converter circuits, sense amplifier circuits, and level-shifter circuits. These circuits require excellent functionality but small area consumption. The complicated analog designs in the pure-analog circuit do not meet the requirements of Flash memory, which requires large array efficiency, large memory density, and large storage volume. Therefore, the design of these analog circuits tends toward reduced design and qualified function. On the other hand, the digital parts of Flash memory are not as complicated as those digital circuits used in pure digital signal process circuits. Therefore, the mixed analog and digital Flash memory system can be implemented in a simplified way. Furthermore, Flash memory is a memory cell-based system. All the functions of the circuits are designed according to the characteristics of the memory cell. Once the cell structure of a memory differs, it will result in a completely different system design.

Dynamic Random Access Memory

Kuo-Hsing Cheng
Tamkang University

52.1 Introduction

The first dynamic RAM (DRAM) was proposed in 1970 with a capacity of 1 Kb. Since then, DRAMs have been the major driving force behind VLSI technology development. The density and performance of DRAMs have increased at a very fast pace. In fact, the densities of DRAMs have quadrupled about every three years.

The first experimental Gb DRAM was proposed in 1995[1,2] and remains commercially available in 2000. However, multi-level storage DRAM techniques are used to improve the chip density and to reduce the defect-sensitive area on a DRAM chip.[3,4] The developments in VLSI technology have produced DRAMs that realize a cheaper cost per bit compared with other types of memories.

52.2 Basic DRAM Architecture

The basic block diagram of a standard DRAM architecture is shown in Fig. 52.1. Unlike SRAM, the addresses on the standard DRAM memory are multiplexed into two groups to reduce the address input pin counts and to improve the cost-effectiveness of packaging. Although the number of address input pin counts can be reduced by half using the multiplexed address scheme on the standard DRAM memory, the timing control of the standard DRAM memory becomes more complex and the operation speed is reduced. For high-speed DRAM applications, separate address input pins can be used to reduce the timing control complexity and to improve the operation speed.

In general, the address transition detector (ATD) circuit is not needed in a DRAM memory. DRAM controller provides Row Address Strobe ($\overline{\text{RAS}}$) and Column Address Strobe ($\overline{\text{CAS}}$) to latch in the row addresses and the column addresses. As shown in Fig. 52.1, the pins of a standard DRAM are:

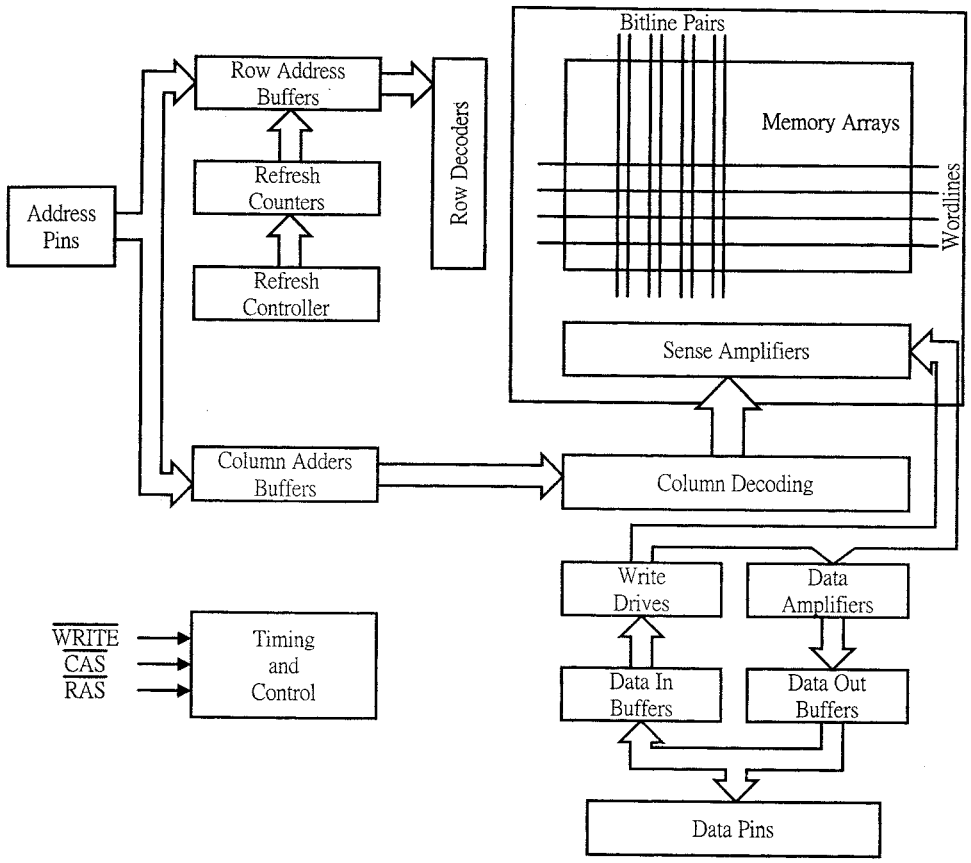

FIGURE 52.1 Basic block diagram of a standard DRAM architecture.

- Address: which are multiplexed in time into two groups, the row addresses and the column addresses
- Address control signals: the Row Address Strobe $\overline{\text{RAS}}$ and the Column Address Strobe $\overline{\text{CAS}}$
- Write enable signal: $\overline{\text{WRITE}}$
- Input/output data pins
- Power-supply pins

An example of address-multiplexed DRAM timing during basic READ mode is shown in Fig. 52.2. The row-falling edge of the address strobe ($\overline{\text{RAS}}$) samples the address and starts the READ operation mode. The row addresses are supplied into the address pins and then comes the row address strobe ($\overline{\text{RAS}}$) signal. Column addresses are not required until the row addresses are sent in and latched. The column addresses are applied into address pins and then latched in by the column address strobe ($\overline{\text{CAS}}$) signal. The access time t_{RAS} is the minimum time for the $\overline{\text{RAS}}$ signal to be low and t_{RC} is the minimum READ cycle time. Notice that the multiplexed address arrangement penalizes the access time of the standard DRAM memory.

The CMOS DRAMs have several rapid access modes in addition to the basic modes. Figure 52.3 shows an example of the rapid access modes. The timing waveform shown in Fig. 52.3 for DRAM operation is the page mode operation. In this mode, the row addresses are applied to the address pins and then clocked by the row address strobe $\overline{\text{RAS}}$ signal, and the column addresses are latched into the DRAM chip on the falling edge of $\overline{\text{CAS}}$ signal as in a basic READ mode. Along a selected row, the individual column

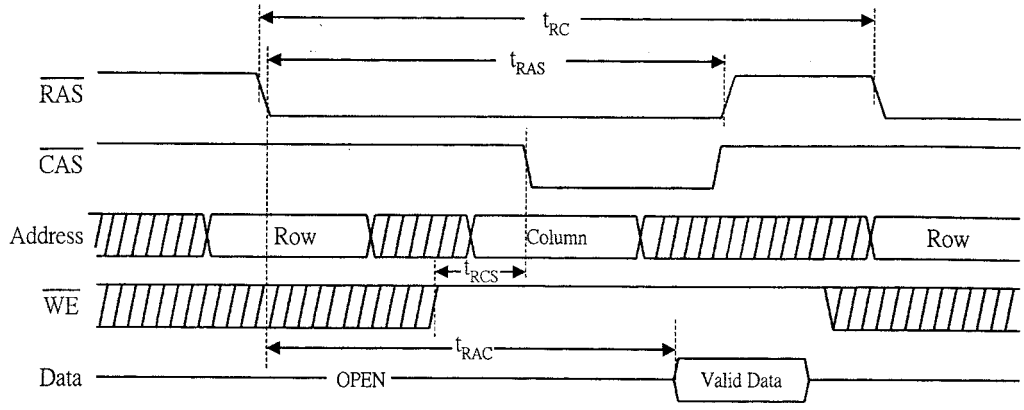

FIGURE 52.2 Read timing diagram for 4M × 1 DRAM.

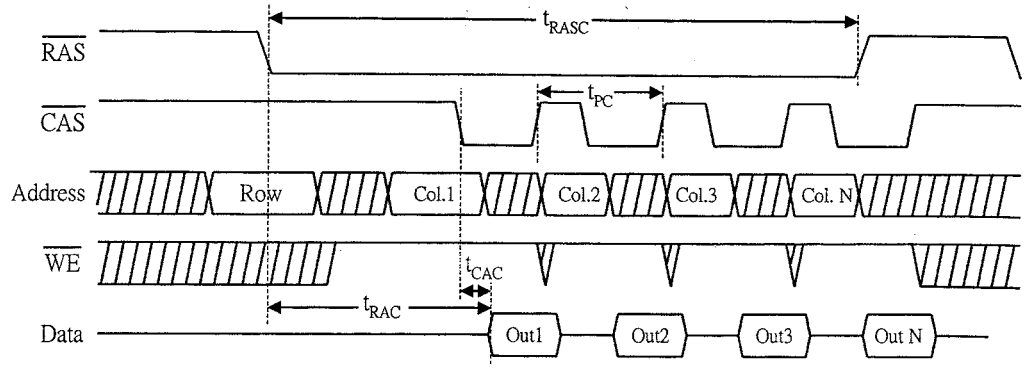

FIGURE 52.3 Fast page mode read timing diagram.

bit can be rapidly accessed, and readout is randomly controlled by the column address and the column address strobe $\overline{CAS}$. By using the page mode, the access time per bit is reduced.

52.3 DRAM Memory Cell

In early CMOS DRAM storage cell design, three-transistor and four-transistor cells were used in 1-Kb and 4-Kb generations. Later, a particular one-transistor cell, as shown in Fig. 52.4(a), became the industry standard.[5,6] The one-transistor (1T) cell achieves smaller cell size and low cost. The cell consists of an n-channel MOSFET and a storage capacitor *Cs*. The charge is stored in the capacitor *Cs* and the n-channel MOSFET functions as the access transistor. The gate of the n-channel MOSFET is connected to the word-line *WL* and its source/drain is connected to the bit-line. The bit-line has a capacity C_{BL}, including the parasitic load of the connected circuits.

The DRAM cell stores one bit of information as the charge on the cell storage capacitor *Cs*. Typical values for the storage capacitor *Cs* are 30 to 50 fF. When the cell stores "1", the capacitor is charged to $V_{DD} - V_t$. When the stores "0", the capacitor is discharged to 0 V.

During the READ operation, the voltage of the selected word-line is high; the access n-channel MOSFET is turned on, thus connecting the storage capacitor *Cs* to the bit-line capacitance C_{BL} as shown in Fig. 52.4(b). The bit-line capacitance C_{BL}, including the parasitic load of the connected circuits, is

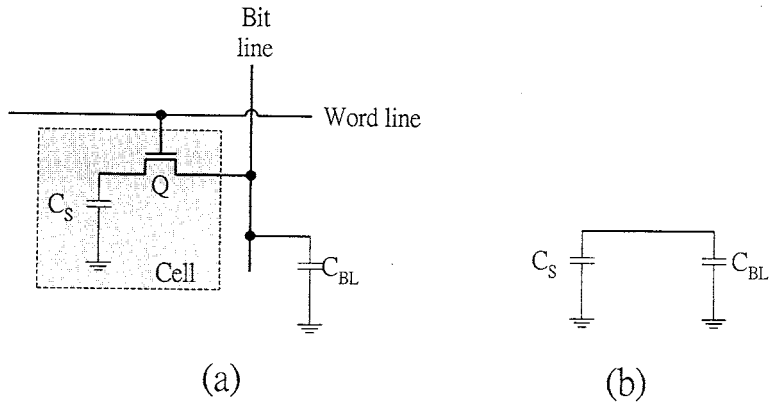

FIGURE 52.4 (a) The one-transistor DRAM cell; and (b) during the READ operation, the voltage of the selected word-line is high, thus connecting the storage capacitor *Cs* to the bit-line capacitance C_{BL}.

about 30 times larger than the storage capacitor *Cs*. Before the selection of the DRAM cell, the bit-line is precharged to a fixed voltage, typically $V_{DD}/2$.[7] By using the charge conservation principle, during the READ operation, the bit-line voltage changes by

$$V_s = \Delta V_{BL} = \frac{C_S}{C_{BL} + C_S}\left(V_{cs} - \frac{V_{DD}}{2}\right) \tag{52.1}$$

Here, V_{cs} is the storage voltage on the DRAM cell capacitor *Cs*. A ratio $R = C_{BL}/Cs$ is important for the read sensing operation. If the cell stores "1" with a voltage $V_{cs} = V_{DD} - V_t$, we have the small bit-line sense signal

$$\Delta V(1) = \frac{1}{1+R}\left(\frac{V_{DD}}{2} - V_t\right) \tag{52.2}$$

If the cell stores "0" with a voltage $V_{cs} = 0$, we have the small bit-line sense signal

$$\Delta V(0) = \frac{1}{1+R}\left(\frac{V_{DD}}{2}\right) \tag{52.3}$$

Since ratio $R = C_{BL}/Cs$ is large, these readout bit-line sense signals $\Delta V(1)$ and $\Delta V(0)$ are very small. Typical values for the sense signal are about 100 mv.

For low-voltage operation, the supply voltage V_{DD} is reduced. Thus, a lower *R* ratio is required to maintain the sense signals to have enough margin against noise. The main approach is to use a large cell storage capacitor *Cs*. As shown in Fig. 52.5, a conventional *Cs* was implemented by a simple planar-type capacitor. The charge storage in the cell takes place on both the poly-1 gate oxide and the depletion capacitances. The planar DRAM cells have been used in the 1-T DRAMs from the 16 kb to the 1 Mb. The limits of the planar DRAM cell for retaining sufficient capacitance were reached in the mid-1980s in the 1-Mb DRAM. With the increased density higher than 1 Mb, smaller horizontal geometry on the surface of the wafer can be achieved by making increased use of the vertical dimension.[8] One approach is to use a trench capacitor, as shown in Fig. 52.6(a).[9] It is folded vertically into the surface of the silicon in the form of a trench. Another approach for reducing horizontal capacitor size is to stack the capacitor *Cs* over the n-channel MOSFET access transistor, as shown in Fig. 52.6(b).

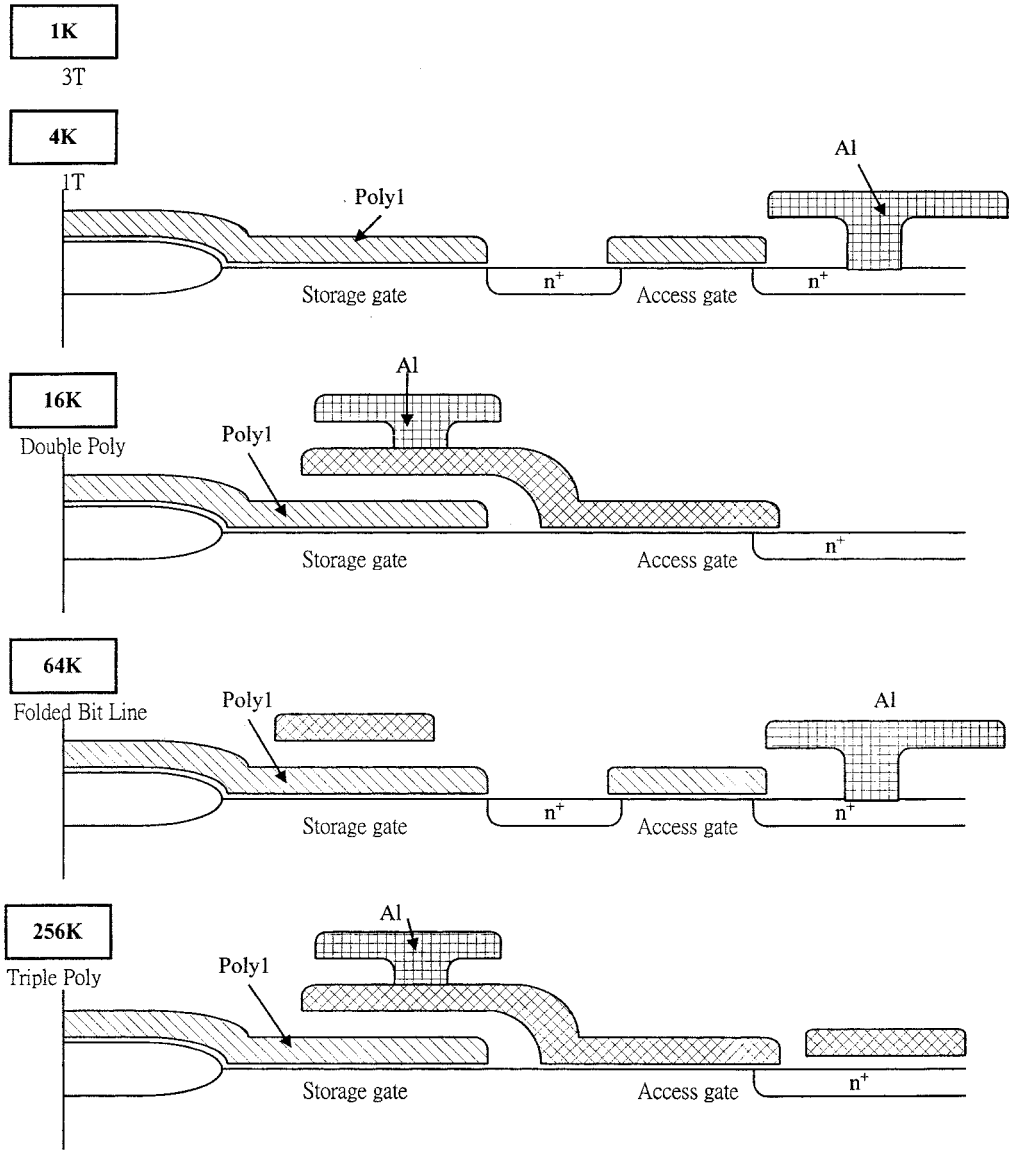

FIGURE 52.5 Structural innovations of planar DRAM cells.

52.4 Read/Write Circuit

As shown in the previous section, the readout process is destructive because the resulting voltage of the cell capacitor *Cs* will no longer be $(V_{DD} - V_t)$ or 0 V. Thus, the same data must be amplified and written to the cell in every readout process.

Next to the storage cells, a sense amplifier with positive feedback structure, as shown in Fig. 52.7, is the most important component in a memory chip to amplify the small readout signal in the readout process. The input and output nodes of the differential positive feedback sense amplifier are connected to the bit-lines *BL* and $\overline{BL}$. The small readout signal appearing between *BL* and $\overline{BL}$ is detected by the differential sense amplifier and amplified to a full-voltage swing at *BL* and $\overline{BL}$. For example, if the DRAM

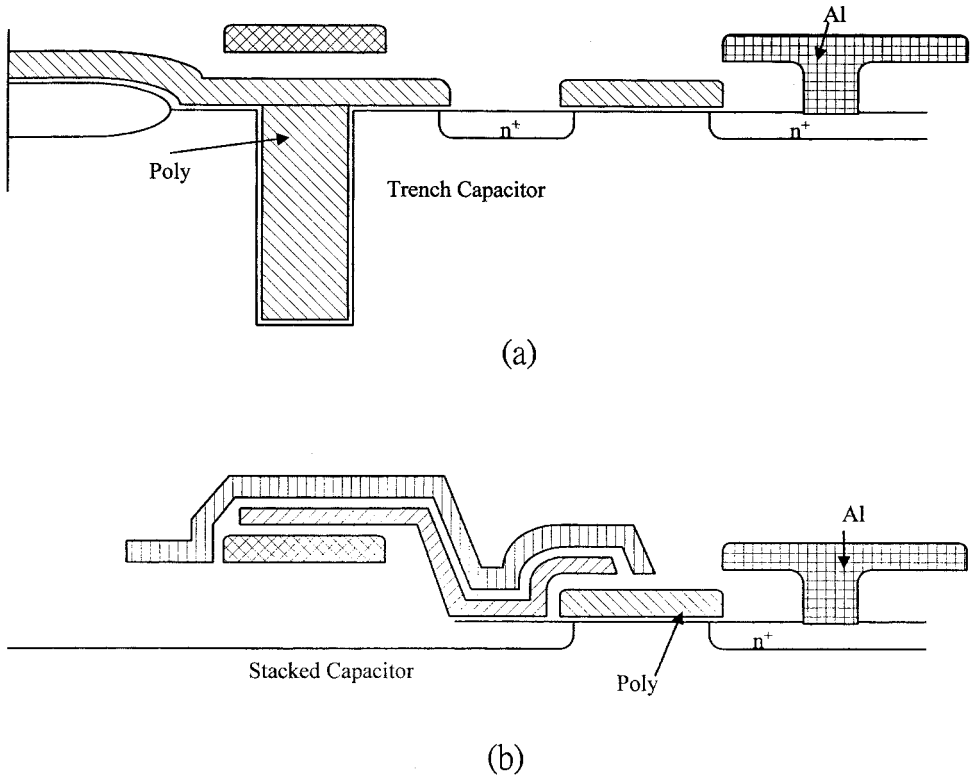

FIGURE 52.6 Schematic cross-section of DRAM cells: (a) trench capacitor cell, and (b) stacked capacitor cell.

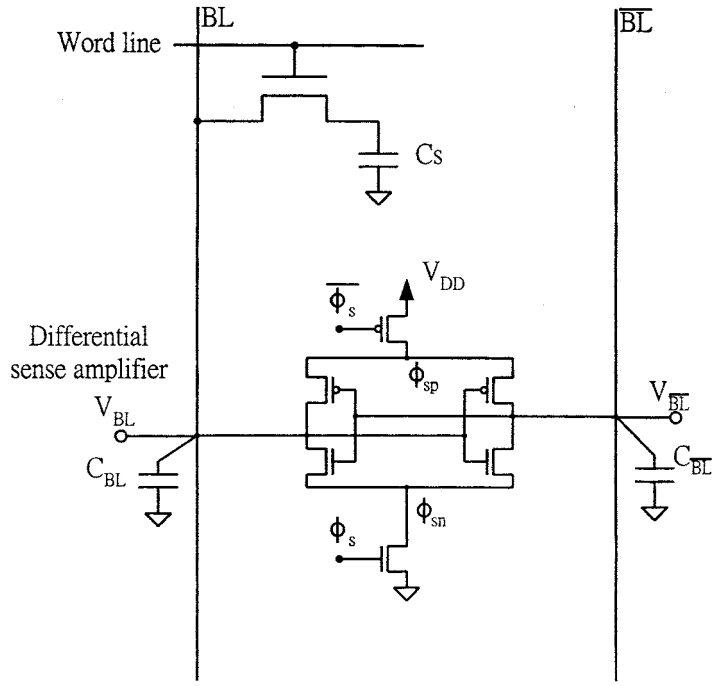

FIGURE 52.7 A differential sense amplifier connected to the bit-line.

memory cell in *BL* has a stored data "1", then a small positive voltage $\Delta V(1)$ will be generated and added to the bit-line *BL* voltage after the readout process. The voltage in the bit-line *BL* will be $\Delta V(1) + V_{DD}/2$. In the same time, the bit-line $\overline{BL}$ will keep its previous precharged voltage level, which is precharged to $V_{DD}/2$. Thus, the small positive voltage $\Delta V(1)$ appears between *BL* and $\overline{BL}$, with V_{BL} higher than $V_{\overline{BL}}$, immediately after the readout process. It is amplified by the differential sense amplifier. The waveforms of V_B before and after activating the sense amplifier are shown in Fig. 52.8. After the sensing and restoring operations, the voltage V_{BL} rises to V_{DD}, and the voltage $V_{\overline{BL}}$ falls to 0 V. The output at *BL* is then sent to the DRAM output pin.

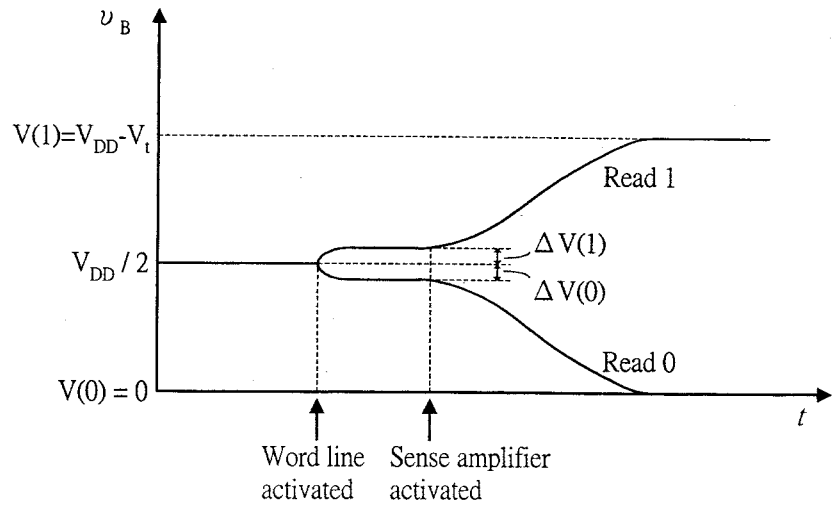

FIGURE 52.8 Timing waveform of V_B.

The various circuits for read, write precharge, and equalization function are shown in Fig. 52.9. The sequence of the read operation is performed as follows.

1. Initially, both the bit-lines *BL* and $\overline{BL}$ are precharged to $V_{DD}/2$ and equalized before the data readout process. The precharge and equalizer circuits are activated by rising the control signal Φ_p. This will cause the bit-lines *BL* and $\overline{BL}$ to be at equal voltage. The control signal Φ_p goes low after the precharge and equalization.
2. The signal *WL* is selected by the row decoder. It goes up to connect the storage cell to the bit-lines *BL* and $\overline{BL}$. A small voltage difference then appears between the bit-lines. The voltage level of the word-line signal *WL* can be greater than V_{DD} to overcome the threshold voltage drop of the n-channel MOSFET transistor. Thus, the stored voltage level of data "1" at the memory cell can be raised to V_{DD}.
3. Once a small voltage difference is generated between the bit-lines *BL* and $\overline{BL}$ by the storage cell, the differential sense amplifier is turned on by pulsing the sense control signal Φ_s high and the sense control signal Φ_s low. Then, the small voltage difference is amplified by the differential sense amplifier. The voltage levels in *BL* and $\overline{BL}$ will quickly move to V_{DD} or 0 V by the regenerative action of the positive feedback operation in the differential sense amplifier.
4. After the readout sensing and restoring operations, the voltage levels of the bit-lines have a full voltage swing. Then the differential voltage levels at the bit-lines are read out to the differential output lines *O* and $\overline{O}$, through a read circuit. A main sense amplifier is used to read and to amplify the output-lines. After these processes, the output data is selected and transferred to the output buffer.

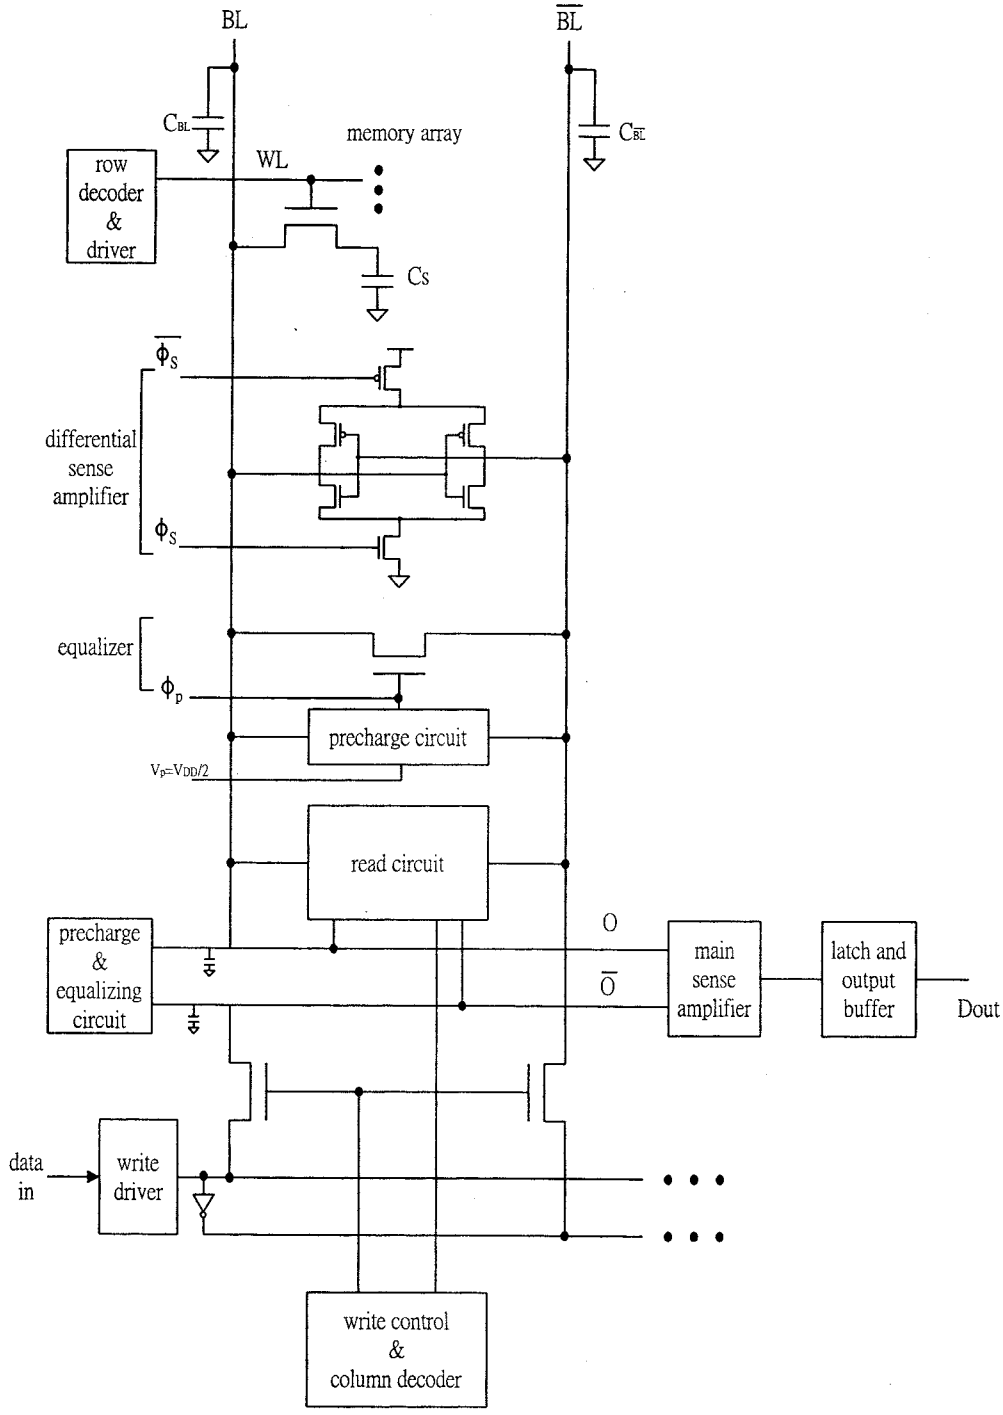

FIGURE 52.9 (a) Schematic circuit diagram of DRAM.

In the write mode, the write control signal $\overline{WRITE}$ is activated. Selected bit-lines *BL* and $\overline{BL}$ are connected to a pair of input data controlled by the write control and write driver. The write circuit drives the voltage levels at the bit-lines to V_{DD} or 0 V, and the data are transferred to the DRAM cell when access transistor is turned on.

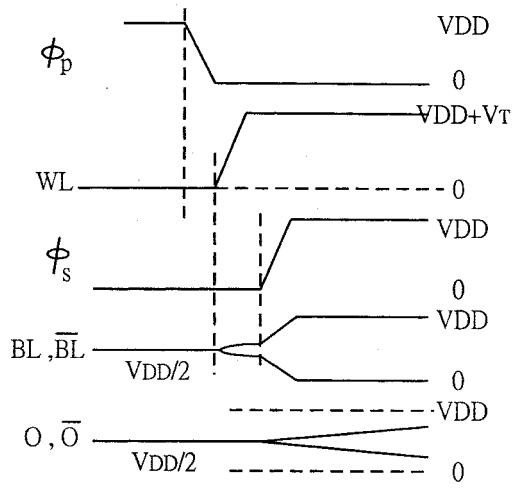

FIGURE 52.9(b) READ operation waveforms.

52.5 Synchronous (Clocked) DRAMs

The application of multimedia is a very hot topic nowadays, and the multimedia systems require high speed and large memory capacity to improve the quality of data processing. Under this trend, high density, high bandwidth, and fast access time are the key requirements of future DRAMs.

The synchronous DRAM (SDRAM) has the characteristic of fast access speed, and is widely used for memory application in multimedia systems. The first SDRAM appeared in the 16-Mb generation, and the current state-of-the-art product is a Gb SDRAM with GB/s bandwidth.[10–14]

Conventionally, the internal signals in asynchronous (non-clocked) DRAMs are generated by "address transition detection" (ATD) techniques. The ATD clock can be used to activate the address decoder and driver, the sense amplifier, and the peripheral circuit of DRAMs. Therefore, the asynchronous DRAMs require no external system clocks and have a simple interface. However, during the asynchronous DRAM access cycle, the process unit must wait for the data from the asynchronous DRAM, as shown in Fig. 52.10. Therefore, the speed of the asynchronous DRAM is slow.

On the other hand, the synchronous interface (clocked) DRAMs making it under the control of the edge of the system clock. The input addresses of a synchronous DRAM are latched into the DRAM, and the output data is available after a given number of clock cycles — during which the processor unit is

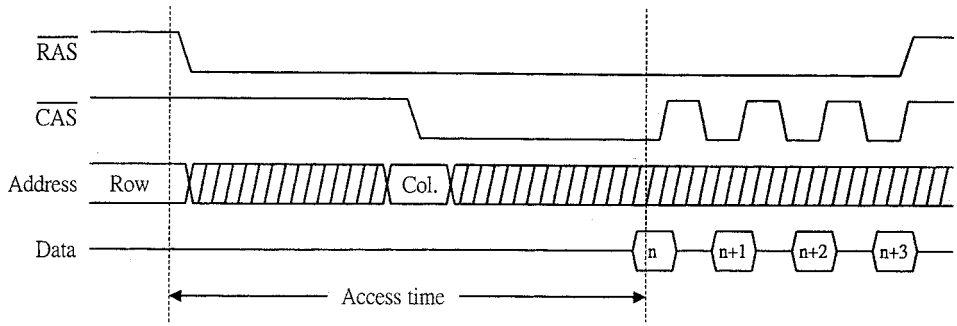

FIGURE 52.10 Read cycle timing diagram for asynchronous DRAM.

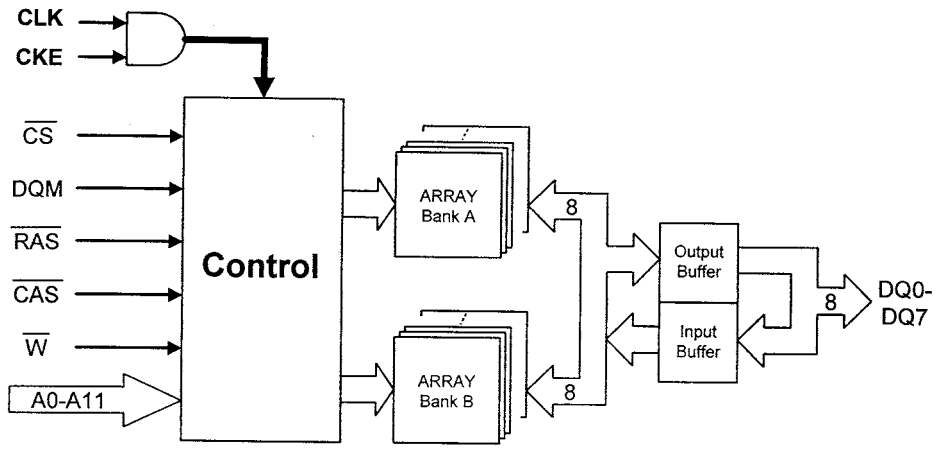

FIGURE 52.11 Read cycle timing diagram for synchronous DRAM.

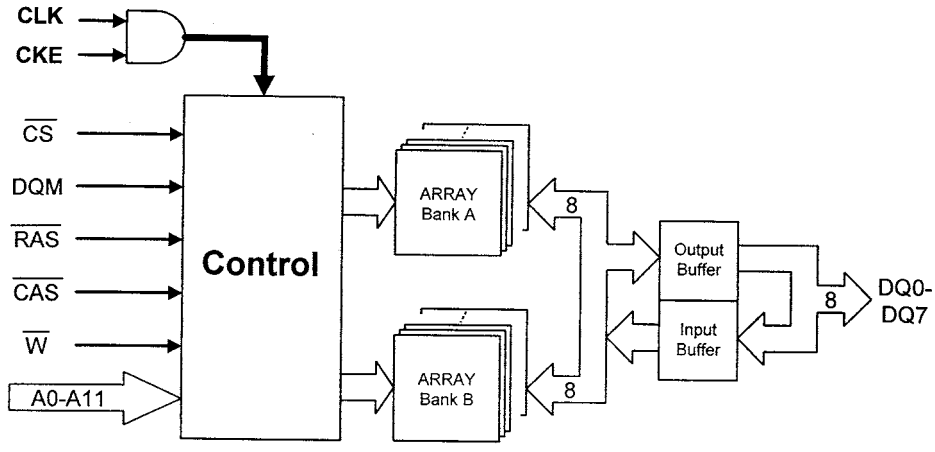

FIGURE 52.12 Block diagrams of a synchronous DRAM.

free and does not wait for the data from the SDRAM, as shown in Fig. 52.11. The block diagram of an SDRAM is shown in Fig. 52.12. With the synchronous interface scheme, the effective operation speed of a given system is improved.

52.6 Prefetch and Pipelined Architecture in SDRAMs

The system clock activates the SDRAM architecture. In order to speed up the average access time, it is possible to use the system clock to store the next address in the input latch or to be sequentially clocked out for each address access output from the output buffer, as shown in Fig. 52.13.[15]

During the read cycle of the prefetch SDRAM, more than one data word is fetched from the memory array and sent to the output buffer. Using the system clock to control the prefetch register and buffer, multiple words of data can be sequentially clocked out for each address access. As shown in Fig. 52.13, the SDRAM has a 6-clock-cycle RAS latency to prefetch 4-bit data.

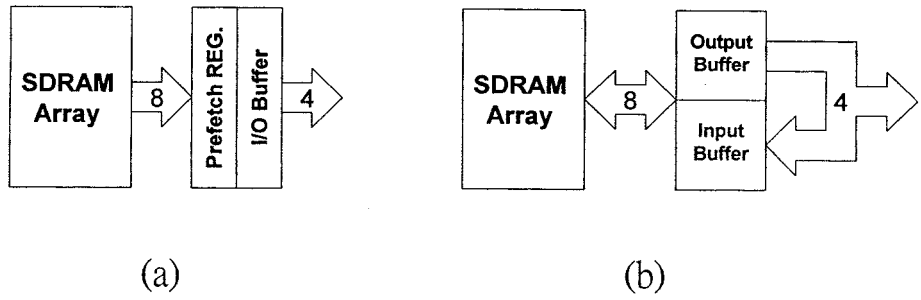

FIGURE 52.13 Block diagrams of two types of synchronous DRAM output: (a) prefetch (b) pipelined.

52.7 Gb SDRAM Bank Architecture

To consider the Gb SDRAM realization, the chip layout and bank/data bus architecture is important for data access. Figure 52.14 shows the conventional bank/data bus architecture of 1-Gb SDRAM.[16] It contains 64 DQ pins, 32 × 32-Mb SDRAM blocks, and four banks; and they all prefetch 4 bits. During the read cycle, the eight 32-Mb DRAM blocks of one bank are accessed simultaneously. The 256-bit data is accessed to the 64 DQ pins and 4 bits are prefetched. In an activated 32-Mb array block, 32-bit data is accessed and associated with eight specific DQ pins. Therefore, it requires a data I/O bus switching circuit between the 32-Mb SDRAM bank and the eight DQ pins. It makes the data I/O bus more complex, and the access time is slower.

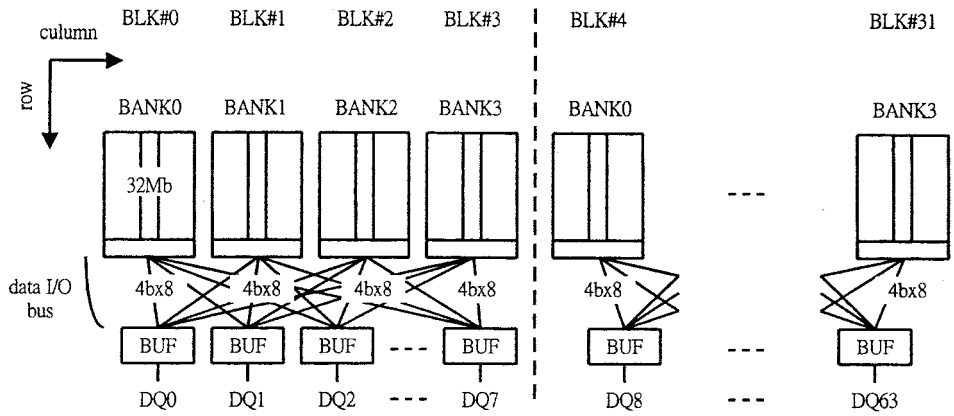

FIGURE 52.14 1-Gb SDRAM bank/data bus architecture.

In order to simplify the bus structure, the distributed bank (D-bank) architecture is proposed as shown in Fig. 52.15. The 1-Gb SDRAM is implemented by 32 × 32-Mb distributed banks. A 32-Mb distributed bank contains two 16-Mb memory arrays as shown in Fig. 52.16. The divided word-line technique is used to activate the segment along the column direction. Using this scheme, each of the eight 2-Mb segments is selectively activated; sense amplifiers of one of the eight segments are activated; and all the 16-K sense amplifiers are activated simultaneously. As compared with the conventional architecture, the distributed bank architecture has a much simplified data I/O bus structure.

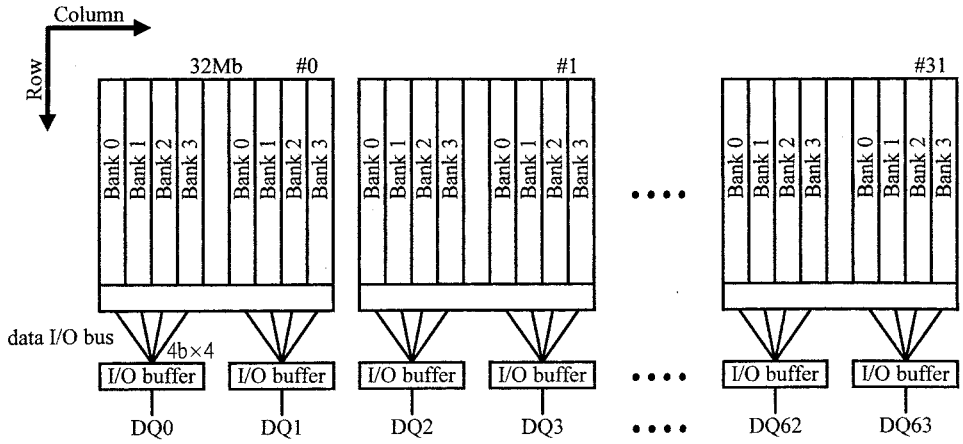

FIGURE 52.15 1-Gb SDRAM D-bank architecture.

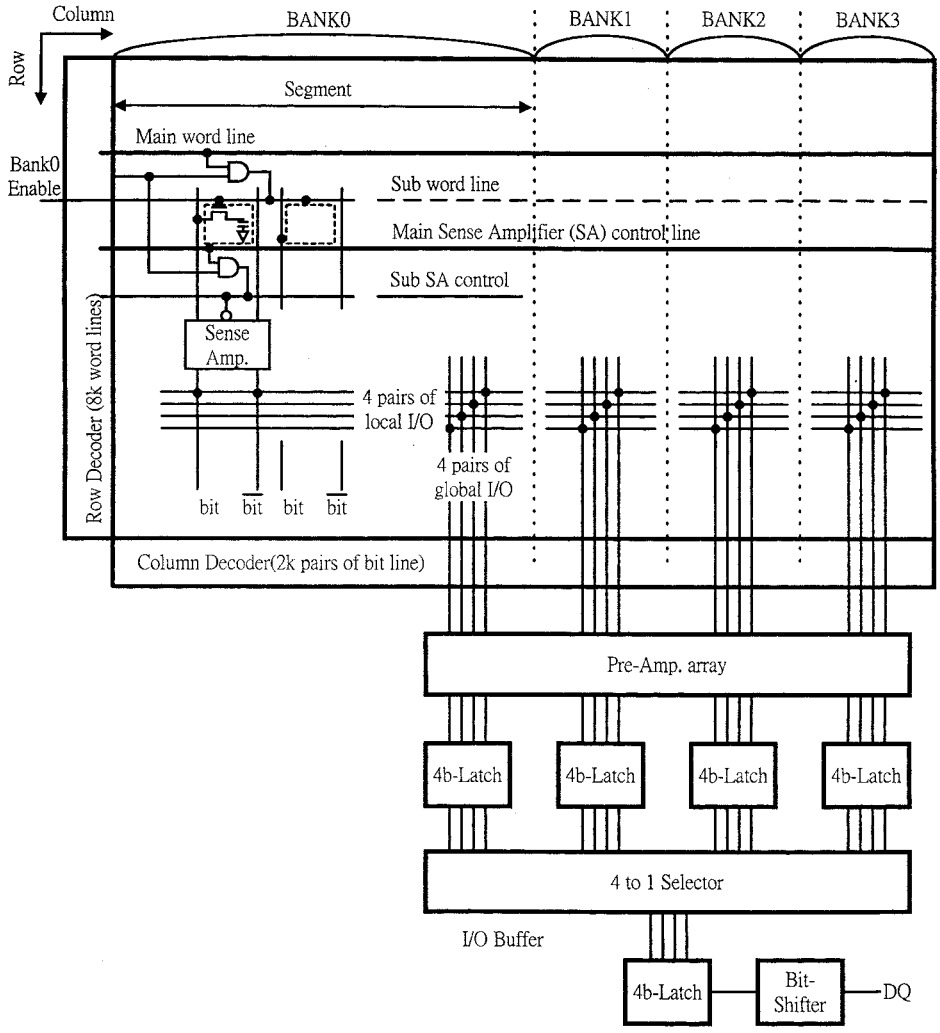

FIGURE 52.16 16-Mb memory array for architecture D-bank.

52.8 Multi-level DRAM

In modern application-specific IC (ASIC) memory designs, there are some important items — memory capacity, fabrication yield, and access speed — that need to be considered. The memory capacity required for ASIC application has been increasing very rapidly, and the bit-cost reduction is one of the most important issues for file application DRAMs. In order to achieve high yield, it is important to reduce the defect-sensitive area on a chip.

The multi-level storage DRAM technique is one of the circuit technologies that can reduce the effective cell size. It can store multiple voltage levels in a single DRAM cell. For example, in a four-level system, each DRAM cell corresponds to 2-bit data of "11", "10", "01", and "00". Thus, the multi-level storage technique can improve the chip density and reduce the defect-sensitive area on a DRAM chip, and it is one of the solutions to the "density and yield" problem.

52.9 Concept of 2-bit DRAM Cell

The 2-bit DRAM is an important architecture in the multi-level DRAM. Let us discuss an example of a multi-level technique used for a 4-Gb DRAM by NEC.[17] Table 52.1 lists both the 2-bit/4-level storage concept and the conventional 1-bit/2-level storage concept. In the conventional 1-bit/2-level DRAM cell, the storage voltage levels are *Vcc* or *GND,* corresponding to logic values "1" or "0". The signal charge is one half the maximum storage charge. In the 2-bit/4-level DRAM cell, the storage voltage levels are *Vcc*, two-thirds *Vcc*, one-third *Vcc*, and *GND,* corresponding to logic values "11", "10", "01", and "10", respectively. Three reference voltage levels are used to detect these four storage levels. Reference levels are positioned at the midlevel between the four storage levels. Thus, the signal charge between the storage and reference levels is one sixth of the maximum storage charge.

TABLE 52.1 Four-Level Storage

	Four-Level Storage			
	Data	Storage Voltage Level	Reference Level	Signal Level
	11	Vcc		1/6 Vcc
			5/6 Vcc	
4-Level	10	2/3 Vcc		
(2-bit)			3/6 Vcc	
Storage	01	1/3 Vcc		
			1/6 Vcc	
	00	GND		
2-Level	1	Vcc	1/2 Vcc	1/2 Vcc
Storage	0	GND		

Sense and Timing Scheme

The circuit diagram of the 2-bit/4-level storage technique is shown in Fig. 52.17. A pair of bit-lines is separated into two sections by transfer switches in order to have a capacitance ratio of two between Sections A and B.

Two sense amplifiers and two cross-coupled capacitors *Cc* are connected to each section. During the stand-by cycle, the transfer signal TG is high and the transfer switch is turned ON. The bit-lines are precharged to the half-*Vcc* level. As shown in Fig. 52.17(b), at time T1, the circuit is operated in the active cycle, and a word-line is selected and the charge stored in the cell *Cs* is transferred to the bit-lines. At time T2, the transfer switches are turned OFF and the bit-lines are isolated. At time T3, the sense amplifier in Section A is activated and the bit-lines in Section A are driven to *Vcc* and *GND,* depending on the stored data. The amplified data in Section A is the most significant bit (MSB) of the stored data because the reference level is half-*Vcc*.

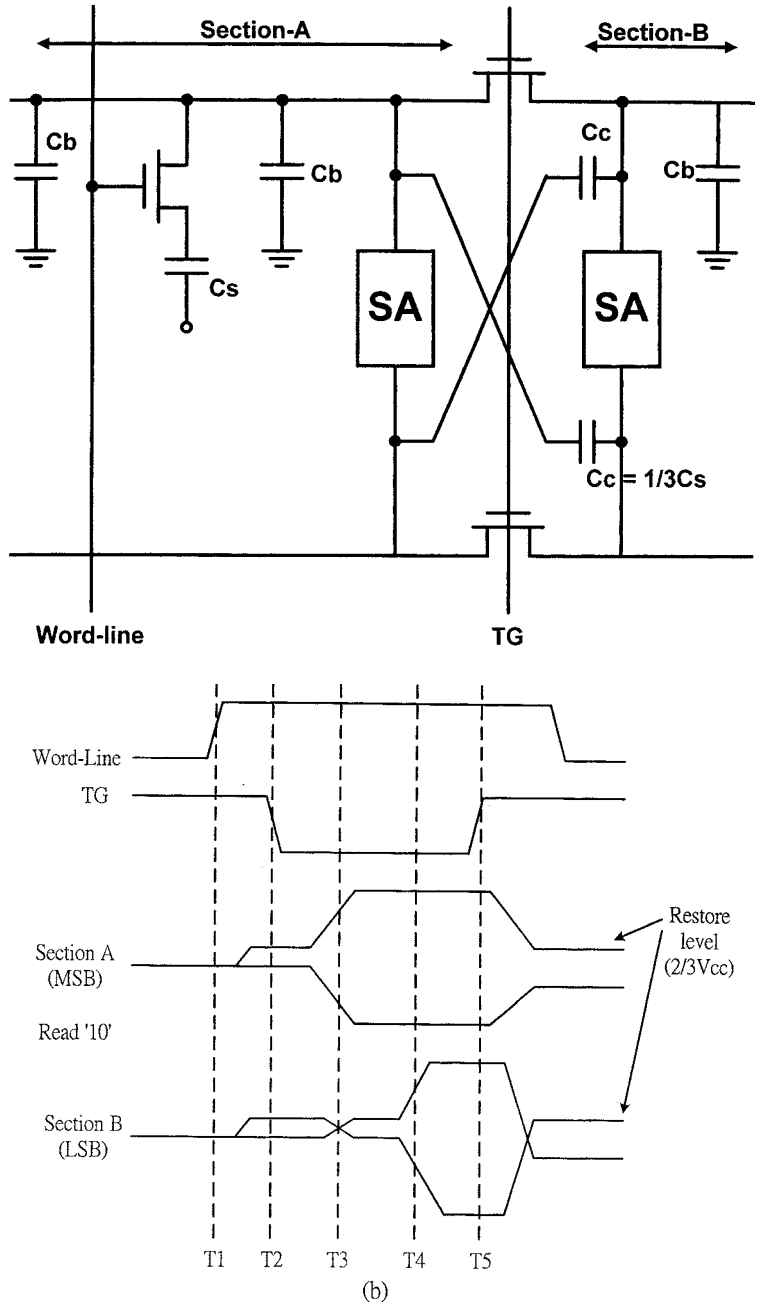

FIGURE 52.17 Principle of sense and restore: (a) circuit diagram, and (b) timing diagram.

At the same time interval, the MSB is transferred to the bit-lines in Section B through a cross-coupled capacitor *Cc*. It can change the bit-line level in Section B for subsequent least significant bit (LSB) sensing. At time T4, the sense amplifier in section B is activated and the LSB is sensed. At time T5, the transfer switch is turned ON, the charge on each bit-line is shared, and the read-out data is restored to the memory cell.

Charge-Sharing Restore Scheme

Table 52.2 lists the restored level generated by the charge-sharing restore scheme. The MSB is latched in Section A, and the LSB is latched in Section B. The capacitance ratio between Sections A and B is 2. The charge of the MSB and the charge of the LSB are combined on the bit-line, and the restore level $V_{restore}$ is generated.

TABLE 52.2 Charge-Sharing Restore Scheme

Charge–Sharing Restore Scheme				
		MSB		
Restore Level		1	0	$V_{restore} = Vcc\frac{2Cb \bullet MSB + Cb \bullet LSB}{3Cb}$
LS	1	Vcc	1/3 Vcc	
B	0	2/3 Vcc	0 (GND)	

Charge-Coupling Sensing

Figure 52.18 shows the charge in bit-line levels due to coupling capacitor *Cc*. The MSB is sensed using the reference level of half-*Vcc*, as mentioned earlier. The MSB generates the reference level for LSB sensing. When V_s is defined as the absolute signal level of data "11" and "00", the absolute signal level of data "10" and "01" is one-third of V_s. Here, V_s is directly proportional to the ratio between storage capacitor *Cs* and bit-line capacitance.

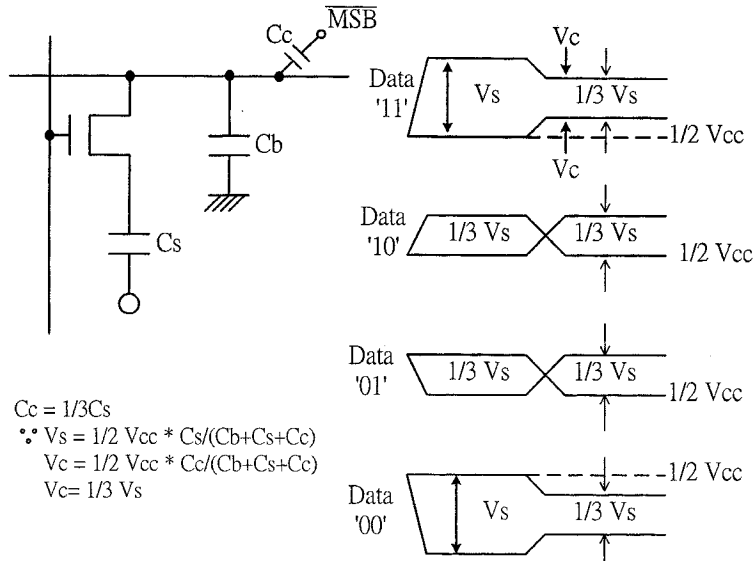

FIGURE 52.18 Charge-coupling sensing.

In the case of sensing data "11", the initial signal level is V_s. After MSB sensing, the bit-line level in Section B is changed for LSB sensing by the MSB through coupling capacitor *Cc*. The reference bit-line in Section B is raised by *Vc*, and the other bit-line is reduced by *Vc*. For LSB sensing, *Vc* is one-third of V_s due to the coupling capacitor *Cc*.

Using the two-step sensing scheme, the 2-bit data in a DRAM cell can be implemented.

Low-Power Memory Circuits

Martin Margala
University of Alberta

53.1 Introduction

In recent years, rapid development in VLSI fabrication has led to decreased device geometries and increased transistor densities of integrated circuits, and circuits with high complexities and very high frequencies have started to emerge. Such circuits consume an excessive amount of power and generate an increased amount of heat. Circuits with excessive power dissipation are more susceptible to run time failures and present serious reliability problems. Increased temperature from high-power processors tends to exacerbate several silicon failure mechanisms. Every 10°C increase in operating temperature approximately doubles a component's failure rate. Increasingly expensive packaging and cooling strategies are required as chip power increases.[1,2] Due to these concerns, circuit designers are realizing the importance of limiting power consumption and improving energy efficiency at all levels of design. The second driving force behind the low-power design phenomenon is a growing class of personal computing devices, such as portable desktops, digital pens, audio- and video-based multimedia products, and wireless communications and imaging systems, such as personal digital assistants, personal communicators, and smart cards. These devices and systems demand high-speed, high-throughput computations, complex functionalities, and often real-time processing capabilities.[3,4] The performance of these devices is limited by the size, weight, and lifetime of batteries. *Serious reliability problems, increased design costs, and battery-operated applications have prompted the IC design community to look more aggressively for new approaches and methodologies that produce more power-efficient designs, which means significant reductions in power consumption for the same level of performance.*

Memory circuits form an integral part of every system design as dynamic RAMs, static RAMs, ferroelectric RAMs, ROMs, or Flash memories significantly contribute to system-level power consumption. Two examples of recently presented reduced-power processors show that 43% and 50.3%, respectively, of the total system power consumption is attributed to memory circuits.[5,6] Therefore, reducing the power dissipation in memories can significantly improve the system power-efficiency, performance, reliability, and overall costs.

In this chapter, all sources of power consumption in different types of memories will be identified; several low-power techniques will be presented; and the latest developments in low-power memories will be analyzed.

53.2 Read-Only Memory (ROM)

ROMs are widely used in a variety of applications (permanent code storage for microprocessors or data look-up tables in multimedia processors) for fixed long-term data storage. The high area density and new submicron technologies with multiple metal layers increase the popularity of ROMs for a low-voltage, low-power environment. In the following section, sources of power dissipation in ROMs and applicable efficient low-power techniques are examined.

Sources of Power Dissipation

A basic block diagram of a ROM architecture is presented in Fig. 53.1.[7,8] It consists of an address decoder, a memory controller, a column multiplexer/driver, and a cell array. Table 53.1 lists an example of a power dissipation in a 2 K × 18 ROM designed in 0.6-μm CMOS technology at 3.3 V and clocked at 10 MHz.[8] The cell array dissipates 89% of the total ROM power, and 11% is dissipated in the decoder, control logic, and the drivers. The majority of the power consumed in the cell array is due to the precharging of large capacitive bit-lines. During the read and write cycles, more than 18 bit-lines are switched per access because the word-line selects more bit-lines than necessary. The example in Fig. 53.2 shows a 12-1 multiplexer and a bit-line with five transistors connected to it. This topology consumes excessive amounts of power because 4 more bit lines will switch instead of just one. The power dissipated in the decoder, control logic, and drivers is due to the switching activity during the read and precharge cycles and generating control signals for the entire memory.

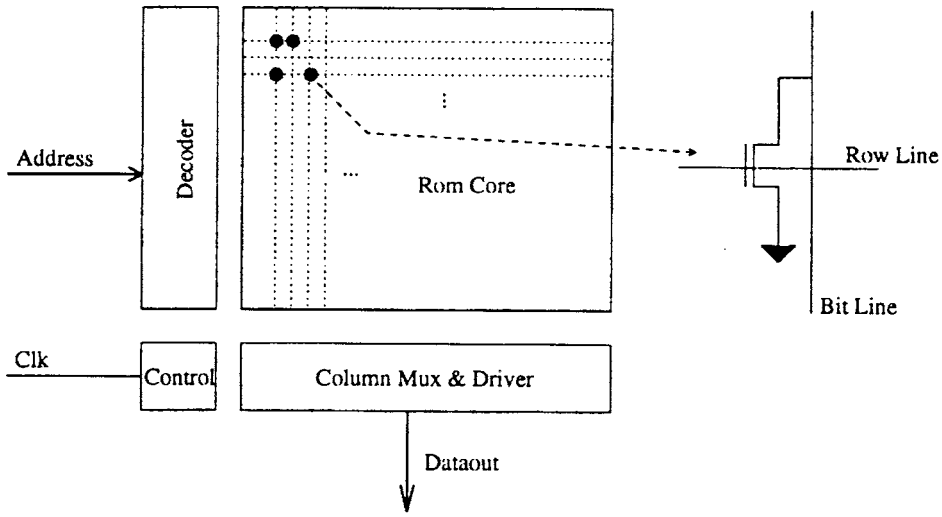

FIGURE 53.1 Basic ROM architecture. (© 1997, IEEE. With permission.)

Low-Power ROMs

In order to significantly reduce the power consumption in ROMs, every part of the architecture has to be targeted and multiple techniques have to be applied. Angel and Swartzlander[8] have identified several architectural improvements in the cell array that minimize energy waste and improve efficiency. These techniques include:

TABLE 53.1 Power Dissipation ROM 2 K × 18

Block **	Power (mW)	Percentage (%)
Decoder	0.06	2.1
ROM core	2.24	89
Control	0.18	7.2
Drivers	0.05	1.7

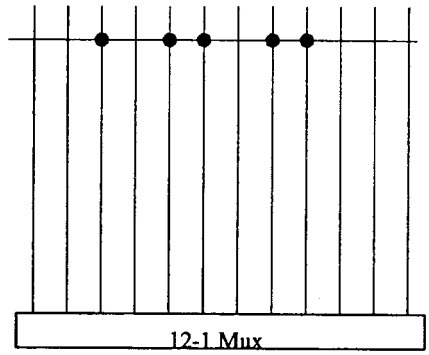

FIGURE 53.2 ROM bit-lines. (© 1997, IEEE. With permission.)

- Hierarchical word line
- Selective precharging
- Minimization of non-zero terms
- Inverted ROM core(s)
- Row(s) inversion
- Sign magnitude encoding
- Sign magnitude and inverted block
- Difference encoding
- Smaller cell arrays

All of these methods result in a reduction of the capacitance and/or switching activity of bit- and row-lines. A *hierarchical word-line* approach divides memory in separate blocks and runs the block word-line in one layer and a global word-line in another layer. As a result, only the bit cells of the desired block are accessed. A *selective precharging* method addresses the problem of activating multiple bit-lines, although only a single memory location is being accessed. By using this method, only those bit-lines that are being accessed are precharged. The hardware overhead for implementing this function is minimum. A *minimization of non-zero terms* reduces the total capacitance of bit- and row-lines because zero-terms do not switch bit-lines. This also reduces the number of transistors in the memory core. An *inverted ROM* applies to a memory with a large number of 1s. In this case, the entire ROM array could be inverted and the final data will be inverted back in the output driver circuitry. Consequently, the number of transistors and the capacitance of bit- and row-lines are reduced. An *inverted row* method also minimizes non-zero terms, but on a row-by-row basis. This type of encoding requires an extra bit (MSB) that indicates whether or not a particular row is encoded. A *sign and magnitude* encoding is used to store negative numbers. This method also minimizes the number of 1s in the memory. However, a two's complement conversion is required when data are retrieved from the memory. A *sign and magnitude and an inverted block* is a combination of the two techniques described previously. A *difference encoding* can be used to reduce the size of the cell array. In applications where

a ROM is accessed sequentially and the data read from one address does not change significantly from the following address, the memory core can store the difference between these two entries instead of the entire value. The disadvantage is a need for an additional adder circuit to calculate the original value. In applications where different bit sizes of data are needed, *smaller memory arrays* are useful to implement. If stored in a single memory array, its bit size is determined by the largest number. However, most of the bit positions in smaller numbers are occupied by non-zero values that would increase the bit-line and row-line capacitance. Therefore, by grouping the data to smaller memory arrays according to their size, significant savings in power can be achieved.

On the circuit level, powerful techniques that minimize the power dissipation can be applied. The most common technique is reducing the power supply voltage to approximately $V_{dd} \approx 2V_t$ in a correlation with the architectural-based scaling. In this region of operation, the CMOS circuits achieve the maximum power efficiency.[9,10] This results in large power savings because the power supply is a quadratic term in a well-known dynamic power equation. In addition, the static power and short-circuit power are also reduced. It is important that all the transistors in the decoder, control logic, and driver block be sized properly for low-power, low-voltage operation. Rabaey and Pedram[9] have shown that the ideal low-power sizing is when $C_d = C_L/2$, where C_d is the total parasitic capacitance from driving transistors and C_L is the total load capacitance of a particular circuit node. By applying this method to every circuit node, a maximum power efficiency can be achieved. Third, different logic styles should be explored for the implementation of the decoder, control logic, and drivers. Some alternative logic styles are superior to standard CMOS for low-power, low-voltage operation.[11,12] Fourth, by reducing the voltage swing of the bit-lines, significant reduction in switching power can be obtained. One way of implementing this technique is to use NMOS precharge transistors. The bit-lines are then precharged to $V_{dd} - V_t$. A fifth method can be applied in cases when the same location is accessed repeatedly.[8] In this case, a circuit called a *voltage keeper* can be used to store past history and avoid transitions in the data bus and adder (if sign and magnitude is implemented). The sixth method involves limiting short-circuit dissipation during address decoding and in the control logic and drivers. This can be achieved by careful design of individual logic circuits.

53.3 Flash Memory

In recent years, flash memories have become one of the fastest growing segments of semiconductor memories.[13,14] Flash memories are used in a broad range of applications, such as modems, networking equipment, PC BIOS, disk drives, digital cameras, and various new microcontrollers for leading-edge embedded applications. They are primarily used for permanent mass data storage. With the rapidly emerging area of portable computing and mobile telecommunications, the demand for low-power, low-voltage flash memories increases. Under such conditions, flash memories must employ low-power tunneling mechanisms for both write and erase operations, thinner tunneling dielectrics, and on-chip voltage pumps.

Low-Power Circuit Techniques for Flash Memories

In order to prolong the battery life in mobile devices, significant reductions of power consumption in all electronic components have to be achieved. One of the fundamental and most effective methods is a reduction in power supply voltage. This method has also been observed in Flash memories. Designs with a 3.3-V power supply, as opposed to the traditional 5-V power supply, have been reported.[15–20] In addition, multi-level architectures that lower the cost per bit, increase memory density, and improve energy efficiency per bit, have emerged.[17,20] Kawahara et al.[22] and Otsuka and Horowitz[23] have identified major bottlenecks when designing Flash memories for low-power, low-voltage operation and proposed suitable technologies and techniques for deep sub-micron, sub-2V power supply Flash memory design. Due to its construction, a Flash memory requires high voltage levels for program and erase operations, often exceeding 10 V (V_{pp}). The core circuitry that operates at these voltage levels cannot be as aggressively

scaled as the peripheral circuitry that operates with standard V_{dd}. Peripheral devices are designed to improve the power and performance of the chip, whereas core devices are designed to improve the read performance. Parameters such as the channel length, the oxide thickness, the threshold voltage, and the breakdown voltage must be adjusted to withstand high voltages. Technologies that allow two different transistor environments on the same substrate must be used. An example of transistor parameters in a multi-transistor process is given in Table 53.2.

TABLE 53.2 Transistor Parameters

	V_{DD} transistor		V_{PP} transistor	
	nmos	pmos	nmos	pmos
Channel length	0.6 μm	1.2 μm		
Oxide thickness	10 nm		22.3 nm	
Threshold voltage	0.4 V		0.79 V	0.97 V

Technologies reaching deep sub-micron levels — 0.25 μm and lower — can experience three major problems (summarized in Fig. 53.3): (1) layout of the peripheral circuits due to a scaled Flash memory cell; (2) an accurate voltage generation for the memory cells to provide the required threshold voltage and narrow deviation; and (3) deviations in dielectric film characteristics caused by large numbers of memory cells. Kawahara et al.[22] have proposed several circuit enhancements that address these problems. They proposed a sensing circuit with a relaxed layout pitch, bit-line clamped sensing multiplex, and intermittent burst data transfer for a three times feature-size pitch. They also proposed a low-power dynamic bandgap generator with voltage boosted by using triple-well bipolar transistors and voltage-doubler charge pumping, for accurate generation of 10 to 20 V that operate at V_{dd} under 2.5 V. They demonstrated these improvements on a 128-Mb experimental chip fabricated using 0.25-μm technology.

On the circuit level, three problems have been identified by Otsuka and Horowitz:[23] (1) interface between peripheral and core circuitry; (2) sense circuitry and operation margin; and (3) internal high voltage generation.

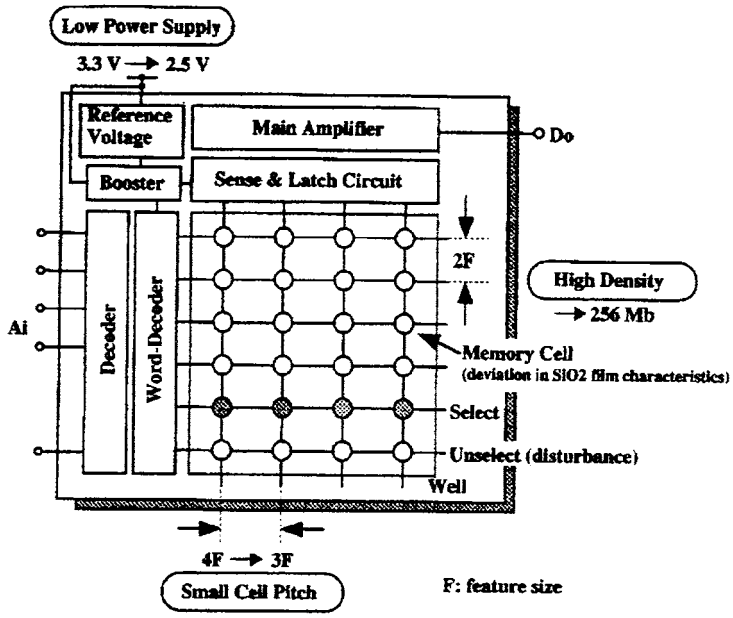

FIGURE 53.3 Quarter-micron flash memory. (© 1996, IEEE. With permission.)

During program and erase modes, the core circuits are driven with higher voltage than the peripheral circuits. This voltage is higher than V_{dd} in order to achieve good read performance. Therefore, a level-shifter circuit is necessary to interface between the peripheral and core circuitry. However, when a standard power supply (V_{dd}) is scaled to 1.5 V and lower, the threshold voltage of V_{pp} transistors will become comparable to one half of V_{dd} or less, which results in significant delay and poor operation margin of the level shifter and, consequently, degrades the read performance. A level shifter is necessary for the row decoder, column selection, and source selection circuit. Since the inputs to the level shifters switch while V_{pp} is at the read V_{pp} level, the performance of the level shifter needs to be optimized only for a read operation. In addition to a standard erase scheme, Flash memories utilizing a negative-gate erase or program scheme have been reported.[15,19] These schemes utilize a single voltage supply that results in lower power consumption. The level shifters in these Flash memories have to shift a signal from V_{dd} to V_{pp} and from Gnd to V_{bb}. Conventional level shifters suffer from delay degradation and increased power consumption when driven with low power supply voltage. There are several reasons attributed to these effects. First, at low V_{dd} (1.5 V), the threshold voltage of V_{pp} transistors is close to half the power supply voltage, which results in an insufficient gate swing to drive the pull-down transistors as shown in Fig. 53.4. This also reduces the operation margin of these shifters for the threshold voltage fluctuation of the V_{pp} transistor. Second, a rapid increase in power consumption at V_{dd} under 1.5 V is due to dc current leakage through V_{pp} to Gnd during the transient switching. At 1.5 V, 28% of the total power consumption of V_{pp} is due to dc current leakage. Two signal shifting schemes have been proposed: one for a standard flash memory and another for a negative-gate erase or program Flash memories. The first proposed design is shown in Fig. 53.5. This high-level shifter uses a bootstrapping switch to overcome the degradation due to a low input gate swing and improves the current driving capability of both pull-down drivers. It also improves the switching delay and the power consumption at 1.5 V because the

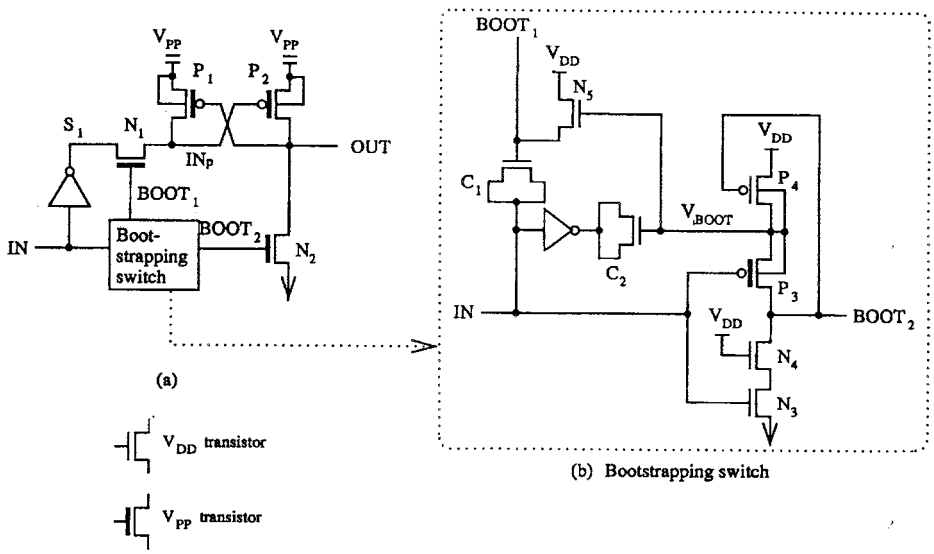

FIGURE 53.5 A high-level shifter circuit with bootstrapping switch. (© 1997, IEEE. With permission.)

bootstrapping reduces the dc current leakage during the transient switching. Consequently, the bootstrapping technique increases the operation margin. The layout overhead from the bootstrapping circuit, capacitors, and an isolated n-well is negligible compared to the total chip area because it is used only as the interface between the peripheral circuitry and the core circuitry. Figure 53.6 shows the operation of the proposed high-level shifter, and Fig. 53.7 illustrates the switching delay and the power consumption

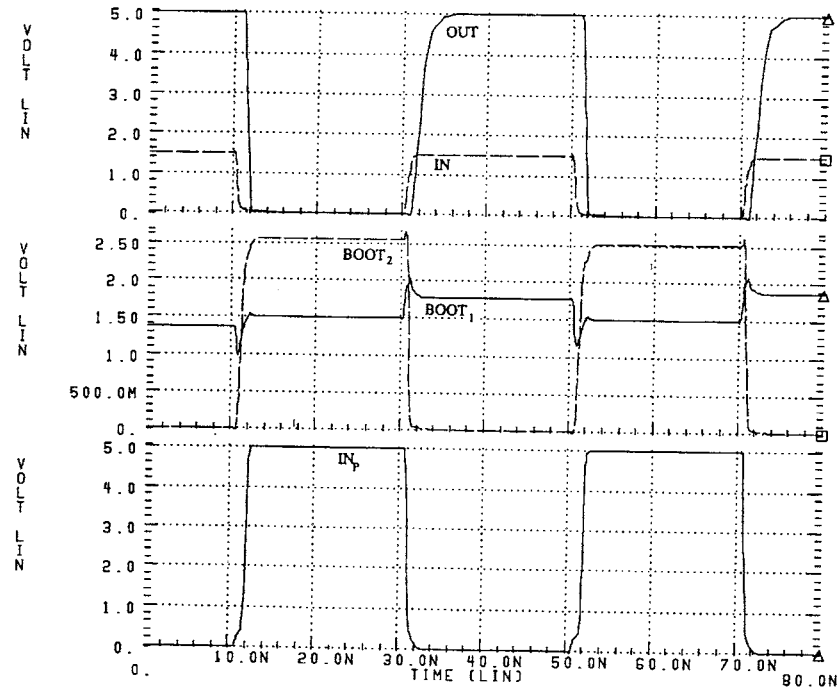

FIGURE 53.6 Operation of the proposed high-level shifter circuit. (© 1997, IEEE. With permission.)

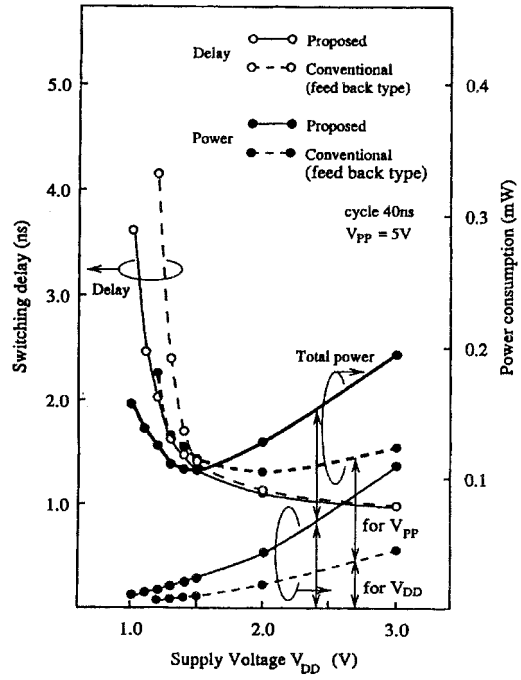

FIGURE 53.7 Comparison between proposed and conventional high-level shifters. (© 1997, IEEE. With permission.)

versus the power supply voltage of the conventional design and the proposed design. The second proposed design, shown in Fig. 53.8, is a high/low-level shifter that also utilizes a bootstrapping mechanism to improve the switching speed, reduce dc current leakage, and improve operation margin. The operation of the proposed shifter is illustrated in Fig. 53.9. At 1.5 V, the power consumption decreases by 40% compared to a conventional two-stage high/low-level shifter, as shown in Fig. 53.10. The proposed level shifter does not require an isolated n-well and therefore the circuit is suitable for a tight-pitch design and a conventional well layout.

In addition to the more efficient level-shift scheme, Otsuka and Horowitz[23] also addressed the problem of sensing under very low power supply voltages (1.5 V) and proposed a new self-bias bit-line sensing method that reduces the delay's dependence on bit-line capacitance and achieves a 19-ns reduction of the sense delay at low voltages. This enhances the power efficiency of the chip.

On a system level, Tanzawa, et al.[25] proposed an on-chip error correcting circuit (ECC) with only 2% layout overhead. By moving the ECC from off-chip to on-chip, 522-Byte temporary buffers that are required for conventional ECC and occupy a large part of ECC area, have been eliminated. As a result, the area of ECC circuit has been reduced by a factor of 25. The on-chip ECC has been optimized, which resulted in an improved power-efficiency by a factor of two.

53.4 Ferroelectric Memory (FeRAM)

Ferroelectric memory combines the advantages of a non-volatile Flash memory and the density and speed of a DRAM memory. Advances in low-voltage, low-power design toward mobile computing applications have been seen in the literature.[28,29] Hirano et al.[28] reported a new 1-transistor/1-capacitor nonvolatile ferroelectric memory architecture that operates at 2 V with 100-ns access time. They achieved these results using two new improvements: a bit-line-driven read scheme and a non-relaxation reference cell. In previous ferroelectric architectures, either a cell-plate-driven or non-cell-plate driven read scheme, as shown in Figs. 53.11(a) and (b), was used.[30,31] Although the first architecture could operate at low

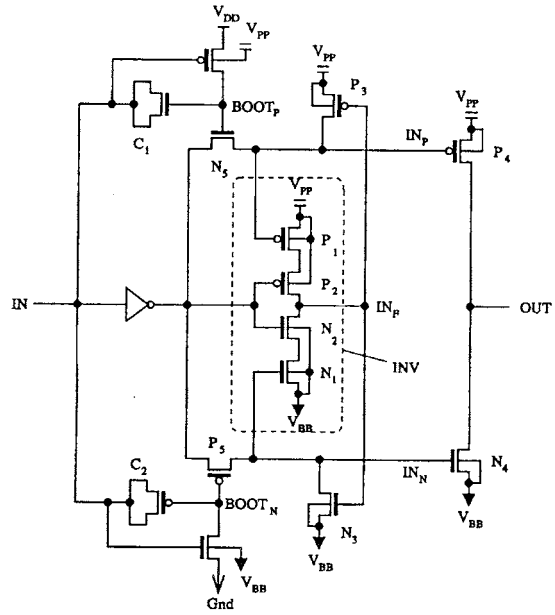

FIGURE 53.8 Proposed high/low-level shifter circuit. (© 1997, IEEE. With permission.)

FIGURE 53.9 Operation of the proposed high/low-level shifter circuit. (© 1997, IEEE. With permission.)

supply voltages, the large capacitance of the cell plate, which connects to many ferroelectric capacitors and a large parasitic capacitor, would degrade the performance of the read operation due to large transient time necessary to drive the cell plate. The second architecture suffers from two problems. The first problem is the risk of losing the data stored in the memory due to the leakage current of a capacitor. The storage

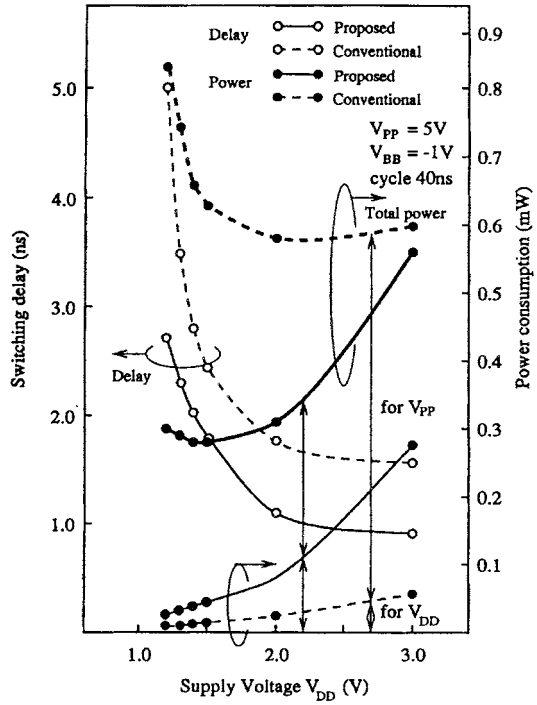

FIGURE 53.10 Comparison between proposed and conventional high/low-level shifters. (© 1997, IEEE. With permission.)

node of a memory cell is floating and the parasitic p-n junction between the storage node and the substrate leaks the current. Consequently, the storage node reaches the V_{ss} level and another node of the capacitor is kept at 1/2 V_{dd}, which causes the data destruction. Therefore, this scheme requires a refresh operation of memory cell data. The second problem arises from a low-voltage operation. Due to a voltage across the memory cell capacitor being at 1/2 V_{dd} under this scheme, the supply voltage must be twice as high as the coercive voltage of ferroelectric capacitors, which prevents the low-voltage operation. To overcome these problems, Hirano et al.[28] have developed a new bit-line-driven read scheme which is shown in Figs. 53.12 and 53.13. The bit-line-driven circuit precharges the bit-lines to supply V_{dd} voltage. The cell plate line is fixed at ground voltage in the read operation. An important characteristic of this configuration is that the bit-lines are driven, while the cell plate is not driven. Also, the precharged voltage level of the bit-lines is higher than that of the cell plate. Figure 53.14 shows the limitations of previous schemes and the new scheme. During the read operation, the first previously presented scheme[30] requires a long delay time to drive the cell plate line. However, the proposed scheme exhibits faster transient response because the bit-line capacitance is less than 1/100 of the cell plate-line capacitance. The second previously presented scheme[31] requires a data refresh operation in order to secure data retention. The read scheme proposed by Hirano et al.[28] does not require any refresh operation since the cell plate voltage is at 0 V during the stand-by mode.

The reference voltage generated by a reference cell is a critical aspect of a low-voltage operation of ferroelectric memory. The reference cell is constructed with one transistor and one ferroelectric capacitor. While a voltage is applied to the memory cell to read the data, the bit-line voltage reading from the reference cell is set to about the midpoint of "H" and "L" which are read from the main-memory-cell data. The state of the reference cell is set to "Ref" as shown at the left side of Fig. 53.15. However, a ferroelectric capacitor suffers from the relaxation effect, which decreases the polarization as shown at the right side of Fig. 53.15. As a result, each state of the main memory cells and the reference cell is shifted, and the read operation of "H" data is marginal and prohibits the scaling of power supply voltage.

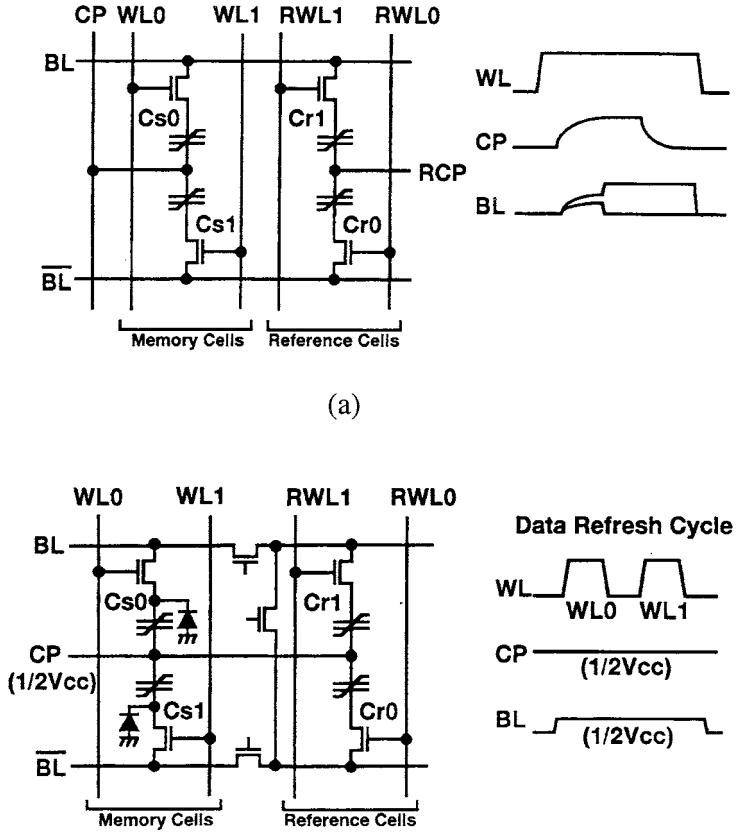

FIGURE 53.11 (a) Cell-plate-driven read scheme, and (b) non-cell-plate-driven read scheme. (© 1997, IEEE. With permission.)

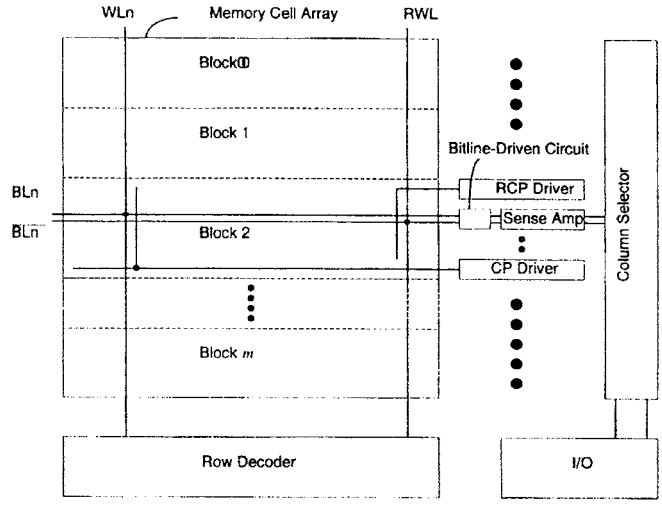

FIGURE 53.12 Memory cell array architecture. (© 1997, IEEE. With permission.)

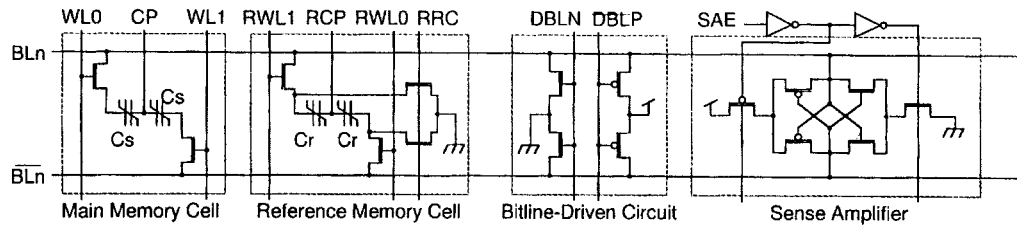

FIGURE 53.13 Memory cell and peripheral circuit with bit-line-driven read scheme. (© 1997, IEEE. With permission.)

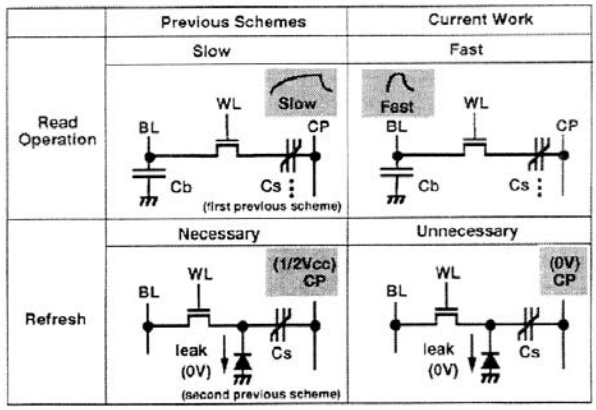

FIGURE 53.14 Limitations of previous schemes and proposed solutions. (© 1997, IEEE. With permission.)

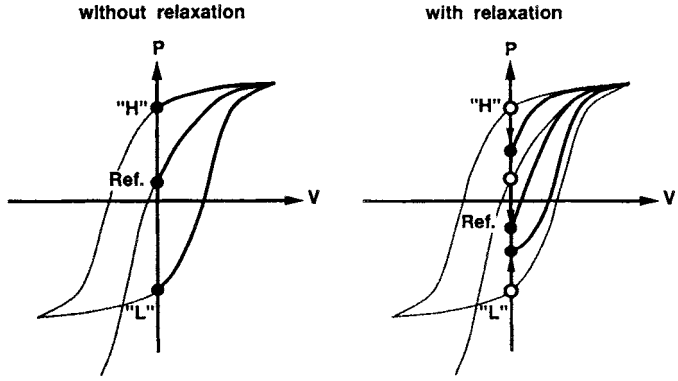

FIGURE 53.15 Reference cell proposed by Sumi et al. in Ref. 30. (© 1997, IEEE. With permission.)

Hirano et al.[28] have developed a reference cell that does not suffer from a relaxation effect, moves always along the curve from the "Ref" point, and therefore enlarges the read operation margin for "H" data. This proposed scheme enables a low-voltage operation down to 1.4 V.

Fujisawa et al.[29] addressed the problem of achieving high speed and low power operation in ferroelectric memories. Previous designs suffered from excessive power dissipation due to the need of a refresh cycle[30,31] because of the leakage current from a capacitor storage node to the substrate where the cell plates are fixed to 1/2 V_{dd}. Figure 53.16 shows a comparison of the power dissipation between ferroelectric memories

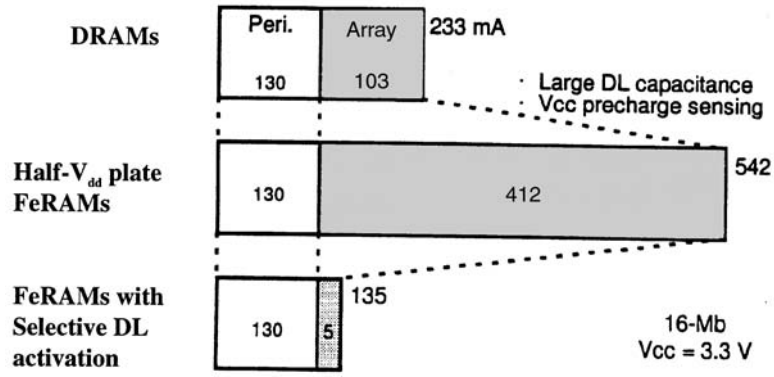

FIGURE 53.16 Comparison of the power dissipation between FeRAMs and DRAMs. (© 1997, IEEE. With permission.)

(FeRAMs) and DRAMs. It can be observed that the power consumption of peripheral circuits is identical, but the power consumption of memory array sharply increases in the 1/2 V_{dd} plate FeRAMs. These problems can be summarized as follows:

- The memory cell capacitance is large and therefore the capacitance of the data-line needs to be set larger in order to increase the signal voltage of non-volatile data.
- The non-volatile data cannot be read by the 1/2 V_{dd} subdata-line precharge technique because the cell plate is set to 1/2 V_{dd}. Therefore, the data-line is precharged to V_{dd} or Gnd.

When the memory cell density rises, the number of activated data-lines increases. This increases power dissipation of the array. A selective subdata-line activation technique as shown in Fig. 53.17, which was proposed by Hamamoto et al., overcomes this problem. However, its access time is slower compared to all-subdataline activation because the selective subdataline activation requires a preparation time. Therefore, neither of these two techniques can simultaneously achieve low-power and high-speed operation.

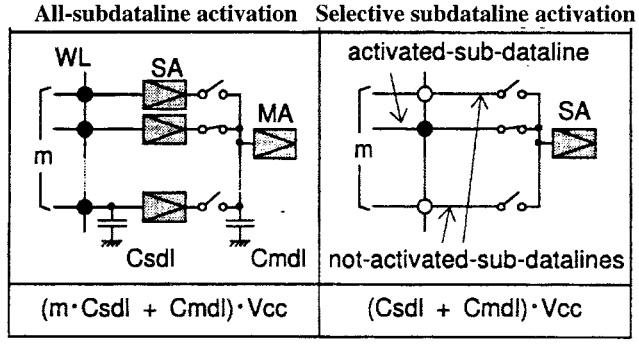

FIGURE 53.17 Low power dissipation techniques. (© 1997, IEEE. With permission.)

Fujisawa et al.[29] demonstrated a low-power high-speed FeRAM operation using an improved charge-share modified (CSM) precharge-level architecture. The new CSM architecture solves the problems of slow access speed and high power dissipation. This architecture incorporates two features that reduce the sensing period, as shown in Fig. 53.18. The first feature is the charge-sharing between the parasitic capacitance of the main data-line (MDL) and the subdata-line (SDL). During the stand-by mode, all SDLs and MDLs are precharged to 1/2 V_{dd} and V_{dd}, respectively. During the read operation, the

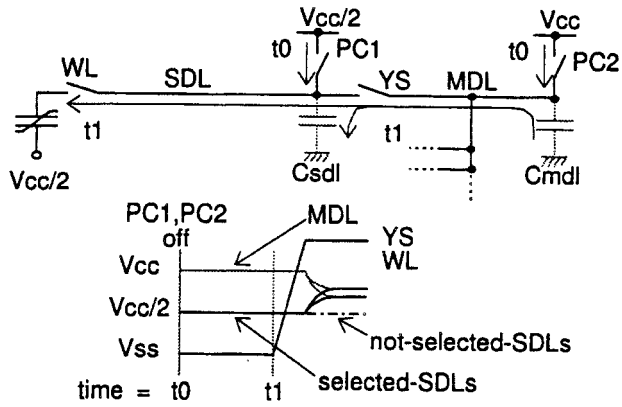

FIGURE 53.18 Principle of the CSM architecture. (© 1997, IEEE. With permission.)

precharge circuits are all cut off from the data lines (time t_0). After the y-selection signal (YS) is activated (time t_1), the charge in the parasitic capacitance of the MDL (C_{mdl}) is transferred to the selected parasitic capacitance of the SDL (C_{sdl}) and the selected SDL potential is raised by charge-sharing. As a result, the voltage is applied only to a memory cell intersecting selected word-line (WL) and YS. The second feature is a simultaneous activation of WL and YS without causing a loss of the readout voltage. During the write operation, only data of the selected memory cell is written, whereas all the other memory cells keep their non-volatile data.

Consequently, the power dissipation does not increase during this operation. The writing period is equal to the sensing period because WL and YS can also be activated simultaneously in the write cycle.

53.5 Static Random-Access Memory (SRAM)

SRAMs have experienced a very rapid development of low-power, low-voltage memory design during recent years due to an increased demand for notebooks, laptops, hand-held communication devices, and IC memory cards. Table 53.3 summarizes some of the latest experimental SRAMs for very low-voltage and low-power operation.

TABLE 53.3 Low-Power SRAMs Performance Comparison

Memory Size (Ref.)	Power Supply	CMOS Technology	Access Time	Power Dissipation
4 Kb (40)	0.9 V	0.6 μm	39 ns	18 μW @ 1 MHz
4 Kb (40)	1.6 V	0.6 μm	12 ns	64 μW @ 1 MHz
32 Kb (44)	1 V	0.35 μm	17 ns	5 μW @ 50 MHz
32 Kb (48)	1 V	0.35 μm	11.8 ns	3 μW @ 10 MHz
32 Kb (49)	1 V	0.25 μm	7.3 ns	0.9 μW @ 100 MHz
32 Kb (42)	1 V	0.25 μm	—	0.9 μW @ 100 MHz
32 Kb (55)	1 V	0.25 μm	7 ns	3.9 μW @ 100 MHz
256 Kb (53)	1.4 V	0.4 μm	60 ns	3.6 μW @ 5 MHz
1 Mb (50)	1 V	0.5 μm	74 ns	1 μW @ 10 MHz
1 Mb (52)	0.8 V	0.35 μm	10 ns	5 μW @ 100 MHz
4.5 Mb (51)	1.8 V	0.25 μm	1.8 ns	2.8 W @ 550 MHz
7.5 Mb (47)	3.3 V	0.6 μm	6 ns	8.42 μW @ 50 MHz
7.5 Mb (58)	3.3 V	0.8 μm	18 ns	4.8 μW @ 20 MHz

In this section, active and passive sources of power dissipation in SRAMs will be discussed and common low-power techniques will be analyzed.

Low-Power SRAMs

Sources of SRAM Power

There are different sources of active and stand-by (data retention) power present in SRAMs. The active power is the sum of the power consumed by the following components:

- Decoders
- Memory array
- Sense amplifiers
- Periphery (I/O circuitry, write circuitry, etc.) circuits

The total active power of an SRAM with $m \times n$ array of cells can be summarized by the expression[9,33,34]:

$$P_{active} = (mi_{active} + m(n-1)i_{leak} + (n+m)fC_{DE}V_{INT} + mi_{DC}\Delta tf + C_{PT}V_{INT}f + I_{DCP})V_{dd} \quad (53.1)$$

where i_{active} is the effective current of selected cells, i_{leak} is the effective data retention current of the unselected memory cells, C_{DE} is the output node capacitance of each decoder, V_{INT} is the internal power supply voltage, i_{DC} is the dc current consumed during the read operation, Δt is the activation time of the dc current consuming parts (i.e., sense amplifiers), f is the operating frequency, C_{PT} is the total capacitance of the CMOS logic and the driving circuits in the periphery, and I_{DCP} is the total static (dc) or quasi-static current of the periphery. Major sources of I_{DCP} are column circuitry and differential amplifiers on the I/O lines.

The stand-by power of an SRAM has a major source represented by $i_{leak}mn$ because the static current from other sources is negligibly small (sense amplifiers are disabled during this mode). Therefore, the total stand-by power can be expressed as:

$$P_{standby} = mni_{leak} \times V_{dd} \quad (53.2)$$

Techniques for Low-Power Operation

In order to significantly reduce the power consumption in SRAMs, all contributors to the total power must be targeted. The most efficient techniques used in recent memories are:

- Capacitance reduction of word-lines and the number of cells connected to them, data-lines, I/O lines, and decoders
- DC current reduction using new pulse operation techniques for word-lines, periphery, circuits, and sense amplifiers
- AC current reduction using new decoding techniques (i.e., multi-stage static CMOS decoding)
- Operating voltage reduction
- Leakage current reduction (in active and stand-by mode) utilizing multiple threshold voltage (MT-CMOS) or variable threshold voltage technologies (VT-CMOS)

Capacitance Reduction

The largest capacitive elements in a memory are word-lines, bit-lines, and data-lines, each with a number of cells connected to them. Therefore, reducing the size of these lines can have a significant impact on power consumption reduction. A common technique often used in large memories is called Divided Word Line (DWL), which adopts a two-stage hierarchical row decoder structure as shown in Fig. 53.19.[34] The number of sub-word-lines connected to one main word-line in the data-line direction is generally four, substituting the area of a main row decoder with the area of a local row decoder. DWL features two-step decoding for selecting one word-line, greatly reducing the capacitance of the address lines to a row decoder and the word-line RC delay.

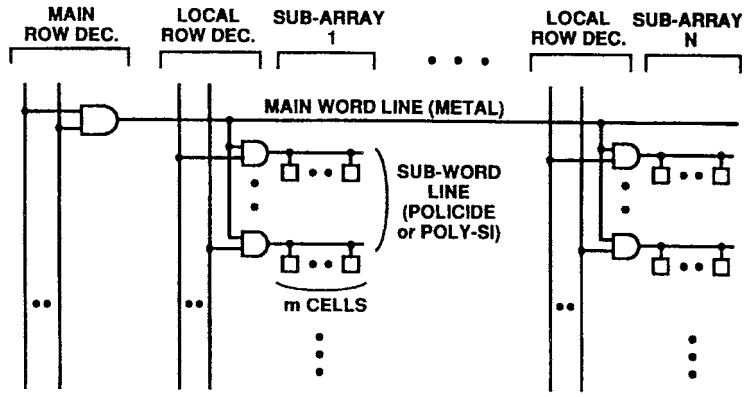

FIGURE 53.19 Divided word-line structure (DWL). (© 1995, IEEE. With permission.)

A single bit-line cross-point cell activation (SCPA) architecture reduces the power further by improving the DWL technique.[36] The architecture enables the smallest column current possible without increasing the block division of the cell array, thus reducing the decoder area and the memory core area. The cell architecture is shown in Fig. 53.20. The Y-address controls the access transistors and the X-address. Since only one memory cell at the cross-point of X- and Y- is activated, a column current is drawn only by the accessed cell. As a result, the column current is minimized. In addition, SCPA allows the number of blocks to be reduced because the column current is independent of the number of block divisions in the SCPA. The disadvantage of this configuration is that during the write "high" cycle, both X- and Y-lines have to be boosted using a word-line boost circuit.

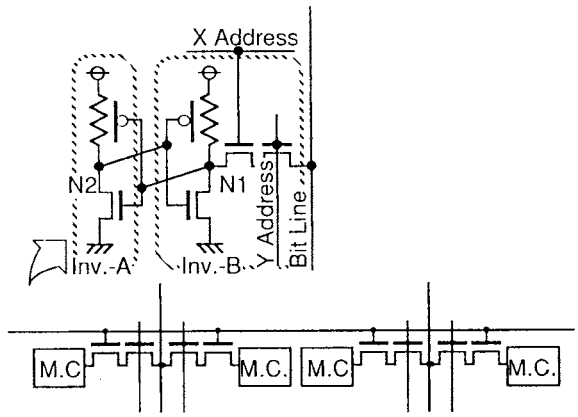

FIGURE 53.20 Memory cell used for SCPA architecture. (© 1994, IEEE. With permission.)

Caravella proposed a similar subdivision technique to DWL, which he demonstrated on 64 × 64 bit cell array.[39,40] If C_j is a parasitic capacitance associated with a single bit cell load on a bit-line (junction and metal) and if C_{ch} is a parasitic capacitance associated with a single bit cell on the word-line (gate, fringe, and metal), then the total bit-line capacitance is $64 \times C_j$ and the total word capacitance is $64 \times C_{ch}$. If the array is divided into four isolated sub-arrays of 32×32 bit cells, the total bit-line and word-line capacitances would be halved, as shown in Fig. 53.21. The total capacitance per read/write that would need to be discharged or charged is given by $1024 \times C_j + 32 \times C_{ch}$ for the sub-array architecture as opposed to $4096 \times C_j + 64 \times C_{ch}$ for the 64×64 array. This technique carries a penalty due to additional decode and control logic and routing.

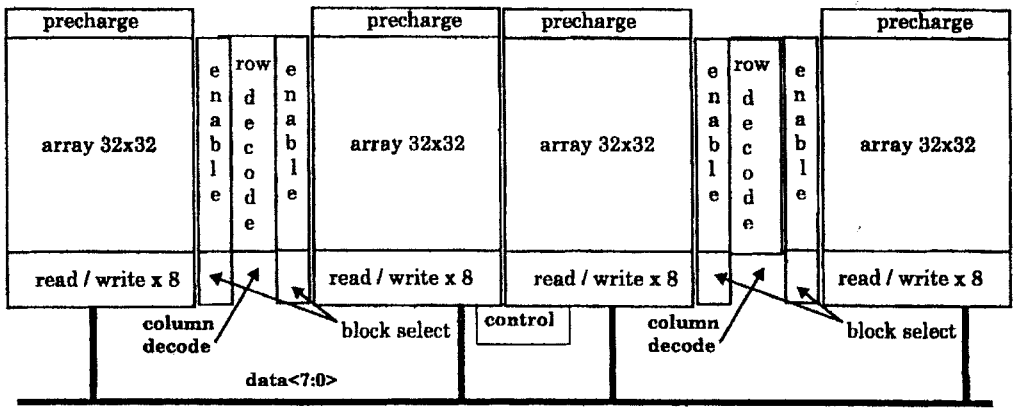

FIGURE 53.21 Memory architecture. (© 1997, IEEE. With permission.)

Pulse Operation Techniques

Pulsing the word-lines, equalization, and sense lines can shorten the active duty cycle and thus reduce the power dissipation. In order to generate different pulse signals, an on-chip address transition detection (ATD) pulse generator is used.[34] This circuit, shown in Fig. 53.22, is a key element for the active power reduction in memories.

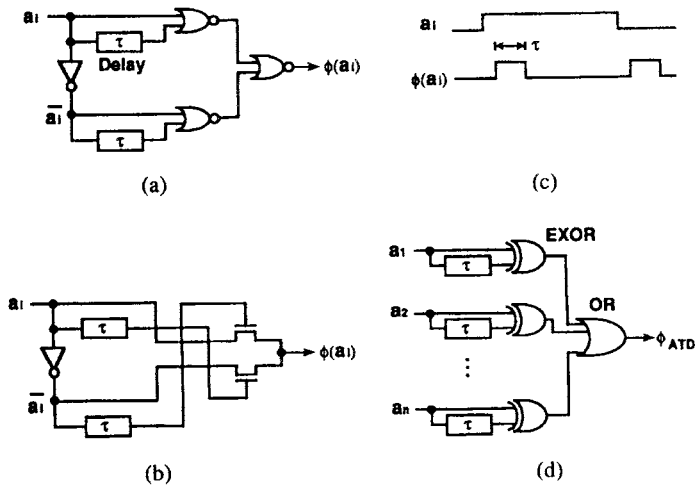

FIGURE 53.22 Address transition detection circuits: (a) and (b) ATD pulse generators; (c) ATD pulse wave-forms; and (d) a summation circuit of all ATD pulses generated from all address transitions. (© 1995, IEEE. With permission.)

An ATD generator consists of delay circuits (i.e., inverter chains) and an XOR circuit. The ATD circuit generates a $\phi(a_i)$ pulse every time it detects an "L"-to-"H" or "H"-to-"L" transition on the input address signal a_i. Then, all ATD-generated pulses from all address transitions are summed through an OR gate to a single pulse ϕ_{ATD}. This final pulse is usually stretched out with a delay circuit to generate different pulses needed in the SRAM and used to reduce power or speed up a signal propagation.

Pulsed operation techniques are also used to reduce power consumption by reducing the signal swing on high-capacitance predecode lines, write-bus-lines, and bit-lines without sacrificing the performance.[37,42,49] These techniques target the power that is consumed during write and decode operations.

Most of the power savings comes from operating the bit-lines from $V_{dd}/2$ rather than V_{dd}. This approach is based on the new half-swing pulse-mode gate family. Figure 53.23 shows a half-swing pulse-mode AND gate. The principle of the operation is in a merger of a voltage-level converter with a logical AND. A positive half-swing (transitions from a rest state $V_{dd}/2$ to V_{dd} and back to $V_{dd}/2$) and a negative half-swing (transitions from a rest state $V_{dd}/2$ to Gnd and back to $V_{dd}/2$) combined with the receiver-gate logic style result in a full gate overdrive with negligible effects of the low-swing inputs on the performance of the receiver. This structure is combined with a self-resetting circuitry and a PMOS leaker to improve the noise margin and the speed of the output reset transition, as shown in Figure 53.24.

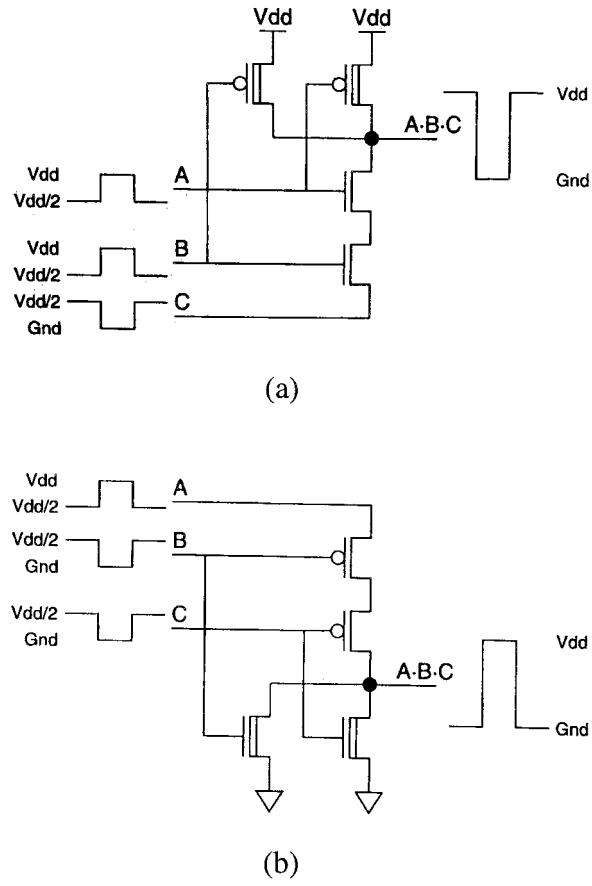

FIGURE 53.23 Half-swing pulse-mode AND gate: (a) NMOS-style, and (b) PMOS-style (© 1998, IEEE. With permission.)

Both negative and positive half-swing pulses can reduce the power consumption further by using a charge recycling. The charge used to produce the assert transition of a positive pulse can also be used to produce the reset transition of a negative pulse. If the capacitances of positive and negative pulses match, then no current would be drawn from the $V_{dd}/2$ power supply ($V_{dd}/2$ voltage is generated by an on-chip voltage converter). Combining the half-swing pulse-mode logic with the charge recycling techniques, 75% of the power on high-capacitance lines can be saved.[49]

AC Current Reduction

One of the circuit techniques that reduces AC current in memories is multi-stage decoding. It is common that fast static CMOS decoders are based on OR/NOR and AND/NAND architectures. Figure 53.25 shows one example of a row decoder for a three-bit address. The input buffers drive the interconnect capacitance

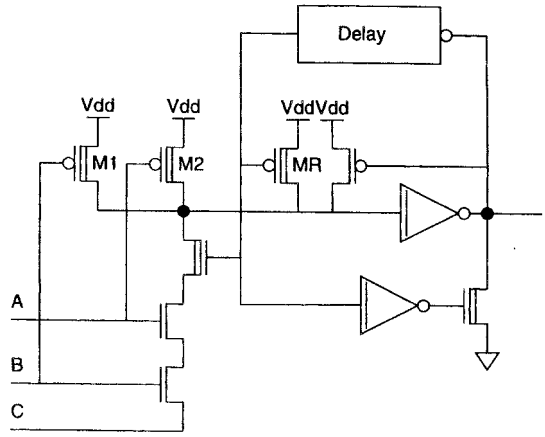

FIGURE 53.24 Self-resetting half-swing pulse-mode gate with a PMOS leaker. (© 1998, IEEE. With permission.)

of the address line and also the input capacitance of the NAND gates. By using a two-stage decode architecture, the number of transistors, fanin and the loading on the address input buffers are reduced, as shown in Fig. 53.26. As a result, both speed and power are optimized. The signal ϕ_x, generated by the ATD pulse generator, enables the decoder and secures pulse-activated word-line

Operating Voltage Reduction and Low-Power Sensing Techniques

Operating voltage reduction is the most powerful method for power conservation. Power supply voltage reductions down to 1 V[35,42,44,46,48–50,55] and below[40,52,53] have been reported. This aggressively scaled environment requires news skills in new fast-speed and low-power sensing schemes. .A charge-transfer sense

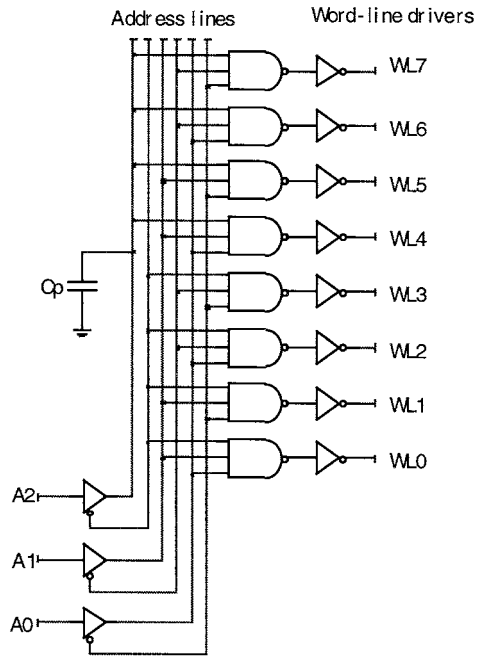

FIGURE 53.25 A row decoder for a three-bit address.

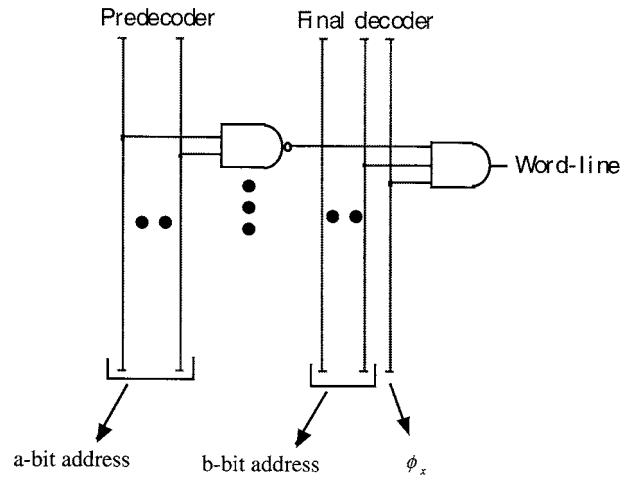

FIGURE 53.26 A two-stage decoder architecture.

amplifying scheme combined with a dual-V_t CMOS circuit achieves a fast sensing speed and a very low power dissipation at 1 V power supply.[44,55] At this voltage level, the "roll-off" on threshold voltage versus gate length, the shortest gate length causes the V_{th} mismatch between the pair of MOSFETs in the differential sense amplifier. Figure 53.27 shows the schematic of a charge-transfer sense amplifier. The charge-transfer (CT) transistors perform the sensing and act as a cross-couple latch. For the read operation, the supply voltage of the sense amplifiers changes from 1 V to 1.5 V by p-MOSFETs. The threshold voltage mismatch between two CTs is completely compensated because CTs themselves form a latch. Consequently, the bit-line precharge time, before the word-line pulse, can be omitted due to improved sensitivity. The cycle time is shortened because all clock timing signals in read operation are completed within the width of the word-line pulse.

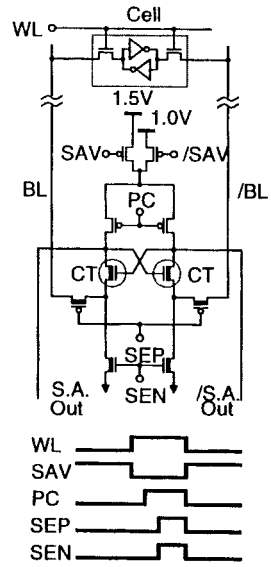

FIGURE 53.27 Charge-transfer sense amplifier. (© 1998 IEEE. With permission.)

Another method is the step-down, boosted-word-line scheme combined with current-sensing amplification. Boosting a selected word-line voltage shortens the bit-line delay before the stored data are sensed. The power consumption is reduced during the word-line selection using a stepping down technique of selected world-line potential.[46] However, this causes an increased power dissipation and a large transition time due to enhanced bit-line swing. The operation of this scheme is shown in Figure 53.28. After the selected word-line is boosted, it is restricted to only a short period at the beginning of the memory-cell access. This enables an early sensing operation. When the bit-lines are sensed, the word-line potential is reduced to the supply voltage level to suppress the power dissipation. Reduced signals on the bit-lines are sufficient to complete the read cycle with the current sensing. A fast read operation is obtained with little power penalty. The step-down boosting method is also used for write operation. The circuit diagram of this method is shown in Fig. 53.29. Word drivers are connected to the boosted-pulse generator via switches S_1 and S_2. These switches separate the parasitic capacitance C_B from the boosted line, thus reducing its capacitance. NMOS transistors are more suitable for implementing these switches because they do not require a level-shift circuit. Transistor Q1 is used for the stepping-down function. During the boost, the gate electrode is set to V_{dd}. If the word-line charge exceeds $V_{dd} + |V_{tp}|$, then Q1 ($|V_{tp}|$ is a threshold voltage of Q1) turns on and the word-line is clamped. After the stepping-down process, ϕ_{SEL} switches low and Q1 guarantees V_{dd} voltage on the word-line.

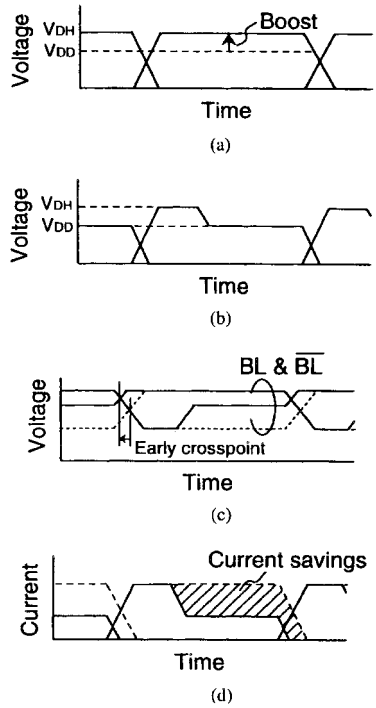

FIGURE 53.28 Step-down boosted word-line scheme: (a) conventional, (b) step-down boosted word-line, (c) bit-line transition, and (d) current consumption of a selected memory cell. (© 1998 IEEE. With permission.)

An efficient method for reducing the AC power of bit-lines and data-lines is to use the current-mode read and write operations based on new current-based circuit techniques.[47,56,57] Wang et al. proposed a new SRAM cell that supports current-mode operations with very small voltage swings on bit-lines and datalines. A fully current-mode technique consumes only 30% of the power consumed by a previous current-read-only design. Very small voltage swings on bit-lines and data-lines lead to a significant reduction of ac power. The new memory cell has seven transistors, as shown in Fig. 53.30. The additional

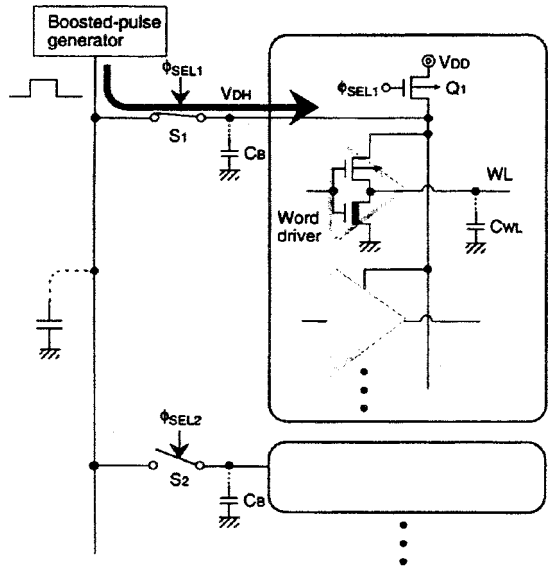

FIGURE 53.29 Circuit schematic of step-down boosted word-line method. (© 1998 IEEE. With permission.)

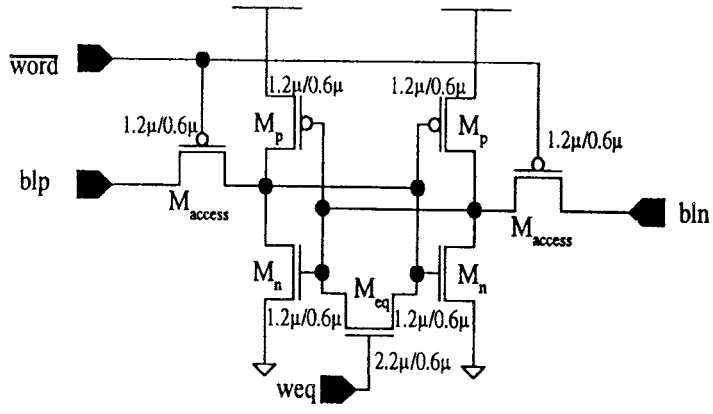

FIGURE 53.30 New 7-transistor SRAM memory cell. (© 1998, IEEE. With permission.)

transistor M_{eq} clears the content of the memory cell prior to the write operation. It performs the cell equalization. This transistor is turned off during the read operation so it does not disrupt the normal operation. An n-type current conveyor is inserted between the data input cell and the memory cell in order to perform a current-mode write operation, which is a complementary way to read. The equalization transistor is sized to be as large as possible to improve fast equalization speed, but not to increase the cell size. After suitable sizing, the new 7-transistor cell is 4.3% smaller than its 6-transistor counterpart, as illustrated in Fig. 53.31.

Another new current-mode sense amplifier for 1.5-V power supply was proposed by Wang and Lee.[57] The new circuit overcomes the problems of a conventional sense amplifier with pattern dependency by implementing a modified current conveyor. A pattern-dependency problem limits the scaling of the operating voltage. Also, the circuit does not consume any DC power because it is constructed as a complementary device. As a result, the power consumption is reduced by 61 to 94% compared with a

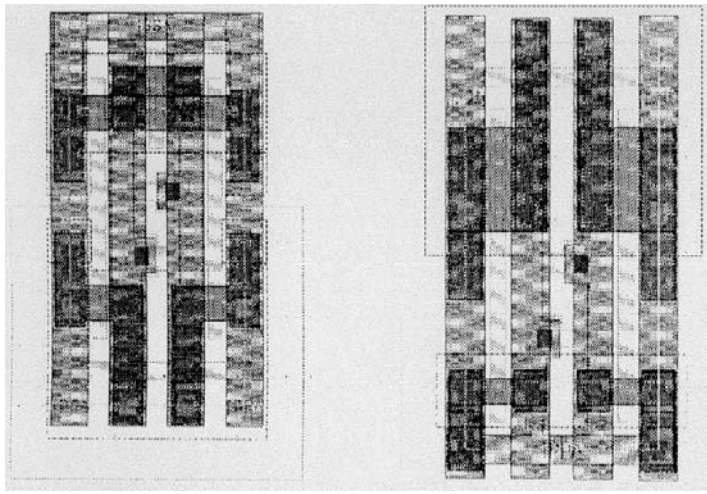

FIGURE 53.31 SRAM cell layout: (a) 6T cell, and (b) new 7T cell. (© 1998, IEEE. With permission.)

conventional design. The circuit structure of the modified current conveyor is similar to a conventional current conveyor design. However, an extra PMOS transistor Mp7, as seen in Fig. 53.32, is used. The transistor is controlled by RX signal (a complement of CS). After every read cycle, transistor Mp7 is turned on and equalizes nodes RXP and RXN, which eliminates any residual differential voltage between these two nodes (limitation in conventional designs).

Leakage Current Reduction

In order to effectively reduce the dynamic power consumption, the threshold voltage is reduced along with the operating voltage. However, low threshold voltages increase the leakage current during both active and stand-by modes. The fundamental method for a leakage current reduction is a dual-V_{th} or a variable-V_{th} circuit technique. An example of one such technique is shown in Fig. 53.33.[44,55] Here, high V_{th} MOS transistors are utilized to reduce the leakage current during stand-by mode. As the supply voltage for the word decoder (g) is lowered to 1 V, all transistors forming the decoder are low V_{th} to retain high performance. The leakage currents during the stand-by mode are substantially reduced by a cut-off switch (SWP, SWN). SWN consists of a high V_{th} transistor, and SWP consists of a low V_{th} transistor. Both switches are controlled by a 1.5-V signal. Hence, the SWN gains considerable conductivity. SWP can be quickly cut off because of the reverse-biasing. The operating voltage of the local decoder (w) is boosted to 1.5 V. The high operating voltage gives sufficient drivability even to high V_{th} transistors.

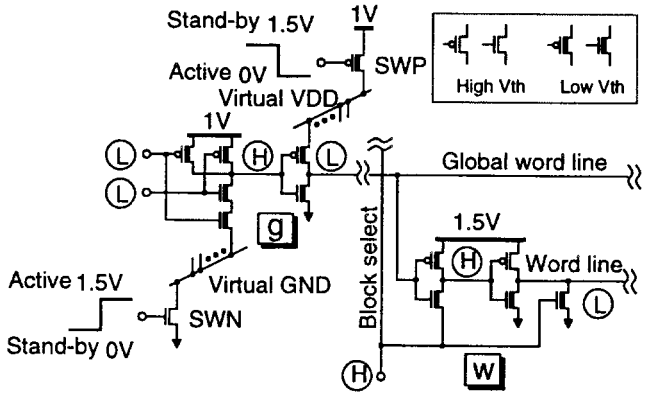

FIGURE 53.33 Dual V_{th} CMOS circuit scheme. (© 1998, IEEE. With permission.)

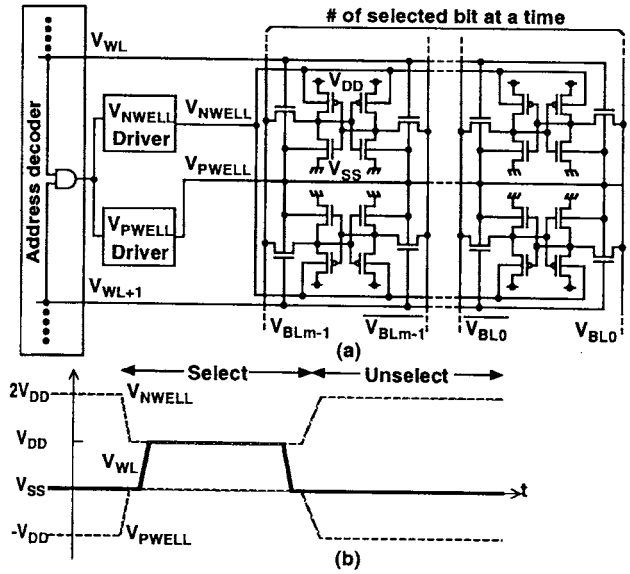

FIGURE 53.34 Dynamic leakage cut-off scheme: (a) circuit schematic and (b) its operation. (© 1998, IEEE. With permission.)

This technique belongs to schemes that use dynamic boosting of the power supply voltage and word-lines. However, in these schemes, the gate voltage of MOSFETs is often raised to more than 1.4 V, although the operating voltage is 0.8 V. This creates reliability problems.

Kawaguchi et al.[54] introduced a new technique — a dynamic leakage cut-off (DLC) scheme. Operation waveforms are shown in Fig. 53.34. A dynamic change of n-well and p-well bias voltages to V_{dd} and V_{ss}, respectively, for selected memory cells is the key feature of this architecture. At the same time, the non-selected memory cells are biased with ~$2V_{dd}$ for V_{NWELL}, and ~–V_{dd} for V_{PWELL}. After this, the V_{th} of the selected cells becomes low, which aids in high drive. Thus, a fast operation is executed. On the other hand, the V_{th} of the unselected memory cells is high enough to achieve low subthreshold current consumption. This technique is similar to the Variable Threshold CMOS (VT CMOS) technique; however, the difference is in the synchronization signal of the well bias. While in VT CMOS, the well bias is synchronized with a stand-by signal, DLC technique is synchronized with the word-line signal.

Nii et al.[48] improved the MT-CMOS technique further and proposed the Auto-Backgate Controlled (ABC) MT-CMOS method. The ABC MT-CMOS reduces significantly the leakage current during the "sleep" mode. The circuit diagram of this method is shown in Fig. 53.35. Transistors Q1-Q4 are high-threshold devices that act as switches to cut off the leakage current. The internal circuitry is designed with low-V_t devices. During the active mode, signal *SL* is pulled low and $\overline{SL}$ is pulled high. Q1, Q2, and Q3 turn on, Q4 turns off, and virtual power supply VVDD and the substrate bias BP become 1 V. During the sleep mode, signal *SL* is pulled high, $\overline{SL}$ is pulled low, and Q1, Q2, and Q3 turn off, whereas Q4 turns on and BP becomes 3.3 V. The leakage current that flows from Vdd2 to ground through D1, and D2 determines voltages Vd1, Vd2, and Vm. Vd1 is a bias between the source and the substrate of the PMOS transistors, Vd2 is a bias of the NMOS transistors, and Vm is a voltage between the virtual power line VVDD and the virtual ground VGND. The leakage current is reduced to 20 pA/cell.

53.6 Dynamic Random-Access Memory (DRAM)

Similar to all previous types of memories, DRAM has undergone a remarkable development toward higher access speed, higher density, and reduced power.[34,61–64] As for reducing power, a variety of techniques targeting various sources of power in DRAMs have been reported. In this section, sources of power consumption will be discussed and then several methods for the reduction of active and data retention power in DRAMs will be described.

Low-Power DRAM Circuits

Sources of DRAM Power

The total power dissipated in a DRAM has two components: the active power and the data retention power. Major contributors to the active power are: decoders (row and column), memory array, sense amplifier, DC current dissipation of other circuits (a refresh circuitry, a substrate back-bias generator, a boosted level generator, a voltage reference circuit, a half-Vdd generator and a voltage down converter), and remaining periphery circuits (main sense amplifier, I/O buffers, write circuitry, etc). The total active power can be described as:

$$P_{active} = [(mC_D\Delta V_D + C_{PT}V_{INT})f + I_{DCP}]V_{dd} \quad (53.3)$$

where C_D is the data-line capacitance, ΔV_D is the data-line voltage swing (0.5 V_{dd}), m is the number of cells connected to the activated data-line, C_{PT} is the capacitance of the periphery circuits, V_{INT} is the internal supply voltage, and I_{DCP} is the static current.

The total data retention power is given as:

$$P_{retention} = = [(mC_D\Delta V_D + C_{PT}V_{INT})(n/t_{REF}) + I_{DCP}]V_{dd} \quad (53.4)$$

where n is the number of words that require refresh and $1/t_{REF}$ is the frequency of the refresh operation (current).

Techniques for Low-Power Operation

To reduce power consumption during both modes of DRAM operation, many circuit techniques can be applied, including:

- Capacitance reduction, especially of data-lines, word-lines, and shared I/O, using partial activation of multi-divided data-lines and partial activation of multi-divided word-lines
- Lowering of external and internal voltages
- DC power reduction of peripheral circuits during the active mode by using static CMOS decoders, pulse techniques, and ATD circuit, similar to SRAMs
- Refresh power reduction (in addition to capacitance reduction and operating voltages reduction, which are also applicable to the refresh mode, decreasing the frequency of refresh cycle or decreasing the number of words n that require refresh affects the total refresh power).
- AC and DC power reduction of circuits such as a voltage down converter (VDC), a half-voltage generator (HVG), a boosted voltage generator (BVG), and a back-bias generator (BBG)

Capacitance Reduction

Charging and discharging large data- and word-lines contribute to large amounts of dissipated power in a DRAM.[34,64] Therefore, minimizing the capacitance of these lines can accomplish significant gains in power savings. There are two fundamental methods used to reduce capacitance in DRAMs: partial activation of multi-divided data-line and partial activation of multi-divided word-line. The concept of both techniques is shown in Figs. 53.36 and 53.37.

The foundation of partial activation of multi-divided data-line (Fig. 53.36) is in reducing the number of memory cells connected to an active data-line, thus reducing its capacitance C_D. The data-lines are divided into small sections with shared I/O circuitry and a sense amplifier. By sharing these resources, further reduction of C_D is achieved. The partial activation is performed by activating only one sense amplifier along the data-line. The principle of the partial activation of multi-divided word-line (see Fig. 53.37) is very similar to that of SRAMs. A single word-line is divided into several ones by the subword-line drivers (SWL). Every SWL has to be selected by the main word-line (MWL) and the row select line signal (RX). Thus, only a partial word-line will be activated.

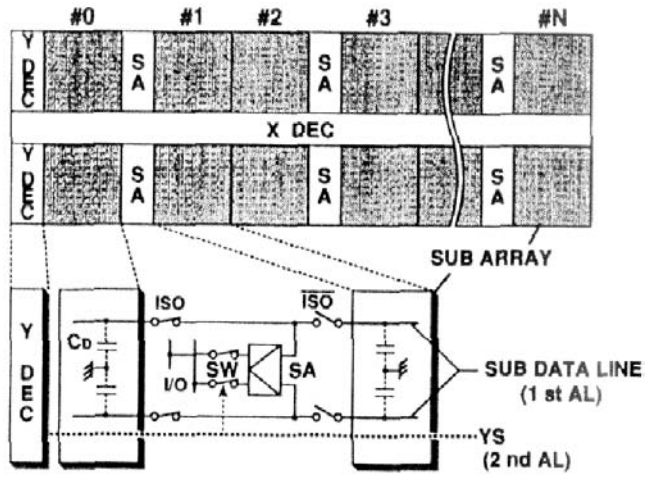

FIGURE 53.36 Multi-divided data-line architecture. (© 1995, IEEE. With permission.)

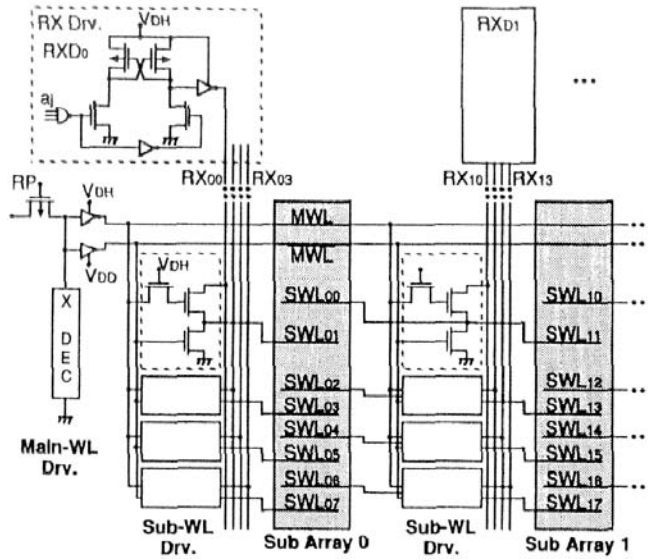

FIGURE 53.37 Hierarchical word-line architecture. (© 1995, IEEE. With permission.)

A similar method, called a hierarchical decoding scheme with dynamic CMOS series logic predecoder, has been proposed for synchronous DRAMs (SDRAMs).[65,66] This method targets the power losses in the peripheral region of the memory. This power is consumed due to the large capacitive loading of the data-lines, the address-lines, and the predecoder lines. The scheme is shown in Fig. 53.38. The hierarchical decoder uses predecoded signal lines where the redundancy circuits are connected directly from the global lines. This results in a reduced capacitive loading and a 50% reduction in the number of bus lines (column and row decoders). This circuit technique can be combined with a design of a small-swing single-address driver with a dynamic predecoder.[65,66] This scheme allows a reduction of 23 address lines. The schematic diagram of this circuit is shown in Fig. 53.39. Also, the scheme achieves a small swing in address lines with a short pulse-driven pull-up transistor with a level holder of half-V_{INT} power. The pull-up for the reduced swing bus line is achieved with a short pulse and its width brings the bus signal close to the small swing voltage (V_{INTL}).

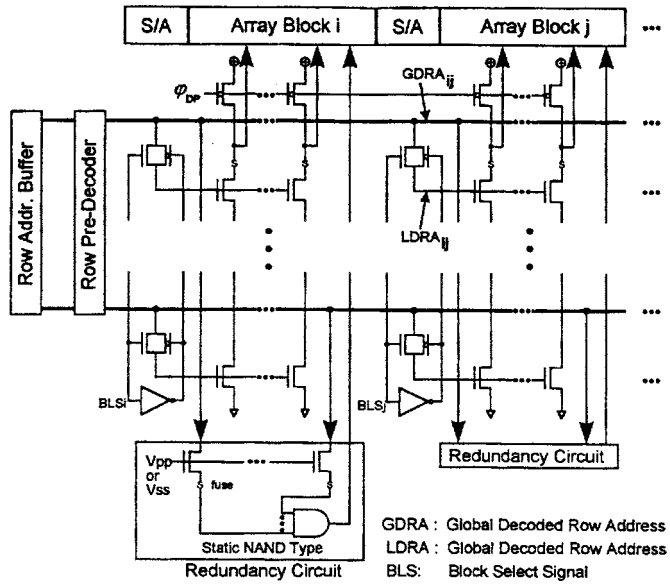

FIGURE 53.38 A decoding scheme with the hierarchical predecoded row signal and global signals shared with redundancy. (© 1998, IEEE. With permission.)

DC Current Reduction

During the active mode, most of the DC power in DRAMs and SDRAMs is consumed by the periphery circuits and I/O lines. The decoding and pulsed operation techniques based on an ATD circuit and similar to those for SRAMs can be applied. In order to minimize power consumption of I/O lines in SDRAMs, two circuit techniques have been proposed.[68] As for the first technique, the extended small-swing read operation ($\Delta V_{I/O} = \pm 200$ mV), the small-swing data paths (local I/O and global I/O) are extended up to the output buffer stages through main I/O (MIO) lines (see Fig. 53.39). Shared current sense amplifiers (I/O sense amplifiers) also reduce power consumption. In the second technique, the single I/O line driving

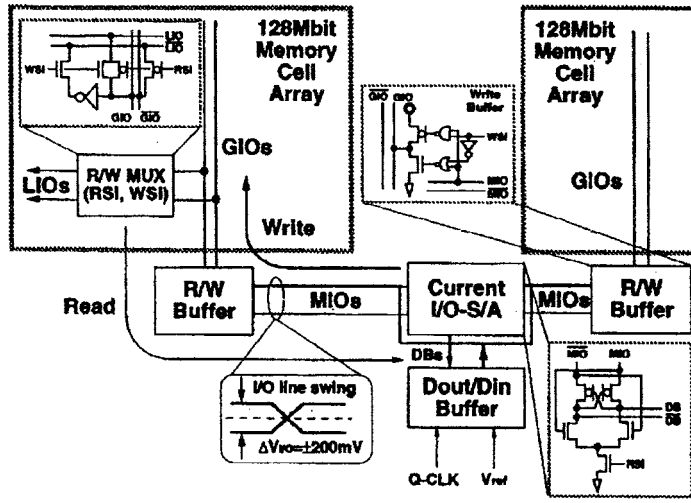

FIGURE 53.39 Block diagram of I/O datapath. (© 1996, IEEE. With permission.)

write operation halves the operating current of long global I/O lines and main I/O lines. By combining these two methods, as much as 30% of total peripheral power can be saved.

Another power-saving method for low-power SDRAMs is based on a new cell-operating concept.[69] When the operating voltage of the memory array is scaled to 1.8 V for 1-Gb SDRAMs, the performance significantly degrades due to the following factors. First, the sensing speed decreases due to the noticeable threshold voltage of source-floated transistors. Second, a triple-pumping circuit may be required to increase the power of boosted word-lines (relatively high V_{pp}). The concept of the proposed method is that the bit-lines are precharged to ground level (V_{ss}). The word-line reset voltage is –0.5 V (as compared with 1/2 V_{dd} in conventional schemes) so that a cell leakage current can be prevented while lowering the threshold voltage of pass transistors. This eliminates word-line boosting because the triple-boosting circuit is no longer required.

Operating Voltages Reduction

Lowering external and internal operating voltages is considered as an important technique for achieving significant savings of power. In both active and stand-by modes, voltages from different sources, such as V_{dd}, V_{INT}, or ΔV_D, as described in Eqs. 53.3 and 53.4, largely contribute to a total power consumption. Over the last decade, a trend in the reduction of the external power supply voltage V_{dd} for DRAMs has been observed, sliding from 12 V down to 3.3, 2.5, and 1.2 V.[66,67,69,76,79] An experimental circuit with V_{dd} as low as 1 V has been recently reported.[77] The lack of a universal standard external operating power supply voltage has resulted in DRAMs with an on-chip voltage-down converter (VDC) that uses widely accepted power supply voltages V_{dd}, such as 5 V or lately 3.3 V, and lowers the operating voltage for the memory core, thus gaining power savings.[33,34,73] VDC is one of the most important DRAM circuits in achieving DRAM operation at battery voltage levels. In power-limited applications, VDC must have a stand-by current less than 1 μA over a wide range of operating temperatures, process, and power supply voltage variations. Also, its output impedance has to be low. There are additional on-chip voltage generators: half-V_{dd} generator (HVG) for precharging bit-lines; back-bias generator (BBG) for subthreshold current and junction capacitance reduction, improving device isolation and latch-up immunity and circuit protection against voltage undershoots of input signals; and boosted voltage generator (BVG) for driving the word-lines.[33,34]

The HVG circuit has been used since 1-Mb DRAM generation. It is an efficient technique to reduce the voltage swing on bit-lines from a full V_{dd} swing to $1/2V_{dd}$ swing. During the sensing, one bit-line switches from $1/2V_{dd}$ to V_{dd} and the second bit-line from $1/2V_{dd}$ to ground. As a result, the peak switching current is reduced and the noise level is suppressed. Recently, a new technique that eliminates $1/2V_{dd}$ bit-line switching was proposed.[70] This new method, called "non-precharged bit-line sensing" (NPBS), provides the following three features (as seen in Fig. 53.40): (1) the precharge operation time is reduced by 78% because the bit-lines are not substantially precharged; (2) the sensing speed increases because the bit-lines that have not been precharged remain at low or high levels, increasing the V_{GS} and V_{DS}

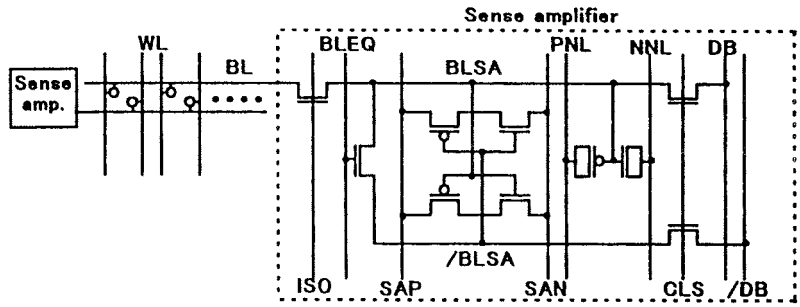

FIGURE 53.40 NPBS circuit and its operation. (© 1998, IEEE. With permission.)

voltages for the sense amplifier transistor; (3) the power dissipation is reduced when the same data occur on the bit-line. The power is reduced by about 43%.

In order to maintain or improve the speed and reliability of DRAM operations, the threshold voltage V_t has to follow the same scaling pattern as the main power supply voltage. This scenario, however, results in a rapid increase of leakage currents in the entire memory during both active and stand-by modes. Therefore, an internal back-bias generator (BBG) circuit, also known as the charge-pump, is needed to improve low-voltage, low-power operation by reducing the subthreshold currents. Figure 53.41 shows the schematic of a pumping circuit that avoids the V_t losses.[71] When the clock (clk) is at logic low, the node voltage of the node A reaches $|V_{tp}| - V_{dd}$. The PMOS transistor p1 clamps the voltage of the node B to the ground level. The VBB voltage settles at $|V_{tp}| - V_{dd} - V_{tn}$. When clk changes to logic high, the node A changes to V_{tp} and the node B is capacitively coupled to $-V_{dd}$. As a result, V_{BB} voltage changes to $-V_{dd}$. This circuit requires triple-well technology to eliminate minority carrier injection of the n1 transistor. To limit the power consumption of this circuit during DRAM's stand-by mode, the frequency of the clk signal can be reduced. This is possible to implement with BBG's own ring oscillator controlled by BBG's enable signal.

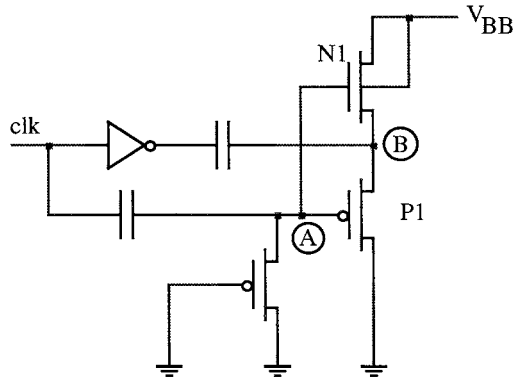

FIGURE 53.41 Low-voltage pumping circuit.

A boosted voltage circuit (BVG) is used in DRAMs to generate a power supply signal higher than V_{dd} for driving the word-lines. This word-line voltage is higher than V_{dd} by at least the threshold voltage. The boosted level cannot be directly applied to drive the load. An isolation transistor is necessary to separate the switching boosted voltage from the load. One such arrangement is shown in Fig. 53.42.[72] This particular circuit generates an output of $2V_{dd}$. Voltage scaling has no effect on its performance and, therefore, it is suitable for V_{dd} reduction down to sub-1V levels.

Leakage Current Reduction and Data-Retention Power

The key limitation in achieving a battery (1 V) or solar cell (0.5 V) operation will be the subthreshold power consumption that will dominate both active and stand-by DRAM modes. In this subsection, circuit techniques that drastically reduce leakage and data-retention power will be described.

Several methods that address the exponentially increasing threshold voltage in rapidly scaled technologies have been proposed. One such method, a well-driving scheme, uses a dynamic Vt by driving the well (see Fig. 53.43).[64,74] Thus, the threshold voltage is higher during the stand-by mode than in the active mode. The advantage of this method is a fast operation in the active mode and a leakage current suppression in the stand-by mode.

To reduce the subthreshold currents in various DRAM voltage generators, a self-off-time detector circuit could be used.[75] It automatically evaluates the optimal off-time interval and controls the dynamic ON/OFF switching ratio of power-dissipation circuits such as level detectors. This method is directly applicable to any on-chip voltage generator or self-refresh circuit. The block diagram of this architecture is shown in Fig. 53.44.

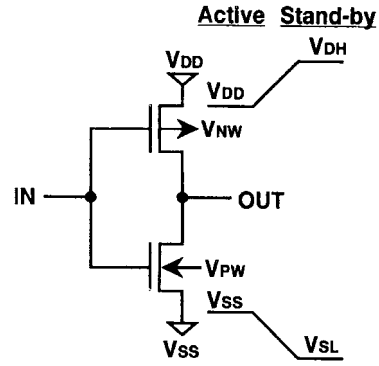

FIGURE 53.43 Low-voltage well-driving scheme. (© 1995, IEEE. With permission.)

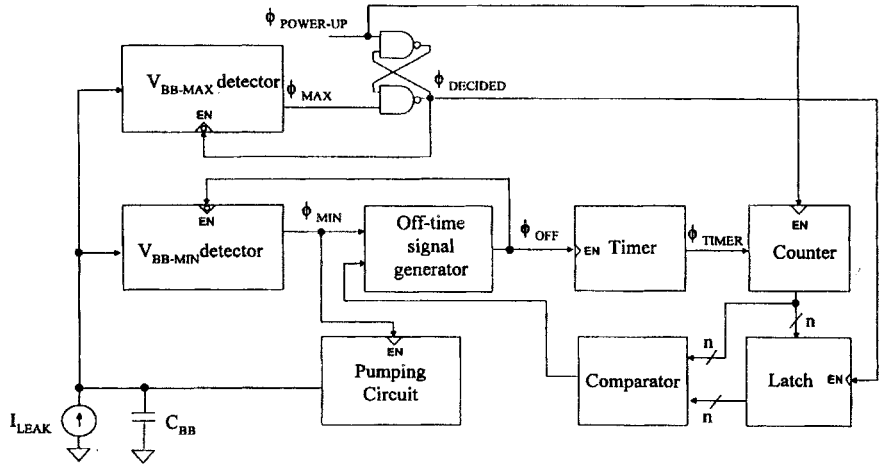

FIGURE 53.44 Block diagram of BBG circuit using the self-off-time detector. (© 1997, IEEE. With permission.)

A charge-transfer presensing scheme (CTPS) with $1/2V_{cc}$ bit-line precharge and a nonreset block control scheme (NRBC) reduces the data-retention current by 75%.[76] The principle of the CTPS technique is shown in Fig. 53.45. The sense amplifier SA and the bit-line BL are separated by the transfer-gate TG. The bit-line is precharged to $1/2V_{ccA}$ (power supply voltage for the array) and the sense amplifier node is precharged to a voltage higher than V_{ccA}. When TG is at a low level, the word-line WL is activated and the data from the memory cell MC is transferred to the bit-line BL. A small voltage change appears on the bit-line pair. Then, the TG voltage is set to the voltage for the charge-transfer condition, and the charge of SA node is transferred to the bit-line. The transfer is complete when the bit-line voltage reaches $V_{TG} - V_{tn}$. After that, a large variation of the readout voltage appears on the SA pair.

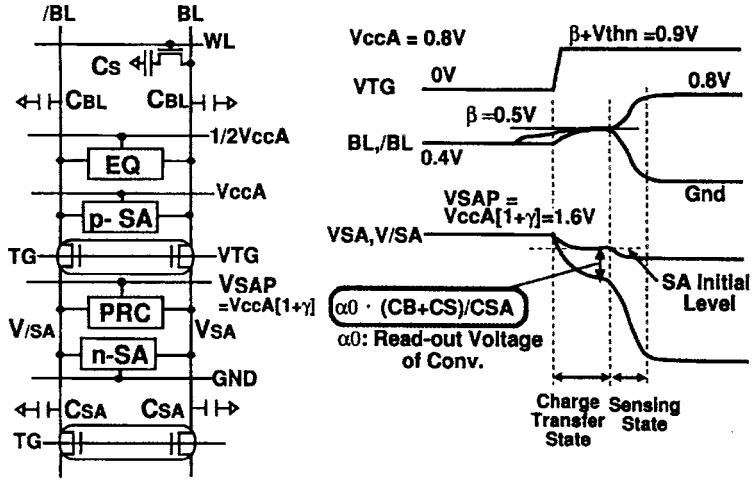

FIGURE 53.45 Concept of CTPS and its circuit organization; BL = $1/2V_{cc}$, V_{ccA} = 0.8 V. (© 1997, IEEE. With permission.)

The CTSP technique reduces the active array current and prolongs the data-retention time. The data-retention power can be reduced further by the nonreset row block control scheme (NRBC), which is used to reduce the charge/discharge number of row block control circuits to 1/128 of the conventional method. The NRBC architecture is shown in Fig. 53.46. NRBC is a divided word-line structure where one subword-line (SWL) in the selected row block is activated if one main word-line (MWL) and one

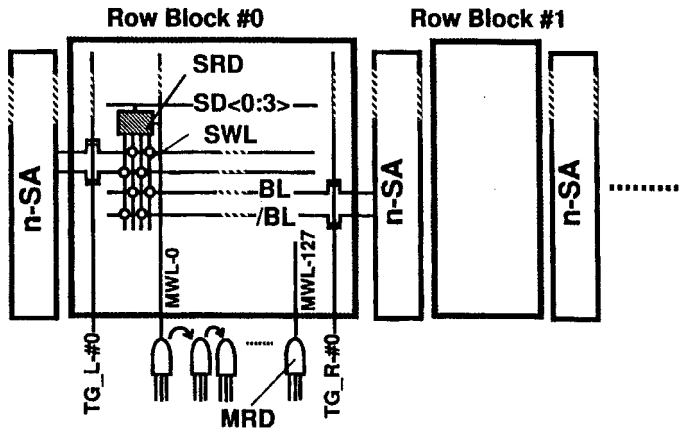

FIGURE 53.46 Basic circuits of the row block control in NRBC. (© 1997 IEEE. With permission.)

of four subdecode signals (SD0~3) are activated in this row block. Also, the transfer-gates TG_L and TG_R are activated at both sides of this row block. After the data-retention mode is set, SD and TG signals do not swing fully at every cycle but only every 128 cycles for activating the same row block. As a result, the row control current is reduced by 70% compared with the conventional scheme.

Another effective method for leakage current reduction is subthreshold leakage current suppression system (SCSS), shown in Fig. 53.47.[78] The method features high drivability (I_{ds}) and low-V_t transistors. The principle of this method is reducing the active mode leakage current with a body bias control and reducing the stand-by mode current by body bias and switched-source impedance. PMOS transistors use the boosted word-line voltage as a body bias, whereas NMOS transistors use memory cell substrate voltage as a body bias. In addition to leakage suppression techniques, extending the refresh time can also significantly reduce power consumption during the stand-by mode, as shown in Eq. 53.4.[67,80,81] The refresh time is determined from the time needed for the stored charge in the memory cell to keep enough margin against leakage at high temperature. In order to achieve long refresh characteristics for a low voltage operation, a negative word-line method can be applied.[67] Figure 53.48 shows the concept of this method.

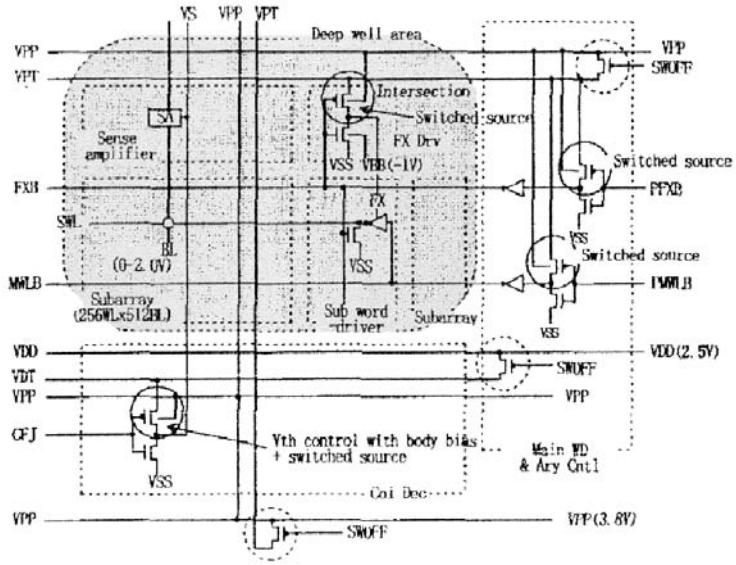

FIGURE 53.47 Subthreshold leakage current suppression system. (© 1998, IEEE. With permission.)

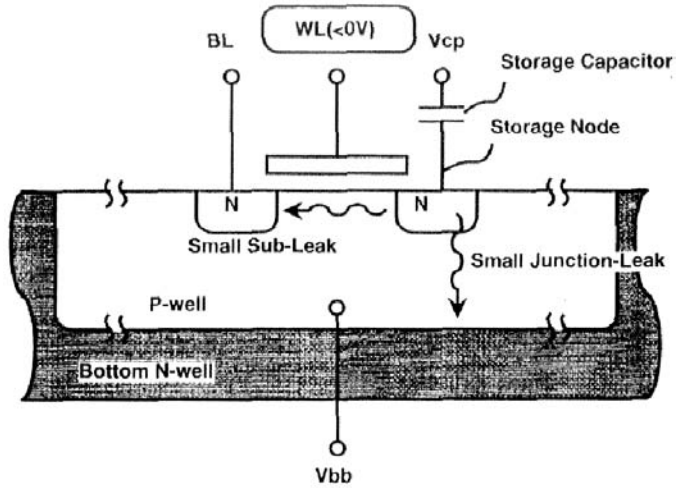

FIGURE 53.48 Principle of the negative voltage word-line technique. (© 1997, IEEE. With permission.)

A negative gate-source voltage V_{gs} is applied, which decreases the subthreshold current of the MC transistor and provides a noise-free dynamic refresh. It also enables the shallow back-bias voltage V_{bb} that reduces the electrical field between the storage node and the p-well region under the memory cell and results in a small junction leakage current. This achieves longer static refresh time. Figure 53.49 shows an example of the negative voltage word-line driver. Dual-period self-refresh (DPS-refresh) scheme is a method that can extend the refresh time by four to six times.[80] The principle of the DPS-refresh scheme is shown in Fig. 53.50 and the corresponding timing diagram in Fig. 53.51. The key concept is to use two different internal self-refresh periods. All word-lines are separated into two groups according to retention test data that are stored in a PROM mode register implemented in the chip periphery. The short period t_1 corresponds to a conventional self-refresh period determined by the minimum retention time in a chip. The long period t_2 is set to the optimum refresh value. If all memory cells connected to a specific word-line have a retention time longer than t_2, they are called long-period word-line cells (LPWL) and are refreshed in the long period of t_2. Otherwise, they are called short-period word-line cells (SPWL) and the word-line is refreshed in the short period t_1. The DPS-refresh operation is then achieved by periodically skipping refresh cycles for LPWLs. The operation is composed of T_1 periods repeated $(n - 1)$, times followed by a T_2. For a refresh cycle during T_1 period, the $\overline{inhibit\_k}$, where k is from 0 to 3, goes low if the word-line selected in the array block k is an LPWL and disables all AND-gated MSi signals. As a result, the refresh operation is not executed. However, during the T_2-

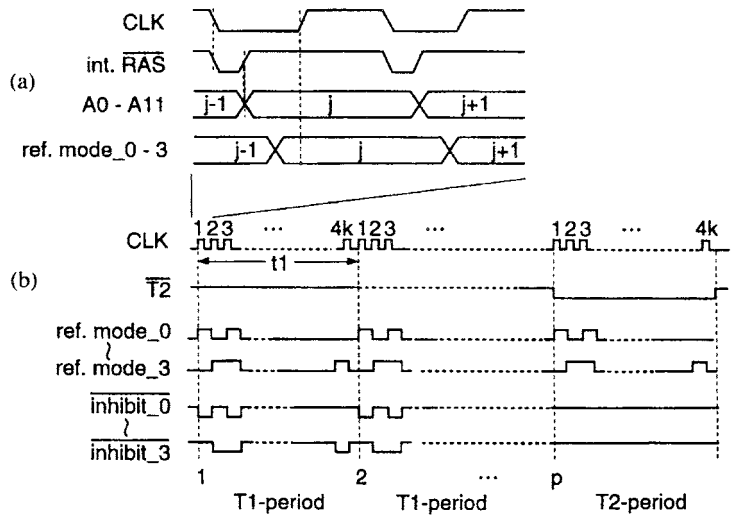

FIGURE 53.51 Timing diagram: (a) PROM read operation, and (b)DPS-refresh operation. (© 1998, IEEE. With permission.)

period, $\overline{inhibit\_k}$ signals are driven high by $\overline{T2}$ clock signal. This signal is generated by the most significant bit refresh address A11 divided by p period using the programmable divide-by-p counter. The period of A11 is equal to the short refresh period t_1. Consequently, LPWLs are refreshed every "$p \times t_1$" periods. The advantage of the DPS-refresh operation is that word-lines which have the same refresh address but are located in different array blocks are individually controlled by $\overline{inhibit\_k}$ signals, which aids in prolonging the refresh time. Using this method, one half of the self-refresh current is saved compared with the conventional self-refresh technique.

53.7 Conclusion

In this chapter, the latest developments in low-power circuit techniques and methods for ROMs, Flash memories, FeRAMs, SRAMs, and DRAMs were described. All major sources of power dissipation in these memories were analyzed. Key techniques for drastic reduction of power consumption were identified. These are: capacitance reduction, very low operating voltages, DC and AC current reduction, and suppression of leakage currents. Many of the reviewed techniques are applicable to other applications such as ASICs, DSPs, etc. Battery and solar-cell operation requires an operating voltage environment in sub-1V area. These conditions demand new design approaches and more sophisticated concepts to retain high device reliability. Experimental circuits operating at these voltage levels slowly start to emerge in all types of memories. However, there is no universal solution for any of these designs, and many challenges still await memory designers.

Nyquist-Rate ADC and DAC

Bang-Sup Song
University of California at San Diego

54.1 Introduction

The rapidly growing electronics field has witnessed the digital revolution that started with the digital telephone switching system in the early 1970s. The trend continued with digital audio in the 1980s and with digital video in the 1990s. The digital technique is expected to prevail in the coming multimedia era and to influence even future wireless PCS/PCN systems. All electrical signals in the real world are analog in nature, and their waveforms are continuous in time. Since most signal processing is done numerically in discrete time, devices that convert an analog waveform into a stream of discrete digital numbers, or vice versa, have become technical necessities in implementing high-performance digital processing systems. The former is called an analog-to-digital converter (ADC or A/D converter), and the latter is called a digital-to-analog converter (DAC or D/A converter).

Typical systems in this digital era can be grouped and explained as in Fig. 54.1. The processed data are stored and recovered later using magnetic or optical media such as tape, magnetic disc, or optical disc. The system can also transmit or receive data through communication channels such as telephone

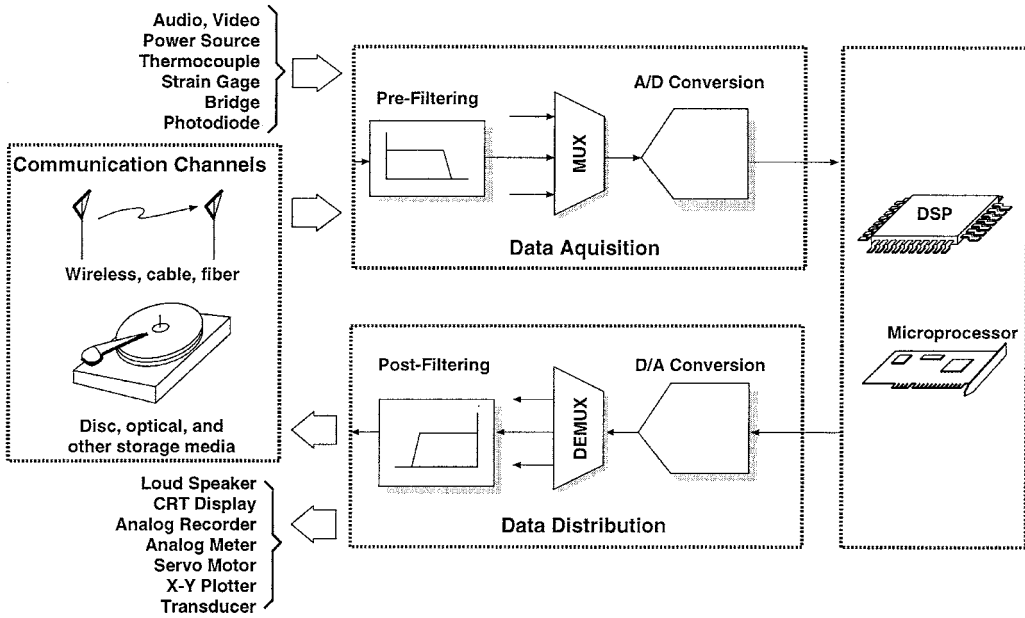

FIGURE 54.1 Information processing systems.

switch, cable, optical fiber, and wireless RF media. Through the Internet computer networks, even compressed digital video images are now made accessible from anywhere and at any time.

Resolution

Resolution is a term used to describe a minimum voltage or current that an ADC/DAC can resolve. The fundamental limit is a quantization noise due to the finite number of bits used in the ADC/DAC. In an N-bit ADC, the minimum incremental input voltage of $V_{ref}/2^N$ can be resolved with a full-scale input range of V_{ref}. That is, limited 2^N digital codes are available to represent the continuous analog input. Similarly, in an N-bit DAC, 2^N input digital codes can generate distinct output levels separated by $V_{ref}/2^N$ with a full-scale output range of V_{ref}. The *signal-to-noise ratio* (SNR) is defined as the power ratio of the maximum signal to the in-band uncorrelated noise. The spectrum of the quantization noise is evenly distributed within the *Nyquist bandwidth* (half the sampling frequency). This inband rms noise decreases by 6 dB when the oversampling ratio is doubled. This implies that, when oversampled, the SNR within the signal band can be made higher. The SNR of an ideal N-bit ADC/DAC is approximated as

$$\text{SNR} = 1.5 \times 2^{2N} \approx 6.02\text{N} + 1.76 \left(\text{dB}\right) \tag{54.1}$$

The resolution is usually characterized by the SNR, but the SNR accounts only for the uncorrelated noise. The real noise performance is better represented by the *signal-to-noise and distortion ratio* (SNDR, SINAD, or TSNR), which is the ratio of the signal power to the total inband noise including harmonic distortion. Also, a slightly different term is often used in place of the SNR. The useful signal range or *dynamic range* (DR) is defined as the power ratio of the maximum signal to the minimum signal. The minimum signal is defined as the smallest signal for which the SNDR is 0 dB, while the maximum signal is the full-scale signal. Therefore, the SNR of the non-ideal ADC/DAC can be lower than the ideal DR because the noise floor can be higher with a large signal present. In practice, performance is not only

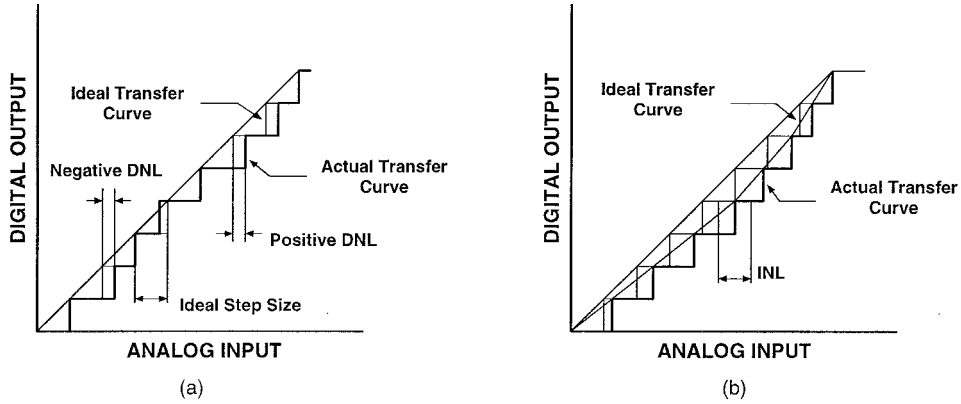

FIGURE 54.2 Definition of ADC nonlinearities: (a) DNL and (b) INL.

limited by the quantization noise but also by non-ideal factors such as noises from circuit components, power supply coupling, noisy substrate, timing jitter, settling, and nonlinearity, etc. An alternative definition of the resolution is the *effective number of bits* (ENOB), which is defined by

$$\text{ENOB} = \frac{\text{SNDR} - 1.76}{6.02} \left(\text{bits}\right) \tag{54.2}$$

Usually, the ENOB is defined for the signal at half the sampling frequency.

Linearity

The input/output ranges of an ideal N-bit ADC/DAC are equally divided into 2^N small units, and one least significant bit (LSB) in the digital code corresponds to the analog incremental voltage of $V_{ref}/2^N$. Static ADC/DAC performance is characterized by *differential nonlinearity* (DNL) and *integral nonlinearity* (INL). The DNL is a measure of deviation of the actual ADC/DAC step from the ideal step for one LSB, and the INL is a measure of deviation of the ADC/DAC output from the ideal straight line drawn between two end points of the transfer characteristic. Both DNL and INL are measured in the unit of an LSB. In practice, the largest positive and negative numbers are usually quoted to specify the static performance. The examples of these DNL and INL definitions for ADC are explained in Fig. 54.2.

However, several different definitions of INL may result, depending on how two end points are defined. In some architectures, the two end points are not exactly 0 and V_{ref}. The non-ideal reference point causes an offset error, while the non-ideal full-scale range gives rise to a gain error. In most applications, these offset and gain errors resulting from the non-ideal end points do not matter, and the integral linearity can be better defined in a relative measure using a straight-line linearity concept rather than the end-point linearity. The straight line can be defined as two end points of the actual transfer function, or as a theoretical straight line adjusted for best fit. The former definition is sometimes called end-point linearity, while the latter is called best-straight-line linearity.

Unlike ADC, the output of a DAC is a sampled-and-held step waveform held constant during a word clock period. Any deviation from the ideal step waveform causes an error in the DAC output. High-speed DACs which usually have a current output are either terminated with a 50 to 75-Ω low-impedance load or buffered by a wideband transresistance amplifier. The linearity of a DAC is often limited dynamically by the non-ideal settling of the output node. Anything other than ideal exponential settling results in linearity errors.

Monotonicity

In both the ADC and the DAC, the output should increase over its full range as the input increases. That is, the negative DNL should be smaller than one LSB for any ADC/DAC to be monotonic. Monotonicity is critical in most applications, in particular digital control or video applications. The source of non-monotonicity is an inaccuracy in binary weighting of a DAC. For example, the most significant bit (MSB) has a weight of half the full range. If the MSB weight is not accurate, the full range is divided into two non-ideal half ranges, and a major error occurs at the midpoint of the full scale. The similar non-monotonicity can take place at the quarter and one-eighth points. In DACs, monotonicity is inherently guaranteed if a DAC uses thermometer decoding. However, it is impractical to implement high-resolution DACs using thermometer codes since the number of elements grows exponentially as the number of bits increases. Therefore, to guarantee monotonicity in practical applications, DACs have been implemented using either a segmented DAC or an integrator-type DAC. Oversampling interpolative DACs also achieve monotonicity using a pulse-density modulated bitstream filtered by a lossy integrator or by a low-pass filter. Similarly, ADCs using slope-type, subranging, or oversampling architectures are monotonic.

Clock Jitter

Jitter is loosely defined as a timing error in analog-to-digital and digital-to-analog conversions. The clock jitter greatly affects the noise performance of both ADCs and DACs. For example, in ADCs, the right signal sampled at the wrong time is the same as the wrong signal sampled at the right time. Similarly, DACs need precise timing to correctly reproduce an analog output signal. If an analog waveform is not generated with the identical timing with which it is sampled, distortion will result because the output changes at the wrong time. This in turn introduces either spurious components related to the jitter frequency or a higher noise floor unless the jitter is periodic. If the jitter has a Gaussian distribution with an rms jitter of Δt, the worst-case SNR resulting from this random clock jitter is

$$\mathrm{SNR} = -20 \times \log \frac{2\pi B \Delta t}{M^{1/2}} \tag{54.3}$$

where B is the signal bandwidth and M is the oversampling ratio. The oversampling ratio M is defined as

$$M = \frac{f_s}{2B} \tag{54.4}$$

where f_s is the sampling clock frequency. The timing jitter error is more critical in reproducing high-frequency components. In other words, for an N-bit ADC/DAC, an upper limit for the tolerable clock jitter is

$$\Delta t \le \frac{1}{2\pi B 2^N} \left(\frac{2M}{3} \right)^{1/2} \tag{54.5}$$

This implies that the error power induced in the baseband by clock jitter should be no larger than the quantization noise. For example, a Nyquist-rate 16-b ADC/DAC with a 22-kHz bandwidth should have a clock jitter of less than 90 ps.

Nyquist-Rate vs. Oversampling

In recent years, high-resolution ADCs and DACs at the low end of the spectrum such as for digital audio, voice, and instrumentation are dominantly implemented using oversampling techniques. Although

Nyquist-rate techniques can achieve comparable resolution, such techniques are in general sensitive to non-ideal factors such as process, component matching, and even environmental changes. The inherent advantage of oversampling provides a unique solution in the digital VLSI environment. The oversampling technique achieves high resolution by trading speed for accuracy. The oversampling lessens the effect of quantization noise and clock jitter. However, the quantization or regeneration of a signal above MHz using oversampling techniques is costly even if possible. Therefore, typical applications for high-sampling rates require sampling at a Nyquist rate.

54.2 ADC Design Arts

The conversion speed of the ADC is limited by the time needed to complete all comparator decisions. Flash ADCs make all the decisions at once, while successive-approximation ADCs make one-bit decisions at a time. Although it is fast, the complexity of the flash ADC grows exponentially. On the other hand, the successive-approximation ADC is simple but slow since the bit decisions are made in sequence. Between these two extremes, there exist many architectures resolving a finite number of bits at a time, such as pipeline and multi-step ADCs. They balance complexity and speed. Figure 54.3 shows recent high-speed ADC applications in the resolution-versus-speed plot. ADC architecture depends on system requirements. For example, with IF (intermediate frequency) filters, wireless receivers need only 5 to 6 b ADC at a few MHz sampling rate. However, without IF filters, the dynamic range of 12 to 14 b is required for the IF sampling depending on IF as shown in Fig. 54.3.

State of the Art

Some architectures are preferred to others for certain applications. Three architectures stand out for three important areas of applications. For example, the oversampling converter is exclusively used to achieve high resolution above the 12-b level at low frequencies. The difficulty in achieving better than 12-b matching in conventional techniques gives a fair advantage to the oversampling technique. For medium

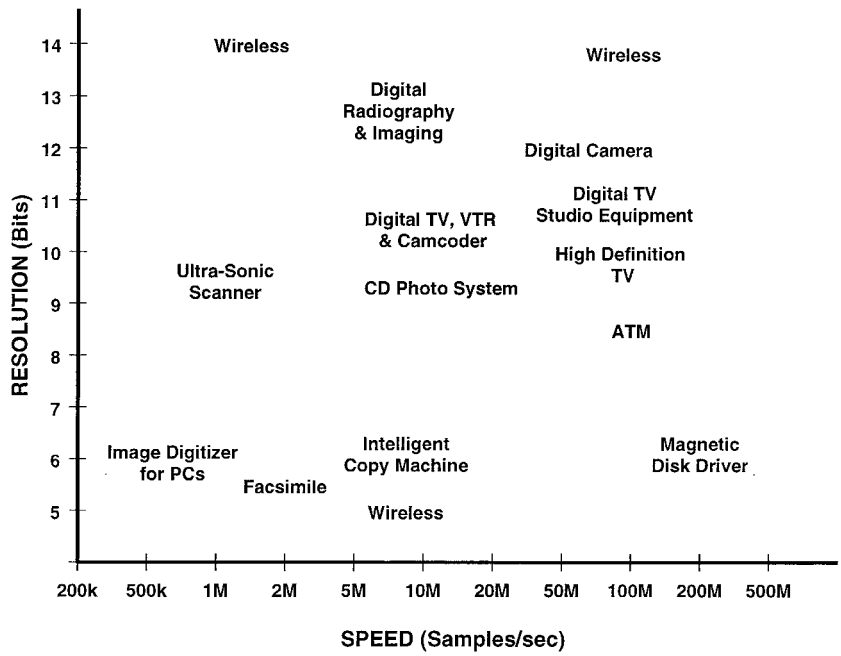

FIGURE 54.3 Recent high-speed ADC applications.

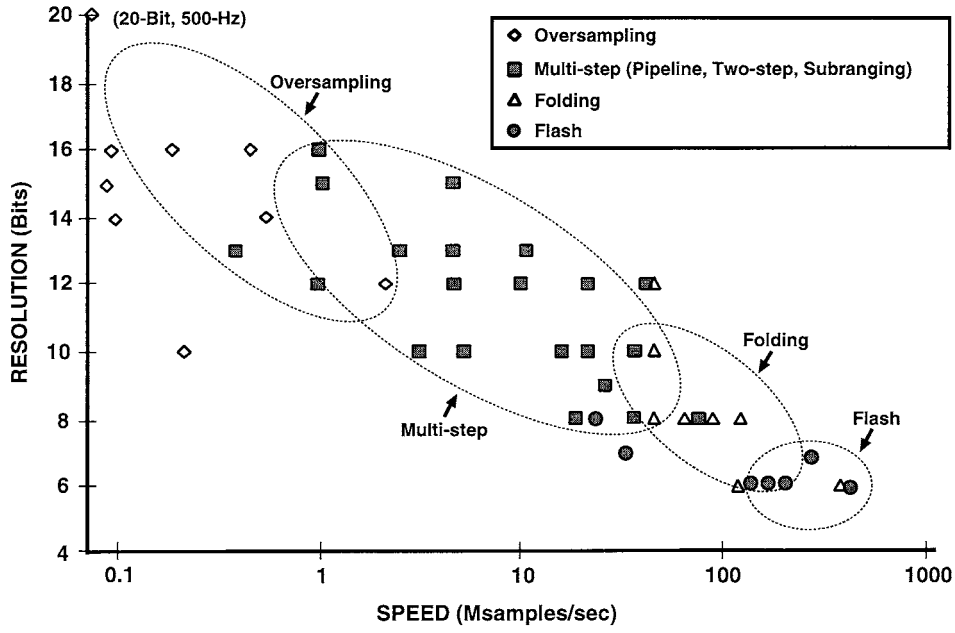

FIGURE 54.4 Performance of recently published ADCs: resolution versus speed.

speed with high resolution, pipeline or multi-step ADCs are promising. At extremely high frequencies, only flash and folding ADCs survive, but with low resolution. Figure 54.4 is a resolution-versus-speed plot showing this trend. As both semiconductor process and design technologies advance, the performance envelope will be pushed further. The demand for higher resolution at higher sampling rates is a main driver of this trend.

Technical Challenge in Digital Wireless

In digital wireless systems, a need to quantize and to create a block of spectrum with low intermodulation has become the single most challenging problem. Implementing IF filters digitally has already become a necessity in wireless cell sites and base stations. Even in hand-held units, placing data conversion blocks closer to the RF (radio frequency) has many advantages. A substantial improvement in system cost and complexity of the RF circuitry can be realized by implementing high selectivity function digitally, and the digital IF can increase immunity to adjacent and alternate channel interferences. Furthermore, the RF transceiver architecture can be made independent of the system and can be adapted to different standards using software. Low-spurious, low-power data converters are key components in this new software radio environment.

The fundamental limit in quantizing IF spectrum is the crosstalk and overload, and the system performance heavily depends on the SFDR (spurious-free dynamic range) of the sampling ADC. To meet this growing demand, low-spurious data conversion blocks are being actively developed in ever-increasing numbers. For a 14b-level ideal dynamic range while sampling at 50 MHz, it is necessary to control the sampling jitter down below 0.32 ps. Considering that the current state-of-the-art commercial bipolar chip exhibits the jitter range of 0.7 ps, the jitter on the order of a fraction of a picosecond is considered to be at the limit of CMOS capability. However, unlike nonlinearity that causes interchannel mixing, the random jitter in IF sampling increases only the random noise floor. As a result, the random jitter is not considered fundamental in this application.

This challenging new application for digital IF processing will lead to the implementation of data converters with very wide SFDR of more than 90 dB. Considering the current state of the art in CMOS

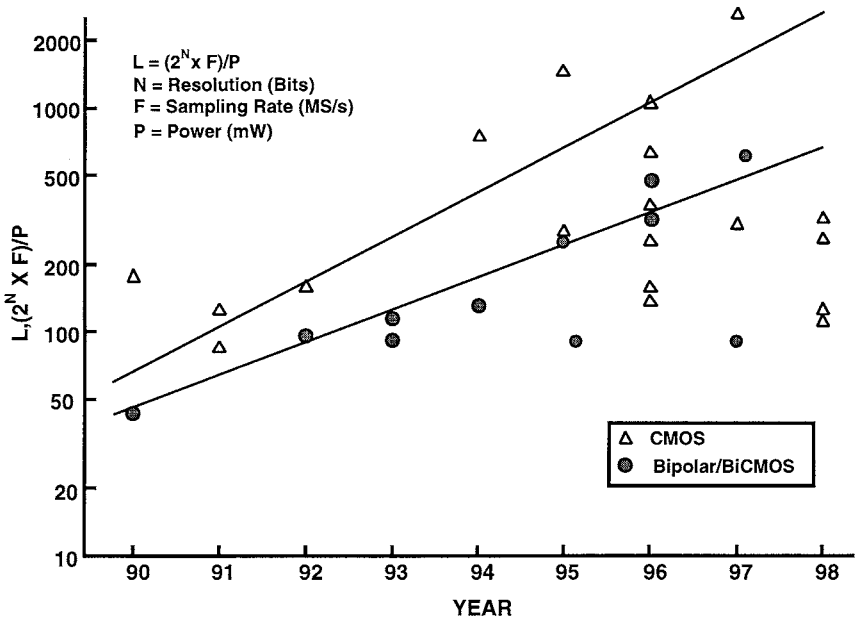

FIGURE 54.5 Figure 54.of merit (L) versus year.

ADCs, most architectures known to date are unlikely to achieve a high sampling rate of over 50 MHz, even with 0.2 to 0.3 μm technologies. Although a higher sampling rate of 65 MHz is reported using bipolar and BiCMOS (bipolar and CMOS), it has been implemented at a 12-b level. However, two high-speed candidate architectures, pipeline (or multi-step) and folding, are potential candidate architectures to challenge these limits with new system approaches.

ADC Figure of Merit

The ADC performance is often represented by a figure of merit L which is defined as $L = 2^N \times f_s/P$, where N is the number of bits, f_s is the sampling rate in Msamples/s, and P is the power consumption in mW. The higher the L is, the more bits are obtained at higher speed with lower power. The plot of L versus year shown in Fig. 54.5 shows the low-power and high-speed trend both for leading integrated CMOS and bipolar/BiCMOS ADCs published in the last decade.

54.3 ADC Architectures

In general, the main criteria of choosing ADC architectures are resolution and speed, but auxiliary requirements such as power, chip area, supply voltage, latency, operating environment, or technology often limit the choices. The current trend is toward low-cost integration without using expensive discrete technologies such as thin film and laser trimming. Therefore, a growing number of ADCs are being implemented using mainstream VLSI technologies such as CMOS or BiCMOS.

Slope-Type ADC

Traditionally, slope-type ADCs have been used for multimeters or digital panel meters mainly because of their simplicity and inherent high linearity. There can be many variations, but dual- or triple-slope techniques are commonly used because the single-slope method is sensitive to the switching error. The resolution of this type of ADC depends on the accurate control of charge on the capacitor. The dual-slope technique in Fig. 54.6(a) starts with the initialization of the integrating capacitor by opening the

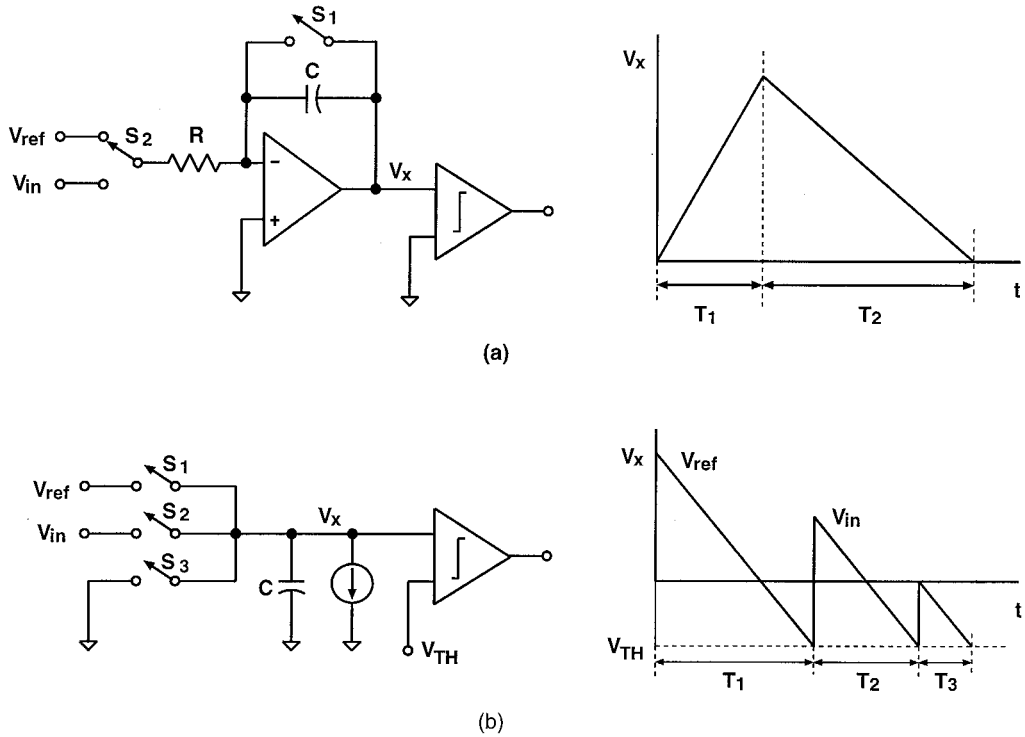

FIGURE 54.6 (a) Dual-slope and (b) triple-slope ADC techniques.

switch S_1 with the input switch S_2 connected to V_{ref}. If V_{ref} is negative, V_x will increase linearly with a slope of V_{ref}/RC. After a time T_1, the switch S_2 is switched to V_{in}. Then, V_x will decrease with a new slope of $-V_{in}/RC$. The comparator detects the zero-crossing time T_2. From T_1 and T_2, the digital ratio of V_{in}/V_{ref} can be obtained as T_1/T_2. The triple-slope technique shown in Fig. 54.6(b) needs no op-amp to reduce the offset effect. Unlike the dual-slope method comparing two slopes, it measures three times T_1, T_2, and T_3 by charging the capacitor with V_{ref}, V_{in}, and ground with three switches S_1, S_2, and S_3, respectively. The comparator threshold can be set to negative V_{TH}. From three time measurements, the ratio of V_{in}/V_{ref} can be computed as $(T_2 - T_3)/(T_1 - T_3)$.

Successive-Approximation ADC

The simplest concept of A/D conversion is comparing analog input voltage with an output of a DAC. The comparator output is fed back through the DAC as explained in Fig. 54.7. The successive-approximation

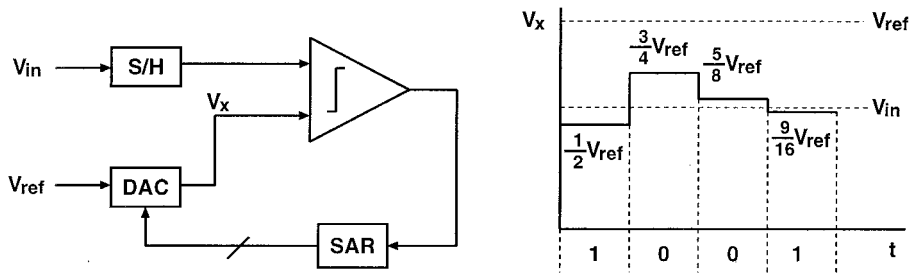

FIGURE 54.7 Successive-approximation ADC technique.

register (SAR) performs the most straightforward binary comparison. The sampled input is compared with the DAC output by progressively dividing the range by two as explained in the 4-b example. The conversion starts by sampling input, and the first MSB decision is made by comparing the sample-and-hold (S/H) output with $V_{ref}/2$ by setting the MSB of the DAC to 1. If the input is higher, the MSB stays as 1. Otherwise, it is reset to 0. In the second bit decision, the input is compared with $3V_{ref}/4$ in this example by setting the second bit to 1. Note that the previous decision set the MSB to 1. If the input is lower, as in the example shown, the second bit is set to 0, and the third bit decision is done by comparing the input with $5V_{ref}/8$. This comparison continues until all the bits are decided. Therefore, the N-bit successive-approximation ADC requires N+1 clock cycles to complete one sample conversion.

The performance of the successive-approximation ADC is limited by the DAC resolution and the comparator accuracy. The commonly used DACs for this architecture are a resistor-string DAC and a capacitor-array DAC. Although binary-weighted capacitors have a 10b-level matching in MOS,[1] diffused resistors have poor matching and high voltage coefficient. If differential resistor-string DACs are used, performance can be improved to the capacitor-array DAC level.[2] In general, the capacitor DAC exhibits poor DNL while the resistor-string DAC exhibits poor INL.

Flash ADC

The most straightforward way of making an ADC is to compare the input with all the divided levels of the reference simultaneously. Such a converter is called a flash ADC, and the conversion occurs in one step. The flash ADC is the fastest among all ADCs. The flash ADC concept is explained in Fig. 54.8, where divided reference voltages are compared to the input. The binary encoder is needed because the output of the comparator bank is thermometer-coded. The resolution is limited both by the accuracy of the

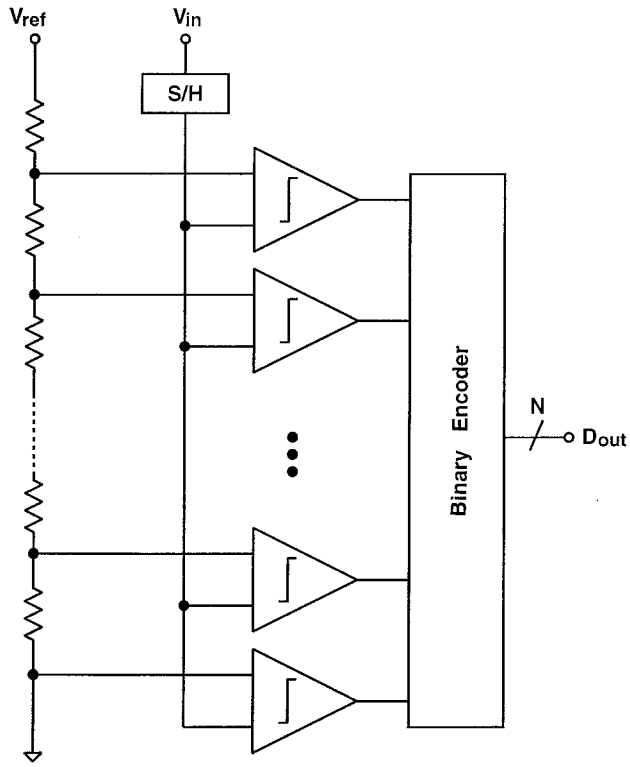

FIGURE 54.8 Flash ADC technique.

divided reference voltages and by the comparator resolution. The metastability of the comparator produces a sparkle noise when the gain of the comparator is low. The reference division can be done using capacitor dividers[3,4] or transistor sizing[5] for small-scale flash ADCs. However, only resistor-string DACs can provide references as the number of bits grows.

In practical implementations, the limit is the exponential growth in the number of comparators and resistors. For example, an N-bit flash needs $2^N - 1$ comparators and 2^N resistors. Furthermore, for the Nyquist-rate sampling, the input needs a S/H to freeze the input for comparison. As the number of bits grows, the comparator bank presents a significant loading to the input S/H, diminishing the speed advantage of this architecture. Also, the control of the reference divider accuracy and the comparator resolution degrades, and the power consumption becomes prohibitively high. As a result, flash converters with more than 10-b resolution are rare. Flash ADCs are commonly used as coarse quantizers in the pipeline or multi-step ADCs. The folding/interpolation ADC, which is conceptually a derivative of the flash ADC, reduces the number of comparators by folding the input range.[6]

For high resolution, the flash ADC needs a low-offset comparator with high gain, and the comparator is often implemented in a multi-stage configuration with offset cancelation. The front-end of the multi-stage comparator is called a preamplifier. A technique called *interpolation* saves the number of preamplifiers by interpolating the adjacent preamplifier outputs as shown in Fig. 54.9(a), where two preamplifier outputs V_a and V_b are used to generate three more outputs V_1, V_2, and V_3 using a resistor divider. The interpolation can improve the DNL within the interpolated range, but the overall DNL and INL are not improved. Interpolating any arbitrary number of levels is possible by making more resistor taps. The interpolation is usually done using resistors, but the interpolation in the current domain is also possible. However, interpolating with independent current sources does not improve the DNL.

Another technique called *averaging*, as explained in Fig. 54.9(b) is often used to average out the offsets of the neighboring preamplifiers as well as to enhance the accuracy of the reference divider.[7] The idea is to couple the outputs of the preamplifier transconductance (G_m) stage so that the significant errors can be spread over the adjacent preamplifier outputs as explained. For example, if the coupling resistor value is infinite, there exists no averaging. As the coupling resistor value decreases, one preamplifier output becomes the weighted sum of the outputs of its neighboring preamplifiers. Therefore, the overall DNL

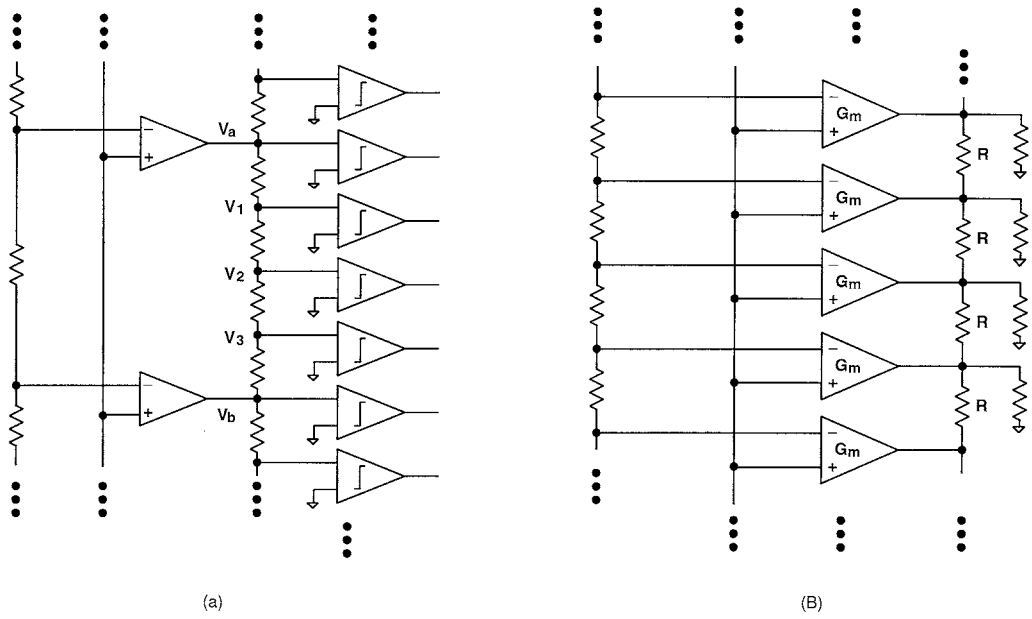

FIGURE 54.9 (a) Interpolation and (b) averaging techniques.

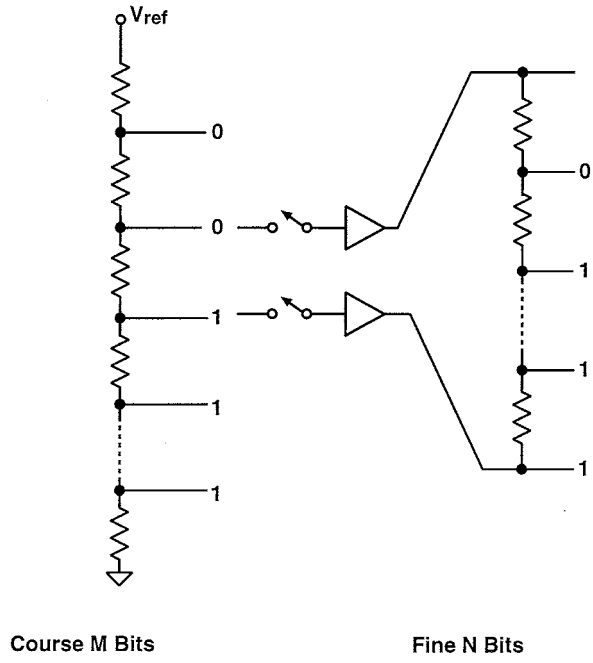

FIGURE 54.10 Coarse and fine reference ladders for two-step subranging ADC.

and INL can improve significantly.[8] However, for the case in which errors to average have the same polarity, the averaging is not that effective. In practice, both the interpolation and the averaging concepts are often combined.

Subranging ADC

Although the interpolation and averaging techniques simplify the flash ADC, the number of comparators stays the same. Instead of making all the bit decisions at once, resolving a few bits at a time makes the system simpler and more manageable. It also enables us to use a digital error correction concept. The simplest subranging ADC concept is explained in Fig. 54.10 for the two-step conversion case. It is a straightforward subranging since one subrange out of 2^M subranges is chosen in the coarse M-bit decision. Once one subrange is selected, the N-bit fine decision can be done using a fine reference ladder interpolating the selected subrange.

Note that the subrange after the coarse decision is $V_{ref}/2^M$ and the fine comparators should have a resolution of M+N bits. Unless the digital error correction with redundancy is used, the coarse comparators should also have a resolution of M+N bits.

Multi-Step ADC

The tactic of making a few bit decisions at a time as shown in the subranging case can be generalized. A slight modification of the subranging architecture shown in Fig. 54.11(a) to include a residue amplifier with a gain of 2^M results in Fig. 54.11(b). The residue is defined as the difference between the input and the nearest DAC output lower than the input. The difference between the two concepts is subtle, but including one residue amplifier drastically changes the system requirements. The obvious advantage of using the residue amplifier is that the fine comparators do not need to be accurate because the residue from the coarse decision is amplified by 2^M. That is, the subrange after the coarse decision is no longer $V_{ref}/2^M$. The disadvantage is the accuracy and settling of the high-gain residue amplifier.

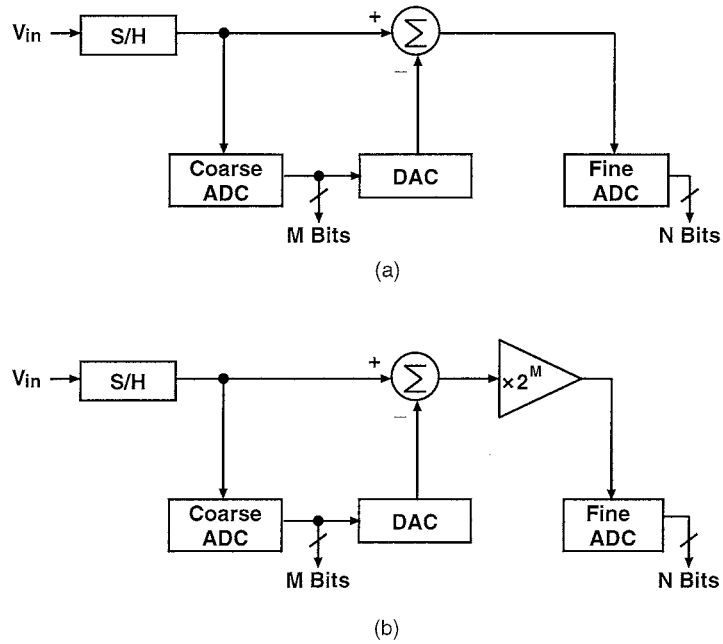

FIGURE 54.11 Variations of the subranging concepts: (a) without and (b) with residue amplifier.

Whether the residue is amplified or not, the subranging block consists of a coarse ADC, a DAC, a residue subtractor, and an amplifier. In theory, this block can be repeated as shown in Fig. 54.12. How many times it is repeated determines the number of steps. So, in general terms, the n-step ADC has n–1 subranging blocks. To complete a conversion in one cycle, usually poly-phase subdivided clocks are needed. Due to the difficulty in clocking, the number of steps for the multi-step architecture is usually limited to two, which does not incur a speed penalty and needs the standard two-phase clocking.

There are many variations in the multi-step architecture. If no ploy-phase clocking is used, it is called a *ripple ADC*. Also in the two-step ADC, if one ADC is repeatedly used both for the coarse and fine decisions, it is called a *recycling ADC*.[9] In this ADC example, the capacitor-array multiplying DAC (MDAC) also performs the S/H function in addition to the residue amplification. This MDAC, with

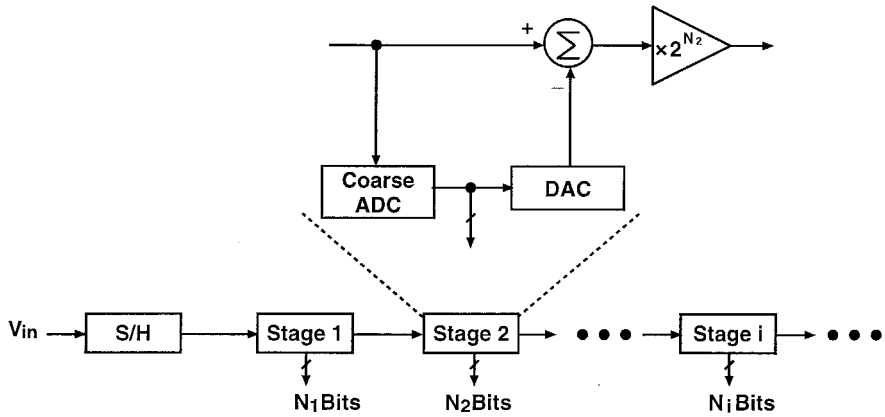

FIGURE 54.12 Multi-step ADC architecture.

either a binary-ratioed or thermometer-coded capacitor array, is a general form of the residue amplifier. The same capacitor array has been used with a comparator to implement a charge-redistribution successive-approximation ADC.[1] This MDAC is suited for MOS technologies, but other forms of the residue amplification are possible using resistor-strings or current DACs.

Pipeline ADC

The complexity of the two-step ADC, although manageable and simpler than the flash ADC, still grows exponentially as the number of bits to resolve increases. Specifically, for high resolution above 12 b, the complexity reaches about the maximum, and a need to pipeline subranging blocks arises. The pipeline ADC architecture shown in Fig. 54.13 is the same as the subranging or multi-step ADC architecture shown in Fig. 54.12 except for the interstage S/H. Since the S/Hs are clocked by alternating clock phases, each stage needs to perform the decision and the residue amplification in each clock phase. Pipelining the residue greatly simplifies the ADC architecture. The complexity grows only linearly with the number of bits to resolve. Due to its simplicity, the pipeline ADCs have been gaining popularity in the digital VLSI environment.

In the pipeline ADC, each stage resolves a few bits quickly and transfers the residue to the following stage so that the residue can be resolved further in the subsequent stages. Therefore, the accuracy of the interstage residue amplifier limits the overall performance. The following four non-ideal error sources can affect the performance of the multi-step or pipeline ADCs: ADC resolution, DAC resolution, gain error of the residue amplifier, and inaccurate settling of the residue amplifier. The offset of the residue amplifier does not affect the linearity, but it appears as a system offset. Among these four error sources, the first three are static, but the residue amplifier settling is dynamic. If the residue amplifier is assumed to settle within one clock phase, three static error sources are limiting the linearity performance.

Figure 54.14 explains the residue from the 2-b stage in the systems shown in Figs. 54.12 and 54.13. In the ideal case, as the input is swept from 0 to the full range V_{ref}, the residue change from 0 to V_{ref} repeats each time V_{ref} is subtracted at the ideal locations of the 2-b ADC thresholds, which are $V_{ref}/4$ apart. In this case, the 2-b stage does not introduce any nonlinearity error. However, in the other cases with ADC, DAC, and gain errors, the residue ranges do not match with the ideal full-scale V_{ref}. If the residue range is smaller than the full range, missing codes are generated; and if the residue goes out of bounds, excessive codes are generated at the ADC thresholds. Unlike the DAC and gain errors, the ADC error appears as a shift of the residue either by the amounts of V_{ref} or $-V_{ref}$ as long as the DAC subtracts the ideal V_{ref} and the residue amplifier gain is ideal. This suggests that the error can be corrected digitally by adding or subtracting the full range.

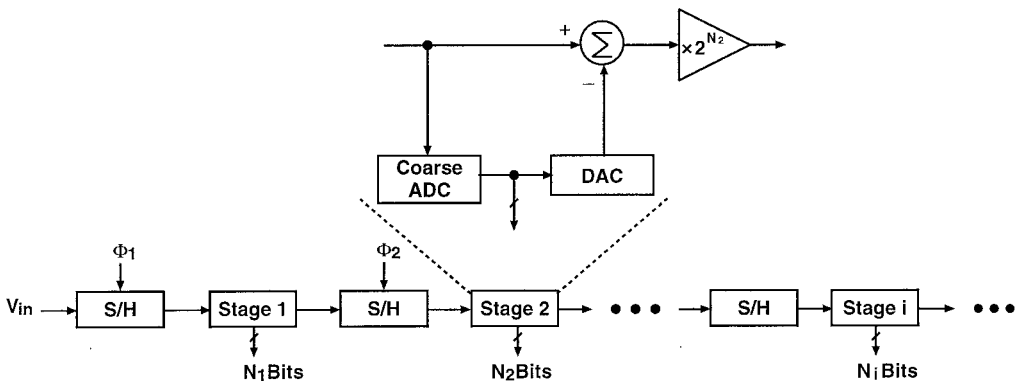

FIGURE 54.13 Pipeline ADC architecture.

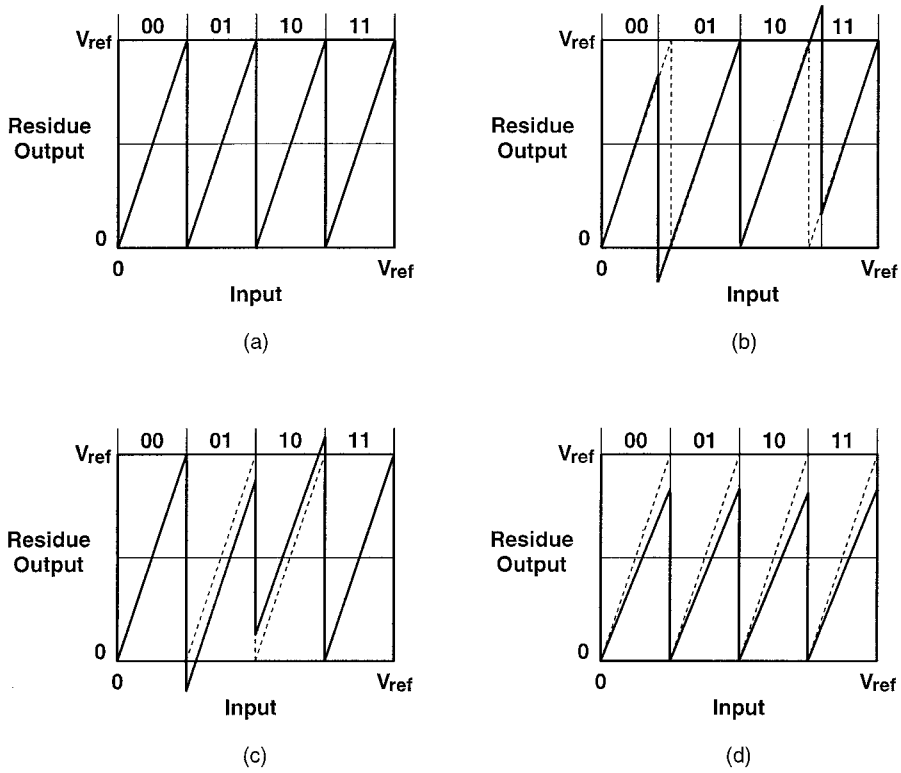

FIGURE 54.14 2b residue versus input: (a) ideal, and with (b) ADC, (c) DAC, and (d) gain errors.

Digital Error Correction

Any multi-step or pipeline ADC system can be made insensitive to the ADC error if the ADC error is digitally corrected. The residue normally going out of the full range can still be digitized by the following stage if the residue amplifier gain is reduced. That is, if the residue amplifier gain is set to 2^{N-1} instead of 2^N, the residue plots are as shown in Fig. 54.15. If the residue is bounded with the full range of 0 to V_{ref}, the inner range from $V_{ref}/4$ to $3V_{ref}/4$ is the normal conversion range, and two redundant outer ranges are used to cover the residue error resulting from the inaccurate coarse conversion. Now the problem is that this redundancy requires extra resolution to cover the overrange. The half ranges on both sides are used to cover the residue error in this 2-b case. That is, one full bit of extra resolution is necessary for

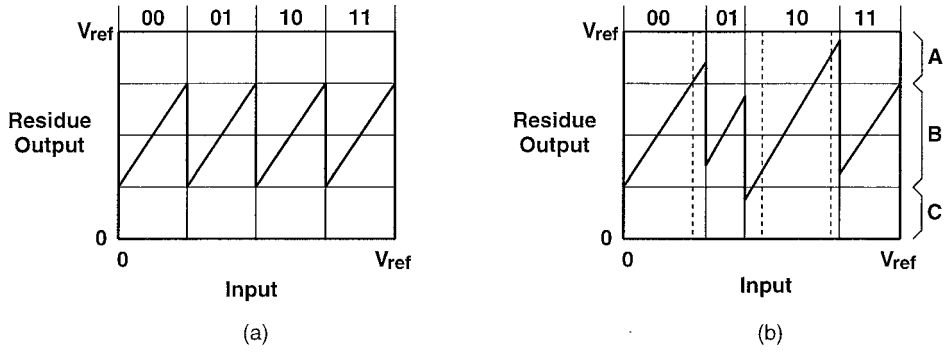

FIGURE 54.15 Over-ranged 2-b residue versus input: (a) ideal and with (b) ADC errors.

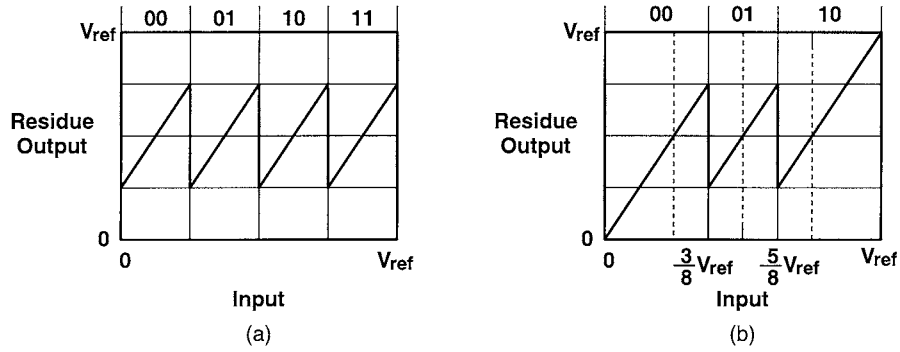

FIGURE 54.16 Half-bit shifted 2-b residue versus input: (a) with and (b) without ADC threshold-level shift.

redundancy in the 2-b case. However, the amount of redundancy depends on the ADC error range to be corrected in the multi-bit cases.[10] In general, it is a tradeoff between comparator resolution and redundancy.

The range marked as B is the normal range, and A and C indicate the correction ranges in Fig. 54.15(b). The digital correction works by subtracting 1 from the previous decision if the residue exceeds $3V_{ref}/4$, as in the case marked as A. On the other hand, if the residue goes below $V_{ref}/4$, as in the case marked as C, 1 is added from the previous decision. Although the digital subtraction is simple, biasing the ADC threshold levels by half the ideal interval has an advantage. Figure 54.16 compares the residue plots for two cases with and without the ADC threshold shift by $V_{ref}/8$. This is to fully utilize the ADC conversion range from 0 to V_{ref}. The shift of $V_{ref}/8$ makes the residue start from 0 and end at V_{ref} in Fig. 54.16(b), contrary to the previous case where the residue starts from $V_{ref}/4$ and ends at $3V_{ref}/4$. This results in saving one comparator. The former case needs 2^N–1 comparators, while the latter case needs 2^N–2. The only minor issue is that the latter exhibits a half LSB systematic offset due to this shift.

This half-bit-level shift makes the ADC error occur only with the same polarity. As a result, only the addition is necessary for digital correction in the case of Fig. 54.16(b). This is explained in the 4-b ADC made of three stages using one-bit correction per stage in Fig. 54.17. The vertical axis marks the signal and residue levels as well as ADC decision levels. The dotted and shaded areas follow the residue paths when the ADC error occurs, but the end results are the same after digital correction. This half interval shift is valid for stages resolving any number of bits. Overall, the digital error correction enables fast data conversion using inaccurate comparators. However, the DAC resolution and the residue gain error still remain as the fundamental limits in multi-step and pipeline ADCs. The currently known ways to overcome these limits are either trimming or self-calibration.

One-Bit Pipeline ADC

The degenerate case of the pipeline ADC is when only one bit is resolved per stage as shown in Fig. 54.18. Each stage multiplies its input V_{in} by two and subtracts the reference voltage V_{ref} to generate the residue voltage. If the sign of $2V_{in} - V_{ref}$ is positive, the bit is 1 and the residue goes to the next stage. Otherwise, the bit is 0 and V_{ref} is added back to the residue before it goes to the next stage. However, in reality, it is more desirable if the reference restoring time is saved. In the non-restoring algorithm, the previous bit decision affects the polarity of the reference voltage to be used in the current bit decision. If the previous bit is 1, the residue voltage is $2V_{in} - V_{ref}$, as in the restoring algorithm. But if the previous bit is 0, the residue voltage is $2V_{in} + V_{ref}$.

The switched-capacitor implementation of the basic functional block performing $2V_{in} \pm V_{ref}$ is explained using two identical capacitors and one op-amp in Fig. 54.19 [11]. During the sampling phase, the bottom plates of two capacitors are switched to the input, and the top plate is connected either to the op-amp output or to the op-amp input common-mode voltage. During the amplification phase, one

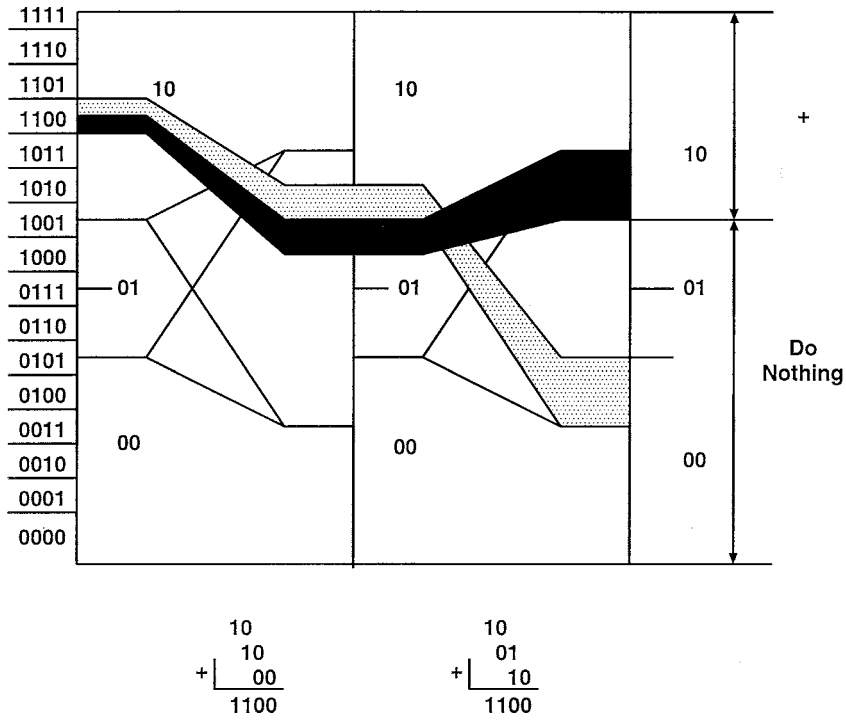

FIGURE 54.17 Example of digital error correction for three-stage 4b ADC (1100).

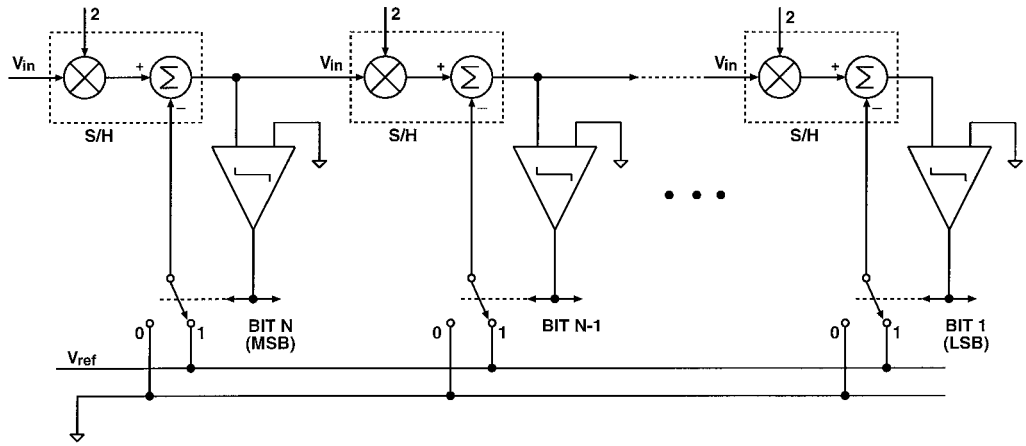

FIGURE 54.18 One-bit per stage pipeline ADC architecture.

of the capacitors is connected to the output of the op-amp for feedback, but the other is connected to $\pm V_{ref}$. Then, the output of the op-amp will be $2V_{in} - V_{ref}$ and $2V_{in} + V_{ref}$, respectively, after the op-amp settles.

However, this simple one-bit pipeline ADC is of no use if the comparator resolution is limited. If any redundancy is used for digital correction, at least two bits should be resolved. A close look at Fig. 54.16(b) gives a clue to using the simple functional block shown in Fig. 54.19 for the 2-b residue amplification. The case explained in Fig. 54.16(b) is sometimes called 1.5-b rather than 2-b because it needs only three

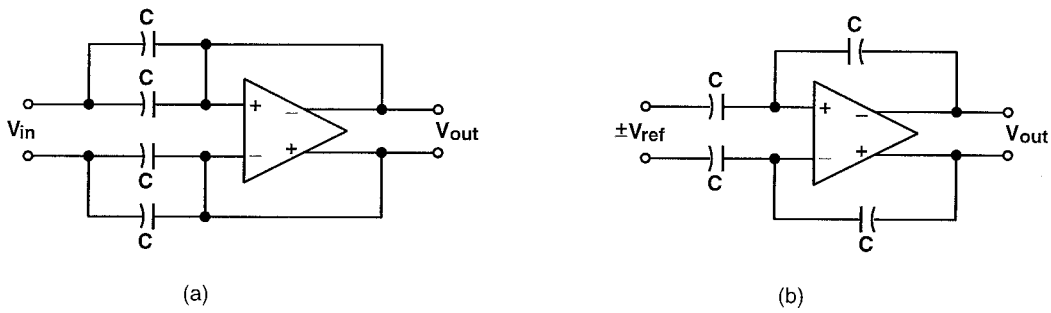

FIGURE 54.19 The simplest two-level MDAC: (a) sampling phase and (b) amplification phase.

DAC levels rather than four. The functional block in Fig. 54.19 can have a two-level DAC subtracting $\pm V_{ref}$. However, in differential architecture, by shorting the input, one midpoint can be interpolated. Using the tri-level DAC, the 1.5-b pipeline ADC can be implemented with the following algorithm.[12] If the input V_{in} is lower than $-V_{ref}/4$, the residue output is $2V_{in} + V_{ref}$. If the input is higher than $V_{ref}/4$, the residue output is $2V_{in} - V_{ref}$. If the input is in the middle, the output is $2V_{in}$.

Algorithmic, Cyclic, or Recursive ADC

The interstage S/H used in the multi-step architecture provides a flexibility of the pipeline architecture. In the pipeline structure, the same hardware repeats as shown in Fig. 54.13. That is, the throughput rate of the pipeline is fast while the overall latency is limited by the number of stages. Instead of repeating the hardware, using the same stage repeatedly greatly saves hardware, as shown in Fig. 54.20. That is, the throughput rate of the pipeline is directly traded for hardware simplicity. Such a converter is called an *algorithmic*, *cyclic*, or *recursive ADC*. The functional blocks used for the algorithmic ADC are identical to the ones used in the pipeline ADC.

Time-Interleaved Parallel ADC

The algorithmic ADC just described sacrifices the throughput rate for small hardware. However, the *time-interleaved parallel ADC* takes quite the opposite direction. It duplicates more hardware in parallel for higher throughput rates. The system is shown in Fig. 54.21, where the throughput rate increases by the number of parallel paths strobed. Although it significantly improves the throughput rate and many refinements have been reported, it suffers from many problems.[13] Due to the multiplexing, even static nonlinearity mismatch between paths appears as a fixed pattern noise. Also, it is difficult to generate clocks with exact delays, and inaccurate clocking increases the noise floor.

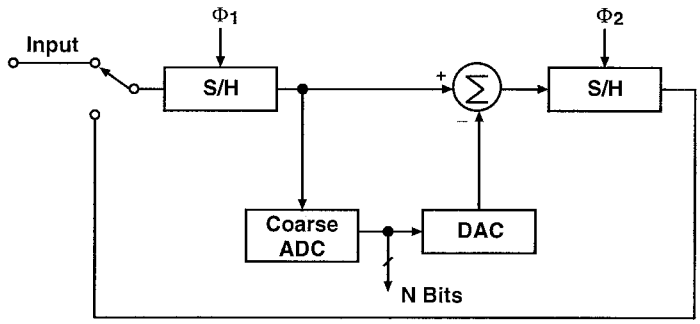

FIGURE 54.20 Algorithmic, cyclic, or recursive ADC architecture.

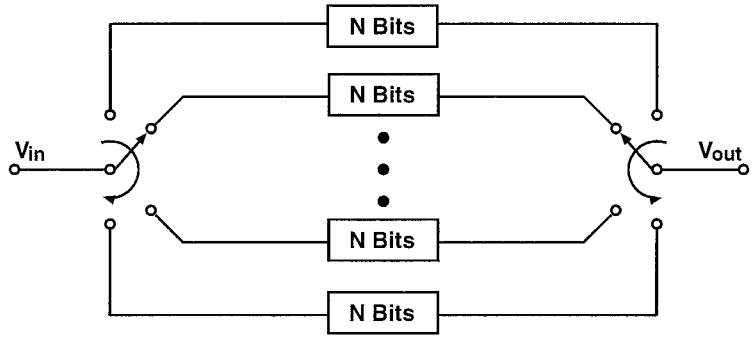

FIGURE 54.21 Time-interleaved parallel ADC architecture.

Folding ADC

The folding ADC is similar to the flash ADC except for using fewer comparators. This reduction in the number of comparators is achieved by replacing the comparator preamplifiers with folding amplifiers. In its original arrangements,[14] the folding ADC digitizes the folded signal with a flash ADC. The folded signal is equivalent in concept to the residue of the subranging, multi-step, or pipeline ADC, but the difference is that the generation of the folding signal is done solely in the analog domain. Since the digitized code from the folding amplifier output repeats over the whole input range, a coarse coding is required, as in all subranging-type ADCs.

Consider a system configured as a 4-b folding ADC as shown in Fig. 54.22. Four folding amplifiers can be placed in parallel to produce four folded signals. Comparators check the outputs of the folding amplifiers for zero crossing. If the input is swept, the outputs of the fine comparators show a repeating pattern, and eight different codes can be obtained by the four comparators. Because there are two identical fine code patterns, one comparator is needed to distinguish them. However, if this coarse comparator is misaligned with the fine quantizer, missing codes will result. A digital correction similar to that for the multi-step or pipeline ADC can be employed to correct the coarse quantizer error. For this system example, one-bit redundancy is used by adding two extra comparators in the coarse quantizer. The shaded region in the figure is where errors occur.

Having several folded signals instead of one has many advantages in designing high-speed ADCs. The folding amplifier requires neither linear output nor accurate settling. This is because in the folding ADC, the zero-crossings of the folded signals matter, but not their absolute values. Therefore, the offset of the folding amplifiers becomes the most important design issue. The resolution of the folding ADC can be further improved using the interpolation concept. When the adjacent folded signals are interpolated by I times, the number of zero-crossing points are also increased by I times. So, the resolution of the final ADC is improved by $\log_2 I$ bits. The higher bound for the degree of interpolation is set by the comparator resolution, the gain of the folding amplifiers, the linearity of folded signals, and the interpolation accuracy. Since the folding process increases the internal signal bandwidth by the number of foldings, the folding ADC performance is limited by the folding amplifier bandwidth. To increase the number of foldings while maintaining the reasonable comparator resolution, the folding amplifier's gain should be high. Since the higher gain limits the amplifier bandwidth, it is necessary to cascade the folding stages.[6,8]

54.4 ADC Design Considerations

In general, multi-step ADCs are made of cascaded low-resolution ADCs. Each low-resolution ADC stage provides a residue voltage for the subsequent stage, and the accuracy of the residue voltage limits the resolution of the converter. One of the residue amplifiers commonly used in CMOS is a switched-capacitor MDAC, whose connections during two clock phases are illustrated in Fig. 54.23 for an N-bit case. An

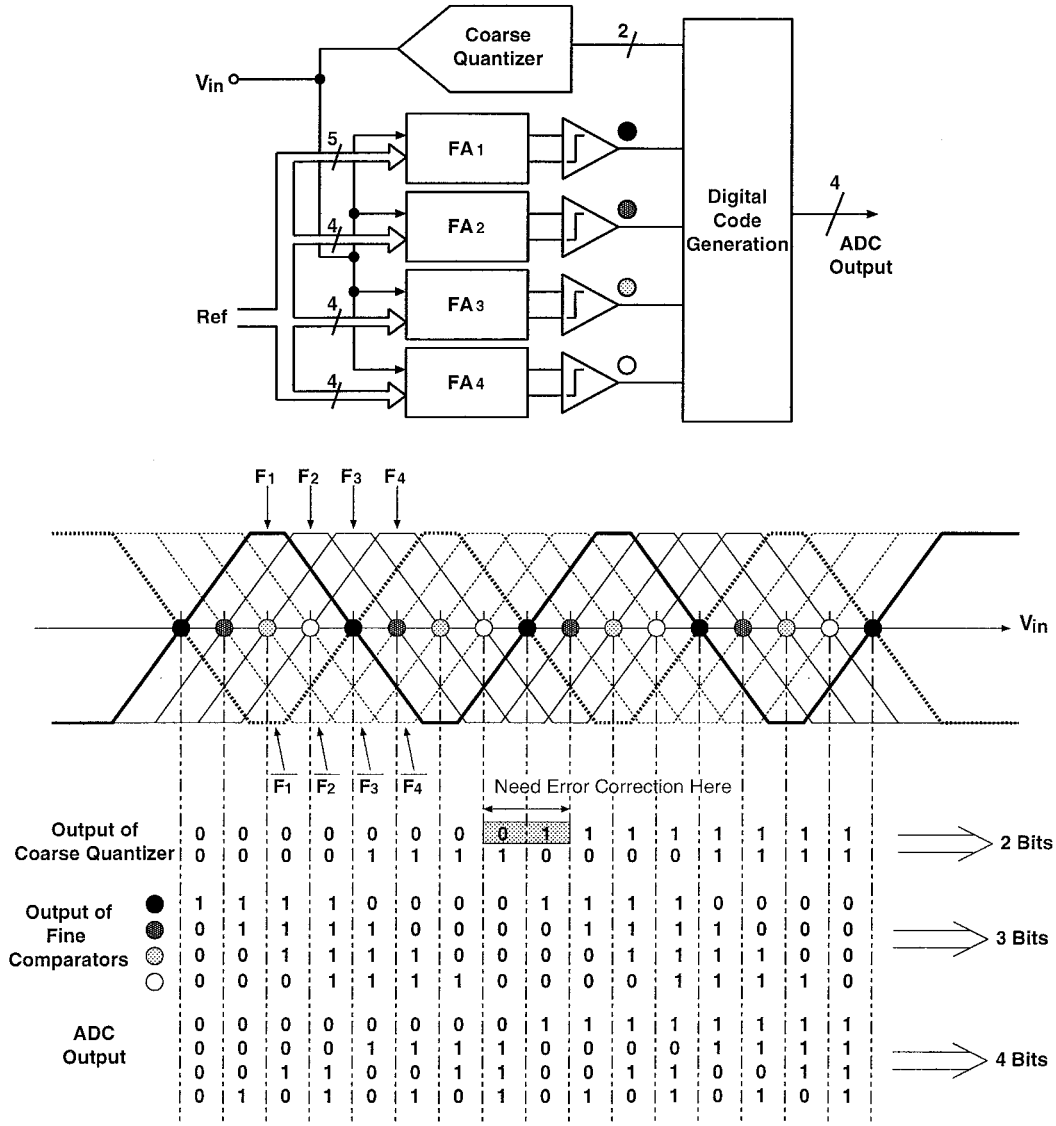

FIGURE 54.22 A 4-b folding ADC example with digital correction.

extra capacitor C is usually added to double the feedback capacitor size so that the residue voltage may remain within the full-scale range for digital correction.

Sampling Error Considerations

Since the ADC works on a sampled signal, the accuracy in sampling fundamentally limits the system performance. It is well known that the noise power to be sampled on a capacitor along with the signal is KT/C. It is inversely proportional to the sampling capacitor size. The sampled rms voltage noise is 64 μV with 1 pF, but decreases to 20 μV with 10 pF. For accurate sampling, sampling capacitors should be large, but sampling on large capacitors takes time. The speed of the ADC is fundamentally limited by the sampling KT/C noise.

In sampling, there exists another important error source. Direct sampling on a capacitor suffers from switch feedthrough error due to the charge injection when switches are opened. A common way to reduce

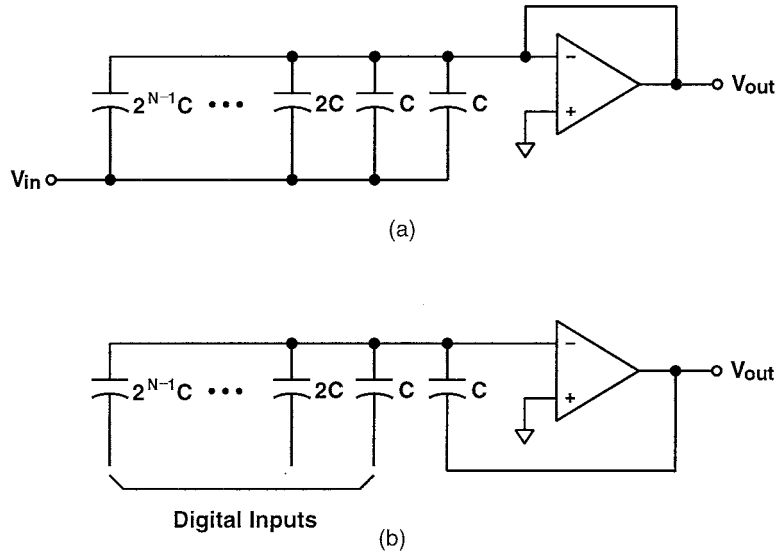

FIGURE 54.23 General N-bit residue amplifier: (a) sampling phase and (b) amplification phase.

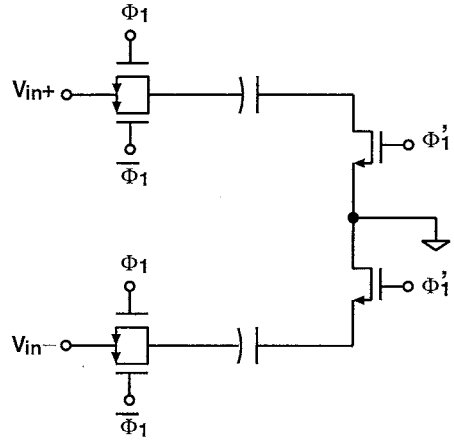

FIGURE 54.24 Open-loop bottom-plate differential sampling on capacitors.

this charge feedthrough error is to turn off the switches connected to the sampling capacitor top plate slightly earlier than the switches connected to the bottom plate. This is explained in Fig. 54.24. Usually, the top plate is connected to the op-amp summing or comparator input node. The top plate switch is switched with one MOS transistor with a clock phase marked as Φ_1' which makes a falling transition earlier than other clocks. The bottom plate is switched with a CMOS switch (both NMOS and PMOS) with clocks marked as Φ_1 and $\overline{\Phi_1}$. These clocks make falling transitions after the prime clock does. The net effect is that the feedthrough voltage stays constant because the top plate samples the same voltage repeatedly. The differential sampling using two capacitors symmetrically is known to provide the most accurate sampling known to date.

Unless limited by speed, the sampling error as well as the low-end spectrum of the sampled noise can be eliminated using a correlated double sampling (CDS) technique. The system has been used to remove the flicker noise or slowly-varying offset such as in charge-coupled device (CCD). The CDS needs two sampling clocks. The idea is to subtract the previously sampled sampling error from the new sample

TABLE 54.1 Three Dominant ADC Architectures

	Interpolated Flash	Multi-step	Pipeline
Matching	Least	Medium	Most critical
Feedthrough	Most critical	Medium	Least
Bandwidth	Least	Most critical	Medium
Settling	Least	Medium	Most critical
Gain	Least	Medium	Most critical
Speed	Fast	Slow	Medium
Complexity	Complex	Medium	Simple
Problems	Clock jitter	Low loop gain	Matching
	Time skew		Wide bandwidth
	Sampling error		High gain

after one clock delay. The result is to null the sampling error spectrum at every multiple of the sampling frequency f_s. The CDS is effective only for the low-frequency spectrum.

Techniques for High-Resolution and High-Speed ADCs

Considering typical requirements, three representative ADC architectures are compared in Table 54.1. To date, all techniques known to improve ADC resolution are as follows: trimming, dynamic matching, ratio-independent technique, capacitor-error averaging, walking reference, and self-calibration. However, the trimming is irreversible and expensive. It is only possible at the factory or with precision equipments. The dynamic matching technique is effective, but it generates high-frequency noise. The ratio-independent techniques either require many clock cycles or are limited to improve differential linearity. The latter case is good for monotonicity, but it also requires accurate comparison. The capacitor-error averaging technique requires three clock cycles, and the walking reference is sensitive to clock sampling error. The self-calibration technique requires extra hardware for calibration and digital storage, but its compatibility with existing proven architectures may provide potential solutions both for high resolution and for high speed.

The ADC self-calibration concepts originated from the direct code-mapping concept using memory. The calibration is to predistort the digital input to the DAC so that the DAC output can match the ideal level from the calibration equipment. Due to the precision equipment needed, this method has limited use. The first self-calibration concept applied to the binary-ratioed successive-approximation ADC is to internally measure capacitor DAC ratio errors using a resistor-string calibration DAC as shown in Fig. 54.25.[15] Later, an improved concept of the digital-domain calibration was developed for the multi-step or pipeline ADCs.[16]

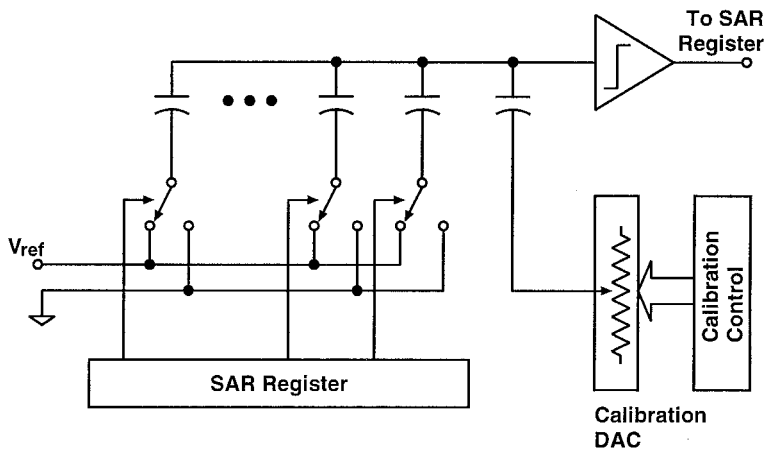

FIGURE 54.25 Self-calibrated successive-approximation ADC.

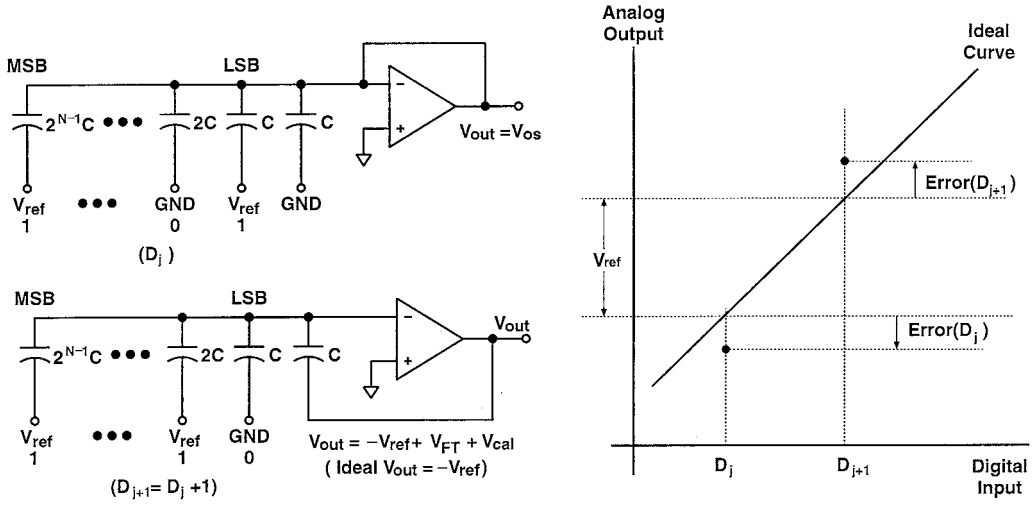

FIGURE 54.26 Segment-error measuring technique for digital self-calibration.

The general concept of the digital-domain calibration is to measure code or bit errors, to store them in the memory, and to subtract them during the normal operation. The concept is explained in Fig. 54.26 using a generalized N-bit MDAC with a capacitor array. If the DAC code increases by 1, the MDAC output should increase by V_{ref} or $V_{ref}/2$ with digital correction. Any deviation from this ideal step is defined as a segment error. Code errors are obtained by accumulating segment errors. This segment-error measurement needs two cycles. The first cycle is to measure the switch feedthrough error, and the next cycle is to measure the segment error. The segment error is simply measured as shown in Fig. 54.26 using the LSB-side of the ADC by increasing the digital code by 1. In the case of N = 1, the segment error becomes a bit error. If binary bit errors are measured and stored, code errors should be calculated for subtraction during the normal operation. How to store DAC errors is a tradeoff issue. Examples of the digital calibration are well documented for the cases of segment-error[17] and bit-error[18] measurements, respectively.

54.5 DAC Design Arts

There are many different circuit techniques used to implement DACs, but the popular ones widely used today are of the parallel type in which all bits change simultaneously upon the application of an input code word. Serial DACs, on the other hand, produce an analog output only after receiving all digital input data in a sequential form. When DACs are used as stand-alone devices, their output transient behaviors limited by glitch, slew rate, word clock jitter, settling, etc. are of paramount importance, but used as subblocks of ADCs, DACs need only to settle within a given time interval. An output S/H, usually called a *deglitcher*, is often used for better transient performance. Three of the most popular architectures of DACs are resistor string, ratioed current sources, and a capacitor array. The current-ratioed DAC finds most applications as a stand-alone DAC, while the resistor-string and capacitor-array DACs are mainly used as ADC subblocks.

For speeds over 100 MHz, most state-of-the-art DACs employ current sources switched directly to output resistors.[19-23] Furthermore, owing to the high bit counts (12 to 16 b), segmented architectures are employed, with the current sources broken into two or three segments. The CMOS design has the advantages of lower power, smaller area, and lower manufacturing costs. In all cases, it is of interest to note that the dynamic performance of the DACs degrades rapidly as input frequencies increase, and true dynamic performance is not attained except at low frequencies. Since a major application of wide-bandwidth, high-resolution DACs is in communications, poor dynamic performance is undesirable,

owing to the noise leakage from frequency multiplexed channels into other channels. The goal of better dynamic performance continues to be a target of ongoing research and development.

54.6 DAC Architectures

An N-bit DAC provides a discrete analog output level, either voltage or current, for every level of 2^N digital words that is applied to the input. Therefore, an ideal voltage DAC generates 2^N discrete analog output voltages for digital inputs varying from 000…00 to 111…11. In the unipolar case, the reference point is 0 when the digital input is 000…00; but in bipolar or differential DACs, the reference point is the midpoint of the full scale when the digital input is 100…00. Although purely current-output DACs are possible, voltage-output DACs are common in most applications.

Resistor-String DAC

The simplest voltage divider is a resistor string. Reference levels can be generated by connecting 2^N identical resistors in series between V_{ref} and ground. Switches to connect the divided reference voltages to the output can be either 1-out-of-2^N decoder or binary tree decoder as shown in Fig. 54.27 for the 3-b example. Since it requires a good switch, the stand-alone resistor-string DAC is easier to implement using CMOS. However, the lack of switches does not limit the application of the resistor string as a voltage reference divider subblock for ADCs in other process technologies.

Resistor strings are widely used as an integral part of the flash ADC as a reference divider. All resistor-string DACs are inherently monotonic and exhibit good differential linearity. However, they suffer from poor integral linearity and also have the drawback that the output resistance depends on the digital input

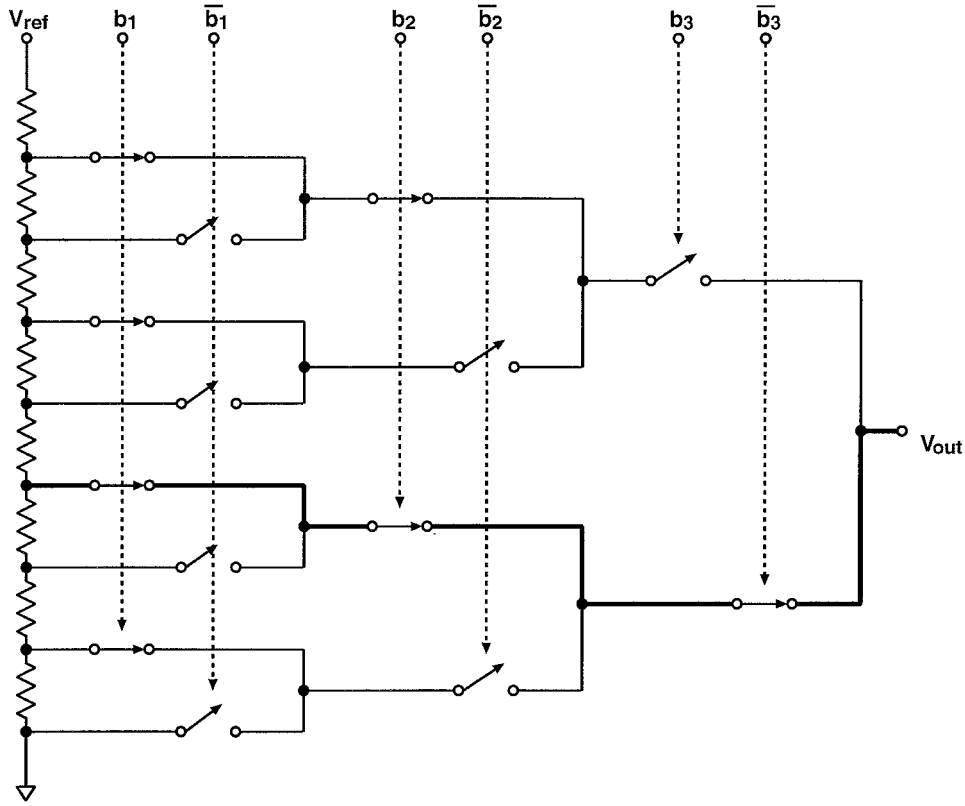

FIGURE 54.27 Resistor-string DAC.

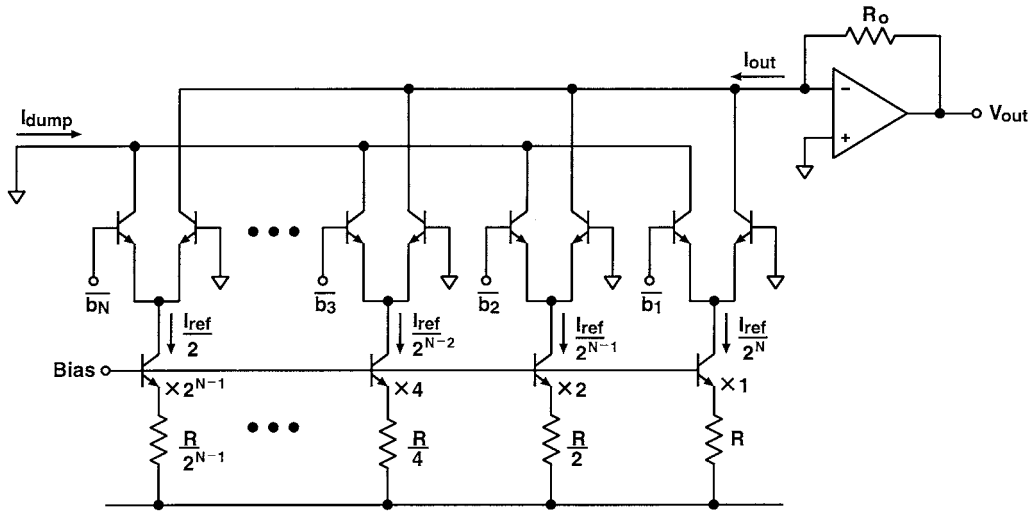

FIGURE 54.28 Current-ratioed DAC.

code. This causes a code-dependent settling time when charging the capacitive load. This non-uniform settling time problem can be alleviated by adding low-resistance parallel resistors or by compensating the MOS switch overdrive voltages.

Current-Ratioed DAC

The most popular stand-alone DACs in use today are *current-ratioed DACs*. There are two types: one is a weighted-current DAC and the other is an R-2R DAC. The weighted-current DAC shown in Fig. 54.28 is made of an array of switched binary-weighted current sources and the current summing network. In bipolar technology, the binary weighting is achieved by ratioed transistors and emitter resistors with binary related values of R, R/2, R/4, etc., while in MOS technology, only ratioed transistors are used. DACs relying on active device matching can achieve an 8b-level performance with a 0.2 to 0.5% matching accuracy using a 10- to 20-μm device feature size, while degeneration with thin-film resistors gives a 10b-level performance. The current sources are switched on or off by means of switching diodes or emitter-coupled differential pairs (source-coupled pairs in CMOS). The output current summing is done by a wideband transresistance amplifier; but in high-speed DACs, the output current directly drives a resistor load for maximum speed. The weighted-current design has the advantage of simplicity and high speed, but it is difficult to implement a high-resolution DAC because a wide range of emitter resistors and transistor sizes are used, and very large resistors cause problems with both temperature stability and speed.

R-2R Ladder DAC

This large resistor ratio problem is alleviated by using a resistor divider known as an *R-2R ladder*, as shown in Fig. 54.29. The R-2R network consists of series resistors of value R and shunt resistors of value 2R. The top of each shunt resistor of value 2R has a single-pole double-throw electronic switch that connects the resistor either to ground or to the current summing node. The operation of the R-2R ladder network is based on the binary division of current as it flows down the ladder. At any junction of series resistor of value R, the resistance looking to the right side is 2R. Therefore, the input resistance at any junction is R, and the current splits into two equal parts at the junction since it sees equal resistances in both directions. As a result, binary-weighted currents flow into shunt resistors in the ladder. The digitally controlled switches direct the currents to either ground or to the summing node. The advantage of the

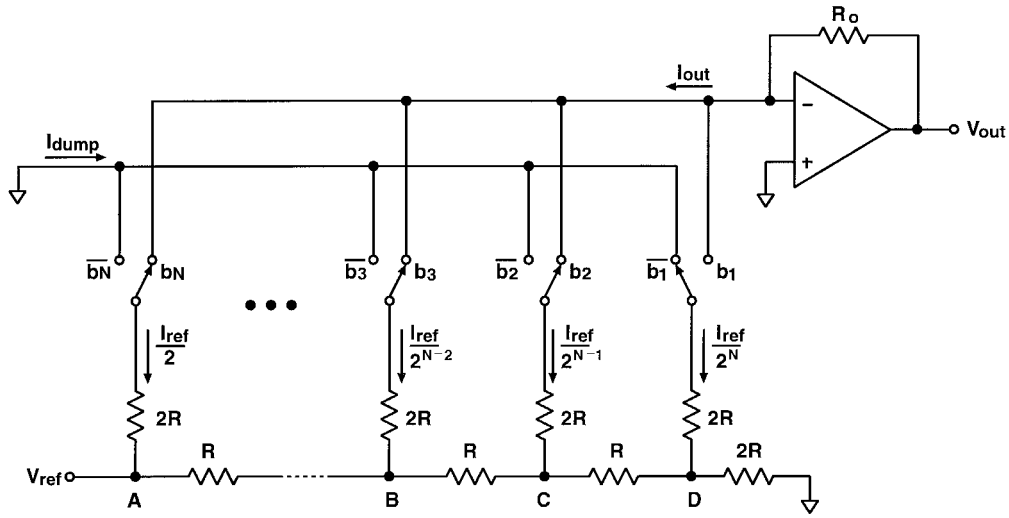

FIGURE 54.29 R-2R DAC.

R-2R ladder method is that only two values of resistors are used, greatly simplifying the task of matching or trimming and temperature tracking. In addition, for high-speed applications, relatively low resistor values can be used. Excellent results can be obtained using laser-trimmed thin-film resistor networks. Since the output of the R-2R DAC is the product of the reference voltage and the digital input word, the R-2R ladder DAC is often called an MDAC.

Capacitor-Array DAC

Capacitors made of double-poly or poly-diffusion in MOS technology are considered one of the most accurate passive components comparable to thin-film resistors in the bipolar process, both in the matching accuracy and voltage and temperature coefficients.[1] The only disadvantage in the capacitor-array DAC implementation is the use of a dynamic charge redistribution principle. A switched-capacitor counterpart of the resistor-string DAC is a parallel capacitor array of 2^N unit capacitors with a common top plate. The capacitor-array DAC is not appropriate for stand-alone applications without a feedback amplifier virtually grounding the top plate and an output S/H or deglitcher. The operation of the capacitor-array DAC shown in Fig. 54.30(a) is based on the thermometer-coded DAC principle and has the distinct advantage of monotonicity. However, due to the complexity of handling the thermometer-coded capacitor array, a binary-weighted capacitor array is often used, as shown in Fig. 54.30(b) by grouping unit capacitors in binary ratio values. One important application of the capacitor-array DAC is as a reference DAC for ADCs. As in the case of the R-2R MDAC, the capacitor-array DAC can be used as an MDAC to amplify residue voltages for multi-step or pipeline ADCs.

Thermometer-Coded Segmented DAC

Applying a two-step conversion concept, a DAC can be made in two levels using coarse and fine DACs. The fine DAC divides one coarse MSB segment into fine LSBs. If one fixed MSB segment is subdivided to generate LSBs, matching among MSB segments creates a non-monotonicity problem. However, if the next MSB segment is subdivided instead of the fixed segment, the segmented DAC can maintain monotonicity regardless of the MSB matching. This is called the next-segment approach. The most widely used segmented DAC is a current-ratioed DAC, whose MSB DAC is made of identical elements for the next-segment approach, except that the LSB DAC is a current divider as shown in Fig. 54.31. To implement a segmented DAC using two resistor-string DACs, voltage buffers are needed to drive the LSB DAC

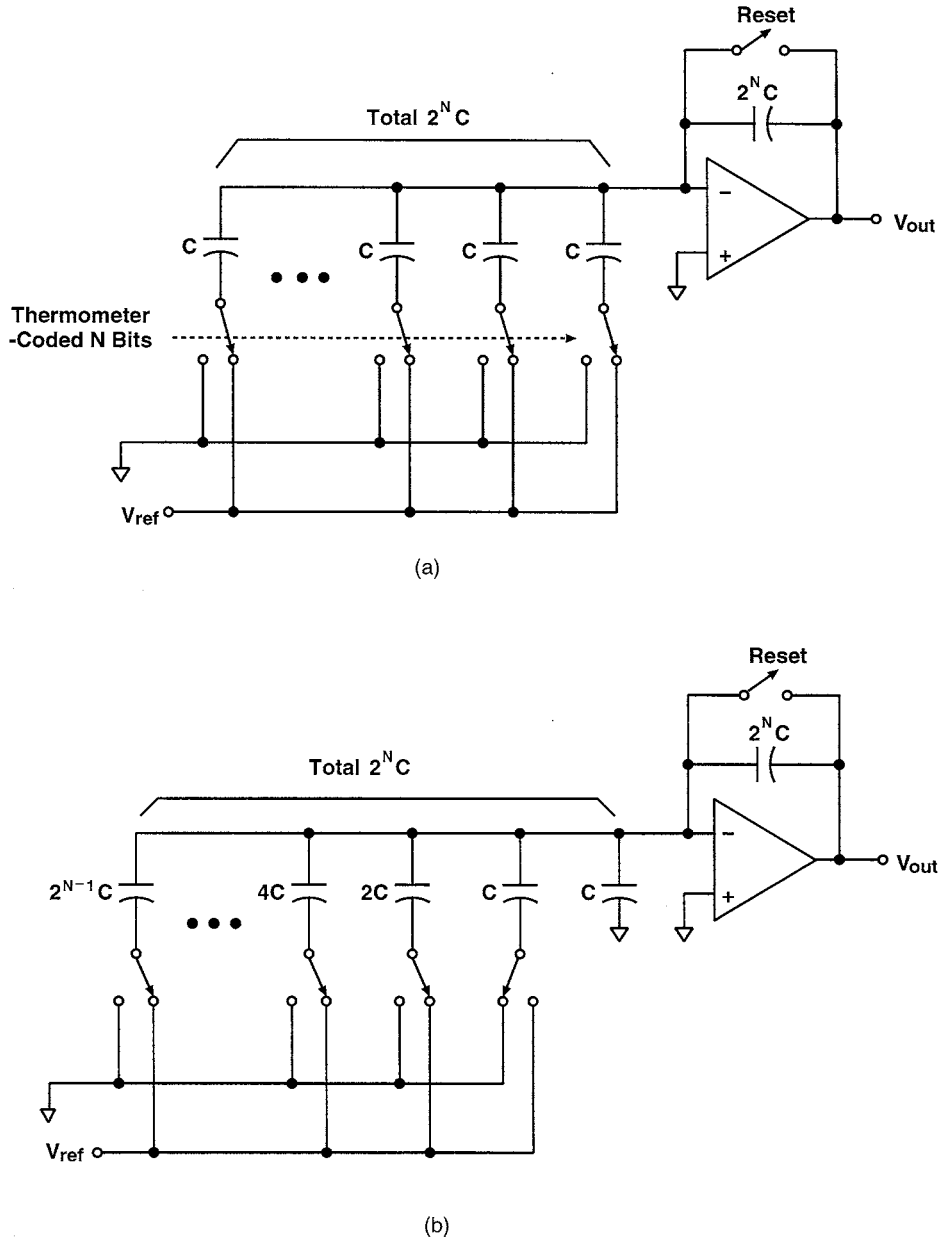

FIGURE 54.30 Capacitor-array DACs: (a) thermometer-coded and (b) binary-weighted.

without loading the MSB DAC. Although the resistor-string MSB DAC is monotonic, overall monotonicity is not guaranteed due to the offsets of the voltage buffers. The use of a capacitor-array LSB DAC eliminates the need for voltage buffers.

Integrator-Type DAC

As mentioned, monotonicity is guaranteed only in a thermometer-coded DAC. The thermometer coding of a DAC output can be implemented either by repeating identical DAC elements many times or by using

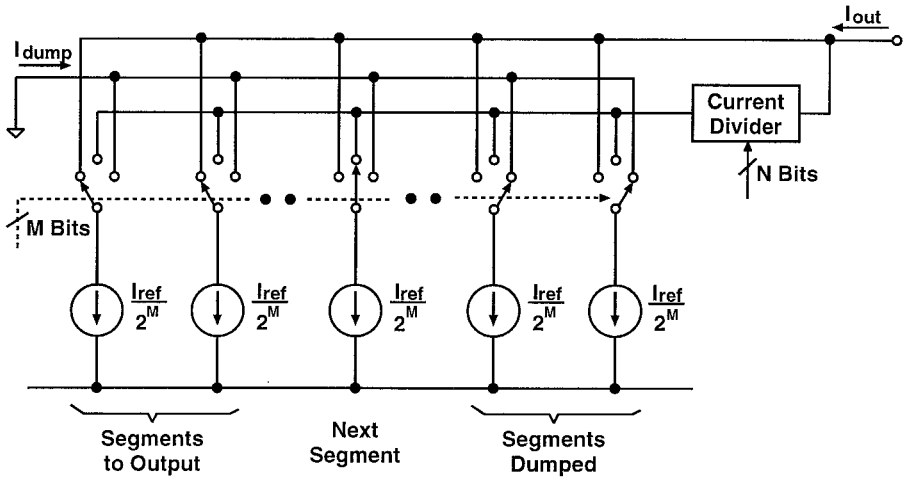

FIGURE 54.31 Thermometer-coded segmented DAC.

the same element over and over. The former requires more hardware, but the latter requires more time. In the continuous-time integrator-type DAC, the integrator output is a linear ramp and the time to stop integration can be controlled digitally. Therefore, monotonicity can be maintained. Similarly, the discrete-time integrator can integrate a constant amount of charge repeatedly and the number of integrations can be controlled digitally. The integration approach can give high accuracy, but its disadvantage is that its slow speed limits its applications.

54.7 DAC Design Considerations

Figure 54.32 illustrates two step responses of a DAC when it settles with a time constant τ and when it slews with a slew rate S. The transient errors given by the shaded areas are h/τ and $h^2/2S$, respectively. This implies that a single time-constant settling of the former case only generates a linear error in the output, which does not affect the DAC linearity, but the slew-limited settling generates a nonlinear error. Even in the single-time constant case, the code-dependent settling time constant can introduce a nonlinearity error because the settling error is a function of the time constant t. This is true for a resistor-string DAC, which exhibits a code-dependent settling time because the output resistance of the DAC depends on the digital input.

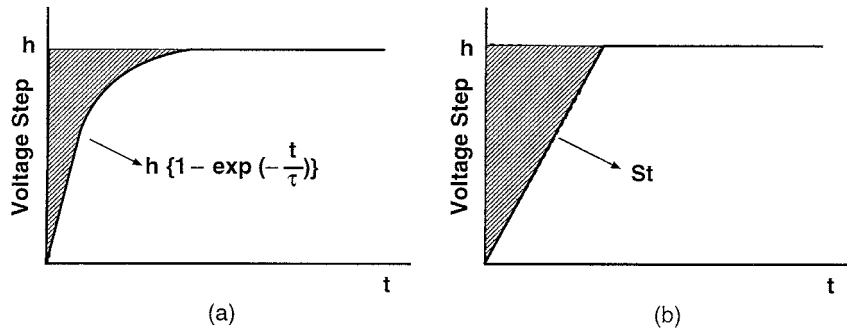

FIGURE 54.32 DAC settling cases: (a) exponential and (b) slew-limited case.

Effect of Limited Slew Rate

The slew-rate limit is a significant source of nonlinearity since the error is proportional to the square of the signal, as shown in Fig. 54.32(b). The height and width of the error term change with the input. The worst-case harmonic distortion (HD) when generating a sinusoidal signal with a magnitude V_o with a limited slew rate of S is[24]:

$$HD_k = 8\frac{\sin^2\frac{\omega T_c}{2}}{\pi k\left(k^2-4\right)} \times \frac{V_o}{ST_c}, \quad k = 1, 3, 5, 7\cdots \tag{54.6}$$

where T_c is the clock period. For a given distortion level, the minimum slew rate is given. Any exponential system with a bandwidth of ω_o gives rise to signals with the maximum slew rate of $2\omega_o V_o$. Therefore, by making $2\omega_o V_o > S$, the DAC system will exhibit no distortion due to the limited slew rate.

Glitch

Glitches are caused by small time differences between some current sources turning off and others turning on. Take, for example, the major code transition at half-scale from 011…11 to 100…00. Here, the MSB current source turns on while all other current sources turn off. The small difference in switching times results in a narrow half-scale glitch, as shown in Fig. 54.33. Such a glitch, for example, can produce distorted characters in CRT display applications. To alleviate both glitch and slew-rate problems related to transients, a DAC is followed by a deglitcher. The deglitcher stays in the hold mode while the DAC changes its output value. After the switching transients have settled, the deglitcher is changed to the sampling mode. By making the hold time suitably long, the output of the deglitcher can be made independent of the DAC transient response. However, the slew rate of the deglitcher is on the same order as that of the DAC, and the transient distortion will still be present — now as an artifact of the deglitcher.

Techniques for High-Resolution DACs

The following methods are often used to improve the linearity of DACs: Laser trimming, off-chip adjustment, common-centroid layout technique, dynamic element matching technique, voltage or current sampling, and electronic calibration techniques. The trend is toward more sophisticated and intelligent electronic solutions that overcome and compensate for some of the limitations of conventional trimming techniques. *Electronic calibration* is a general term to describe various circuit techniques, which

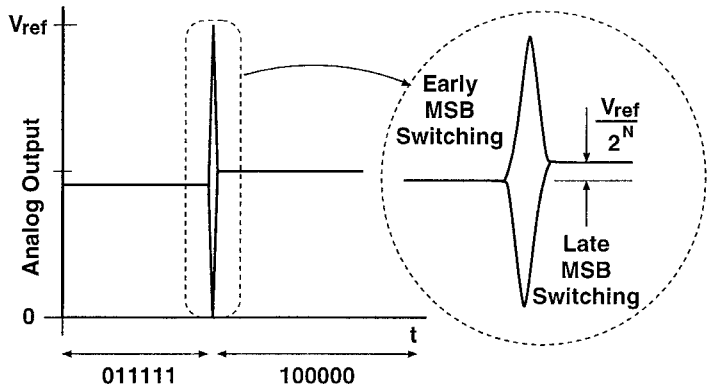

FIGURE 54.33 DAC output glitch.

usually predistort the DAC transfer characteristic so that the DAC linearity can be improved. The self-calibration is to incorporate all the calibration mechanisms and hardware on the DAC as a built-in function so that users can recalibrate whenever necessary.

The application of *dynamic element matching* to the binary-weighted current DAC is a straightforward switching of two complementary currents.[25] Its application to the binary voltage divider using two identical resistors or capacitors requires exchanging resistors or capacitors. This can be easily achieved by reversing the polarity of the reference voltage for the divide-by-two case. However, in the general case of N-element matching, the current division is inherently simpler than the voltage division. In general, to match the N independent elements, a switching network with N inputs and N outputs is required. The function of the switching network is to connect any input out of N inputs to one output with an average duty cycle of 1/N. The simplest one is a barrel shifter rotating the input-output connections in a predetermined manner. This barrel shifter generates a low-frequency modulated error when N gets larger because the same pattern repeats every N clocks. A more sophisticated randomizer with the same average duty cycle can distribute the mismatch error over the wider frequency range.

The *voltage or current sampling concept* is an electronic alternative to direct mechanical trimming. The voltage sampler is usually called a S/H, while the current sampler is called a current copier. The voltage is usually sampled on the input capacitor of a buffer amplifier, and the current is usually sampled on the input capacitor of a transconductance amplifier such as MOS transistor gate. Therefore, both voltage and current sampling techniques are ultimately limited by their sampling accuracy.

The idea behind the voltage or current sampling DAC is to use one voltage or current element repeatedly. One example of the voltage sampling DAC is a discrete-time integrating DAC. The integrator integrates a constant charge repeatedly, and its output is sampled. This is equivalent to generating equally spaced reference voltages by stacking identical unit voltages.[26] The fundamental problem associated with this sampling voltage DAC approach is the accumulation of the sampling error and noise in generating larger voltages. Similarly, the current sampling DAC can sample a constant current on current sources made of MOS transistors.[27] Since one reference current is copied on other identical current samplers, the matching accuracy can be maintained as long as the sampling errors are kept constant. Since it is not practical to make a high-resolution DAC using voltage or current sampling alone, this approach is limited to generating MSB DACs for the segmented DAC or for the subranging ADCs.

Self-calibration is based on an assumption that the segmented DAC linearity is limited by the MSB DAC so that only errors of MSBs can be measured, stored in memory, and recalled during normal operation. There are two different ways of measuring the MSB errors. In one method, individual-bit non-linearities, usually appearing as component mismatch errors, are measured digitally,[15,18] and a total error, which is called a code error, is computed from individual-bit errors depending on the output code during normal conversion. On the other hand, the other method measures and stores digital code errors directly and eliminates the digital code-error computation during normal operation.[16,17] The former requires less digital memory, while the latter requires fewer digital computations.

Oversampled Analog-to-Digital and Digital-to-Analog Converters

John W. Fattaruso

Texas Instruments, Incorporated

55.1 Introduction

In the absence of some form of calibration or trimming, the precision of the Nyquist rate converters described Chapter 54 is strictly dependent on the precision of the VLSI components that comprise the converter circuits. Oversampled data converters are a means of exchanging the speed and data processing capability of modern sub-micron integrated circuits for precision that would otherwise not be readily attainable.[1,2] The precision of an oversampled data converter can exceed the precision of its circuit components by several orders of magnitude.

In this chapter, the basic operation and design techniques of the most widely used class of oversampled data converters — *sigma-delta*[1] *modulators* — are described. In Section 55.2, the basic theory of sigma-delta

[1]The reader will find functionally identical modulator blocks in the literature named either "sigma-delta" modulators or "delta-sigma" modulators, with the choice of terminology largely up to personal preference. We use the former term here.

modulators is presented, using both time-domain and frequency-domain approaches. The issue of non-harmonic tones is also discussed. In Section 55.3, more complex sigma-delta architectures are described, including higher-order architectures, cascaded architectures, and bandpass architectures. Filtering techniques unique to sigma-delta modulators are presented in Section 55.4. In Section 55.5, the basic circuit building blocks for sigma-delta modulators are described; and in Section 55.6, circuit design issues specific to sigma-delta-based data converters are discussed.

55.2 Basic Theory of Operation

Oversampled data conversion techniques have their roots in the design of signal coders for communication systems.[3-6] Oversampling techniques differ from Nyquist techniques in that their comprehension and design procedures draw equally from time-domain and frequency-domain representations of signals, whereas Nyquist techniques are readily understood in just the time domain.

In general, the function of data conversion by oversampling is typically performed by a serial connection of a modulator and various filter blocks. In analog-to-digital (A/D) conversion, shown in Fig. 55.1, the analog input signal $x_i(t)$ is first bandlimited by an anti-alias filter, then sampled at a rate f_S. This sampling rate is M times faster than a comparable Nyquist rate converter with the same signal bandwidth; the value of M is the oversampling ratio. The sampled signal $x[n]$ is coded by a modulator block that quantizes the data into a finite number of discrete levels. The resulting coded signal $y[n]$ is down-sampled, or decimated, by a factor of M to produce an output that is comparable to a Nyquist rate converter. Digital-to-analog oversampled data conversion is basically the reverse of analog-to-digital conversion. As shown in Fig. 55.2, the Nyquist-rate digital samples are oversampled by an interpolation filter, coded by a modulator, and then reconstructed in the analog domain by an analog filter.

In both analog-to-digital and digital-to-analog data conversion, the block with the most unique signal processing properties is the modulator. The remainder of this section and the subsequent sections focus on the properties and architectures for oversampled data modulators.

Time-Domain Representation

The simplest modulator that would perform the requisite conversion to discrete output levels is the quantization function $Q(x)$ shown in Fig. 55.3. This quantization can be thought of as merely the sum

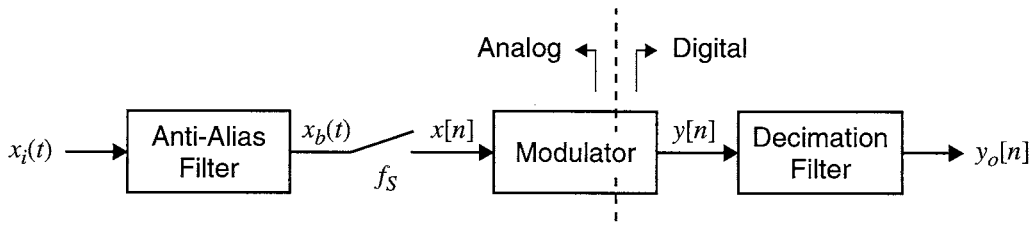

FIGURE 55.1 Oversampled A/D conversion.

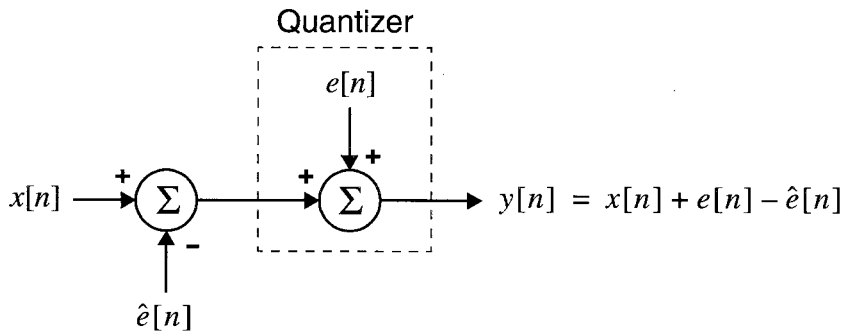

FIGURE 55.5 Error correction feedback.

of the original signal $x[n]$ with a sampled error signal $e[n]$, as illustrated in Fig. 55.4. In Nyquist rate converters, the error is reduced by using a large number of small steps in the quantizer characteristic. In oversampled data converters, specifically sigma-delta modulators, the error is corrected by a feedback network. This correction is made by estimating the error in advance and subtracting it from the input, as shown in Fig. 55.5, where is the error estimate. If this estimate were perfect, $\hat{e}[n]$ would equal $e[n]$ and the output $y[n]$ would equal the input $x[n]$. However, since the error is not known until it is made, $e[n]$ is not known when $\hat{e}[n]$ is needed. Therefore, some means must be found to estimate the error. In the case of sigma-delta converters, the error can be estimated by exploiting some knowledge of the frequency domain behavior of the input signal. Specifically, it is assumed that the signal is changing very slowly from sample to sample, or equivalently, its bandwidth is much less than the sampling rate.

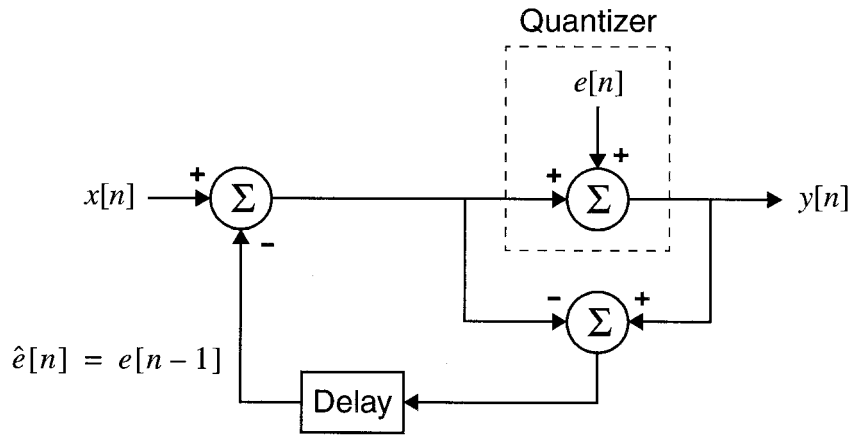

FIGURE 55.6 First-order error estimation.

For exceedingly slow signals, a first-order estimate of the error to be committed in quantization can be formed. The first-order estimate of the current error $e[n]$ is simply the previous error $e[n-1]$. This error may be found simply by a subtraction across the quantization block as shown in Fig. 55.6, and the output $y[n]$ is

$$y[n] = x[n] + e[n] - e[n-1] \tag{55.1}$$

The essential property of this structure is that if an error is committed that is not large enough to be corrected by a displacement to another quantizer level on the next sample, then the history of successive errors accumulate in the feedback loop until they eventually push the quantizer into another level. In this manner, the output of the quantizer will, over time, correct the errors committed in previous samples, increasing the precision of the information being generated as a time sequence of samples.

As will be shown in Section 55.5, the most convenient and accurate sampled-data circuit building block in practice is an integrator. With a few straightforward steps, the system of Fig. 55.6 can be transformed into that of Fig. 55.7, where the delay element is now immersed in an integrator feedback loop. The output of this transformed modulator is

$$y[n] = x[n-1] + e[n] - e[n-1] \tag{55.2}$$

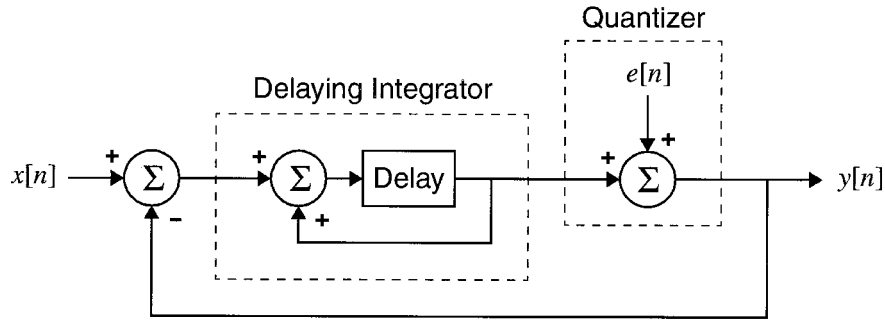

FIGURE 55.7 First-order equivalent modulator.

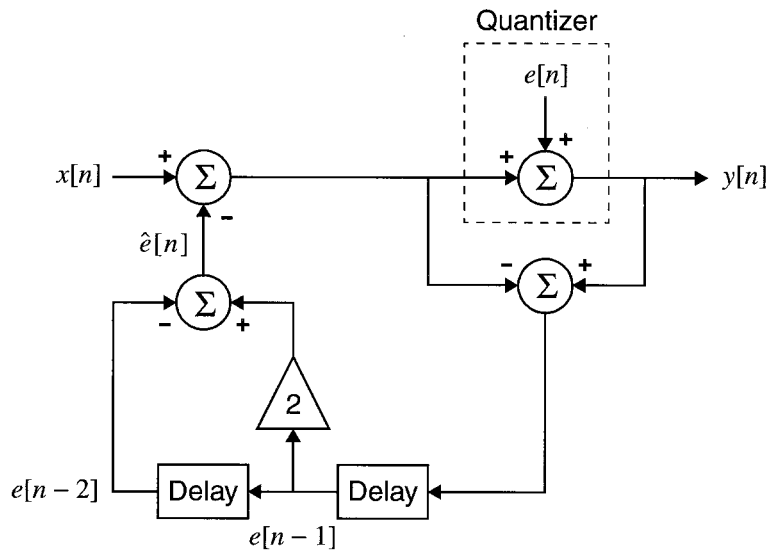

FIGURE 55.8 Second-order error estimation.

Comparing Eqs. 55.1 and 55.2, it is evident that this transformation does require the addition of a single clock delay block in the input path $x[n]$, but this extra clock cycle of latency has no effect on the precision or frequency response of the modulator. The structure in Fig. 55.7 is generally known as a first-order sigma-delta modulator.[7-9]

An increase in precision can be obtained by using more accurate estimates of the expected quantizer error.[6] A second-order estimate of $e[n]$ may be formed by assuming that the error $e[n]$ varies linearly with time. In this case, an estimate of the current error $e[n]$ may be computed by changing the previous error $e[n-1]$ by an amount equal to the change between $e[n-2]$ and $e[n-1]$. The second order error estimate is thus

$$\hat{e}[n] = e[n-1] + \left(e[n-1] - e[n-2]\right) = 2e[n-1] - e[n-2] \tag{55.3}$$

and is illustrated in Fig. 55.8. The output of the second-order estimation modulator is

$$y[n] = x[n] + e[n] - 2e[n-1] + e[n-2] \tag{55.4}$$

It can be shown, after a number of steps, that the modulator in Fig. 55.8 can be transformed into a modulator in which the feedback loop delays are again immersed in practical integrator blocks. This second-order sigma-delta modulator[10-12] is shown in Fig. 55.9; the output of this transformed modulator is

$$y[n] = x[n-2] + e[n] - 2e[n-1] + e[n-2] \tag{55.5}$$

which is entirely equivalent to that given by Eq. 55.4, except for the addition of two inconsequential delays of the input signal $x[n]$.

A further increase in precision can be obtained using even higher-order estimates of the quantizer error, such as quadratic or cubic. These high-order error estimate modulators can also be transformed

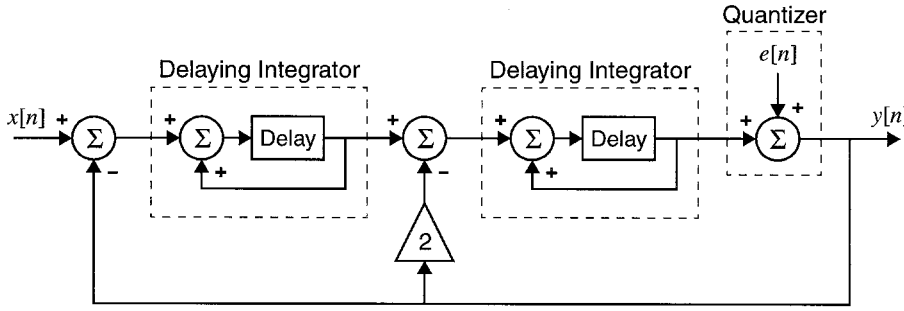

FIGURE 55.9 Second-order equivalent modulator.

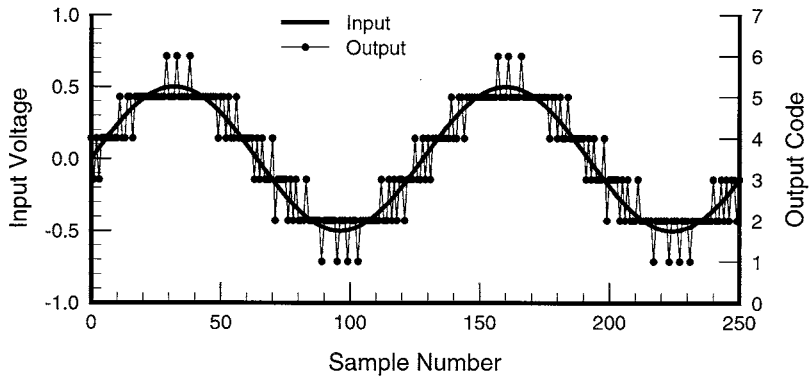

FIGURE 55.10 First-order sample output.

into a series of delaying integrators in a feedback loop. Unfortunately, as discussed in Section 55.3, practical difficulties emerge for orders greater than two, and alternative architectures are generally needed.

Computer simulation of modulator systems is straightforward, and Fig. 55.10 shows the simulated output of the first-order modulator of Fig. 55.7 when fed with a simple sinusoidal input. The resolution of the quantizer in the modulator loop was assumed to be eight levels. (The modulator output is drawn with continuous lines to emphasize the oscillatory nature of the modulator output, but the quantities plotted have meaning only at each sample time.) The coarsely quantized output code generally follows the input, but with occasional transitions that track intermediate values over local sample regions.

A second-order modulator with an eight-level quantizer exhibits the simulated behavior shown in Fig. 55.11. Note that the oscillations by which the loop attempts to minimize quantization error appear "busier" than in the first-order case of Fig. 55.10. It will be shown in the frequency domain that, for a given signal bandwidth, the more vibrant output code oscillations in Fig. 55.11 actually represent the input signal with higher precision than the first-order case in Fig. 55.10.

A special case that is of practical significance is the second-order modulator with a two-level quantizer, that is, simply a comparator closing the feedback loop. A simulation of such a modulator is shown in Fig. 55.12. Although the quantized representation at the output appears crude, the continuous nature of the input level is expressed in the density of output codes. When the input level is high (around sample numbers 32 and 160), there is a greater preponderance of '1' output codes; and at low swings of the input (around sample numbers 96 and 224), the '0' output code dominates.

The examples in Figs. 55.10 to 55.12 demonstrate that information generated from the modulator expresses, in a high-speed coded form, the coarsely quantized input signal and the deviation between the signal and the quantization levels. Although the time domain coded modulator output looks somewhat unintelligible, the output characteristics are clearer in the frequency domain.

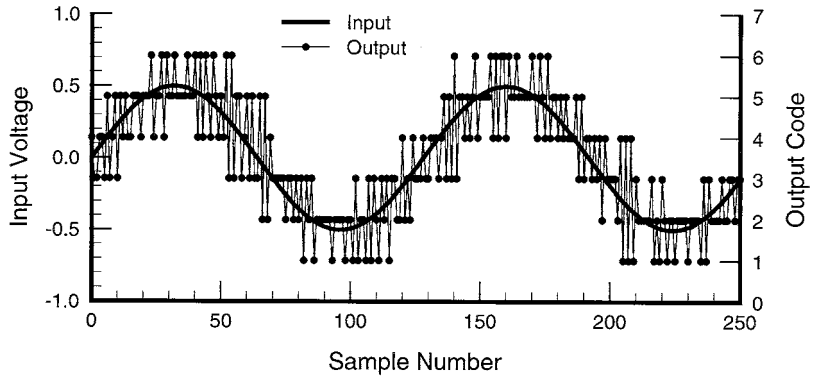

FIGURE 55.11 Second-order sample output.

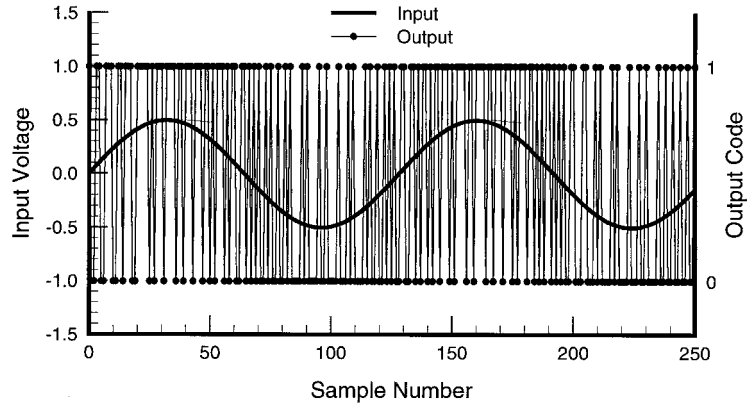

FIGURE 55.12 Second-order one-bit modulator sample output.

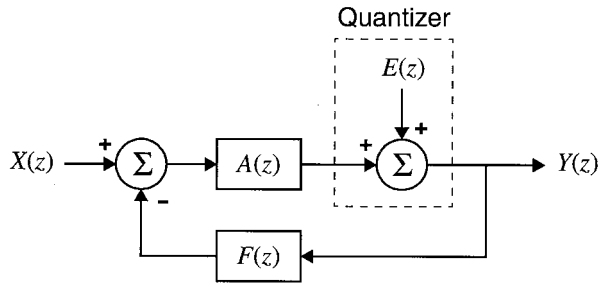

FIGURE 55.13 Generalized sigma-delta modulator.

Frequency-Domain Representation

The modulators in Figs. 55.7 and 55.9 can be generalized as the sampled-data system shown in Fig. 55.13, where the time domain signals $x[n]$, $y[n]$, and $e[n]$ are written as their frequency-domain equivalents $X(z)$, $Y(z)$, and $E(z)$. The modulator output in Fig. 55.13 can be written in terms of the input $X(z)$ and the quantizer error $E(z)$ as

$$Y(z) = H_x(z)X(z) + H_e(z)E(z) \tag{55.6}$$

where the input transfer function, $H_x(z)$, is

$$H_x(z) = \frac{A(z)}{1 + A(z)F(z)} \tag{55.7}$$

and the error transfer function, $H_e(z)$, is

$$H_e(z) = \frac{1}{1 + A(z)F(z)}. \tag{55.8}$$

Strictly speaking, the error $E(z)$ is directly dependent on the input $X(z)$. Nonetheless, if the input to the quantizer is sufficiently busy, that is, the input to the quantizer crosses through several quantization levels, the quantizer error approaches having the behavior of a random value that is uniformly distributed between $\pm\delta/2$ and is uncorrelated with the input, where δ is the quantization level separation illustrated in Fig. 55.3. In the frequency domain, the error noise power spectrum is uniform with a total error power of $\delta^2/12$.[13,14] The error power between the frequencies f_L and f_H is

$$S_{ee} \approx \frac{\delta^2}{6 f_S} \int_{f_L}^{f_H} \left| H_e\left(e^{j\pi f/f_s}\right) \right|^2 df \tag{55.9}$$

where f_S is the sampling rate. The error power between f_L and f_H can be reduced independent of the quantizer error level separation δ by having a small error transfer function $H_e(z)$ in that frequency band. Sigma-delta modulators have this property.

A sigma-delta modulator is a system such as that in Fig. 55.13 in which the error transfer function $H_e(z)$ is small and the input transfer function $H_x(z)$ is about unity for some band of frequencies. That is,

$$\left| H_e\left(e^{j2\pi f/f_s}\right) \right| \ll 1; \quad f_L \le f \le f_H \tag{55.10}$$

$$\left| H_x\left(e^{j2\pi f/f_s}\right) \right| \approx 1; \quad f_L \le f \le f_H \tag{55.11}$$

The requirements in Eqs. 55.10 and 55.11 are equivalent to requiring that the loop gain be large and the feedback gain be unity, that is

$$\left| A\left(e^{j2\pi f/f_s}\right) \right| \gg 1; \quad f_L \le f \le f_H \tag{55.12}$$

$$\left| F\left(e^{j2\pi f/f_s}\right) \right| \approx 1; \quad f_L \le f \le f_H \tag{55.13}$$

There are many system designs that have the sigma-delta properties of high loop gain and unity feedback gain. The previous examples in Figs. 55.7 and 55.9 are part of an important class of modulator architectures called *noise-differencing modulators* that are particularly well suited to VLSI implementation. The forward path in a noise-differencing sigma-delta modulator consists of a series of delaying integrators. The *order* of the modulator is defined as the number of integrators. The forward gain of an L-th order modulator is

$$A(z)=\left(\frac{z^{-1}}{1-z^{-1}}\right)^{L} \tag{55.14}$$

The feedback gain in a noise-differencing modulator is designed such that the modulator open-loop gain is

$$A(z)F(z)=\frac{1}{\left(1-z^{-1}\right)^{L}}-1 \tag{55.15}$$

From Eqs. 55.14 and 55.15, it follows that the output for an L-th order noise-differencing sigma-delta modulator is

$$Y(z)=z^{-L}X(z)+\left(1-z^{-1}\right)^{L}E(z) \tag{55.16}$$

The simulated frequency response for a second-order noise-differencing sigma-delta modulator with a sinusoidal input is shown in Fig. 55.14. The large spike in the center is the original input signal. It is clear from the plot that the noise energy is lowest at low frequencies. Noise-differencing modulators are designed to reduce the quantization noise in the baseband, that is, $f_L = 0$ and $f_H \ll f_S$. The oversampling ratio, M, is

$$M=\frac{f_S}{2f_H} \tag{55.17}$$

(In a Nyquist rate converter, $M = 1$.) The baseband noise power for a noise-differencing modulator is

$$S_{ee}\approx\frac{\delta^2}{6f_S}\int_0^{f_H}\left|\left(1-e^{-j2\pi f/f_S}\right)^{L}\right|^2 df\approx\frac{\delta^2}{12}\frac{\pi^{2L}}{2L+1}\frac{1}{M^{2L+1}} \tag{55.18}$$

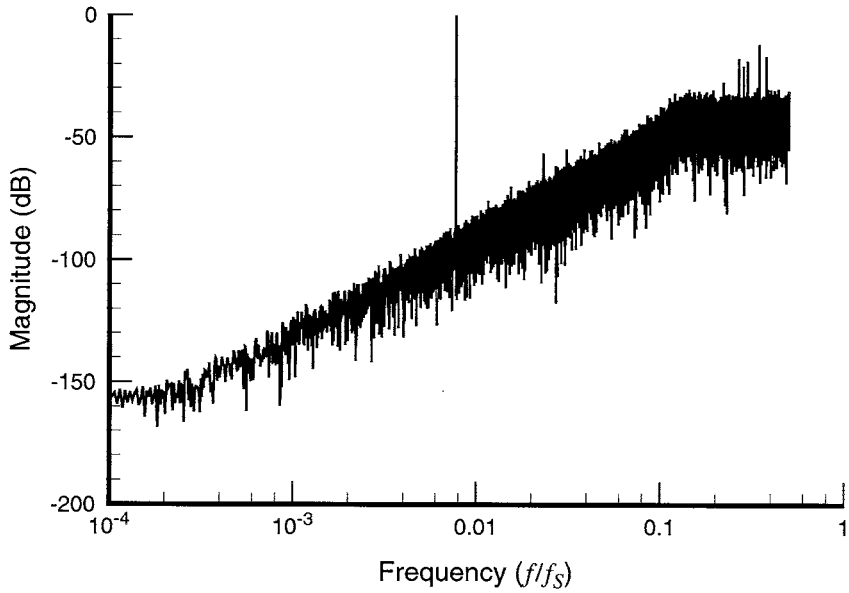

FIGURE 55.14 Second-order simulated frequency response.

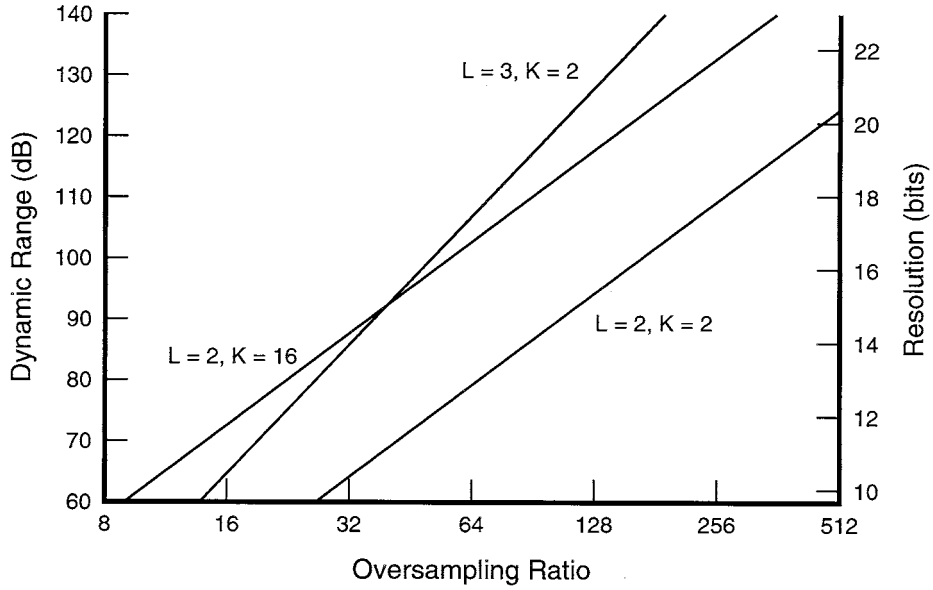

FIGURE 55.15 Calculated dynamic range vs. oversampling ratio.

One important measure of a sigma-delta modulator is its dynamic range, defined here as the ratio of the maximum sinusoidal input power to the noise power. With the quantizer output limited, as shown in Fig. 55.3, to a range of Δ, the maximum sinusoidal signal power is $\Delta^2/8$. The quantizer range Δ is related to the quantizer level separation δ by the number of quantization levels K, where

$$\delta = \frac{\Delta}{K-1} \tag{55.19}$$

The dynamic range of a noise-differencing sigma-delta modulator is then

$$DR = \frac{3}{2}\frac{2L+1}{\pi^{2L}} M^{2L+1}\left(K-1\right)^2 \tag{55.20}$$

Because the dynamic range is such a strong function of the oversampling ratio, the number of bits required to achieve a given dynamic range is substantially less in a sigma-delta modulator than in a Nyquist-rate converter. To illustrate this, the dynamic range, as given by Eq. 55.20, is shown in Fig. 55.15 as a function of the oversampling ratio, M, for three combinations of modulator order, L, and number of quantization levels, K. The equivalent resolution in bits that would be required of a Nyquist-rate converter to achieve the same dynamic range is shown in the right-hand axis of this figure. It can be inferred from Eq. 55.20 that a large dynamic range can be obtained even with only two quantization levels. This is important when circuit imperfections in actual sigma-delta data converter implementations are considered.

Sigma-Delta Modulators in Data Converters

The generalized modulator shown in Fig. 55.13 must be subtly modified when applied to the A/D and D/A converters in Figs. 55.1 and 55.2. In an A/D converter, the quantizer is actually a coarse K-level A/D converter (ADC), having an analog input and a digital output. (Since K is generally small, the K-level ADC is usually just a small flash converter, as described in Chapter 54.) The quantized digital code is fed

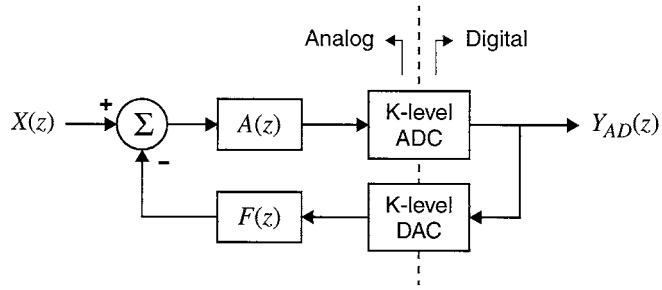

FIGURE 55.16 Sigma-delta modulator for A/D conversion.

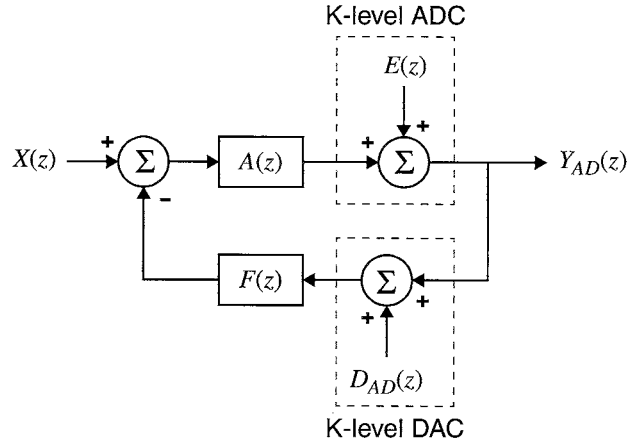

FIGURE 55.17 *K*-level DAC error in sigma-delta A/D converter.

back into the analog $F(z)$ through a K-level D/A converter (DAC), as shown in Fig. 55.16. Imperfections in this K-level DAC will introduce an additional error term $D_{AD}(z)$ as shown in Fig. 55.17. With the addition of this DAC error term, the modulator output is

$$Y_{AD}(z) = H_x(z)\left[X(z) - F(z)D_{AD}(z)\right] + H_e(z)E(z) \tag{55.21}$$

Since the feedback transfer function, $F(z)$, is unity in the band of interest (see Eq. 55.13), the DAC error is indistinguishable from the input. If there are more than two quantization levels, any mismatch between the level separations in the DAC will manifest itself as distortion because the DAC input is signal dependent. On the other hand, if there are only two quantization levels, there is only one level separation, and errors in the DAC levels will not cause distortion. (At worst, DAC errors in a two-level modulator will introduce a dc offset and a gain error.) Thus, with two-level sigma-delta modulators, it is possible to achieve low distortion and low-noise performance without precise component matching.

Unfortunately, most, if not all, of the statistical conditions that led to Eq. 55.9 and the subsequent equations are violated when a two-level single-threshold quantizer is used in a sigma-delta modulator.[15] Furthermore, the effective gain of the quantizer, which in Fig. 55.3 is implied to be unity, is undefined for a single-threshold quantizer. Nonetheless, empirical evidence has indicated that Eq. 55.20 is still a reasonable approximation for two-level noise-differencing sigma-delta modulators, and is useful as a design guideline for the amount of oversampling needed to achieve a specific dynamic range for a given modulator order.[16]

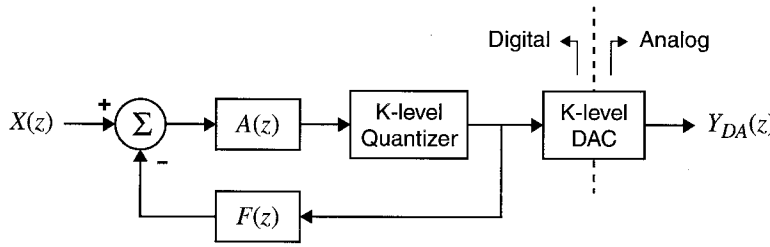

FIGURE 55.18 Sigma-delta modulator for D/A conversion.

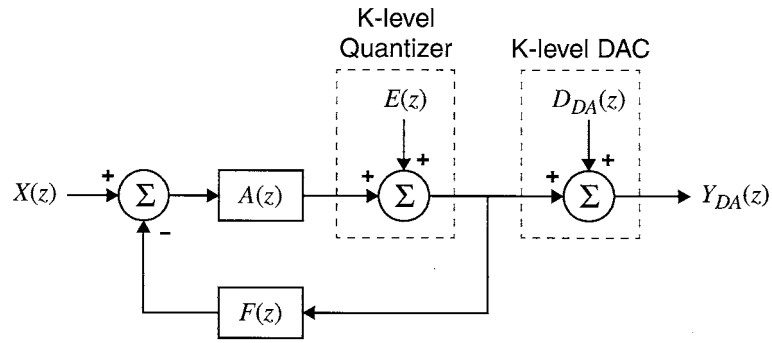

FIGURE 55.19 *K*-level DAC error in sigma-delta D/A converter.

As in sigma-delta ADCs, there is also a DAC error term in sigma-delta based DACs. In a sigma-delta DAC, the modulator loop is implemented digitally, and the output of that loop is applied to a coarse *K*-level DAC that provides the analog input for the reconstruction filter, as shown in Fig. 55.18. Imperfections in the *K*-level DAC will introduce an error term $D_{DA}(z)$ as shown in Fig. 55.19. With the addition of this error term, the modulator output is

$$Y_{DA}(z) = H_x(z)X(z) + D_{DA}(z) + H_e(z)E(z) \tag{55.22}$$

Since the input transfer function $H_x(z)$ is unity in the band of interest (see Eq. 55.11), the DAC error is indistinguishable from the input, just as in the A/D case. Once again, two-level quantization can be used to avoid DAC-introduced distortion.

Tones

One problem with the simplified noise model of sigma-delta modulators that led to Eq. 55.20 is the failure to predict non-harmonic tones. This is especially true for two-level modulators. Repetitive patterns in the coded modulator output that cause discrete spectral peaks at frequencies not harmonically related to any input frequency can occur in sigma-delta modulators.[10,16-18] These tones can manifest themselves as odd "chirps" or "pops," and they exist even in ideal sigma-delta modulators; they are not caused by circuit imperfections.[2]

The origin of sigma-delta tones is illustrated in the following example. Consider a first-order sigma-delta modulator, such as that in Fig. 55.7, with a dc input of 0.0005. Let the quantizer have two output levels, +0.5 and –0.5. The output of such a modulator will be a sequence of +0.5's and –0.5's such that the time average of the outputs is 0.0005. To achieve this average, the output of the first-order modulator will be a stream of alternating +0.5's and –0.5's, with an extra +0.5 every 1000 clock cycles. This is

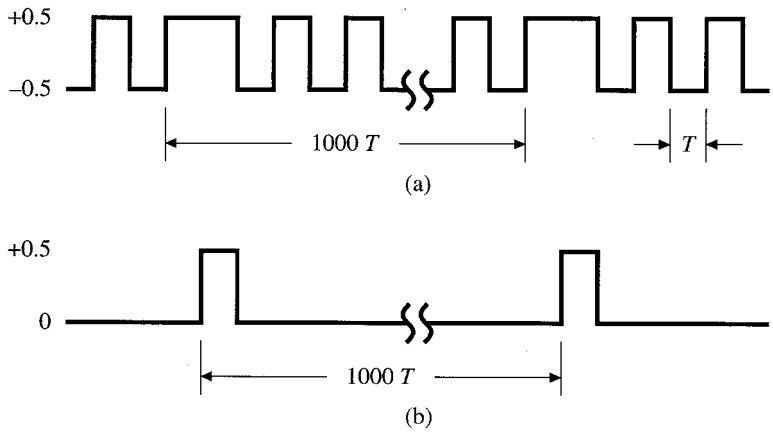

FIGURE 55.20 (a) Output sequence with average of 0.0005; and (b) running average of (a).

illustrated in Fig. 55.20(a), where T is the clock period ($T = 1/f_S$). The two-cycle running average of this output is shown in Fig. 55.20(b). For the most part, this running average is zero, except that at every 1000 clock cycles, there is a one clock cycle pulse. This repetitive pulse produces a tone in the output spectrum at a frequency of

$$f_P = \frac{f_S}{1000} = \frac{M}{500} f_H \tag{55.23}$$

If the oversampling ratio M is less than 500, this tone will appear in the baseband spectrum.

In sigma-delta modulators with more active input signals, the output sequence is typically more complex than that illustrated in Fig. 55.20. Nonetheless, the concept underlying tone behavior is that repeating patterns in the quantizer output cause non-uniformity in the quantizer error spectrum, which in the worst case is a discrete spectral peak. A measured tone for a second-order modulator with a dc input is shown in Fig. 55.21.[19]

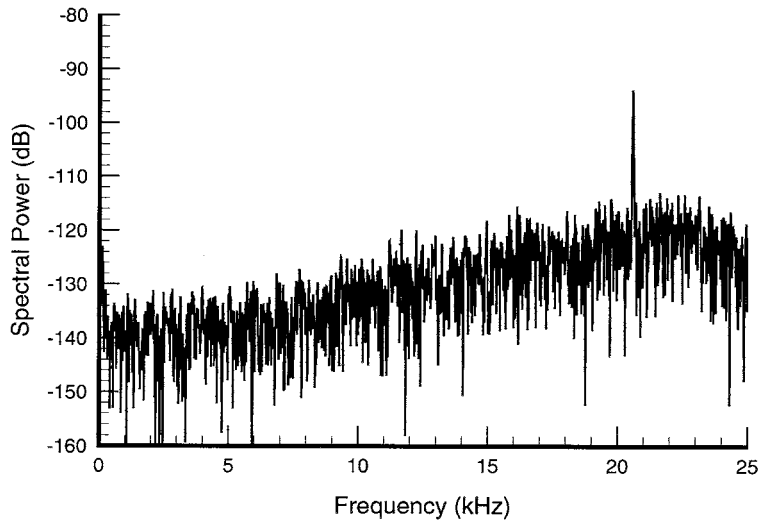

FIGURE 55.21 Measured tone in second-order modulator with dc input.

Several means of mitigating sigma-delta tones have been used. The first rule is to avoid using first-order sigma-delta modulators. Aside from having inferior noise-shaping properties compared to other modulator architectures, first-order modulators have terrible tone properties.[15,16] The situation improves dramatically with second- and higher-order modulators. In fact, the presence of tones may only be a perceptual or marketing concern, as the total tone power is usually less than the broadband quantization noise power.[20]

When tone magnitudes must be reduced, several techniques have proven effective. These include dither, cascaded architectures, and multi-level quantization. Of these three, dither is the only technique whose sole benefit is the reduction of tones. The simplest type of dither is to add a moderate amplitude out-of-band signal, such as a square wave, to the input.[9,21,22] This dither signal is attenuated by the same filter that attenuates the quantization noise. The purpose of this dither is to keep the sigma-delta modulator out of modes that produce patterns, and for some types of tones this technique is effective. A more rigorously effective technique is to add a large amplitude pseudo-random noise signal at the quantizer input.[23] This noise is spectrally shaped just like the quantization noise, and is the most effective dither scheme for eliminating tones. Its drawbacks are the expense in silicon area of the random noise generator and the 2- to 3-dB reduction in dynamic range caused by the dither noise.

The other two tone mitigation techniques, cascaded architectures and multi-level quantization, are simply more complex sigma-delta architectures that happen to have improved tone properties over simple noise-differencing two-level sigma-delta modulators. These techniques are covered in Sections 55.3 and 55.4, respectively.

55.3 Alternative Sigma-Delta Architectures

Equation 55.20 appears to indicate that the order of the modulator, L, can be any value, and that increasing L would be beneficial. However, one further problem with two-level sigma-delta modulators is that two-level noise-differencing modulators of order greater than two can exhibit unstable behavior.[10] For this reason, only first- and second-order modulators were discussed in the Section 55.2. Nonetheless, there have been acceptably stable practical alternative architectures that achieve quantization noise shaping that is superior to a second-order modulator. Two such architectures, high-order and cascaded modulators, are discussed in this section.

Another assumption in the previous section was that the noise-shaped region in a sigma-delta modulator is centered around dc. This is not necessarily the case; sigma-delta modulators with noise-shaped regions at frequencies other than near dc are called *bandpass modulators* and are discussed at the end of this section.

High-Order Modulators

A high-order modulator is a modulator such as that depicted in Fig. 55.13 in which there are more than two zeros in the noise transfer function. As stated earlier, if two-level quantization is employed, a simple noise-differencing series of integrators cannot be used, as such architectures produce unstable oscillations with large inputs that do not recover when the input is removed. To overcome this problem, high-order modulators use forward and feedback transfer functions that are more complex than the noise-differencing functions in Eqs. 55.14 and 55.15.[24-26]

The general rule of thumb in the design of high-order modulators is that the modulator can be made stable if

$$\lim_{z\to\infty} H_e(z) = 1 \tag{55.24}$$

$$\left|H_e(z)\right| \le A, \text{ for } |z| = 1 \tag{55.25}$$

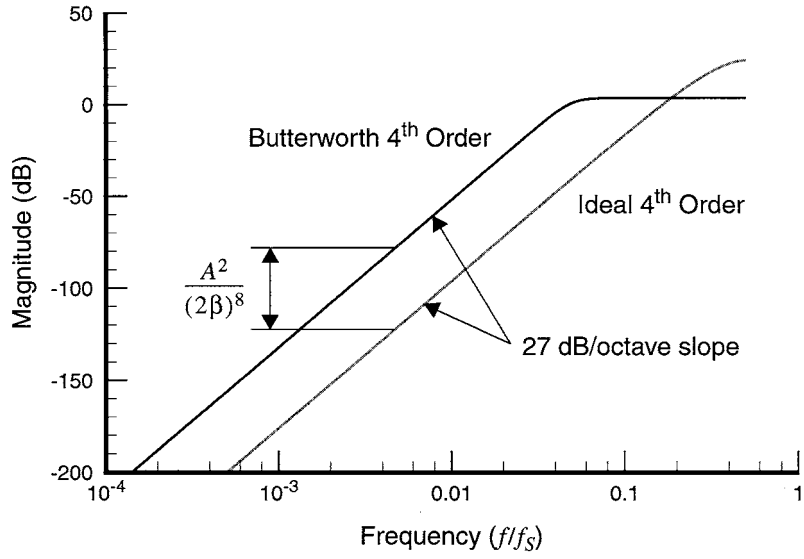

FIGURE 55.22 Fourth-order error spectrum.

and the integrator outputs are clipped and/or scaled to prevent self-sustaining instability.[26,27] The maximum error gain A is about 1.5, but the value used represents a tradeoff between noise attenuation and modulator stability. These rules cover a broad class of filter types and modulator architectures, and the type of filter used generally follows the traditions of the previous designers in an organization.

As an example, consider a fourth-order modulator with a highpass Butterworth error transfer function having a maximum gain, A, of 1.5, and a cutoff frequency set such that Eq. 55.24 is satisfied. The error spectrum of the Butterworth filter is shown in Fig. 55.22, along with the error transfer function of an ideal fourth-order difference. While the Butterworth filter holds the maximum gain to 1.5 (3.5 dB), and while both filters have a fourth-order noise shaping slope in the baseband (27 dB/octave), the error power in the baseband is 44 dB higher with the Butterworth filter than with the ideal noise-differencing filter. This error penalty is typical of high-order designs; there is usually a direct tradeoff between stability and noise reduction.

Consider the more general case of an L-th order highpass Butterworth error transfer function. The error transfer function of such a filter around the unit circle is

$$\left|H_e\left(e^{j\omega}\right)\right|^2 = \frac{A^2\left(\frac{1}{\beta}\tan\frac{\omega}{2}\right)^{2L}}{1+\left(\frac{1}{\beta}\tan\frac{\omega}{2}\right)^{2L}} \tag{55.26}$$

The filter coefficients $H_e(z)$ for needed to satisfy Eq. 55.26 can be computed using standard digital filter design techniques.[28] For a given filter order, L, and gain, A, the parameter β must be chosen to satisfy Eq. 55.24. (The condition in Eq. 55.25 is always satisfied when Eq. 55.26 is true.) These solutions can be computed numerically, and it is found empirically that

$$\beta = A^e\beta_N \tag{55.27}$$

TABLE 55.1 High-Order Butterworth Gain Factors and Dynamic Range (DR) Loss

				Zero Placement	
L	β_N	β	Loss in DR (dB)	DR Improvement (dB)	Net Loss in DR (dB)
3	0.052134	0.1570	33.7	8.0	25.8
4	0.051709	0.1557	44.1	12.8	31.2
5	0.033866	0.1020	72.6	17.9	54.7
6	0.034903	0.1051	84.8	23.2	61.6
7	0.025390	0.0764	117.7	28.6	89.1

Note: Except for β_N, all values are calculated for $A = 1.5$.

where the values for β_N are tabulated in Table 55.1. The loss in dynamic range relative to an ideal noise-differencing modulator, given by, $A^2/(2\beta)^{2L}$, is also tabulated. In spite of this loss, high-order modulators can still achieve better noise performance than second-order modulators. However, because of the compromise in dynamic range required to stabilize high-order modulators, third-order modulators are generally not worth the effort. More common are fourth-and fifth-order modulators.

The noise penalty required to stabilize high-order modulators can be mitigated to some extent by alternate zero placement.[25] Classic noise-differencing modulators place all of the zeros of the error transfer function at dc ($z = 1$). This causes most of the noise power to be concentrated at the highest baseband frequencies. If, instead, the zeros are distributed throughout the baseband, the total noise in the baseband can be reduced, as illustrated in Fig. 55.23. The amount by which zero placement can improve the noise transfer function is summarized in Table 55.1. Also tabulated is the net loss in dynamic range of a high-order Butterworth modulator that uses zero placement relative to an ideal noise-differencing modulator that has zeros at dc.

Cascaded Modulators

Cascaded, or multi-stage, architectures are an alternative means of achieving higher-order noise shaping without the stability problems of the high-order modulators described in the previous section.[29,30] In a cascaded modulator, two or more stable first- or second-order modulators are connected in series, with

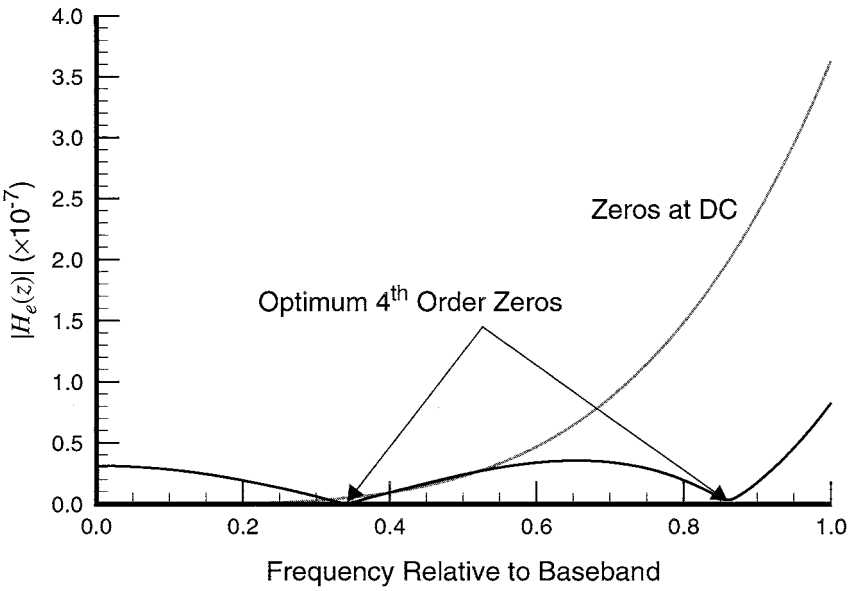

FIGURE 55.23 Fourth-order distributed zeros.

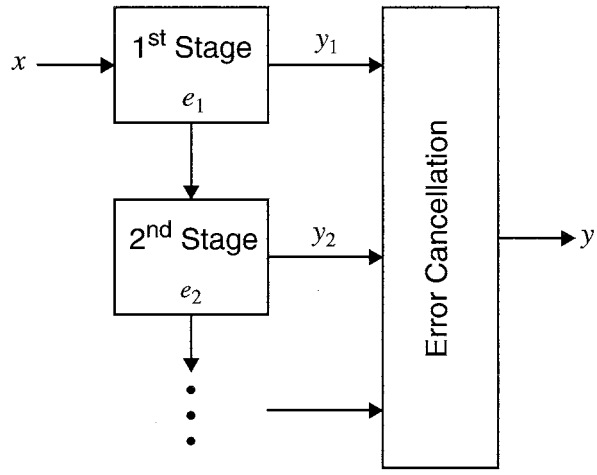

FIGURE 55.24 Cascaded sigma-delta modulators.

the input of each stage being the error from the previous stage, as illustrated in Fig. 55.24. Referring to this illustration, the first stage of the cascade has two outputs, y_1 and e_1. The output y_1 is an estimate of the input x. The error in this estimate is e_1. The second stage has as its input the error from the first stage, e_1, and its outputs are y_2 and e_2. The second stage output y_2 is an estimate of the first stage error e_1. By subtracting this estimate of the first stage error from the output of the first stage, y_1, only the second stage error remains. Thus, the error cancellation network uses the output of one stage to cancel the error in the previous stage.

For example, in a cascaded architecture comprising a second-order noise-differencing modulator followed by a first-order noise-differencing modulator, the transforms of the output of the two stages, as given by Eq. 55.16, are

$$Y_1(z) = z^{-2}X(z) + \left(1 - z^{-1}\right)^2 E_1(z) \tag{55.28}$$

$$Y_2(z) = z^{-1}E_1(z) + \left(1 - z^{-1}\right)E_2(z) \tag{55.29}$$

If the error cancellation network combines the two outputs such that

$$Y(z) = z^{-1}Y_1(z) - \left(1 - z^{-1}\right)^2 Y_2(z) \tag{55.30}$$

then the error in the first stage will be cancelled, and the output will be

$$Y(z) = z^{-3}X(z) - \left(1 - z^{-1}\right)^3 E_2(z) \tag{55.31}$$

The final output of this cascaded modulator is third-order noise shaped. As a general rule, the noise shaping of a cascaded architecture is comparable to a single-stage modulator whose order is the sum of all the orders in the cascade.

The extent to which the errors in a cascaded modulator can be cancelled depends on the matching between the stages. The earliest multi-stage modulators were cascades of three first-order stages, often called the MASH architecture.[29] The disadvantage of this structure is that in order to achieve third-order

performance, the error in the first stage, which is only first-order shaped, must be cancelled. Cancelling this relatively large error places a stringent requirement on inter-stage matching. An alternative architecture that has much more relaxed matching requirements is the cascade of a second-order modulator followed by a first-order modulator. This architecture, like the MASH, ideally achieves third-order noise shaping. Its advantage is that the matching can be 100 times worse than a MASH and still achieve better noise shaping performance.[31]

An additional benefit of cascaded modulators is improved tone performance. It has been shown both analytically and experimentally that the error spectra of the second and subsequent stages in a cascade are not plagued by the spectral tones that can exist in single-stage modulators.[19,32] To the extent that the first-stage error is cancelled, any tones in the first-stage error spectrum are attenuated, and the final output of the cascaded modulator is nearly tone-free.

Bandpass Modulators

The aforementioned sigma-delta architectures, called herein *baseband modulators*, all have zeros at or near dc; that is, at frequencies much less than the modulator sampling rate. It is also possible to group these zeros at some other point in the sampling spectrum; such architectures are called *bandpass modulators*. Bandpass architectures are useful in systems that need to quantize a narrow band signal that is centered at some frequency other than dc. A common example of such a signal is the intermediate frequency (IF) signal in a communications receiver.

The simplest method for designing a bandpass modulator is by applying a transformation to an existing baseband modulator architecture. The most common transformation is to replace occurrences of z with $-z^2$.[2] Such an architecture has zeros at $f_S/4$ and is stable if the baseband modulator is stable.[33] A comparison of the error transfer function of baseband and bandpass modulators is shown in Fig. 55.25. Note that a bandpass modulator generated through this transformation has twice the order of its equivalent baseband counterpart. For example, a fourth-order bandpass modulator is comparable to a second-order baseband modulator.

The noise shaping properties of a bandpass modulator generated through the $-z^2$ transformation are equivalent to the baseband modulator that was transformed. Thus, the approximation in Eq. 55.20 can be used where L is the order of the baseband modulator that was transformed and M is the effective oversampling ratio, which in a bandpass modulator is the sampling rate divided by the signal bandwidth.

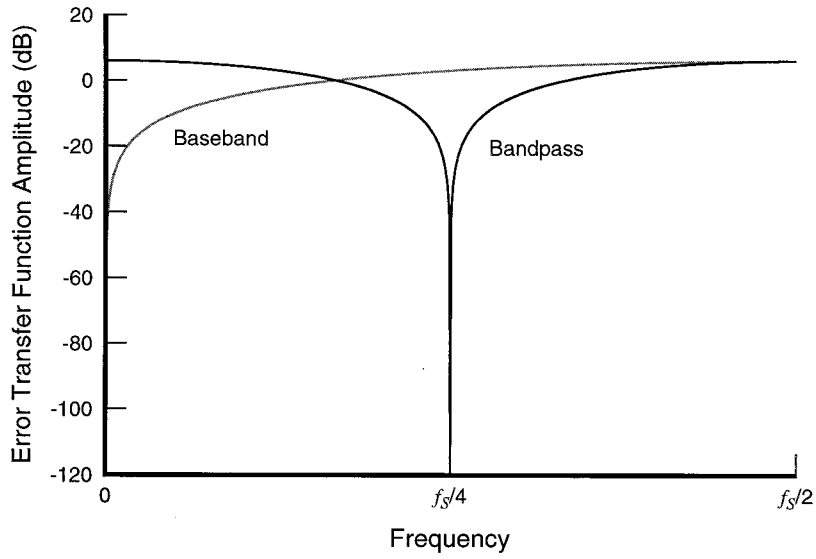

FIGURE 55.25 Bandpass noise transfer function.

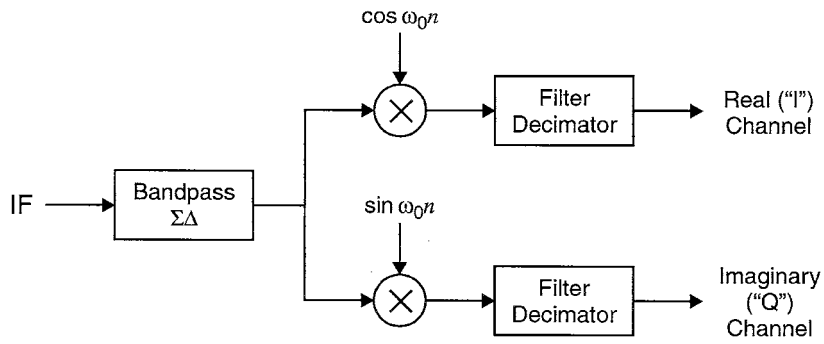

FIGURE 55.26 IQ demodulation with a bandpass modulator.

There are advantages and disadvantages to bandpass modulators when compared with traditional down-conversion and baseband modulation. One advantage of the bandpass modulator is its insensitivity to $1/f$ noise. Since the signal of interest is far from dc, $1/f$ noise is often insignificant. Another advantage of bandpass modulation applies specifically to bandpass modulators having zeros at $f_S/4$ that are used in quadrature I and Q demodulation systems. If the narrowband IF signal is to be demodulated by a cosine and sine waveform, as shown in Fig. 55.26, the demodulation operation becomes simple multiplication by 1, –1, or 0 when the demodulation frequency is $f_S/4$.[34] Furthermore, because a single modulator is used, the bandpass modulator is free of the I/Q path mismatch problems that can exist in baseband demodulation approaches.

Two disadvantages of bandpass modulators involve the sampling operation. Sampling in a bandpass modulator has linearity requirements that are comparable to a Nyquist-rate converter sampling at the same IF frequency; this is much more severe than the linearity requirements of the sampling operation in a baseband converter with the same signal bandwidth. Also, because of the higher signal frequencies, the sampling in bandpass modulators is much more sensitive to clock jitter. To date, the state of the art in bandpass modulators has about 20 dB less in dynamic range than comparable baseband modulators.[2] While the remainder of this chapter focuses once again on baseband modulators, many of the techniques are applicable to bandpass modulators as well.

55.4 Filtering for Sigma-Delta Modulators

In Sections 55.2 and 55.3 of this chapter, the discussion focused on the operation of the sigma-delta modulator core. While this core is the most unique aspect of sigma-delta data conversion, there are also filtering blocks that constitute an important part of sigma-delta A/D and D/A converters. In this section, the non-modulator components in baseband sigma-delta converters, namely the analog and digital filters, are described. First, the requirements of the analog anti-alias and reconstruction filters are described. Second, typical architectures for the decimation and interpolation filters are discussed. While much of the design of these filters use standard techniques covered elsewhere in this volume, there are aspects of these filters that are specific to sigma-delta modulator applications.

Anti-alias and Reconstruction Filters

The purpose of the anti-alias filter, shown in Fig. 55.1 at the input of the sigma-delta A/D converter, is, as the name would indicate, to prevent aliasing. The sampling operation maps, or aliases, all frequencies into the range bounded by $\pm f_S/2$.[28] Specifically, all signals within a baseband bandwidth of multiples of the sampling rate are mapped into the baseband. This is generally undesirable, so the anti-alias filter is designed to attenuate this aliasing to some tolerable level. One advantage of sigma-delta converters over Nyquist-rate converters is that this anti-aliasing filter has a relatively wide transition region. As illustrated in Fig. 55.27, the passband region for this filter is the signal bandwidth f_B, while the stopband region for

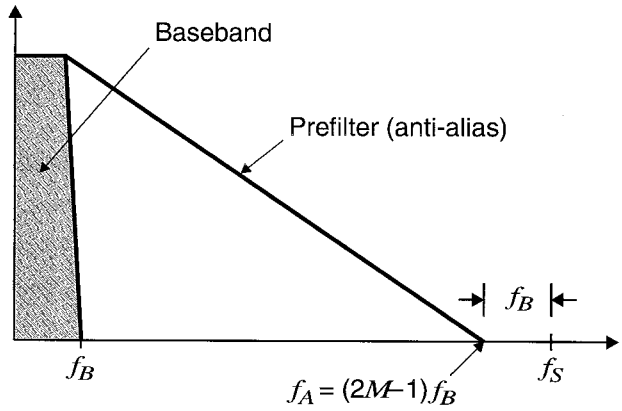

FIGURE 55.27 Anti-alias filter for sigma-delta A/D converters.

this filter is only within f_B of the sampling rate. Thus, the transition region is $2(M-1)\,f_B$, and since $M \gg 1$, the transition region is relatively wide. A wide transition region generally means a simple filter design. The precise nature of the anti-alias filter is application dependent, and can be designed using any number of standard analog filter techniques.[35]

The reconstruction filter, shown in Fig. 55.2 at the output of the sigma-delta D/A converter, is also an analog filter. Its primary purpose is to remove unwanted out-of-band quantization noise. The extent to which this noise must be removed varies widely from system to system. If the analog output is to be applied to an element that is naturally bandlimited, such as a speaker, then very little attenuation may be necessary. On the other hand, if the output is applied to additional analog circuitry, care must be taken lest the high-frequency noise distort and map itself into the baseband. Circuit techniques for this filter are addressed further in Section 55.5.

Decimation and Interpolation Filters

In general, the filter characteristics of the decimation filter, shown in Fig. 55.1 at the output of the sigma-delta A/D converter, are much sharper than those of the anti-alias filter; that is, the transition region is narrower. The saving grace is that the filter is implemented digitally, and modern sub-micron processes have made complex digital filters economically feasible. Nonetheless, care must be taken or the filter architecture will become more computationally complex than is necessary.

The basic purpose of the decimation filter is to attenuate quantization noise and unwanted signals outside the baseband so that the output of the decimation filter can be down-sampled, or decimated, without significant aliasing. Normally, the most efficient means of accomplishing this is to apply a multi-rate filter architecture, such as that illustrated in Fig. 55.28.[36,37] The comb filter is a relatively crude, but easy to implement, filter that has zeros equally spaced throughout the sampled spectrum. The frequency response of an N-th order comb filter, $H_C(z)$, is

$$H_C(z) = \left(\frac{1}{R} \frac{1 - z^{-R}}{1 - z^{-1}} \right)^N \tag{55.32}$$

where R is the impulse response length of the comb filter. If R is set equal to the decimation ratio of the comb filter (the comb filter input rate divided its output rate), then the filter zeros will occur at every point that would alias to dc.[38,39] If the filter order N is one more than the modulator order, then the comb filter will be adequate to attenuate the out-of-band quantization noise to the point where it does not adversely increase the baseband noise after decimation.[40]

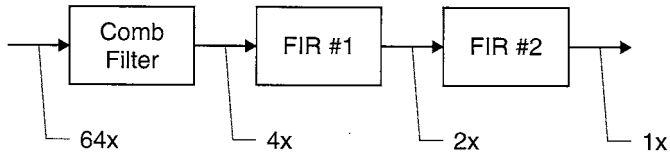

FIGURE 55.28 Typical decimation filter architecture.

Following the comb filter is typically a series of one or more FIR filters. Since the sample rates of these FIR filters are much slower than the oversampled clock rate, each filter output can be computed over many clock cycles. Also, since the output of each filter is decimated, only the samples that will be output need to be calculated. These properties can be exploited to devise computationally efficient structures for decimation filtering.[41]

In the example in Fig. 55.28, the first FIR filter is decimating from 4× to 2× oversampling. Since the output of this filter is still oversampled, the transition region is relatively wide and the attenuation at midband need not be very high. Thus, an economical half-band filter (a filter in which every other coefficient is zero) can be used.[37]

The final FIR filter is by far the most complex. It usually has to have a very sharp transition region, and for strict anti-alias performance, it cannot be a halfband filter. In high-performance sigma-delta modulators, this filter is often in the range of 50 to 200 taps in length. Standard digital filter design techniques can be used to select that tap weights for this filter.[28] Since it is going to be a complex filter anyway, it can also be used to compensate for any frequency droop in the previous filter stages.

The interpolation filter, shown in Fig. 55.2 at the input of the sigma-delta D/A converter, up-samples the input digital words to the oversampling rate. In many ways, this filter is the inverse of a decimation filter, typically comprising a complex up-sampling FIR filter, optionally followed by one or more simple FIR filters, followed by an up-sampling comb filter. The up-sampling operation, without this filter, would produce images of the baseband spectrum at multiples of the baseband frequency. The purpose of the interpolation is to attenuate these images to a tolerable level. What constitutes tolerable is very much a system-dependent criterion. Design techniques for the interpolation filter parallel those of the decimation filter discussed above.

55.5 Circuit Building Blocks

For analog-to-digital conversion, the modulator is implemented primarily in the analog domain as shown in Fig. 55.16. In digital-to-analog conversion, the modulator output if filtered by an analog reconstruction filter as depicted in Fig. 55.2. The basic analog circuit building blocks for these data converters are described in this section. These building blocks include switched-capacitor integrators, the amplifiers that are imbedded in the integrators, comparators, and circuits for sigma-delta based D/A conversion. At the end of this section, the techniques for continuous-time sigma-delta modulation are briefly discussed.

Switched-Capacitor Integrators

Switched-capacitor integration stages are commonly used to perform the signal processing functions of integration and summation required for realization of the discrete time transfer functions $A(z)$ and $F(z)$ in Fig. 55.16. The circuit techniques outlined herein are drawn from a rich literature of switched-capacitor filters[42-45] that is detailed elsewhere in this volume.

Figure 55.29 is a typical integrator stage for the case of single bit feedback,[11,20] and is designed to perform the discrete time computation

$$V_{OUT}(z) = K\frac{z^{-1}}{1-z^{-1}}\left(V_{IN}(z) - V_{DAC}(z)\right) \tag{55.33}$$

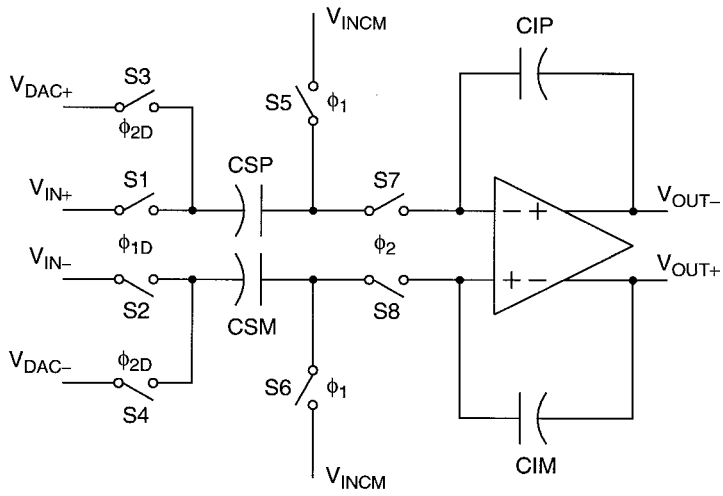

FIGURE 55.29 Typical integrator stage.

independent of the parasitic capacitances associated with the capacitive devices shown. The curved line in the capacitor symbol is the device terminal with which the preponderance of the parasitic capacitance is associated. For example, this will be the bottom plate of a stacked planar capacitance structure, where the parasitic capacitance is that between the bottom plate and the IC substrate. The circuit's precision stems from the conservation of charge at the two input nodes of the operational amplifier, and the cyclic return of the potential at those nodes to constant voltages. More details may be found in the chapter on switched capacitor filters (Chapter 59).

Fully differential circuits will be shown here, as these are almost universally preferred over single-ended circuits in monolithic implementations owing to their greatly improved power supply rejection, MOS switch feedthrough rejection, and suppression of even-order non-linearities. The switches shown in Fig. 55.29 are generally full CMOS switches, as detailed in Fig. 55.30. However, integrators with very low power supply voltages may necessitate the use of only one polarity of switch device, possibly with a switch gate voltage-boosting arrangement.[46] Sampling capacitors CSP and CSM are designed with the same capacitance C_S, and the effect of slight fabrication mismatches between the two will be mitigated by the common-mode rejection of the amplifier. Similarly, integration capacitors CIP and CIM are designed to be identical with capacitance C_I.

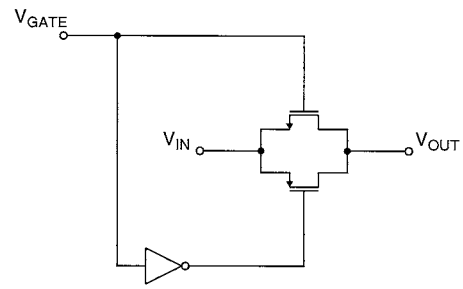

FIGURE 55.30 Full CMOS switch.

The discrete-time signal to be integrated is applied between the input terminals V_{IN+} and V_{IN-}, and the output is taken between V_{OUT+} and V_{OUT-}. V_{INCM} is the common mode input voltage required by the amplifier. The single-bit DAC feedback voltage is applied between V_{DAC+} and V_{DAC-}. The stage must be clocked by two non-overlapping signals, ϕ_1 and ϕ_2. During the ϕ_1 phase, the differential input voltage is sampled on the bottom plates of CSP and CSM, while their top plates are held at the amplifier common-mode input level. During this phase, the amplifier summing nodes are isolated from the capacitor network, and the amplifier output will remain constant at its previously integrated value. During the ϕ_2 phase, the bottom plates of the sampling capacitors CSP and CSM experience a differential potential shift of $(V_{DAC} - V_{IN})$, while the top plates are routed into the amplifier summing nodes. By forcing its differential input voltage to a small level, the amplifier will effect a transfer of a charge of $C_S(V_{IN} - V_{DAC})$ to the integration capacitors, and therefore the differential output voltage will shift to a new value by an

increment of $(C_S/C_I)(V_{IN} - V_{DAC})$. Since this output voltage shift will accumulate from cycle to cycle, the discrete-time transfer function will be that of Eq. 55.33, with

$$K = \frac{C_S}{C_I} \tag{55.34}$$

Over several cycles of initial operation, the amplifier input terminals will be driven to the common-mode level that is precharged onto the top plates of the sampling capacitors.

In order to suppress any signal-dependent clock feedthrough from the switches, it is helpful to slightly delay the clock phases that switch variable signal voltages with respect to the phases that switch current into constant potentials. The channel charge in each turned-on switch device can potentially dissipate onto the sampling capacitors when the switches are turned off, producing an error in the sampled charge. This channel charge is dependent on the difference between the switch gate-to-source voltage and its threshold voltage; and as the source voltage varies with signal voltage, the clock feedthrough charge will vary with the signal. By turning the switches that see constant potentials at the end of each cycle off first, and thus floating the sampling capacitor, the only clock feedthrough is a charge that is to the first order independent of signal level, and results only in a common-mode shift that is suppressed by the amplifier. This acts to reduce the non-linearity of the integrator and the harmonic distortion generated by the modulator.

The timing for the delayed and undelayed clocks is illustrated in Fig. 55.31, where the clock phases ϕ_{1D} and ϕ_{2D} represent phases that are slightly delayed versions of ϕ_1 and ϕ_2, respectively. The delayed clocks drive the switches that are subject to full-signal voltage swings, the analog and reference voltage inputs, as shown in Fig. 55.29. The undelayed clocks drive the switches associated with the amplifier summing node and common-mode input bias voltage, which will always be driven to the same potential by the end of each clock cycle. A typical clock generator circuit to produce these phase relationships is shown in Fig. 55.32. The delay time Δt is generated by the propagation delay through two CMOS inverters.

Other, more complex integration circuits are used in some sigma-delta implementations, for example, to suppress errors due to limited amplifier gain[47,48] or to effectively double the sampling rate of the integrators.[49,50] For the modulator structures discussed in Section 55.3 that are more elaborate than a second-order loop, more complex switched-capacitor filtering is required. These may still, however, be designed with the same basic integrator architecture as in Fig. 55.29, but with extra sampling capacitors feeding the amplifier summing node to implement additional signal paths.[26,33,51] Consult Chapter 59 in this volume on switched-capacitor filtering for more information.

Operational Amplifiers

Embedded in the switched-capacitor integrator shown in Fig. 55.29 is an operational amplifier. There are three major types of operational amplifiers typically used in switched-capacitor integrators[52]: the

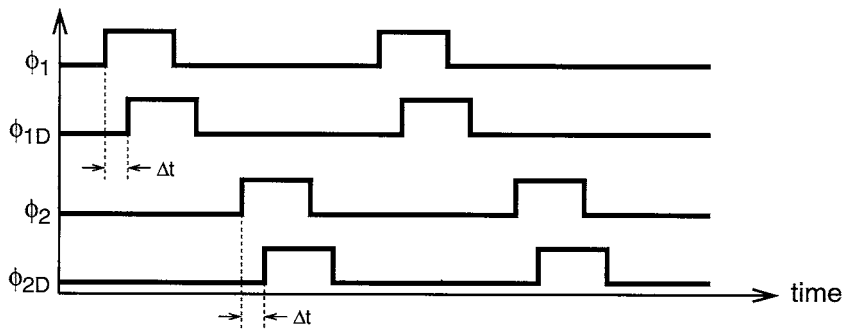

FIGURE 55.31 Delayed clock timing.

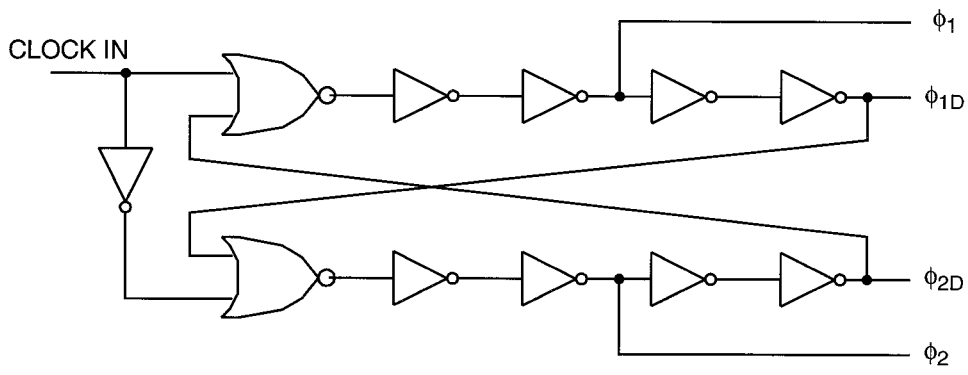

FIGURE 55.32 Non-overlapping clock generator with delayed clocks.

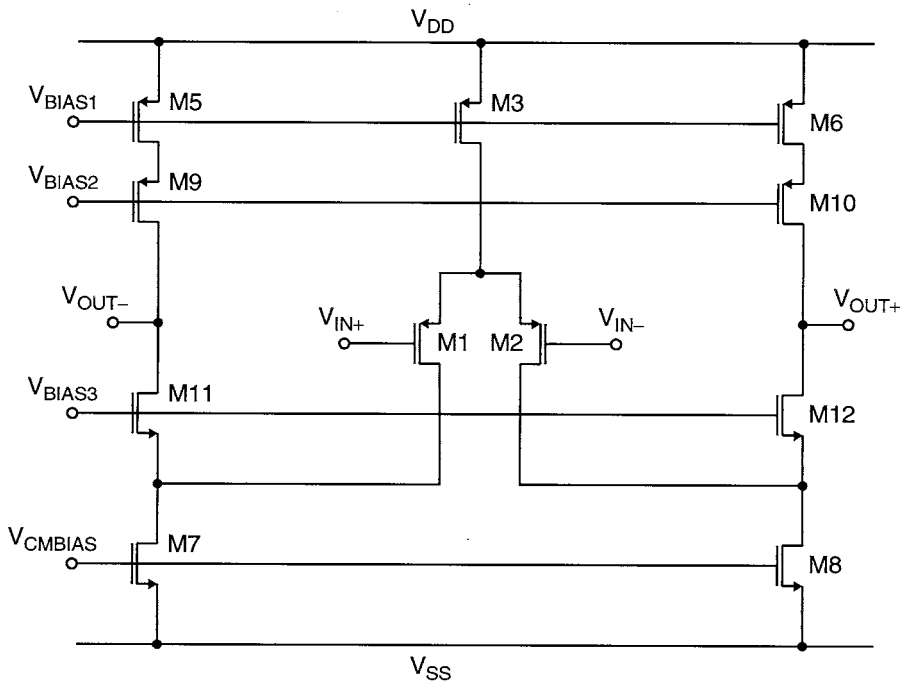

FIGURE 55.33 Folded cascode amplifier.

folded cascode amplifier,[42] shown in Fig. 55.33; the two-stage amplifier,[43] shown in Fig. 55.34; and the class AB amplifier,[45] shown in Fig. 55.35.

When the available supply voltage is high enough to permit stacking of cascode devices to develop high gain, a *folded cascode amplifier* is commonly used. A typical topology is shown in Fig. 55.33. The input devices are PMOS, since most IC processes feature PMOS devices that exhibit lower $1/f$ noise than their NMOS counterparts.[53] The input differential pair M1 and M2 is biased with the drain current of M3. FETs M5-M8 function as current sources, and M9-M12 form cascode devices that boost the output impedance. The amplifier is compensated for stability in the integrator feedback loop by the dominant pole that is formed at its output node with the high output impedance and the load capacitance. In an integrator stage, the amplifier will be loaded with the load capacitance of the following stage sampling capacitance as well as its own integration capacitance. The non-dominant pole at the drains of M1 and M2 limit the unity-gain frequency, which can be quite high.

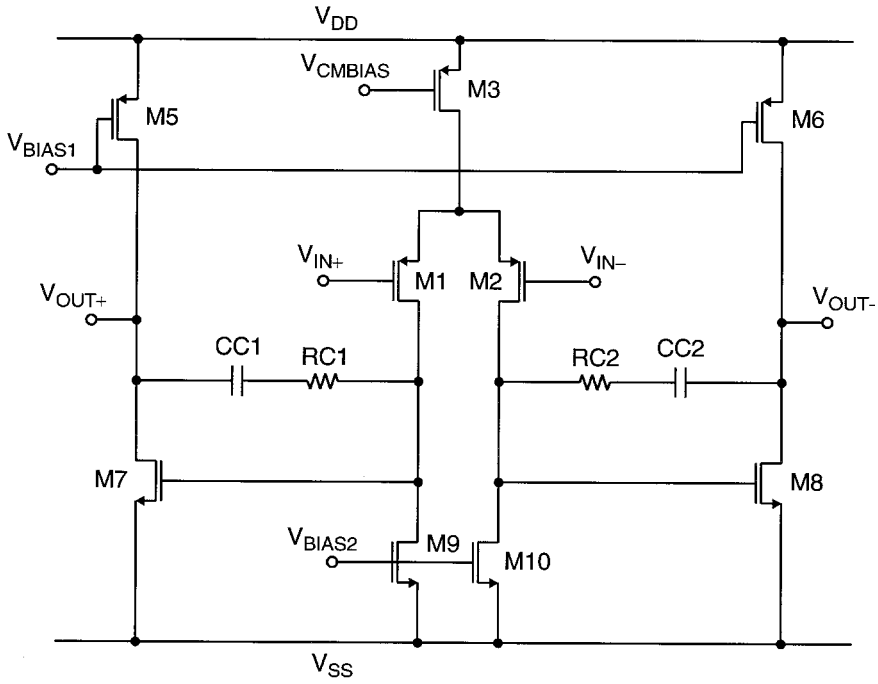

FIGURE 55.34 Two-stage amplifier.

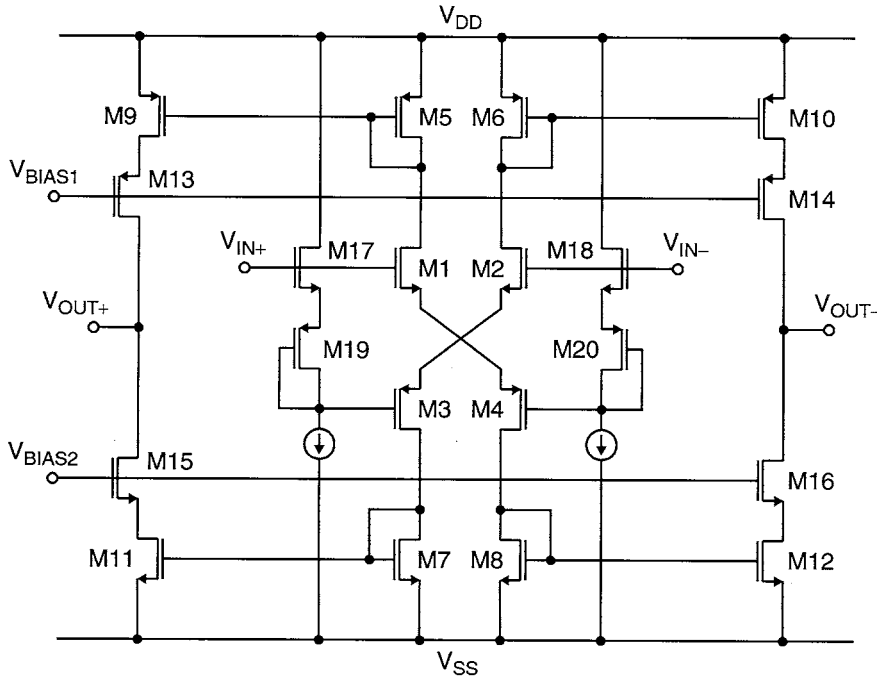

FIGURE 55.35 Class AB amplifier.

When the power supply voltage is limited, and cascode devices cannot be stacked and still preserve adequate signal swing, a *two-stage amplifier* is a common alternative to the folded cascode amplifier. As shown in Fig. 55.34, the input differential pair of M1 and M2 now feed the active load current sources

of M9 and M10 to form the first stage. The second stage comprises common-source amplifiers M7 and M8, loaded with current sources M5 and M6. Due to the presence of two poles from the two stages of roughly comparable frequencies, compensation is generally achieved with a pole-splitting RC local feedback network as shown.[52] Often, the resistors RC1 and RC2 are actually implemented as NMOS devices biased into their ohmic region by tying their gates to V_{DD}. In this arrangement, the effective resistance of RC1 and RC2 will approximately track any drift in mobility of M7 and M8 over temperature and processing variations, preserving the compensated phase margin. For a given process, the bandwidth of a two-stage amplifier is less than what can be achieved than by a folded cascode design; but because the two-stage has no stacked cascode devices, the signal swing is higher.

In the case of modulators with higher clock speeds, both folded cascode and two-stage amplifiers may have unacceptably long settling times; in these amplifiers, the maximum slewing current that can be applied to charge or discharge the load capacitance is limited by fixed current sources. This slewing limitation can be overcome by a *class AB amplifier* topology that can supply a variable amount of output current and is capable of providing a large pulse of current early in the settling cycle when the differential input error voltage is high. A typical class AB amplifier topology is shown in Fig. 55.35. The input differential pair from the folded cascode and two-stage designs is replaced by M1 through M4, and their drain currents are mirrored to the output current sources M9–M12 by diode-connected devices M5–M8. Cascode devices M13–M16 enhance the output impedance and gain. As with the folded cascode design, frequency compensation is accomplished by a dominant pole at the output node. The input voltage is fed directly to the NMOS input devices and to the PMOS input devices through the level-shifting source follower and diode combination M17–M20. This establishes the quiescent bias current through the input network M1–M4, and therefore through the output devices as well.

In each of the three amplifier topologies discussed above, there is either one or a set of two matched current sources driving both differential outputs. These current sources are controlled by a gate bias line labeled V_{CMBIAS}. The current output of these devices will determine the common-mode output voltage of the amplifier independent, to the first order, of the amplified differential signal. The appropriate potential for V_{CMBIAS} is determined by a feedback loop that is only operable in the common mode and is separate from the differential feedback instrumental in the charge integration process.

Since a discrete time modulator is, by its nature, clocked periodically, a natural choice for the implementation of this common-mode feedback loop is the switched-capacitor network of Fig. 55.36.[44,45] Capacitors CCM1 and CCM2 act as a voltage divider for transient voltages that derives the average, or common-mode, voltage of the amplifier output terminals. This applies corrective negative feedback transients to the V_{CMBIAS} node to stabilize the feedback loop during each clock period while the amplifier is differentially settling.

A dc bias is then maintained on CCM1 and CCM2 by the switched-capacitor network on the left side of the figure. This will slowly transfer the charge necessary to establish and maintain a dc level shift that

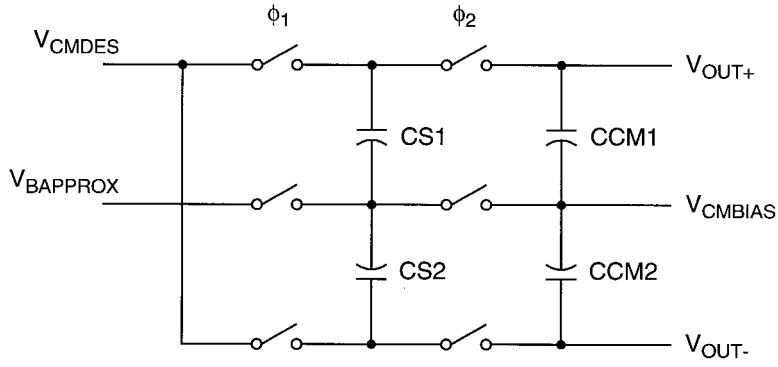

FIGURE 55.36 Switched-capacitor common-mode feedback.

makes up the difference between the common-mode level desired at the amplifier output terminals (V_{CMDES}) and the approximate gate bias required by the common mode current devices ($V_{BAPPROX}$). The former is usually set at mid-supply by a voltage divider, and the latter can be derived from a matched diode-connected device. Since the clocking of this switching network is done synchronously to the amplifier integrator clocking, no charge injection will occur during the sensitive settling process of the amplifier. In order to minimize the charge injection at the clock transitions, capacitors CS1 and CS2 are usually made very small, and therefore dozens of clock cycles may be required for the common-mode bias to settle and the modulator to become operable.

Comparators

The noise shaping mechanism of the modulator feedback loop allows the loop behavior to be tolerant of large errors in circuit behavior at locations closer to the output end of the network. Modulators are generously tolerant of large offset errors in the comparators used in the A/D converter forming the feedback path. For this reason, almost all modulators use simple regenerative latches as comparators. No preamp is generally needed, as the small error from clock kickback can easily be tolerated. Simulations show that offset errors that are even as large as 10% of the reference level will not degrade modulator performance significantly.

The circuit of Fig. 55.37 is typical.[54] This is essentially a latch composed of two cross-connected CMOS inverters, M1–M4. Switch devices M5–M8 will disconnect this network when the clock input is low, and throw the network into a regenerative mode with the rising edge of the clock. The state in which the regeneration will settle may be steered by the relative strengths of the bias current output by devices M9 and M10, which in turn depend on the differential input voltage.

Complete Modulator

Figure 55.38 illustrates a complete second-order, single-bit feedback modulator assembled from the components discussed above.[11] The discrete time integrator gain factors that are derived in Sections 55.2 and 55.3 are realized by appropriate ratios between the integration and sampling capacitors in each stage.

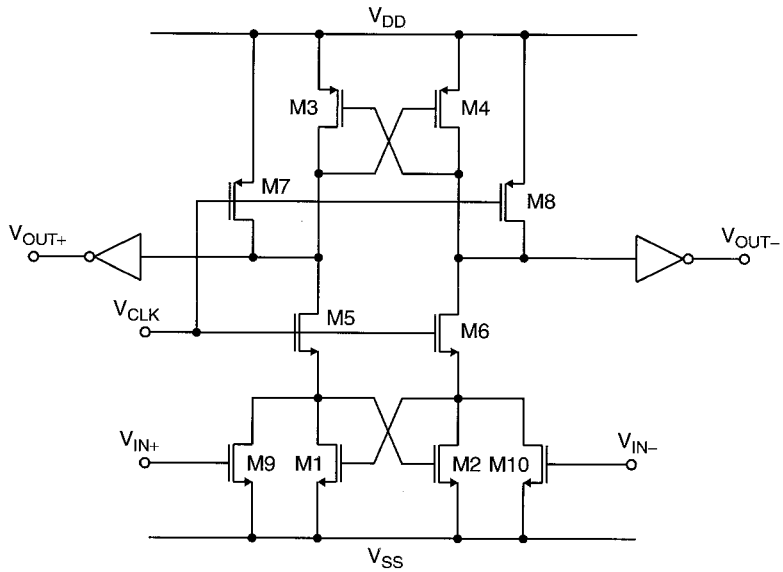

FIGURE 55.37 Typical modulator comparator.

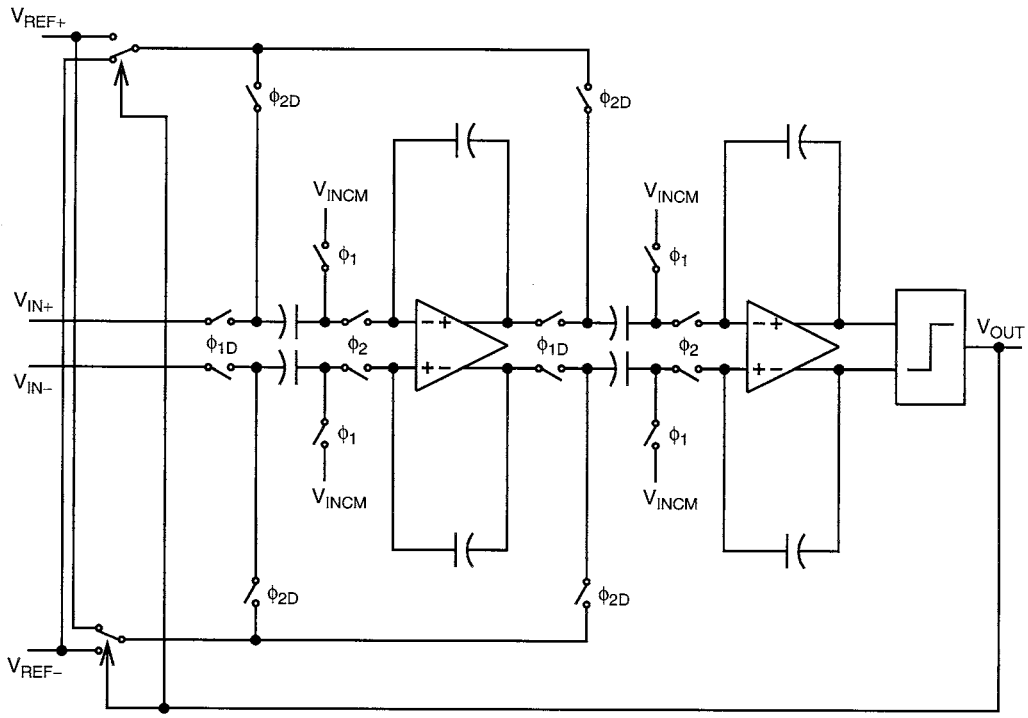

FIGURE 55.38 Complete second-order sigma-delta modulator.

Since the single-bit feedback DAC is only responsible for generating two output levels, it may be implemented by simply switching an applied differential reference voltage V_{REF+} to V_{REF-} in a direct or reversed sense to the sampling capacitor bottom plates during the amplifier integration phase, ϕ_2.

D/A Circuits

For the DAC system shown in Fig. 55.2, the oversampled bit stream is generated by straightforward digital implementations of the modulator signal flow graphs discussed in Section 55.2. The remaining analog components are the low-resolution DAC block and the reconstruction filter. Integrated sigma-delta D/A implementations often employ two-level quantization, and the DAC block may either be designed as charge-based[55] or current-based.[56] Multi-level DAC approaches are also used, but for harmonic content less than about –60 dB below the reference, some form of dynamic element matching must be added, as discussed in Section 55.6.

The charge-based approach for sigma-delta D/A conversion is illustrated in Fig. 55.39, which is similar to the switched-capacitor integrator of Fig. 55.29, but without an analog signal input. As in Fig. 55.38, V_{DAC} may be either polarity of V_{REF} according to the bit value to be converted. Figure 55.40 shows a typical topology for current-based converters. In both cases, the leaky integration function around the amplifier contributes to the first pole of the reconstruction filtering. An efficient combination of the current-based approach and a digital delay line realizing an FIR reconstruction filter is also possible.[57]

Additional reconstruction filtering beyond that provided by in the DAC may also be necessary. This is accomplished using the appropriate analog sampled-data filtering techniques described in Chapter 59 of this section.

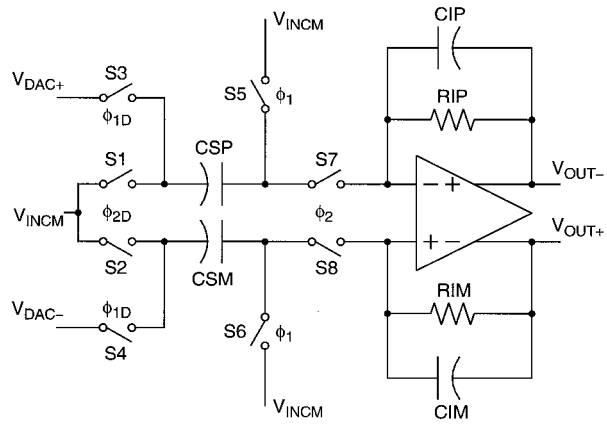

FIGURE 55.39 Charge-based DAC.

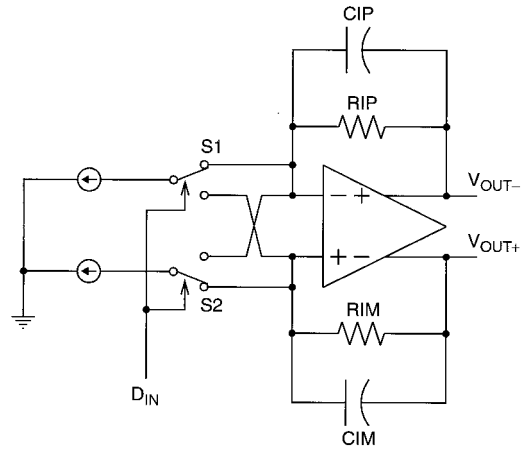

FIGURE 55.40 Current-based DAC.

Continuous-Time Modulators

In general, the amplifiers contained in the switched-capacitor integrators in a sampled-data sigma-delta data converter dissipate the majority of the analog circuit power. Since the integrator sections must settle accurately within each clock period at the oversampled rate, the amplifiers must often be designed with a unity-gain frequency much higher than the oversampled rate; typical unity-gain frequencies are in the hundreds of MHz.

In applications in which dissipating the lowest possible power is important, sigma-delta modulators may also be implemented using continuous-time integrators. In these continuous-time modulators, the analog signal is not sampled until the quantizer at the back of the modulator loop.[58] Owing to the typical means employed for the DAC feedback, continuous-time modulators tend to be more sensitive to sampling clock jitter, but the influences of any aliasing distortion and non-linearity at the sampler take place late in the loop where noise shaping is steepest, and as a consequence the anti-aliasing filter of Fig. 55.1 may often be omitted.[59] The power advantage comes from the relaxed speed requirement of the integrator stages, which now need only have unity-gain frequencies on the order of the oversampled clock frequency.

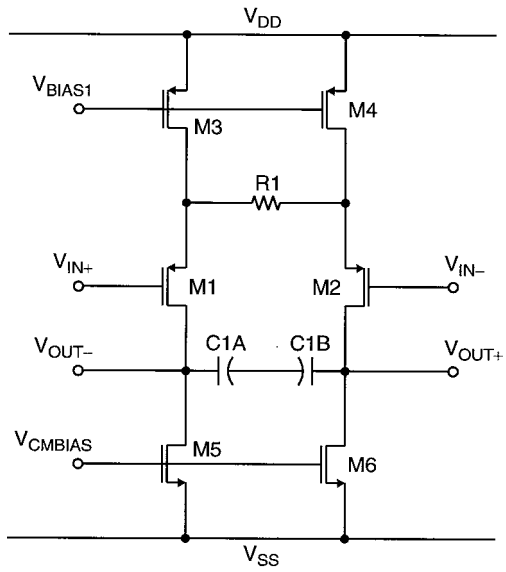

FIGURE 55.41 Gm-C integrator.

Instead of switched-capacitor discrete-time integrators, the continuous-time modulators generally use active Gm-C integrators. Circuits like that shown in Fig. 55.41 are typical.[59] The input differential pair M1 and M2 is degenerated by source resistance R1 to improve linearity. The output analog voltage is developed across capacitor C1, which may be split as shown to place the bottom plate parasitic capacitance at a common-mode node. As the integrator is now unclocked, continuous-time common-mode feedback must be used, as discussed in the literature for continuous time filtering.[60]

55.6 Practical Design Issues

As with any design involving analog components, there are a number of circuit limitations and tradeoffs in sigma-delta data converter design. The design considerations discussed in this section include *kT/C* noise, integrator scaling, amplifier gain, and sampling non-linearity. Also discussed in this section are the techniques of integrator reset and multi-level feedback.

kT/C Noise

In switched-capacitor-based modulators, one fundamental non-ideality associated with using a MOS device to sample a voltage on a capacitor is the presence of a random variation of the sampled voltage after the MOS switch opens.[61-63] This random component has a Gaussian distribution with a variance of *kT/C*, where *k* is Boltzman's constant, *C* is the capacitance, and *T* is the absolute temperature. The variation stems from thermal noise in the resistance of the MOS channel as it is opening. The noise voltage has a mean power of $4kTRB$, where *R* is the channel resistance and *B* is the bandwidth. It is low-pass filtered by its characteristic resistance and the sampling capacitor to an equivalent noise bandwidth of $1/RC$. The total integrated variance will thus be *kT/C*, independent of the resistance of the switch.

If, in the process of developing the integrated signal, a sampling operation on *n* capacitors is used, then since we assume Gaussian noise distribution, the variance of the eventual integrated value will be *nkT/C*. For the case of a fully differential integrator, where a differential signal is sampled onto two sampling capacitors and then transferred to two integration capacitors, *n* is 4. This effect, along with the input referred noise of the amplifier, will limit the achievable noise floor of the modulator. The first stage sampling capacitors must be sized so as to limit this noise contribution to an acceptable level. From this

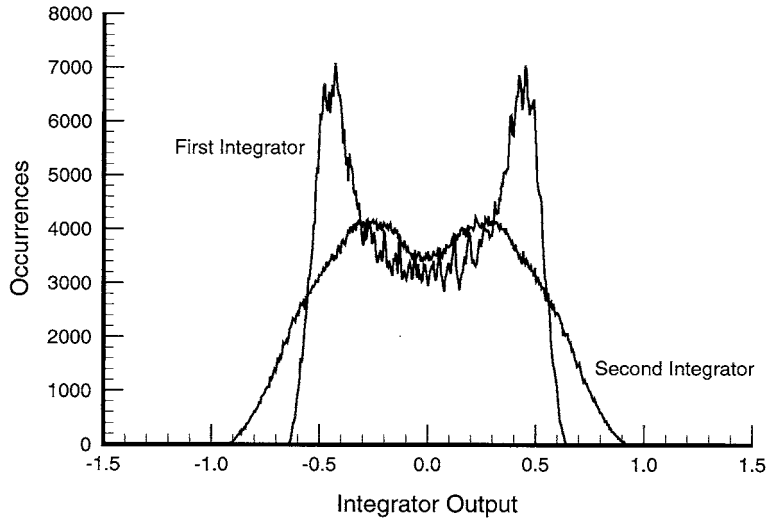

FIGURE 55.42 Integrator output distribution for an eight-level modulator.

starting point, and the capacitive ratios required for realizing the various integrator gains, the remaining capacitor sizes can be determined. The modulator will be much less sensitive to kT/C noise generated in integrators past the first, and the capacitors in theses integrators can be made considerably smaller.

Integrator Gain Scaling

The integration stages in Section 55.2 were discussed as ideal elements, capable of developing any real output voltage. In practice, the output voltage of real integrators is limited to at most the supply voltage of the embedded amplifier. To ensure that this limitation does not adversely affect the modulator performance, a survey of the likely limit of integrator output voltages must be made for a given value of the DAC reference voltage. The modulator may be simulated over a large number of samples with a representative sinusoidal input, and a histogram of all encountered output voltages tabulated. These histograms may be expected to scale linearly with the reference voltage level. In general, this statistical survey will show that a modulator designed to realize the integrator gain constants in the ideal topologies of Sections 55.2 and 55.3 will have different ranges of expected output voltages from each of its integrators. For example, Figs. 55.42 and 55.43 show the simulated output voltages at the two integrators in a second-order modulator with eight-level and two-level feedback, respectively. Since the largest value possible of reference level will generally mean the best available signal-to-noise ratio for a given circuit power consumption, the integrator gain constants may be adjusted from their straightforward values so that the overall modulator transfer function remains the same, but the output voltages are scaled so that no integrator limits the signal swing markedly before the other.[11] Figures 55.44 and 55.45 illustrate the properly scaled second-order modulator examples.

Amplifier Gain

Another mechanism by which the actual characteristic of the integrator circuits fall short of the ideal is the limitation of finite amplifier gain. A study of many simulations of modulators with various amplifier gains[11] has shown that a modulator needs amplifiers with gains about numerically equal to the decimation ratio of the filter that follows it in order to avoid significant noise shaping errors. At least this is the result with perfectly linear amplifiers, and in practice, amplifier gains often need to be at least 10 times this high to avoid distortion in the integrator characteristic due to the non-linearity of the amplifier gain characteristic.

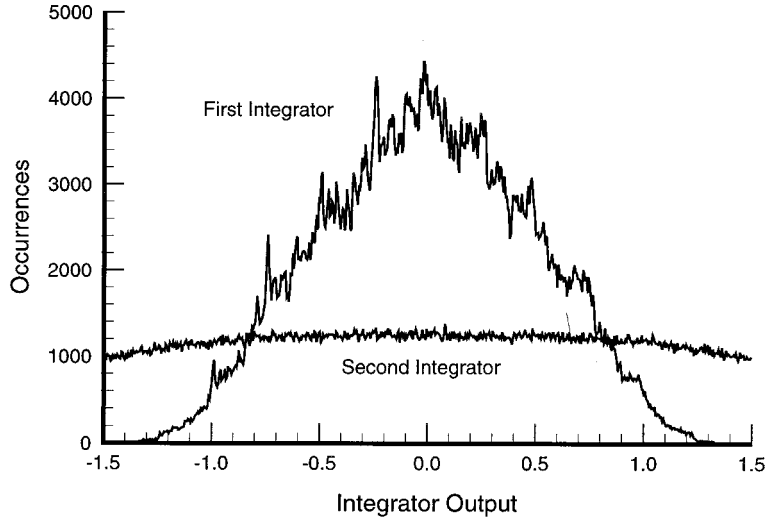

FIGURE 55.43 Integrator output distribution for a two-level modulator.

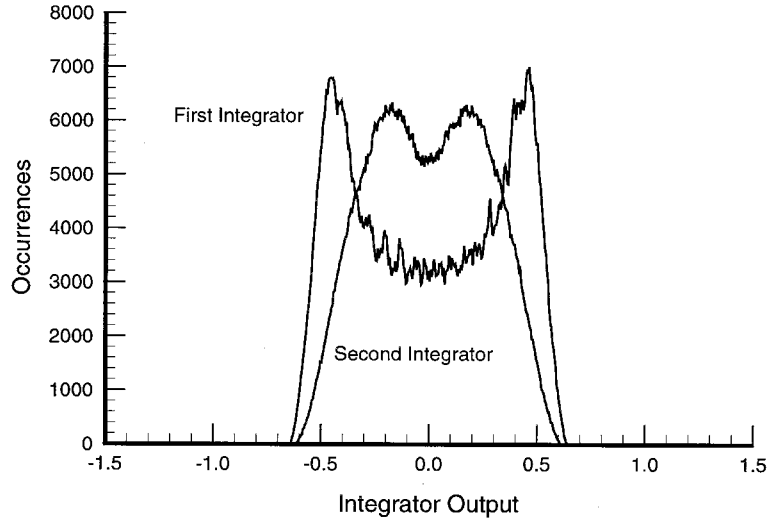

FIGURE 55.44 Integrator output distribution for a scaled eight-level modulator.

One approach used when the simple circuits of Section 55.5 (Operational Amplifiers) do not develop enough gain in a given process is the regulated cascode gain enhancement.[64,65,68] Figure 55.46 illustrates a typical circuit topology. This subcircuit may be substituted for the output common-source amplifier stages in the amplifiers of Figs. 55.33 to 55.35 if the power supply voltage can accommodate its somewhat increased requirement for headroom.

Sampling-Nonlinearity and Reference Corruption

The sigma-delta modulator is remarkably tolerant of most circuit non-idealities past the input sampling network. However, the linearity of the sampling process at the very first input sampling capacitor will be the upper bound for the linearity for the entire modulator. Care must be exercised to ensure the

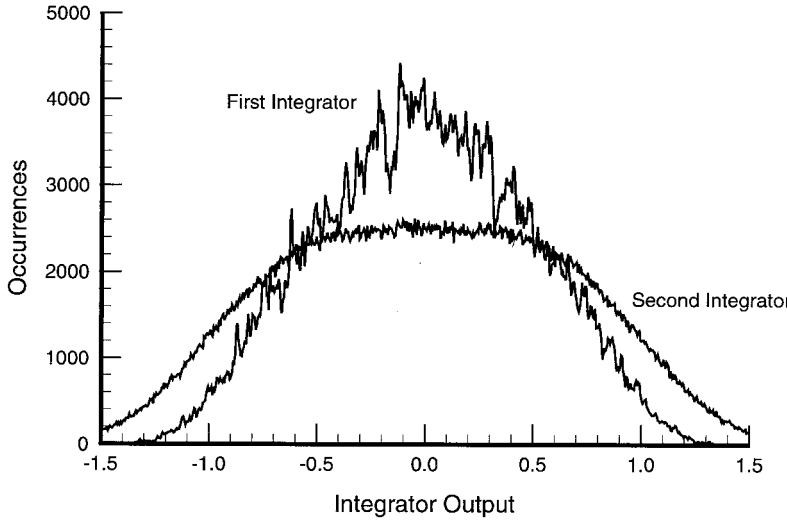

FIGURE 55.45 Integrator output distribution for a scaled two-level modulator.

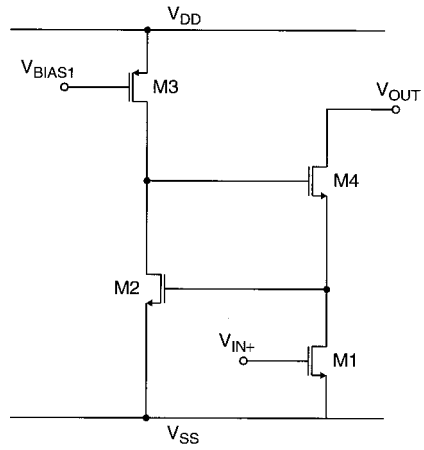

FIGURE 55.46 Regulated cascode topology.

switches are sufficiently large so that the sampled voltage will be completely settled through their non-linear resistance, but not so large that any residual signal dependent clock feedthrough is significant.

Another susceptibility of modulators is to non-linear corruption of the reference voltage. If the digital bit stream output, through a parasitic feedback path either on- or off-chip, can affect the reference voltage sampled during clock phase ϕ_2 in Fig. 55.29, then there will be a term in the output signal dependent on the square of the input voltage. This will distort the noise shaping properties of the modulator and generate second harmonic distortion, even with fully differential circuitry. This is illustrated in the spectrum in Fig. 55.47, which is the output of a modulator having the same conditions as Fig. 55.14, except that a parasitic feedback path is assumed that would change the reference voltage by 1% for the "1" output bits on the previous cycle, relative to its value with "0" output bits. As can be seen by comparison with Fig. 55.14, that the ability of the modulator to shift quantization noise out of the baseband has been greatly compromised, and a prominent second harmonic has been generated. Care must be taken in chip and printed circuit board application design so that the reference voltage remains isolated from the signals carrying the output bit stream.

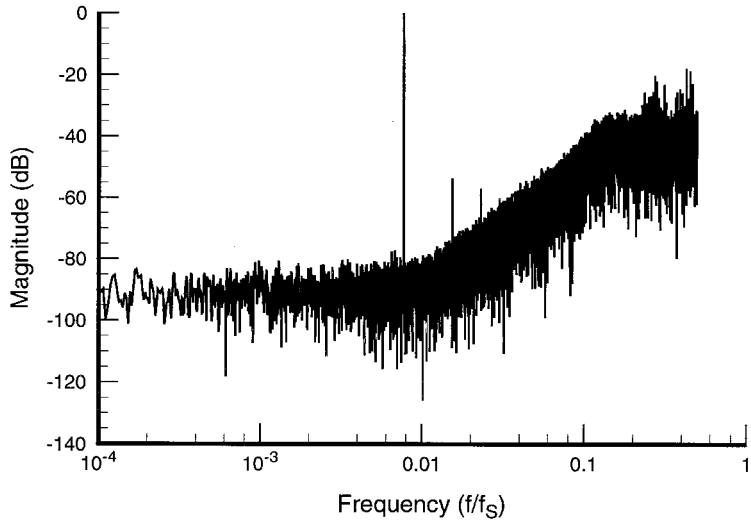

FIGURE 55.47 Output spectrum with reference corruption.

Fully differential circuitry is almost universally employed in integrated VLSI modulators to reduce sampling non-linearity and reference contamination. Even-order non-linearities and common-mode switch feedthrough are cancelled with fully differential circuits, and power supply rejection is greatly improved, leading to more isolated reference potentials. For high-precision modulators, the integrator topology is often changed from that of Fig. 55.29 to Fig. 55.48.[26,51] The input signal and the DAC output voltage are sampled independently during phase ϕ_1, and then both are discharged together into the summing node during ϕ_2. At the expense of additional area for capacitors and higher kT/C noise, this

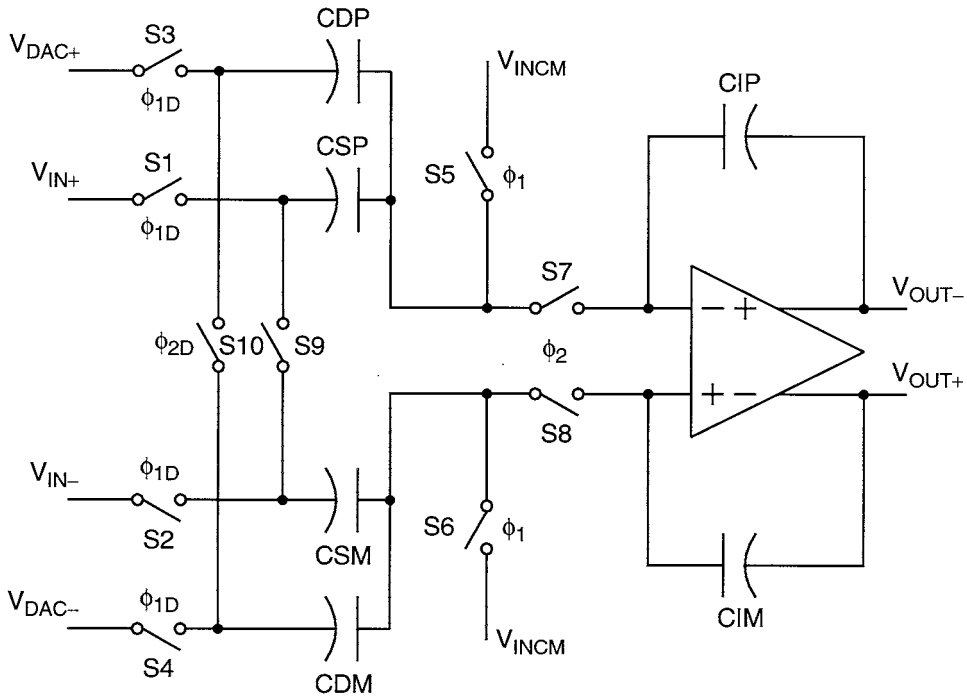

FIGURE 55.48 Integrator with separate DAC feedback capacitor.

arrangement ensures that the same charge is drawn from the reference supply onto the DAC sampling capacitors CDP and CDM and then discharged into the summing node each cycle. Thus, a potentially undesirable mechanism for reference supply loading that is dependent on the output bit history is eliminated.[66]

High-Order Integrator Reset

Although careful design of the loop filter for higher-order modulators, as discussed above in Section 55.3 (High-Order Modulators), will yield a generally stable design, their stability cannot be mathematically guaranteed, as in the case of second-order loops. To protect against the highly undesirable state of low frequency limit cycle oscillations due to an occasional, but improbable, input overload condition, some form of forced integrator reset is sometimes used.[26,51] Generally, these count the consecutive '1' or '0' bits out of the modulator, and close a resetting switch to discharge integration capacitors for a short time if the modulator generates a longer consecutive sequence than normal operation allows. This will naturally interrupt the operation of the modulator, but will only be triggered in the case of pathological input patterns for which linear operation would not necessarily be expected.

Another approach to a stability safety mechanism for higher-order loops is to arrange the scaling of the integrator gains so that they clip against their maximum output voltage swings in a prescribed sequence as the input level rises. The sequence is designed to gradually lower the effective order of the modulator,[59] and return operation to a stable mechanism.

Multi-level Feedback

Expanding the second-order modulator to more than two-level feedback can be accomplished by the circuit in Fig. 55.49. For K-level feedback, $K-1$ latch comparators are arranged in a flash structure as

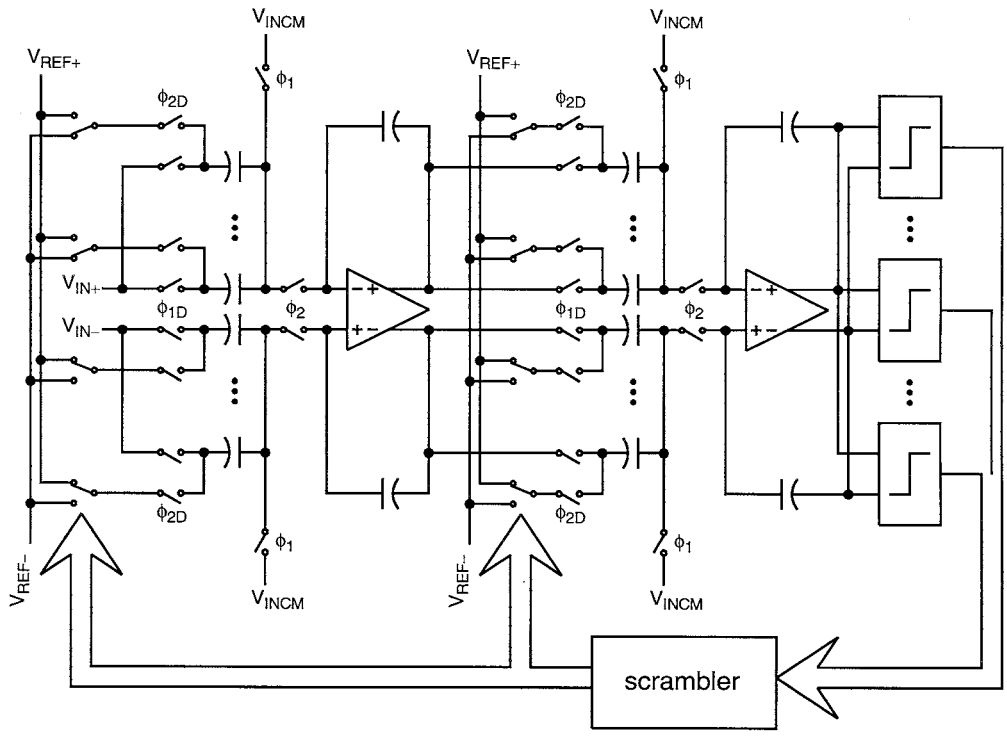

FIGURE 55.49 Multi-bit second-order modulator.

shown on the right. There must be a different offset voltage designed into each of the comparators so that they detect when each quantization level is crossed by the second integrator output. This can be implemented by a resistor string[54,67] or an input capacitive sampling network.[68] The output of the $K-1$ comparators is then a thermometer code representation of the integrator output. This may be translated into binary for the modulator output, but the raw thermometer code is the most convenient to use as a set of feedback signals. They each will drive a switch that will select either V_{REF+} or V_{REF-} to be used as the bottom plate potential for the integrator sampling capacitors. If all sampling capacitors are of equal value, the net charge being integrated will have a term that varies linearly with the quantization level. Each comparator output drives two switches, so there are $2(K-1)$ switches and capacitors in the sampling array.

In any practical integrated structure, even if careful common-centroid layout techniques are used, the precision with which the various capacitors forming the sampling array will be matched is typically limited to 0.1 or 0.2%. As discussed in Section 55.2, this will limit the harmonic distortion that is inherent in the modulator to about –60 dB or higher. However, by varying the assignment of which sampling switch is driven by which comparator output dynamically as the modulator is clocked, much of this distortion may be traded off for white or frequency-shaped noise at the modulator output. This technique is referred to as *dynamic element matching*.

One simple way of implementing dynamic element matching is indicated in Fig. 55.49 with the block labeled "scrambler." This block typically comprises an array of switches that provide a large number of permutations in the way the comparator output lines can be mapped onto sampling switch lines. A multiple-stage butterfly network is one relatively simple approach.[69] The mapping permutation is then changed every modulator clock cycle. Assuming each comparator output will, over a time period less than the final baseband period, end up mapped to all the sampling capacitors, all of the capacitor mismatches will be averaged out. The energy that would be found in input signal harmonics without scrambling will be spread out in some fashion into a higher modulator noise output.

There have been various algorithms published in the literature on how best to control the sequence of mapping perturbations. A simple random sequence will render the mismatch into white noise, increasing the baseband output noise floor.[68,69] More complex sequences relying on a knowledge of the history of quantizer levels are capable of coloring the spread noise so that much of it appears outside the baseband and is suppressed by the following decimation filtering.[70-73]

55.7 Summary

In this chapter, a brief overview of sigma-delta data converters has been presented. Sigma-delta data conversion is a technique that effectively trades speed for resolution. High-linearity data conversion can be accomplished in modern IC processes without expensive device trimming or calibration. For a far more detailed treatment of this topic, refer to Norsworthy, Schreier, and Temes.[2] For a compilation of some of the seminal papers that helped establish sigma-delta modulation as a mainstream technique, refer to Candy and Temes.[1]

56.1 Introduction

A few years ago, the world of wireless communications and its applications started to grow rapidly. The main cause for this event was the introduction of digital coding and digital signal processing in wireless communications. This digital revolution is driven by the development of high-performance, low-cost, CMOS technologies that allow for the integration of an enormous amount of digital functions on a single die. This allows, in turn, for the use of sophisticated modulation schemes, complex demodulation algorithms, and high-quality error detection and correction systems, resulting in high-performance lossless communication channels.

Today, the digital revolution and the high growth of the wireless market also bring many changes to the analog transceiver front-ends. The front-ends are the interface between the antenna and the digital modem of the wireless transceiver. They have to detect very weak signals (μV) which come in at a very high frequency (1 to 2 GHz) and, at the same time, they have to transmit at the same high-frequency high power levels (up to 2 W). This requires high-performance analog circuits, like filters, amplifiers, and mixers which translate the frequency bands between the antenna and the A/D-conversion and digital signal processing. Low cost and a low power consumption are the driving forces and they make the analog front-ends the bottleneck for future RF design. Both low cost and low power are closely linked to the trend toward full integration. An even further level of integration renders significant space, cost, and power reductions. Many different techniques to obtain a higher degree of integration for receivers, transmitters, and synthesizers have been presented over the past years.[1-3] This chapter introduces and analyzes some advantages and disadvantages and their fundamental limitations.

Parallel to the trend to further integration, there is the trend to the integration of RF circuitry in CMOS technologies. The mainstream use for CMOS technologies is the integration of digital circuitry. The use of these CMOS technologies for high-performance analog circuits yields, however, many benefits. The technology is, of course — if used without any special adaptations toward analog design — cheap. This is especially true if one wants to achieve the ultimate goal of full integration: the complete transceiver system on a single chip, with both the analog front-end and the digital demodulator implemented on the same die. This can only be achieved in either a CMOS or a BiCMOS process. BiCMOS has better devices for analog design, but its cost will be higher, not only due to the higher cost per area, but also due to the larger area that will be needed for the digital part. Plain CMOS has the extra advantage that the performance gap between devices in BiCMOS and nMOS devices in deep sub-micron CMOS, and even nMOS devices in the same BiCMOS process, is becoming smaller and smaller due to the much higher investments in the development of CMOS than bipolar. The f_T's of the nMOS devices are getting close to the f_T's of npn devices.

Although some research had been done in the past on the design of RF in CMOS technologies,[4] it is only in the few years that real attention has been given to its possibilities.[5,6] Today several research groups at universities and in industry are researching this topic.[2,3,7,9] As bipolar devices are inherently better than CMOS devices, RF CMOS is by some seen as a possibility for only low-performance systems, with reduced specification (like ISM),[8,10] or that the CMOS processes need adaptations, like substrate etching under inductors.[7] Others feel, however, that the benefits of RF CMOS can be much bigger and that it will be possible to use plain deep sub-micron CMOS for the full integration of transceivers for high-performance applications, like GSM, DECT, and DCS 1800.[2,3] First, this chapter analyzes some trends, limitations, and problems in technologies for high-frequency design. Second, the down-converter topologies and implementation problems are addressed. Third, the design and trends toward fully integrated low-phase noise PLL circuits are discussed. Finally, the design of fully integrated up-converters is studied.

56.2 Technology

Active Devices

Due to the never-ending progress in technology and the requirement to achieve a higher degree of integration for DSP circuits, sub-micron technologies are nowadays considered standard CMOS technologies. The trend is even toward deep sub-micron technologies (e.g., transistor lengths of 0.1 μm. Using the square law relationship for MOS transistors to calculate the f_t of a MOS device no longer holds, due to the high electrical fields. Using a more accurate model, which includes the mobility degradation due to the high electrical fields, results in

$$f_t = \frac{g_m}{2\pi C_{gs}} = \frac{\mu}{2\pi 2/3L^2} \frac{\left(V_{gs} - V_t\right)}{\left(1 + 2\left(q + \frac{\mu}{v_{\max} L}\right)\left(V_{gs} - V_t\right)\right)} \tag{56.1}$$

Hence, by going to deep sub-micron technologies, the square law benefit in L for speed improvement drastically reduces due to the second term in the denominator of Eq. 56.1. Even for very deep sub-micron technologies, the small signal parameter g_m has no square law relationship anymore:

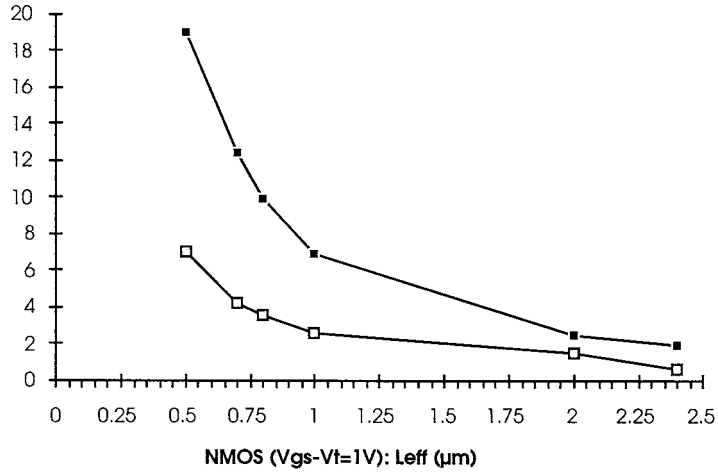

FIGURE 56.1 Comparison of f_t and f_{max}.

$$g_m = \frac{\mu C_{ox} W\left(V_{gs} - V_t\right)}{L\left(1 + 2\left(\theta + \frac{\mu}{v_{\max} L}\right)\left(V_{gs} - V_t\right)\right)} \tag{56.2}$$

with transistor lengths smaller than approximately

$$L < \frac{\mu}{v_{\max}} \frac{1}{\frac{1}{2\left(V_{gs} - V_t\right)} - q} \approx 0.12\,\mu\text{m} \tag{56.3}$$

with $\mu/v_{max} = 0.3$, $V_{gs} - V_t = 0.2$ (boundary of strong inversion), and $\theta = 0.06$, the transistor has only the weak inversion and the velocity saturation area. This will result in even higher biasing currents in order to achieve the required g_m and will result in higher distortion and intermodulation components, which will be further discussed in the tradeoff of low-noise amplifier designs.

Furthermore, the speed increase of deep sub-micron technologies is reduced by the parasitic capacitance of the transistor, meaning the gate-drain overlap capacitances and drain-bulk junction capacitances. This can clearly be seen in Fig. 56.1 in the comparison for different technologies of the f_t and the f_{max} defined as the 3-dB point of a diode-connected transistor.[11] The f_{max} is more important because it reflects the speed limitation of a transistor in a practical configuration. As can be seen, the f_t rapidly increases; but for real circuit designs (f_{max}), the speed improvement is only moderate.

Passive Devices

The usability of a process for RF design does not only depend on the quality of the active devices, but also, more and more, on the availability of good passive devices. The three passive devices (resistors, capacitors, and inductors) will be discussed.

Low-ohmic resistors are available today in all CMOS technologies and their parasitic capacitance is such that they allow for more than high enough bandwidth (i.e., more than 2 to 3 GHz). A more

important passive device is the capacitor. In RF circuits, capacitors can be used for ac-coupling. This allows dc-level shifting between different stages, resulting in a more optimal design of each stage and in the ability to use lower power supply voltages. The quality of a capacitor is mainly determined by the ratio between the capacitance value and the value of the parasitic capacitance to the substrate. Too high a parasitic capacitor loads the transistor stages, thus reducing their bandwidth, and it causes an inherent signal loss due to a capacitive division. Capacitors with ratios lower than 8 are, as a result, difficult to use in RF circuit design as coupling devices.

The third passive device, the inductor, is gaining more and more interest in RF circuit design on silicon. The use of inductors allows for a further reduction of the power supply voltage and for compensation of parasitic capacitances by means of resonance, resulting in higher operating frequencies. The problem is that the conducting silicon substrate under a spiral inductor reduces the quality of the inductor. Losses occur due to capacitive coupling to the substrates, and eddy currents induced in the substrate will also result in losses and in a reduction of the effective inductance value. This problem can be circumvented by using extra processing steps that etch away the substrate under the spiral inductor,[23] having the large disadvantage that it eliminates all the benefits of using a standard CMOS process. It is therefore important that in CMOS, spiral inductors are used without any process changes and that their losses are accurately modeled. In Ref. 12, it is shown that spiral inductors can be accurately modeled and that they can be used in CMOS RF circuit design. As an example, Section 56.4 discusses all the different possibilities for the use of inductors in the design of VCOs. It shows that high-performance VCOs can be integrated with spiral inductors, even on lossy substrates, without requiring any external component.

56.3 The Receiver

Receiver Topologies

The heterodyne or IF receiver is the best known and most frequently used receiver topology. In the IF receiver, the wanted signal is down-converted to a relatively high intermediate frequency. A high quality passive bandpass filter is used to prevent a mirror signal to be folded upon the wanted signal on the IF frequency. Very high performances can be achieved with the IF receiver topology, especially when several IF stages are used (e.g., 900 MHz to 300 MHz, 300 MHz to 70 MHz, 70 MHz to 30 MHz, 30 MHz to 10 MHz). The main disadvantage of the IF receiver is the poor degree of integration that can be achieved as every stage requires going off-chip and requires the use of a discrete bandpass filter. This is both costly (the cost of the discrete filters and the high pin-count for the receiver chip) and power consuming (often the discrete filters have to be driven by a 50-Ω signal source).

The homodyne or zero-IF receiver, introduced as an alternative to the IF receiver, can achieve a much higher degree of integration. The zero-IF receiver uses a direct, quadrature down-conversion of the wanted signal to the baseband. In this case, the wanted signal has itself as mirror signal and sufficient mirror signal suppression can therefore be achieved, even with a limited quadrature accuracy (e.g., 3 degrees phase accuracy and 1-dB amplitude accuracy). Theoretically, there is thus no discrete high-frequency bandpass filter required in the zero-IF receiver, allowing in this way the realization of a fully integrated receiver. The limited performance of the LNA and the mixers reveals, however, that — although not for mirror signal suppression — a high-frequency bandpass filter is still required. The reason why LNAs and mixers require bandpass filtering and how this can be prevented, is explained later.

In the zero-IF receiver, down-conversion can be performed in a single stage (e.g., directly from 900 MHz to the baseband), giving large benefits toward full integration, low cost, and low power consumption.[13] The problem with the zero-IF receiver, however, is its poor performance compared to IF receivers. The zero-IF receiver is intrinsically very sensitive to parasitic baseband signals like dc-offset voltages and crosstalk products caused by RF and LO self-mixing. It is precisely these drawbacks that have kept the zero-IF receiver from being used on a large scale in new wireless applications. The use of the zero-IF receiver has therefore been limited to either low-performance applications like pagers and ISM[10] or as a second stage in a combined IF–zero-IF receiver topology.[14,15] It has, however, been shown

that by using dynamic non-linear dc-correction algorithms, implemented in the DSP, the zero-IF topology can be used for high-performance applications like GSM and DECT.[1,16]

In recent years, new receiver topologies, like the quasi-IF receiver[3] and the low-IF receiver[2] have been introduced for use in high-performance applications. The quasi-IF receiver uses a quadrature down-conversion to an IF frequency, followed by a further quadrature down-conversion to the baseband. The channel selection is done with the second local oscillator on the IF frequency, giving the advantage that a fixed-frequency first local oscillator can be used. The disadvantages of the quasi-IF receiver are that, with a limited accuracy of the first quadrature down-converter (e.g., a phase error of 3 degrees), the mirror signal suppression is not good enough and an HF filter that improves the mirror signal suppression is still necessary. A second disadvantage is that a high IF is required in order to obtain a high enough ratio between the IF frequency and the full band of the application. Otherwise, the tunability of the second VCO has to be too large. Unfortunately, a high IF requires a higher power consumption. Moreover, the first stage of mixers cannot be true down-conversion mixers in the sense that they still need to have a relatively high output bandwidth. To conclude, multi-stage topologies inherently require more power.

The low-IF receiver performs a down-conversion from the antenna frequency directly down to — as the name already indicates — a low IF (i.e., in the range a few 100 kHz).[2] Down-conversion is done in quadrature and the mirror signal suppression is performed at low frequency, after down-conversion, in the DSP. The low-IF receiver topology is thus closely related to the zero-IF receiver. It can be fully integrated (it does not require an HF mirror signal suppression filter) and uses a single-stage direct-down-conversion. The difference is that the low-IF does not use baseband operation, resulting in a total immunity to parasitic baseband signals, resolving in this way the main disadvantage of the zero-IF receiver. The drawback is that the mirror signal is different from the wanted signal in the low-IF receiver topology; but by carefully choosing the IF frequency, an adjacent channel with low signal levels can be selected for which the typical mirror signal suppression (i.e., a phase accuracy of 3 degrees) is sufficient.

Full Integration

With newly developed receiver topologies such as the zero-IF receiver and the low-IF receiver, the need disappears for the use of external filters that suppress the mirror signal (see previous section). This does not mean, however, that there would not be any HF filtering required anymore. Filtering before the LNA is, although not for mirror signal suppression, still necessary to suppress the blocking signals. Moreover, between the LNA and the mixer, filtering may be necessary in order to suppress second and third harmonic distortion products that are introduced by the LNA. Due to the use of a switching down-converter or the non-linearities of the mixer and local oscillator harmonics, these distortion products will be down-converted to the same frequency as the wanted signal. The latter problem can be eliminated by using either a very good blocking filter before the LNA (resulting in small signals after the LNA) or by using a highly linear LNA. The use of linear down-converters (i.e., based on the multiplication with a sinusoidal local oscillator signal) reduces of course the problem as well.

In mobile communications systems, very high, out-of-band signals may be present. In order to prevent saturation of the LNA, these signals must be suppressed with an HF filter that passes only the signals in the band of the application. In the GSM system, for example, the ratio between the largest possible out-of-band signal and the lowest detectable signal is 107 dB. Without a blocking filter, the LNA and the mixer must be able to handle this dynamic range. For the LNA, this means that the input should be able to handle an input signal of 0 dBm (i.e., the –1 dB compression point P_{-1dB} should be about 0 dBm), while having a noise figure of 6 dB. Consequently, this means that the IP3 value should be +10 dBm (IP3 ≈ P_{-1dB} + 10.66 dB). The IMFDR3 (intermodulation free dynamic range) of an LNA or mixer for a given channel bandwidth is given by:

$$\mathrm{IMFDR3} = \frac{2}{3}\left[\mathrm{IP3} + 174\,\mathrm{dB} - 10\log\left(\mathrm{BW}\right) - \mathrm{NF}\right] \tag{56.4}$$

The required IMFDR3 for an LNA is thus (for a 200-kHz bandwidth) 80 dB. CMOS down-converters can be made very linear by using MOS transistors in the linear region,[2,6,17] much more linear than the bipolar cross-coupled multipliers. IP3 values of +45 dBm and noise figures of 18 dB have been demonstrated for CMOS realizations.[2,6] This results in an IMFDR3 for a 200-kHz bandwidth of more than 95 dB. The consequence is that the IMFDR3 spec of 80 dB (i.e., without blocking filter) is achievable for the mixer. In this manner, CMOS opens the way to the development of a true fully integrated single-chip receiver for wireless systems that does not require a single external component, not even a blocking filter. In order to achieve this goal, highly linear mixers that multiply with a single sine must be used. However, the noise performance of mixers is intrinsically worse than the noise of an amplifier, and the use of an LNA is still necessary. In order to be able to cope with the blocking levels, the LNA will have to be highly linear and its gain will have to be reduced from a typical value of, for example, 18 dB to 12 dB. The mixers' noise figure will then have to be lowered by about 6 dB too. This will require a higher power consumption from the down-conversion mixer, but the benefit would be that the receiver can then be fully integrated.

The Down-converter

The most-often used topology for a multiplier is the multiplier with cross-coupled variable transconductance differential stages. The use of this topology or related topologies (e.g., based on the square law) in CMOS is limited for high-frequency applications. Two techniques are used in CMOS: the use of the MOS transistor as a switch and the use of the MOS transistor in the linear region.

The technique often used in CMOS down-conversion for its ease of implementation is subsampling on a switched-capacitor amplifier.[5,18,19] Here, the MOS transistor is used as a switch with a high input bandwidth. The wanted signal is commutated via these switches. Subsampling is used in order to be able to implement these structures with a low-frequency op-amp. The switches and the switched capacitor circuit run at a much lower frequency (comparable to an IF frequency or even lower). The clock jitter must, however, be low so that the high-frequency signals can be sampled with a high enough accuracy. The disadvantage of subsampling is that all signals and noise on multiples of the sampling frequency are folded upon the wanted signal. The use of a high-quality HF filter in combination with the switched-capacitor subsampling topology is therefore absolutely necessary.

Figure 56.2 shows the block diagram of a fully integrated quadrature down-converter realized in a 0.7-μm CMOS process.[2] The proposed down-converter does not require any external components, nor does it require any tuning or trimming. It uses a newly developed double-quadrature structure, which renders a very high performance in quadrature accuracy (less than 0.3 degrees in a very large passband). The down-converter topology is based on the use of nMOS transistors in the linear region.[2,6] By using capacitors on the virtual ground, a low-frequency op-amp can be used for down-conversion. The MOS transistors in the linear region result in very high linearity (input-referred IP3 is +27 dBm) for both the RF and the LO input. The advantages of such high linearity on both inputs are, as explained in the previous section, that the mixer can handle a very high IMFDR3, resulting in no need for any kind of HF filtering. This opens the way to the implementation of a fully integrated receiver.

The LNA

As denoted in the previous section, the HF down-conversion mixer tends to have a high noise floor; if the mixer is positioned directly behind the antenna, small antenna signals will be drowned in noise and the overall receiver sensitivity will be low. In order to increase the receiver sensitivity and the SNR at minimum antenna input power, the antenna signal has to be pushed above the noise floor of the mixer by means of a low noise amplifier (LNA). As long as the output noise of the LNA is greater than the input noise of the mixer, the sensitivity is fully determined by the LNA noise figure (NF). This is illustrated in Fig. 56.3.

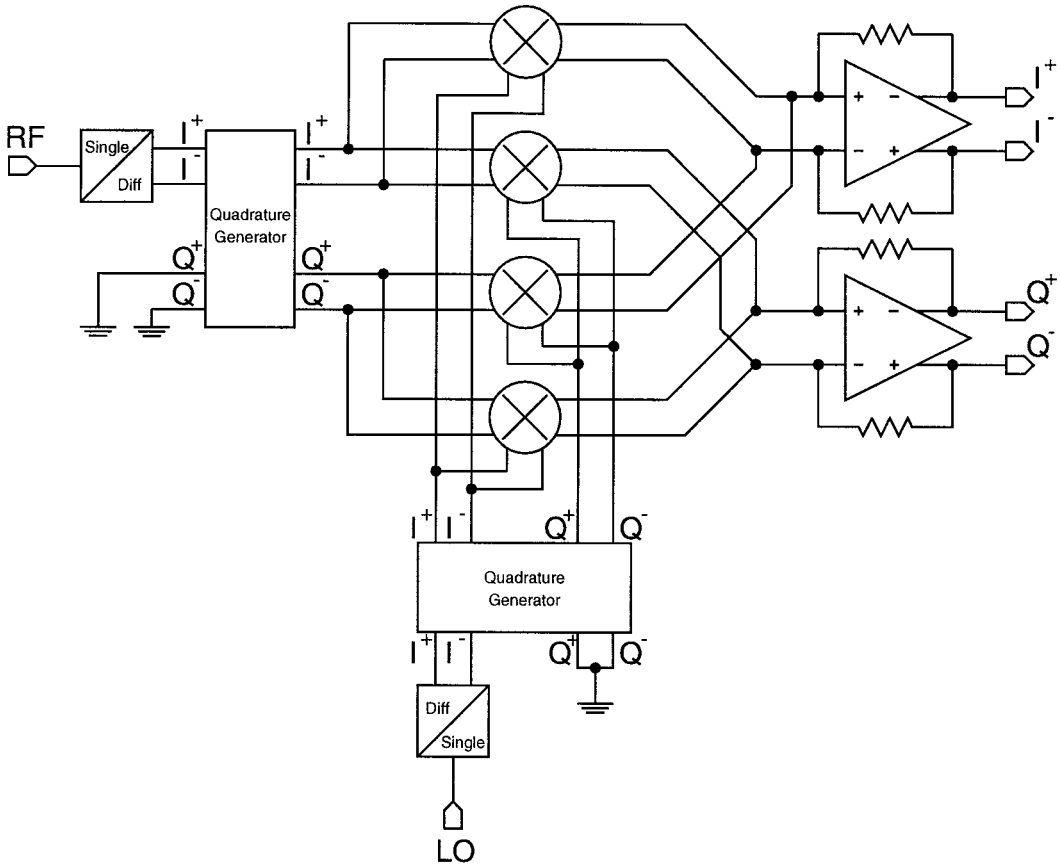

FIGURE 56.2 A double-quadrature down-conversion mixer.

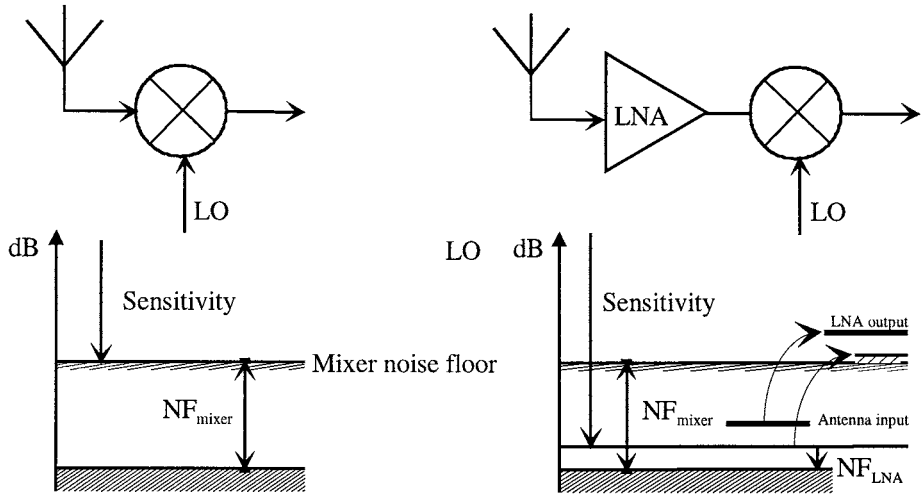

FIGURE 56.3 The benefit of using a low-noise amplifier.

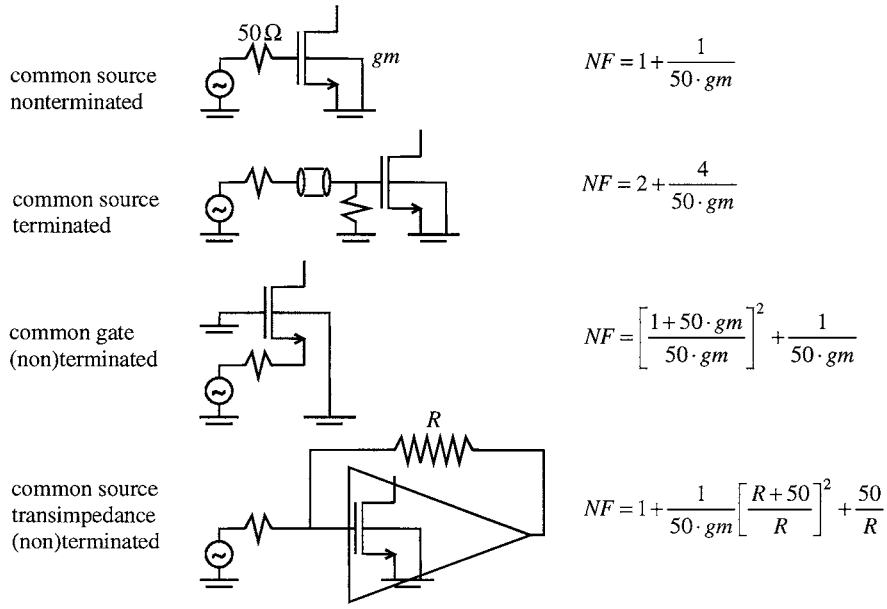

FIGURE 56.4 Noise figure of some common input structures.

The noise figure (NF) of a low-noise amplifier embedded in a 50-Ω system is defined as:

$$\mathrm{NF} = 10\log_{10}\left(\frac{\text{LNA output noise}}{\text{LNA output noise if the LNA itself was noiseless}}\right) \tag{56.5}$$

that is, the real output noise power (dv^2/Hz) of the LNA (consisting of the amplified noise of the 50-Ω source and including all the noise contributions of the amplifier itself to the output noise), divided by the amplified noise of the 50-Ω source only (dv^2/Hz). In this way, the noise figure can be seen as the deterioration of the SNR due to insertion of the non-ideal amplifier. The noise figure is generally dominated by the noise of the first device in the amplifier.

Figures 56.4 and 56.5 compare some common input structures regarding noise. As can be seen from the NF equations and the plotted noise figure as function of the g_m of the transistor for the different topologies, the non-terminated common-source input stage and the (terminated) transimpedance stage are superior as far as noise is concerned. For those circuits, the NF can be approximated as:

$$\left(NF - 1\right) = \frac{1}{50 \cdot g_m} = \frac{\left(V_{gs} - V_t\right)}{50 \cdot 2 \cdot I} \tag{56.6}$$

indicating that a low noise figure needs a high transconductance in the first stage. In order to generate this transconductance with high power efficiency, a low $V_{gs} - V_t$ is preferred. However, this will result in a large gate capacitance. Together with the 50-Ω source resistance in a 50-Ω antenna system, the achievable bandwidth is limited by:

$$f_{3dB} \cong \frac{1}{2\pi \cdot 50\Omega \cdot C_{gs}} \tag{56.7}$$

Together with Eq. 56.6, this results in (f_T is the cutoff frequency of the input transistor)

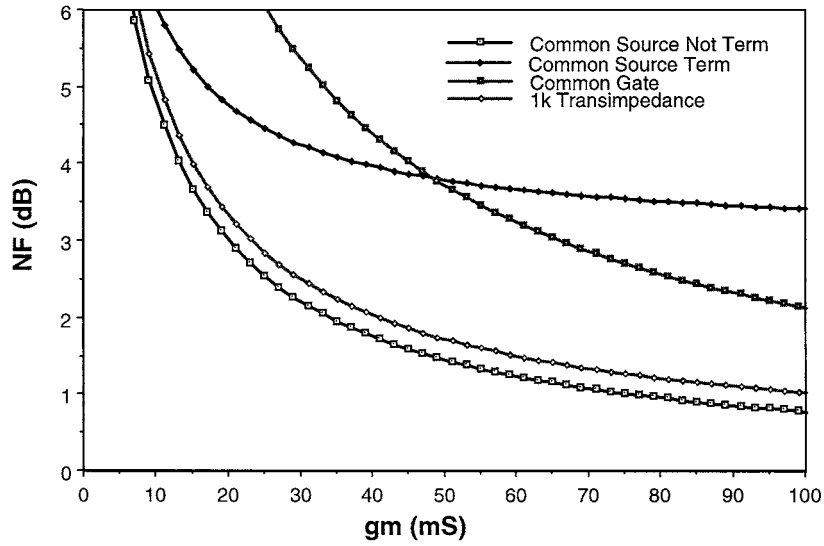

FIGURE 56.5 Performance comparison.

$$\left(\mathrm{NF}-1\right)=\frac{f_{3dB}}{f_T} \tag{56.8}$$

Due to overlap capacitances and Miller effect, this relationship becomes approximately (f_d is the 3-dB point of a transistor in diode configuration):[11]

$$\left(\mathrm{NF}-1\right)=\frac{f_{3dB}}{f_d} \tag{56.9}$$

This means that a low noise figure can only be achieved by making a large ratio between the frequency performance of the technology (f_d) and the working frequency (f_{3dB}). Because for a given technology, f_d is proportional to $V_{gs} - V_t$, this requires a large $V_{gs} - V_t$ and, associated with it, a large power drain. Only by going to real deep sub-micron technologies, will the f_d be high enough to achieve GHz working frequencies with low $V_{gs} - V_t$ values. Only then can the power drain be reduced to an acceptable value.

In practice, the noise figure and the power transfer from the antenna to the LNA is further optimized by doing, respectively, noise and source impedance matching. These matching techniques often rely on inductors to cancel out parasitics by a resonance phenomenon to boost up the maximum working frequency; the LNA works in "overdrive" mode. Although these aspects are not discussed in this chapter, they are very important when designing LNAs for practical boundary conditions like antenna termination, etc.

In contrast to what one might think, there are still some drawbacks in using short-channel devices for low noise. The large electric field at the drain of a sub-micron transistor may produce hot carriers, having a noise temperature significantly above the lattice temperature.[20] This indicates that a good LDD (lightly doped drain) is as crucial for low noise as it is for device reliability.

At high antenna input powers, the signal quality mainly degrades due to in-band distortion components that are generated by third-order intermodulation in the active elements. The linearity performance of LNAs is generally described by the input-referred third-order intercept point (IIP3), as can be seen in Fig. 56.6. IIP3 specifies the extrapolated input signal where third-order intermodulation products start to dominate the output.

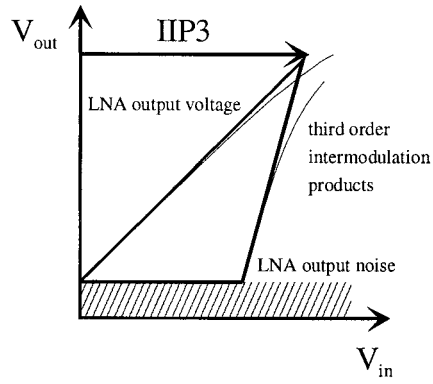

FIGURE 56.6 Linearity performance of an LNA.

As out-of band signals are, in general, orders of magnitude larger than the wanted signal ("blocking levels"), the mixing of out-of-band signals toward an in-band intermodulation product must be avoided by all means. Therefore, it is very important to know the limiting factors and the dynamics of the most important linearity spec, that is, IIP3. Because the core of an amplifier always contains one or more active elements, we will focus on their internal distortion mechanisms.

Long-channel transistors are generally described by a quadratic model. Consequently, a one-transistor common-source amplifier ideally suffers only from second-order distortion and produces no third-order intermodulation products. As a result, high IP3 values should easily be achieved. In fact,

$$\mathrm{IM2} = \frac{1}{2}\frac{v}{V_{gs} - V_t} \quad \text{and} \quad \mathrm{IM3} = 0 \tag{56.10}$$

where v denotes the input amplitude of the amplifier.

However, when the channel length decreases toward deep sub-micron, this story no longer holds; third-order intermodulation starts to become important. To understand the main mechanism behind third-order distortion in a sub-micron CMOS transistor, we start from the equation for the drain current of a short-channel transistor,

$$I_{ds} = \frac{\mu_0 C_{ox}}{2n} \cdot \frac{W}{L} \cdot \frac{\left(V_{gs} - V_t\right)^2}{1 + \Theta \cdot \left(V_{gs} - V_t\right)} \tag{56.11}$$

with

$$\Theta = \theta + \frac{\mu_0}{L_{eff} \cdot v_{\max} \cdot n} \tag{56.12}$$

where θ stands for the mobility degradation due to the transversal electrical field (surface scattering at the oxide–silicon interface) and the $\frac{\mu}{L_{eff} \cdot v_{\max} \cdot n}$-term models the degradation caused by the longitudinal electric field (electrons reaching the thermal saturation speed). As the $_{\theta}$-term is small in today's technologies (increasingly better quality of the oxide–silicon interface), it can often be neglected relative to the longitudinal term. For a typical 0.5 μm CMOS technology, the Θ-parameter equals about 0.9.

It can be seen from Eq. 56.11 that for large values of $V_{gs} - V_t$, the current becomes a linear function of $V_{gs} - V_t$. The transistor is then operating in the velocity saturation region. For smaller vales of $V_{gs} - V_t$, the effect of Θ consists apparently of "linearizing" the quadratic characteristic… but in reality, the effect results in an intermodulation behavior that is worse than in the case of quadratic transistors.

Indeed, we will have a slightly lower amount of second-order intermodulation, but it comes at the cost of third-order intermodulation.

The following equations for the intermodulation ratios *IMx* can be found[13] by calculating the Taylor expansion of the drain current around a certain $V_{gs} - V_t$ value:

$$\mathrm{IM2} = \frac{v}{V_{gs} - V_t} \cdot \frac{1}{(1+r)\cdot(2+r)} \tag{56.13}$$

and

$$\mathrm{IM3} = \frac{3}{4}\,\frac{v}{(V_{gs} - V_t)} \cdot \frac{v}{V_{sv}} \cdot \frac{1}{(1+r)^2 \cdot (2+r)} \tag{56.14}$$

where

$$V_{sv} = \frac{1}{\Theta} \tag{56.15}$$

represents the transit voltage between strong inversion and velocity saturation and

$$r = \frac{V_{gs} - V_t}{V_{sv}} \equiv \Theta \cdot (V_{gs} - V_t) \tag{56.16}$$

denotes the relative amount of velocity saturation. The transit voltage V_{sv} depends only on technology parameters and is about 2 V for a 0.7-μm CMOS technology. For deep sub-micron processes (e.g., a 0.1-micron technology), this voltage becomes even smaller than 300 mV, which is very close to the $V_{gs} - V_t$ at the boundary of strong inversion.

Based on Eq. 56.14, one can directly derive an expression for IIP3:

$$\mathrm{IIP3} \cong 11.25 + 10 \cdot \mathrm{Log}_{10}\left((V_{gs} - V_t)\cdot V_{sv} \cdot (1+r)^2 \cdot (2+r)\right) \tag{56.17}$$

This value is normalized to 0 VdBm, the voltage that corresponds to a power of 0 dBm in a 50-Ω resistor. For the 0.5-μm technology that was mentioned before and a $V_{gs} - V_t$ value of 0.2 V, IIP3 equals +9.5 VdBm. It is worth noting that for a given L_{eff}, the intrinsic IIP3-value of a transistor is only a function of the gate overdrive.

In Figure 56.7, the formula for IP3 is evaluated for a minimum-length transistor in three different technologies. As can be seen from the figure, for a given L_{eff}, the linearity becomes better with increasing gate overdrive. For small gate overdrives, the increase in IIP3 is proportional to the square root of $V_{gs} - V_t$. At high $V_{gs} - V_t$ values (near velocity saturation), the increase in IIP3 becomes even more pronounced. However, this region of operation exhibits a very low transconductance efficiency (g_m/I_{ds}), particularly for sub-micron transistors, where this parameter is given by

$$\frac{g_m}{I_{ds}} = \frac{2}{V_{gs} - V_t} \cdot \frac{1 + \Theta \cdot (V_{gs} - V_t)}{1 + 2\Theta \cdot (V_{gs} - V_t)} \tag{56.18}$$

The influence of L_{eff} on IIP3 can be seen in Fig. 56.7; For practical values of the gate overdrive, the linearity gets worse with decreasing gate length, because V_{sv} is proportional to L_{eff}. This may pose a

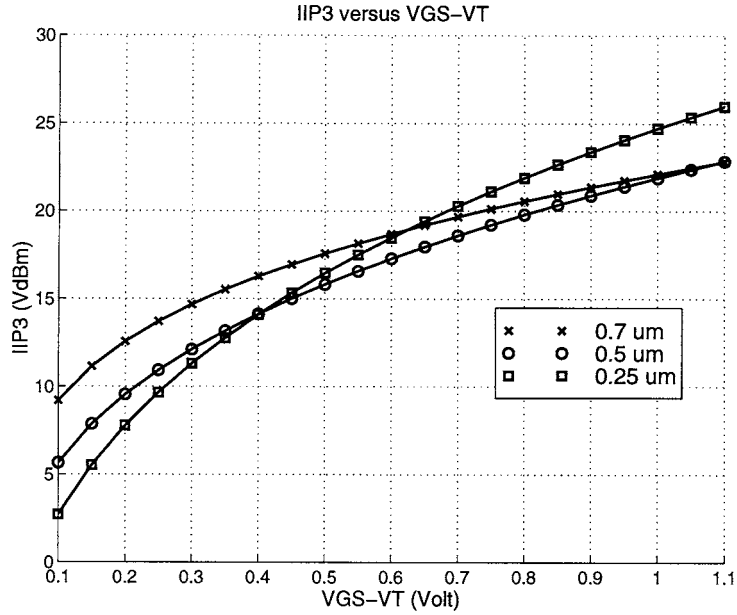

FIGURE 56.7 IIP3 versus $V_{gs} - V_t$ for three different technologies.

problem when very small transistor lengths are required to reduce the power drain and a high IP3 is necessary to avoid the blocking filters. For large values of the gate overdrive, there is a point where the intermodulation performance of a short-channel transistor gets better compared to a large-channel one, because the first already enters the velocity saturation region. As mentioned before, this region of operation is not highly recommended.

Nevertheless, when a certain IIP3 is required, there are basically two methods to ensure this: using a high enough $V_{gs} - V_t$ or using some kind of feedback mechanism (e.g., source degeneration). It can be shown that for the same equivalent g_m and the same distortion performance, the required dc current is lower when local feedback at the source is applied. It comes, however, at the cost of a larger transistor width, eventually compromising the amplifier bandwidth.

56.4 The Synthesizer

Synthesizer Topology

The *frequency synthesizer* generates the local oscillator signal, responsible for the correct frequency selection in the up- and down-converters. Since the frequency spectrum in modern wireless communication systems must be used as efficiently as possible, channels are placed very close together. The signal level of the desired receiving channel can be made very small, whereas adjacent channels can have very large power levels. Therefore, the phase noise specifications for the LO signal are very high, which makes the design of the frequency synthesizer very critical.

Meanwhile, mobile communication means low power consumption, low cost, and low weight. This implies that a completely integrated synthesizer is desirable, where integrated means a standard CMOS technology without any external components or processing steps. Usually, the frequency synthesizer is realized as a phase-locked loop (PLL) as shown in Fig. 56.8. The most critical building blocks of a PLL for integration in CMOS are the building blocks that operate at high frequency: the voltage-controlled oscillator (VCO) and the prescaler. Both will be discussed in the following sections.

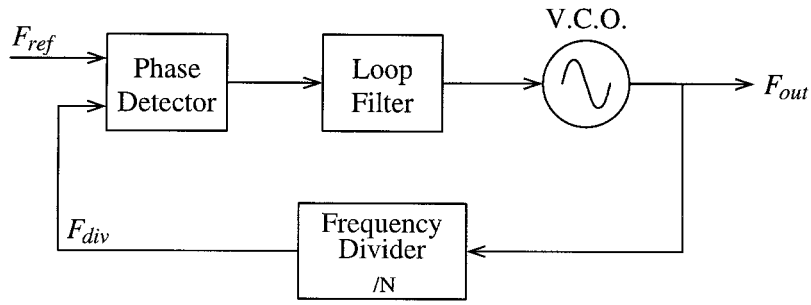

FIGURE 56.8 PLL-based frequency synthesizer.

As stated above, the most important specification of a frequency synthesizer is low phase noise. The following formulae indicate how the noise of the different building blocks is transferred toward the synthesizer's output.

$$\frac{\theta_{out}(s)}{\theta_{vco}(s)} = \frac{N \cdot s}{N \cdot s + K_{pd} \cdot G_{lf}(s) \cdot K_{vco}} \tag{56.19}$$

$$\frac{\theta_{out}(s)}{\theta_{other}(s)} = \frac{N \cdot K_{pd} \cdot G_{lf}(s) \cdot K_{vco}}{N \cdot s + K_{pd} \cdot G_{lf}(s) \cdot K_{vco}} \tag{56.20}$$

with θ_{out} the synthesizer's output noise, θ_{vco} the phase noise of the VCO, θ_{other} the phase noise of the reference signal, the prescaler, the phase detector, and the loop filter, N the prescaler division factor, K_{pd} the phase detector gain, $G_{lf}(s)$ the loop filter transfer function, and K_{vco} the VCO gain.

With $G_{lf}(s)$ as the transfer function of a low-pass filter, the phase noise of the VCO is high-passed toward the output. The phase noise of the other components is low-passed. In other words, the VCO is the main contributor for out-of-band phase noise, while the other building blocks account for the in-band noise.

As can be seen, the choice of the loop bandwidth is critical for phase noise performance. In order to have enough suppression of phase noise at frequency offsets, important for communication standards (e.g., 600kHz for GSM and DCS-1800) and of spurious due to the reference signal, the loop bandwidth cannot be chosen very large (a few kHz typically). Also, for stability reasons, the loop bandwidth has to be small compared to the PLL reference frequency. To realize relatively small loop bandwidths, large capacitor and resistor values are necessary to implement the large time constant. In current commercial designs, the capacitors are often implemented off-chip, to limit the chip area. To go to full integration of the frequency synthesizer, a way must be found to implement the loop filter without the need for large amounts of capacitance. Several possibilities exist.

The first possibility is to increase the resistance needed to create the large time constant of a narrow low-pass filter, which means a decrease of capacitance. The disadvantage of this approach is the increase of loop filter phase noise. Hence, a tradeoff between integrated capacitance and phase noise exists.

A more appealing approach is the one used in Ref. 31. Here, a type-II fourth-order PLL is integrated, using a dual-path filter topology. The loop filter consists of two filter paths: one active filter path and one passive filter path. By combining the signals of both paths, a zero is realized without the need for an extra capacitor and resistor. The zero is necessary to provide enough phase margin for loop stability. The principle is explained in Figure 56.9. In this way, the integrated capacitance is small enough to be integrated on-chip, without degrading the phase noise performance. The total chip area was only 1.9 μm by 1.6 μm.

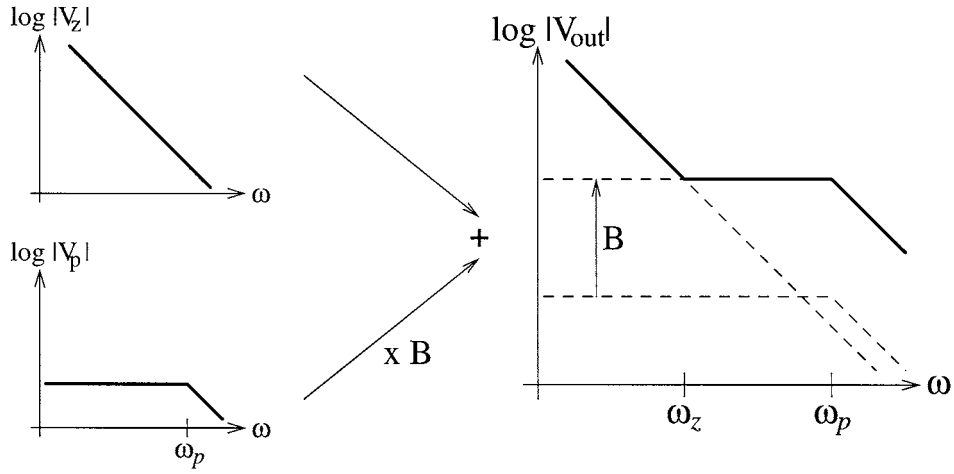

FIGURE 56.9 Dual-path filter principle.

A third possibility is increasing the reference frequency. As a consequence, the loop bandwidth can be made larger, with still enough suppression of the reference spurious noise. This means less integrated capacitance and a better PLL settling time. In addition, the prescaler's division factor *N* will be decreased. As can be seen in Eq. 56.20, the phase noise of the phase detector, the loop filter, the reference signal, and the prescaler is multiplied by *N*. In other words, increasing the reference frequency also results in better in-band phase noise. One disadvantage exists. The prescaler can only divide by integer values, so the smallest frequency step that can be synthesized is equal to the reference frequency. In GSM and DCS-1800 systems, this would mean that the reference frequency must be 200 kHz in order to select all possible channels. This problem can be circumvented by the use of the fractional-N technique. This technique allows the use of fractional division factors by very fast switching between different integer division factors. By combining fractional-N with delta-sigma modulation,[32] the spurs generated by the switching action are shaped to high-frequency noise. This noise can then be filtered by the PLL loop filter.

The Oscillator

As stated above, the *oscillator* will be the main source of out-of-band phase noise. Therefore, its design is one of the most critical parts in the integration of a frequency synthesizer for high-quality communication standards. For the realization of a gigahertz VCO in a sub-micron CMOS technology, two options exist: ring oscillators or oscillators based on the resonance frequency of an LC-tank. The inductor in this LC-tank can be implemented as an active inductor or a passive one. It has been shown that for ring oscillators[21] as well as active LC-oscillators,[22] the phase noise is inversely related to the power consumption.

$$\text{Ring osc. (Ref. 21):}\quad L\{\Delta\omega\} \sim kTR\left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = \frac{1}{R}$$
$$\text{Active-LC (Ref. 22):}\quad L\{\Delta\omega\} \sim \frac{kT}{2\omega C}\cdot\left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = 2\omega C \tag{56.21}$$

Therefore, the only viable solution to a low-power, low-phase-noise VCO is an LC-oscillator with a passive inductor. In this case, the phase noise changes proportionally with the power consumption:

$$\text{Passive-LC (Ref. 22):}\quad L\{\Delta\omega\} \sim kTR\left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = R(\omega C)^2 \tag{56.22}$$

As could be expected, the only limitation in this oscillator is the integrated passive inductor. Equation 56.22 shows that for low phase noise, the resistance R (i.e., the equivalent series resistance in the LC-loop) must be as small as possible. A low resistance also means low losses in the circuit and thus low power needed to compensate for these losses. Capacitors are readily available in most technologies. But since the resistance R will be dominated by the contribution of the inductors' series resistance, the inductor design is critical. Three solutions exist.

Spiral inductors on a silicon substrate usually suffer from high losses in this substrate, which limit the obtainable Q-factor. Recently, techniques have been developed to etch this substrate away underneath the spiral coil in a post-processing step.[7,23] The cavity created by such an etching step can clearly be seen in Fig. 56.10. However, since there is an extra etching step required after normal processing of the ICs, this technique is not allowed for mass production.

For extremely low phase noise requirements, the concept of bondwire inductors has been investigated. Since a bondwire has a parasitic inductance of approximately 1 nH/mm and a very low series resistance, very-high-Q inductors can be created. Bondwires are always available in IC technology, and can therefore be regarded as being standard CMOS components. Two inductors, formed by four bondwires, can be combined in an enhanced LC-tank[22] to allow a noise/power tradeoff. A microphotograph of the VCO is shown in Fig. 56.11.[25] The measured phase noise is as low as –115 dBc/Hz at an offset frequency of 200 kHz from the 1.8-GHz carrier. The power consumption is only 8 mA at 3 V supply. Although chip-to-chip bonds are used in mass commercial products,[28] they are not characterized on yield performance for mass production. Therefore, the industry is reluctant with regard to this solution.

The most elegant solution is the use of a spiral coil on a standard silicon substrate, without any modifications. Bipolar implementations do not suffer from substrate losses because they usually have a

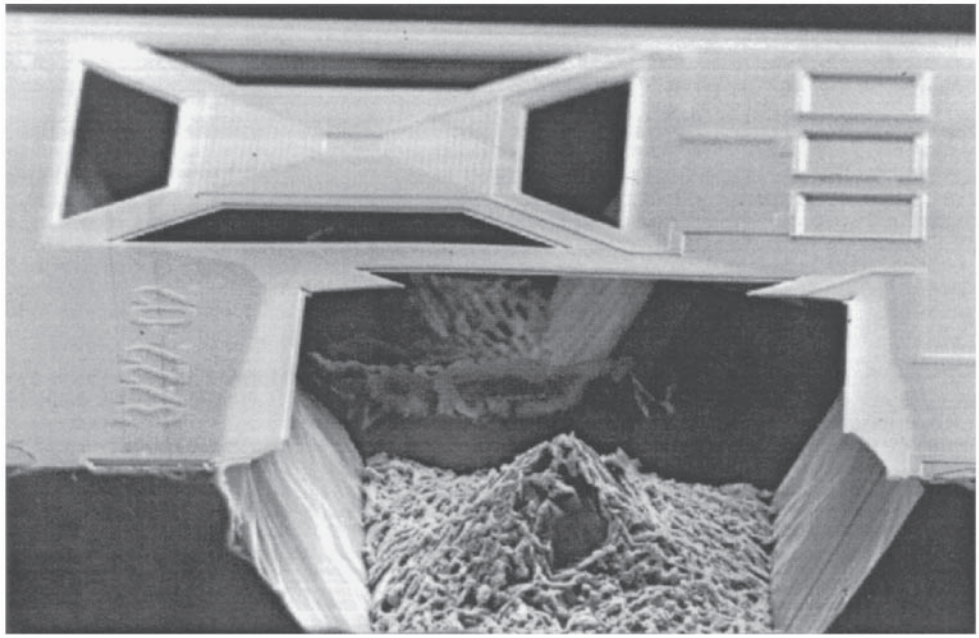

FIGURE 56.10 Etched spiral inductor.

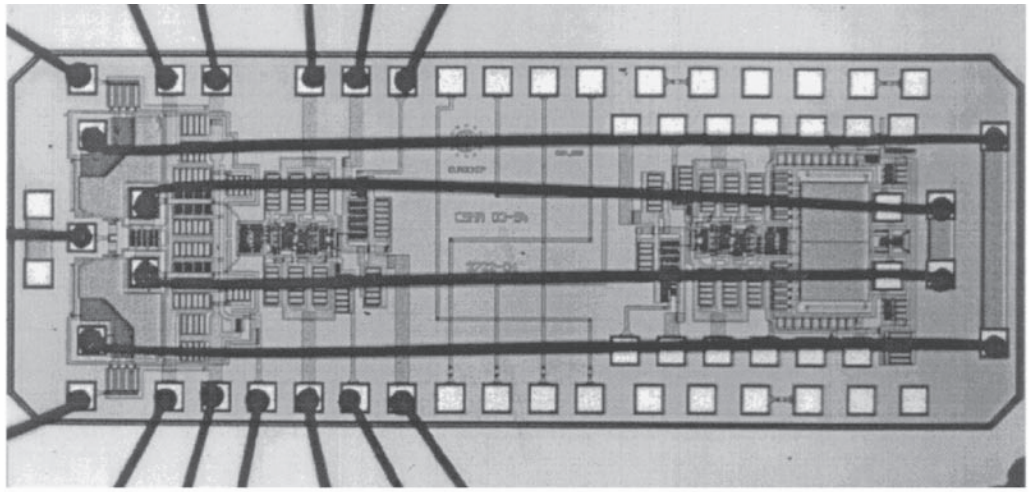

FIGURE 56.11 Microphotograph of the bondwire LC-oscillator.

high-ohmic substrate.[24] Most sub-micron CMOS technologies use a highly doped substrate, and therefore have large induced currents in the substrate, which is responsible for the high losses. The effects present in these low-ohmic substrates can be investigated with finite-element simulations. The finite-element simulations also take the losses in the metal conductors into account. Three phenomena contribute to these losses. The first is the dc series resistance of the metal. The others are high frequency effects, the skin effect, and eddy currents. Due to the skin effect, the metal turns are only partially used for conduction of the high frequency current. Eddy currents are generated by the changing magnetic field that crosses the metal lines, resulting in an increased resistance, especially in the inner turns of the inductors. This analysis can lead to a coil design optimized for a certain technology. A coil was implemented, using the above analysis, in a spiral-inductor LC-oscillator. The technology is a standard two-metal layer, 0.4-μm CMOS technology. With a power consumption of only 11 mW, a phase noise of –122.5 dBc/Hz at 600 kHz offset of the 1.8 GHz carrier has been obtained.[29] A microphotograph is shown in Fig. 56.12.

The Prescaler

To design a high-speed dual-modulus prescaler, a new architecture has been developed that is based on the 90-degrees phase relationship between the master and the slave outputs of an M/S toggle-flip-flop.[26] This architecture is shown in Fig. 56.13. No additional logic is present in the high frequency path to realize the dual-modulus division, as is the case in classic prescalers, based on synchronous counters. Here, the dual-modulus prescaler is as fast as an asynchronous fixed divider. Using this new principle, a 1.75-GHz input frequency has been obtained at a power consumption 24 mW and 3 V power supply. At 5 V power supply, input frequencies above 2.5 GHz can even be processed in a standard 0.7-μm CMOS technology. By going to sub-micron technologies, even higher frequencies can be obtained at low power consumption.

Fully Integrated Synthesizer

The fully integrated VCO and dual-modulus prescaler make it possible to integrate a complete LO synthesizer in a standard CMOS technology, without tuning, trimming, or post-processing, that achieves modern telecom specs. Using the dual-path filter topology for minimizing the necessary integrated capacitance, a type-II, fourth-order, fully integrated PLL frequency synthesizer for DCS-1800 applications has been realized. The PLL is implemented in a standard 0.4-μm CMOS, achieving a phase noise of –121 dBc/Hz at 600 kHz offset frequency, while consuming only 51 mW from a 3-V power supply. The

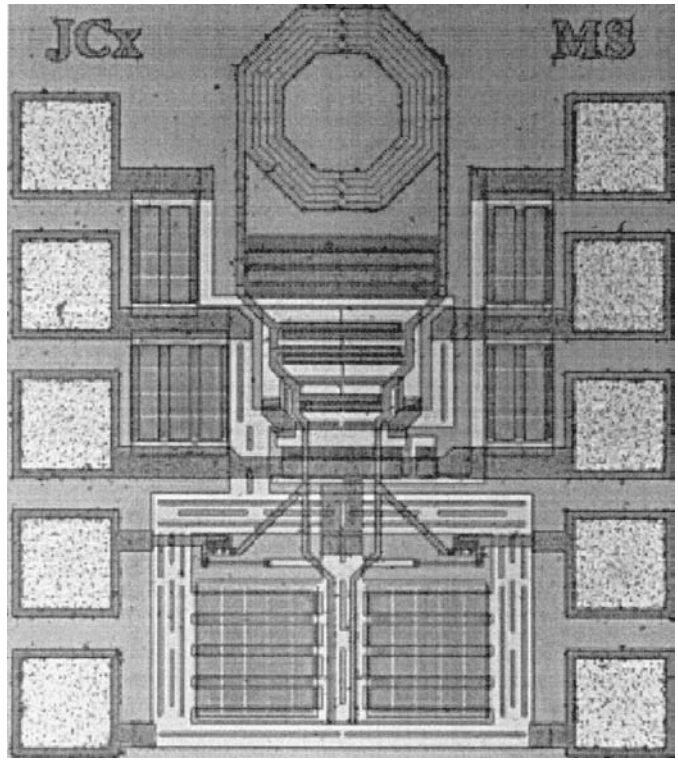

FIGURE 56.12 Microphotograph of the integrated spiral LC-oscillator.

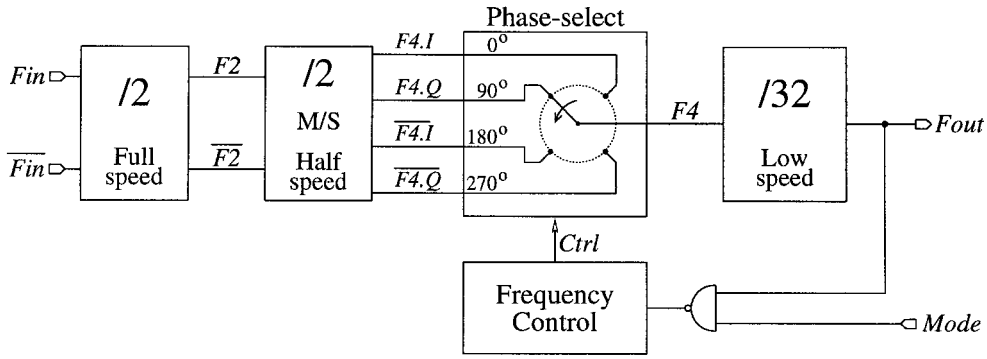

FIGURE 56.13 New dual-modulus prescaler architecture.

integrated capacitance could be decreased to less than 1 nF, for a loop bandwidth of 45 kHz, resulting in a chip area of 1.7 μm by 1.9 μm. A chip microphotograph is shown in Fig. 56.14.

56.5 The Transmitter

For communication systems like GSM, two-way communication is required and a transmitter circuit must be implemented to achieve a full transceiver system. In the open literature, most reported mixer circuits in CMOS are down-conversion mixers. However, as will be explained in the first section below, there is a huge difference between receivers. This implies that a lot of research for the development of CMOS transmitter circuits still needs to be done.

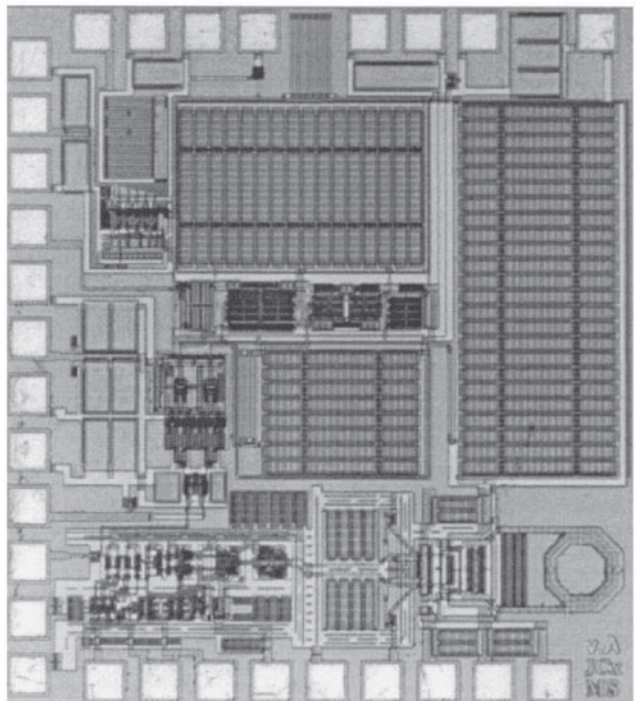

FIGURE 56.14 A fully integrated frequency synthesizer.

Down-conversion vs. Up-conversion

The modulation of the baseband signals on the local oscillator carrier frequency requires an up-conversion mixer topology. In classical bipolar transceiver implementations, the up- and down-converter mixer use typically the same four-quadrant topology. There are, however, some fundamental differences between up- and down-converters, which can be exploited to derive optimal dedicated mixer topologies.

In a down-conversion topology, the two input signals are at a high frequency (e.g., 900 MHz for GSM systems) and the output signal is a low-frequency signal of maximum a few MHz for low-IF or zero-IF receiver systems. This low-frequency output signal can easily be processed making optimal use of the advantages of feedback circuits. Also, high-frequency spurious signals (e.g., LO feedthrough) can be filtered.

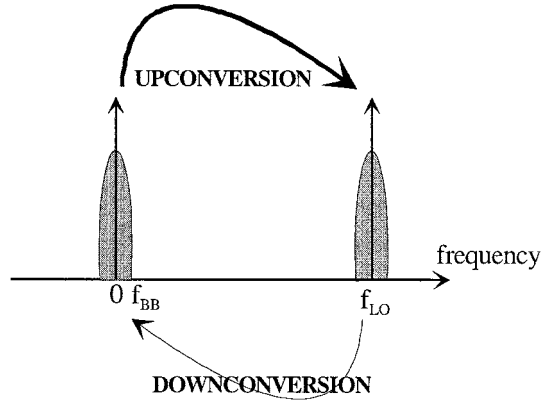

FIGURE 56.15 The difference between up-conversion and down-conversion.

For up-conversion mixers, the situation is totally different. The high frequent local oscillator (LO) and the low frequent baseband (BB) input signal are multiplied to form a high frequent (RF) output signal. All further signal processing has to be performed at high frequencies, which is very difficult and power consuming when using current sub-micron CMOS technologies. Furthermore, all unwanted signals (like the intermodulation products and LO-leakage) have to be limited to a specified level (e.g., below –30 dBc) as they cannot be filtered.

Also, the specifications have to be interpreted differently for both kinds of mixer circuits: for example, an important specification for down-conversion mixers is the conversion gain G_c, defined as the ratio between the output signal and the RF input signal. As for a down-conversion mixer, the RF input signal is fixed — and usually very small; G_c is a good measure of the circuit performance. For an up-conversion mixer, the situation is different. G_c would be the ratio between the RF output signal and the baseband signal. However, in this case, both the input ports, the baseband signal, and the LO signal are free design parameters. As it is easier and more power-friendly to amplify the low-frequency signal, a large baseband signal is preferred. Because of this extra design parameter, it should be better to compare up-conversion circuits based on, for example, the same distortion level or on the same output power level.

CMOS Mixer Topologies

Switching Modulators

Many published CMOS mixer topologies are based on the traditional variable transconductance multiplier with cross-coupled differential modulator stages. Since the operation of the classical bipolar cross-coupled differential modulator stages is based on the translinear behavior of the bipolar transistor, the MOS counterpart can only be effectively used in the modulator or switching mode. Large LO-signals have to be used to drive the gates and this results in a huge LO-feedthrough. In CMOS down-converters, this is already a problem; in Ref. 9, for example, the output signal level is –23 dBm with an LO-feedthrough signal of –30 dBm, which represents a suppression of only –7 dB. This gives rise to very severe problems in direct up-conversion topologies. Moreover, by using a square wave modulating LO signal, 30% of the signal power is present at the third-order harmonic. This unwanted signal can only be filtered with an extra external output blocking filter.

In CMOS, the variable transconductance stage is typically implemented using a differential pair biased in the saturation region. To avoid distortion problems, large $V_{gs} - V_t$ values or a large source degeneration resistance have to be used, which results in large power drain and noise problems, especially compared to the bipolar converter circuits. This can be avoided by replacing the bottom differential pair by a pseudo-differential topology with MOS transistors in the linear region.[17]

Linear MOS Mixers

Next, an intrinsically linear CMOS mixer topology is presented. The modulation is performed by biasing MOS transistors in the linear region. The circuit is focused on a real single-ended output topology, which avoids the use of external combining and the circuits have been optimized based on the analysis of the non-linearities of the mixer structure. The understanding of the origins of the distortion, results in a better compromise between the linearity, the output signal power, and the power consumption. Therefore, the results of the linearity analysis and some guidelines to optimize the circuit performance are also presented in this section. The general design ideas will be illustrated by numerical data from realized chips[33,34]

Figure 56.16 shows the four up-conversion mixers M1a, M1b, M1c, and M1d and the single-ended output current buffer. The realized mixer topology is based on an intrinsic linear mixer circuit that converts the baseband and LO voltages into modulated currents.

Each mixer transistor converts a quadrature LO voltage and baseband voltage to a linearly modulated current. The expression for the drain-source current for a MOS transistor in the linear region is given by:

$$I_{ds} = \beta\left[\left(V_{gs} - V_t\right)V_{ds} - \frac{V_{ds}^2}{2}\right] \tag{56.23}$$

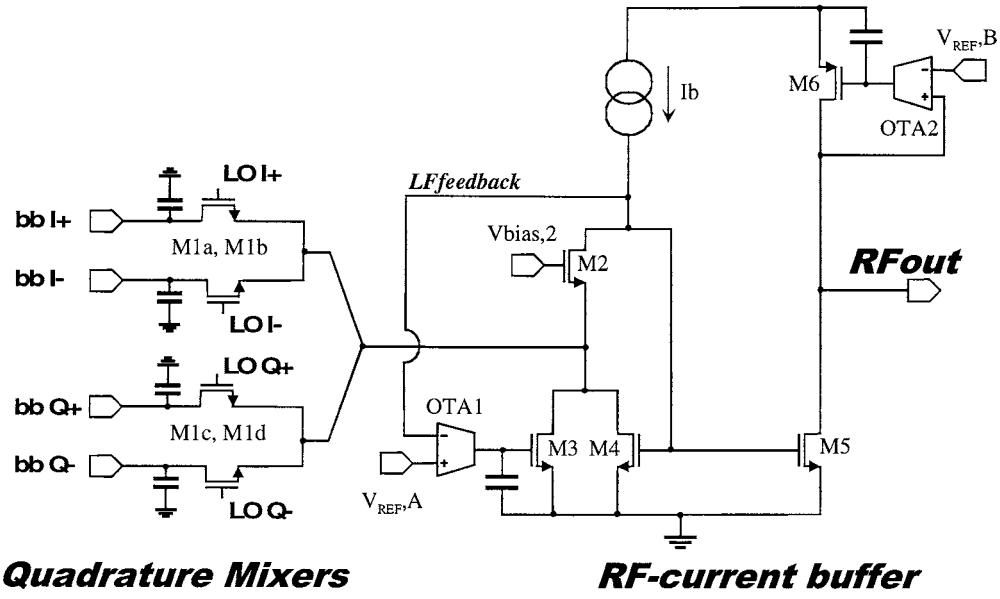

FIGURE 56.16 Schematic of the quadrature up-conversion mixers and output driver.

This equation is rewritten in terms of dc and ac terms as:

$$I_{ds} = \beta\left(V_{ds} + v_{ds}\right)\left(V_{gs} - V_t - \frac{V_d - V_s}{2} + v_g - \frac{v_d + v_s}{2}\right) \tag{56.24}$$

The differential baseband voltage is applied at the drain/source of the mixer transistors M1a and M1b, and the LO signal is applied at the gates of the mixers. Equation 56.24 shows that only two high-frequency components (products with the LO signal v_g) occur in the signal current of each mixer transistor: $\beta V_{DS} v_g$ and $\beta v_{ds} v_g$. The last term is the wanted mixed signal. The first term is proportional to the product of the dc drain-source voltage and the gate (LO) signal. Hence, it is situated at the oscillator frequency. This unwanted signal has been eliminated by applying zero dc drain-source voltage over the mixer transistor. In this way, only the wanted frequency component is formed by each mixer transistor.

The voltage-to-current conversion is performed balanced. The currents are immediately added at the common node, which is made virtual ground by the very low input impedance of the buffer stage (Fig. 56.16).

Quadrature modulation is performed by summing the four modulated currents of each mixer transistor. The resulting single-ended signal current is given by Eq. (56.25).

$$I_{mixer} = \delta\beta\left(v_{bb,I}^2 + v_{bb,Q}^2 + 2 v_{lo} v_{bb}\left(SSB\right)\right) \tag{56.25}$$

where:

δ	= A reduction factor due to the degeneration by the finite input conductance of the output stage
β	= $\mu C_{ox} W/L$
$v_{bb,I}$ and $v_{bb,Q}$	= the baseband I and Q voltage signals, respectively
v_{lo}	= the local oscillator voltage

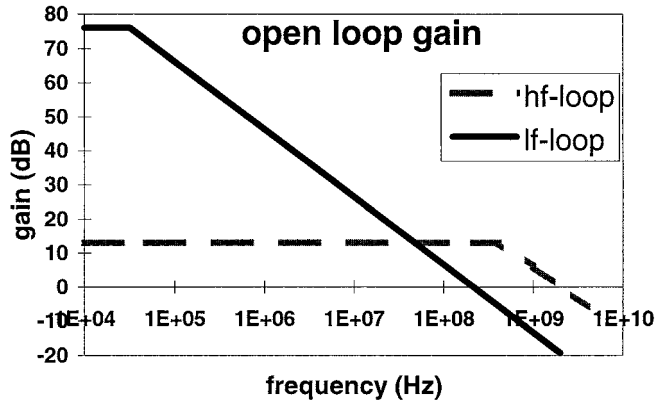

FIGURE 56.17 Open loop conversion gain of the feedback loops.

The modulated current contains a low frequent square baseband signal and the wanted RF single side band (SSB) mixing product.

The mixer has been designed to have all distortion and intermodulation components, including LO-feedthrough, lower than –30 dBc, which is typical for wireless GSM, DECT, and DCS applications.

An essential improvement in the RF mixer design is the implementation of large on-chip capacitors to the ground at the baseband nodes of the mixer transistors. In this way, the modulated RF current flows through the capacitor and not through the bonding wires, which form a considerable impedance at GHz frequency. The RF signal linearity and amplitude becomes independent of the bonding wire matching and length as the RF signal remains on-chip. Also, a degeneration of the high-frequency signal current by the output impedance of the baseband signal source is prevented by this low impedance.

The Low-Frequency Feedback Loop.

The low-frequency feedback loop, which consists of OTA1 and transistors M2 and M3, suppresses the low-frequency (square baseband) signals to enlarge the dynamic range of the output stage and to prohibit intermodulation products of the unwanted low frequent square baseband mixer current with the high-frequency signal. It also lowers the input impedance of the output stage at low frequencies. The operation can be further explained and illustrated by the numerical data given in Ref. 33 and Fig. 56.17. The LF loop has a gain bandwidth of 500 MHz and a high dc gain, which is obtained by using a cascoded OTA structure. The large gain results in a very small (<1 Ω) LF input impedance. In this way, no LF voltage signal is formed at the summing node. This is absolutely essential to obtain a linear operation of the mixer as an additional voltage signal is also up-converted. This structure offers the advantage that the LF and HF modulated current components are separated, and only the high-frequency component of the signal current is mirrored to the output. The dc current through M3 needs to be sufficiently large to reject all the LF current generated in the mixer transistors.

The High-Frequency Current Buffer.

The high-frequency current buffer (M2, M4) ensures a very low input impedance at high frequencies to realize the virtual ground node and mirrors the RF current component (~vlo·vbb) to the output. In Ref. 33, a 2.0-GHz GBW was obtained by designing gm_4 = 14 mS, consuming 5 mA dc current, and the parasitic capacitance at node 2 = 1.1 pF. As the loop gain is unity at 2 GHz, the input impedance of the output driver is determined by $1/g_m2$ = 12 Ω (Fig. 56.18). This low impedance also ensures the stability of the HF feedback loop. The pole at node 1, determined by the parasitic capacitance at the summing node and this input impedance, is at more than 3 times the GBW of HF feedback loop. For the second-order feedback system, this results in a phase margin of more than 68 degrees.

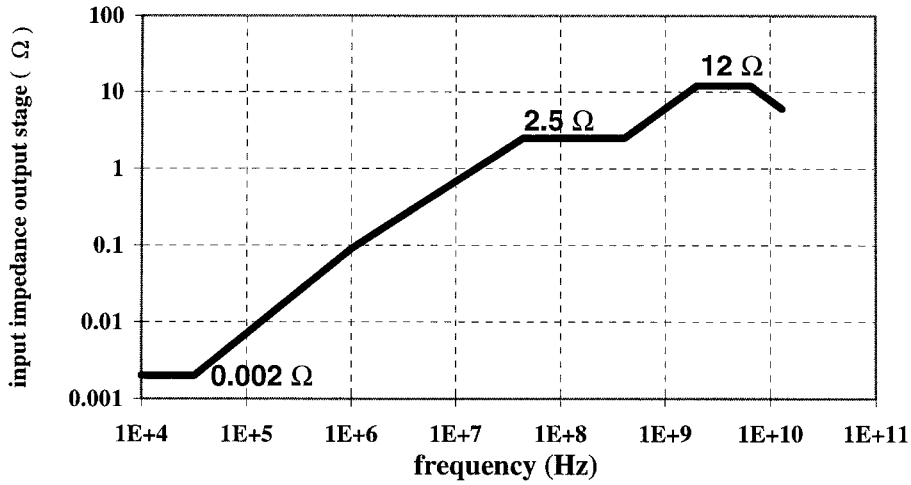

FIGURE 56.18 Input impedance on the virtual ground summing node.

Analysis of the Non-Linearities and the LO-Feedthrough

To obtain an optimal tradeoff between distortion, power consumption, frequency performance, signal power, and distortion, a profound analysis of the causes of the non-linearities is indispensable.

First, the intrinsic non-linearity of the voltage-to-current conversion by the mixer transistors is examined. As the LO feedthrough is also an unwanted signal in the signal band, it is also covered in this section.

A non-ideal virtual ground at the summing node has severe consequences for the modulated signal. A finite output conductance of the baseband signal has similar influences on the linearity of the output signal. These elements are investigated.

Intrinsic Non-Linearity of the Mixer Transistors.

Equations 56.24 and 56.25, which describe the generated current, are only valid if a very low impedance is seen at the drain and source nodes of the mixer transistors. If this condition is fulfilled, no unwanted high-frequency mixing components seem to appear in the modulated current. However, both in measurements and in simulations, a significant unwanted signal is noticed at oscillator frequency (f_{lo}) ± 3 times the baseband frequency (f_{bb}). As this signal originates from a product $v_{lo} \cdot v_{bb}^3$, the magnitude of this distortion component is expected to have the same third-order relationship to the baseband signal. However, only a second-order magnitude relationship is perceived if the virtual ground condition is fulfilled. An explanation for this effect has been searched and the result is described in the paragraphs that follow.

The observed phenomenon is a result of the short-channel effects in a MOS transistor. Both the mobility and the threshold voltage are affected by the gate-source and drain-source voltage. However, the calculated impact of the V_t dependency on the signal is an order of magnitude lower than the observed effect.

The distortion component can be explained by exploring the drain-source voltage dependency of μ_{eff} in the β factor. The expressions for β and μ_{eff} in the linear region are given by:

$$\beta = \mu_{eff} C_{ox} W/L, \text{ where } \mu_{eff} = \frac{\mu_0}{1 + \vartheta\left(V_{gs} - V_t\right) + \frac{\mu_0}{V_{max} L} V_{ds}} \tag{56.26}$$

where: μ_{eff} = The effective mobility
μ_0 = The surface mobility
ϑ = The empirical mobility modulation factor
V_{max} = The maximum drift velocity

If the summing node is made virtual ground and zero dc drain-source voltage is applied, drain and source of each mixer transistor alternate when a sinusoidal signal is applied. If the applied baseband signal is positive, the virtual ground node is the source of that mixer transistor; if the signal is negative, this node is the drain. Mathematically, the source and drain voltages of a mixer transistor can be described as:

$$v_s = \frac{v_{bb} - |v_{bb}|}{2} \qquad v_d = \frac{v_{bb} + |v_{bb}|}{2} \tag{56.27}$$

Equation 56.27 can be transformed to:

$$\mu_{eff} = \frac{\mu_0}{1 + \vartheta\left(V_{gs} - V_t\right)_{dc} + \vartheta\left(v_{lo} - \frac{v_{bb}}{2}\right) + \left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right)|v_{bb}|} \tag{56.28}$$

Substituting v_{bb} by $A\sin(\omega_{bb}t)$ and making the Fourier series expansion of $|v_{bb}|$ results in Eq. 56.29:

$$\mu_{eff} = \frac{\mu_0}{B\left(1 + \frac{\vartheta}{B}v_{lo} - \frac{\vartheta A}{2B}\sin\left(\omega_{bb}t\right) + C\cos\left(2\omega_{bb}t\right) + D\cos\left(4\omega_{bb}t\right) + \ldots\right)}$$

where: $A\sin\left(\omega_{bb}t\right) =$ The baseband signal

$$\begin{aligned} B &= 1 + \left(V_{gs} - V_t\right)_{DC} + \frac{2}{\pi}A\left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right) \\ &\approx 1 + \left(V_{gs} - V_t\right)_{DC} \\ C &= \frac{A}{B}\frac{4}{\pi 3}\left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right) \\ D &= \frac{A}{B}\frac{4}{\pi \cdot 3 \cdot 5}\left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right) \end{aligned} \tag{56.29}$$

The equation for μ_{eff} shows that a second-order baseband frequency component ($\cos(2\,\omega_{bb}t)$) appears. In the dc reduction factor B, the third term is an order of magnitude smaller than 1. Hence, it appears that the magnitude C of the second-order component has only a first-order relationship to the baseband signal amplitude A. In the mixer voltage-to-current relationship, μ_{eff} is multiplied with $v_{lo} \cdot v_{bb}$. As a result, a mixing component at $f_{lo} \pm 3f_{bb}$ occurs. The magnitude of this signal is only second-order related to the amplitude of the baseband signal. This explains the observed effect.

In the amplitude C of this distortion component, $\frac{\mu_0}{V_{max}L}$ is dominant to $\frac{\theta}{2}$ for most sub-micron CMOS technologies. It is important to notice that the distortion is inversely proportional to the gate length. This implies that this effect will become even more important when going to deeper sub-micron technologies.

Oscillator Feedthrough.

As a direct up-conversion topology is used, the oscillator feedthrough cannot be filtered and, consequently, it has to be as low as the other in-band unwanted frequency components. A signal at oscillator

frequency can have several origins: for example, capacitive feedthrough of the gate voltage or a component due to mixing of a dc drain-source voltage with the oscillator gate signal (see Eq. 56.23). The last is avoided by applying zero dc drain-source voltage over the mixer transistor, as stated earlier.

Due to the differential input voltages, the capacitive LO-feedthrough is canceled at the virtual ground node. However, this cancellation is never perfect, due to technology mismatch. The capacitive LO-feedthrough of one mixer transistor is given by (Eq. 56.30).

$$i_{lo} = \left(\frac{C_{ox}}{2} + \frac{C_{ov}}{L} \right) WLv_{lo} 2\pi f \tag{56.30}$$

where: C_{ox} = The oxide capacitance
C_{ov} = The gate-drain overlap capacitance
v_{lo} = The amplitude of the LO signal
f = The LO frequency

When the asymmetry caused by mismatches in the differential mixer structure is taken into account, the expression for the capacitive L.O.-feedthrough current is given by:

$$\Delta\left(i_{lo}\right) = \delta\left(i_{lo}\right) i_{lo} \tag{56.31}$$

where $\delta(i_{lo})$ is the relative difference in the LO-feedthrough for the differential mixer transistors.

Based on Eqs. 56.25, 56.30, and 56.31, the ratio between the LO feedthrough current and the modulated signal is given in Eq. 56.32.

$$\frac{i_{signal}}{\Delta\left(i_{lo}\right)} = \frac{2\mu C_{ox} \frac{W}{L} v_{bb} v_{lo}}{\delta\left(i_{lo}\right)\left(\frac{C_{ox}}{2} + \frac{C_{ov}}{L} \right) WLv_{lo} 2\pi f} \tag{56.32}$$

This formula can be simplified to:

$$\frac{i_{signal}}{\Delta\left(i_{lo}\right)} = \frac{\mu C_{ox} v_{bb}}{\delta\left(i_{lo}\right)\left(\frac{C_{ox}}{2} + \frac{C_{ov}}{L} \right) L^2 \pi f} \tag{56.33}$$

Even in the case where the two LO-feedthrough currents are added instead of canceled ($\delta(i_{lo}) = 1$), a ratio of 30 dBc signal to LO-feedthrough is achieved with a 1-GHz oscillator signal and a 316 mV baseband signal. If a relative inaccuracy ($\delta(i_{lo})$) of, for example, 10% on the parameters is taken into account, 50 dBc can easily be accomplished. This analysis illustrates the strategy not to rely on cancelling of RF signals to achieve the requirements.

56.6 Toward Fully Integrated Transceivers

Combining all of the above techniques has resulted in the recent development of single-chip CMOS transceiver circuits.[30] Figure 56.19 provides a microphotograph of the 0.25-μm CMOS transceiver test-circuit. The chip does not require a single external component, nor does it require any tuning or trimming. The objective of this design is to develop a complete system for wireless communications at 1.8 GHz that can be built with a minimum of surrounding components: only an antenna, a duplexer, a power amplifier,

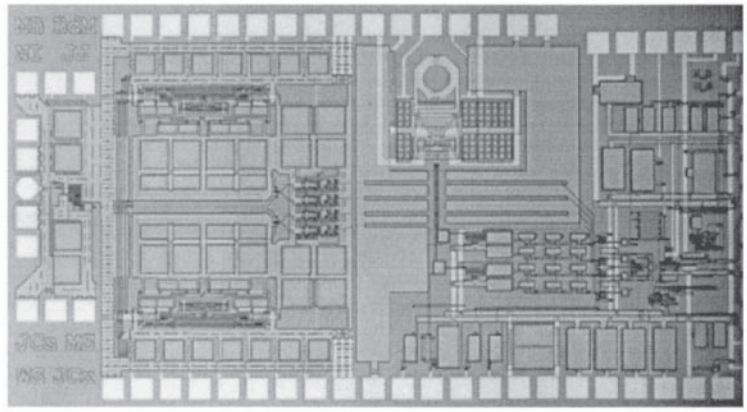

FIGURE 56.19 Microphotograph of a 0.25-μm CMOS transceiver test-circuit.

and a baseband signal processing chip. The high level of integration is achieved using a low-IF topology for reception, a direct quadrature up-conversion topology for transmission, and an oscillator with on-chip integrated inductor. The presented chip has been designed for the DCS-1800 system, but the broadband nature of the LNA, the down-converter, the up-converter, and the output amplifier makes the presented techniques equally suited for use at other frequencies, for example, for use in a DCS-1900 or a DECT system. The presented circuit consumes 240 mW from a 2.5-V supply and occupies a die area of 8.6 mm^2.

56.7 Conclusions

The trends toward deep sub-micron technologies have resulted in the exploration by several research groups of the possible use of CMOS technologies for the design of RF circuits. Especially the development of new receiver topologies, such as quasi-IF and low-IF topologies, in combination with highly linear down-converters, has opened the way to fully integrated down-converters with no external filters or components. However, due to the moderate speed performance of the present sub-micron technologies, lower noise circuits in combination with less power drain have to be worked out. The trends toward deep sub-micron technologies will allow us to achieve those goals as long as the short-channel effects do not limit the performance concerning linearity and intermodulation problems.

Concerning synthesizers, in the last few years, high-performance, low phase noise, low power drain, fully integrated VCO circuits have been demonstrated. Starting with difficult post-processing techniques, research has resulted in the use of standard CMOS technologies using bondwires as inductors. Today, even low phase noise performances with optimized integrated spiral inductors in standard CMOS technologies without any post-processing, tuning, trimming, or external components have been announced. This opens the way toward fully integrated receiver circuits.

However, telecommunication systems are usually two-way systems, requiring transmitter circuits as well. It is only recently that CMOS up-converters with moderate output power have been announced in open literature. Again, thanks to the trends toward deep sub-micron technologies, fully integrated CMOS transmitter circuits with an acceptable power consumption will be feasible. This opens the way for fully integrated transceiver circuits in standard CMOS technologies.

57.1 Introduction

What Is and Why Phase-Locked?

Phase-locked loop (PLL) is a circuit architecture that causes a particular system to track with another one. More precisely, PLL synchronizes a signal (usually a local oscillator output) with a reference or an input signal in frequency as well as in phase.

Phase locking is a useful technique that can provide effective synchronization solutions in many data transmission systems such as optical communications, telecommunications, disk drive systems, and local networks, in which data is transmitted in baseband or passband. In general, only data signals are transmitted in most of these applications; namely, clock signals are not transmitted in order to save hardware cost. Therefore, the receiver should have some schemes to extract the clock information from the received data stream in order to recover transmitted data. The scheme is called a *timing recovery* or *clock recovery* circuit.

The cost of electronic interfaces in communication systems is higher in conjunction with the higher data rate. Hence, high-speed circuits are the practical issue of the high data rate systems implementation, and advanced VLSI technology plays an important role in cost reduction for the high-speed communication systems.

Basic Operation Concepts of Phase-Locked Loops (PLLs)

Typically, a PLL consists of three basic functional blocks: a phase detector (PD), a loop filter (LF), and a voltage-controlled oscillator (VCO). The PD detects the phase difference between the VCO output and the input signal, and generates a signal proportional to the phase error. The PD output contains a dc component and an ac component; the former is accumulated and the latter is filtered by the loop filter. The loop filter output that is near a dc signal is applied to the VCO. This almost dc control voltage

changes the VCO frequency toward a direction to reduce the phase error between the input signal and the VCO. Depending on the type of loop filter used, the steady-state phase error will be reduced to zero or to a finite value.

PLL has an important feature: the ability to suppress both the noises superimposed on the input signal and generated by the VCO. The narrower the bandwidth of the PLL, the more effective jitter filtering the PLL can achieve. However, the error of the VCO frequency cannot be reduced rapidly. Although a narrow bandwidth is better for rejecting large amounts of input noise, it also prolongs the settling time in the acquisition process. So, there is a tradeoff between jitter filtering and fast acquisition.

Classification of PLL Types

Different PLL types are built from different classes of building blocks. The first PLL ICs appeared around 1965 and were purely analog devices. In the so-called "*linear PLLs*" (LPLLs), an analog multiplier (four-quadrant) is used as the phase detector, the loop filter is built from a passive or an active RC filter, and the voltage-controlled oscillator is used to generate the output signal of the PLL. In most cases, the input signal to this linear PLL is a sine wave, whereas the VCO output signal is a symmetrical square wave.

The classical *digital PLL* (DPLL) uses a digital phase detector such as an XOR gate, a JK-flipflop, or a phase-frequency detector (PFD), with the remaining blocks still being the same as LPLL. In many aspects, the DPLL performance is similar to the LPLL.

The function blocks of the *all-digital PLL* (ADPLL) is implemented by purely digital circuits, and the signals within the loop are digital too. Digital versions of the phase detector are the same as DPLL. The digital loop filter is built from an ordinary up/down counter, N-before-M counter, or K-counter.[1] The digital counterpart of the VCO is the digital-controlled oscillator (DCO).[2,3]

Analogous to filter designs, PLLs can be implemented by software such as a microcontroller, microcomputer, or digital signal processing (DSP); this type of PLL is called *software PLL* (SPLL).

57.2 PLL Techniques

Basic Topology

A phase-locked loop is a feedback system that operates and minimizes the phase difference between two signals. Figure 57.1 is the basic function block of a PLL, which consists of a phase detector (PD), a loop filter, and a VCO. The PD works as a phase error amplifier. It compares the phase of the VCO output signal $u_o(t)$ with the phase of the reference signal $u_i(t)$ and develops an output signal $u_d(t)$, that is proportional to the phase error θ_e. Within a limited range

$$u_d\left(t\right) = k_d\theta_e \tag{57.1}$$

where k_d represents the gain of the PD and the unit of k_d is volt/rad.

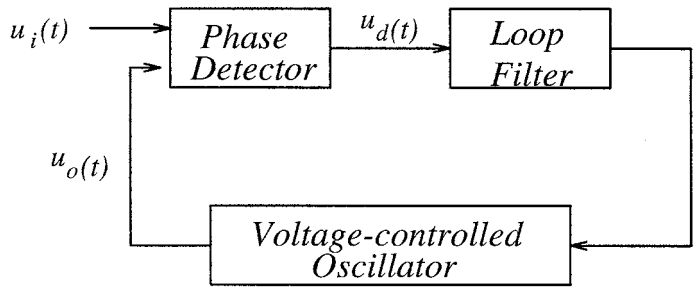

FIGURE 57.1 Basic block diagram of the PLL.

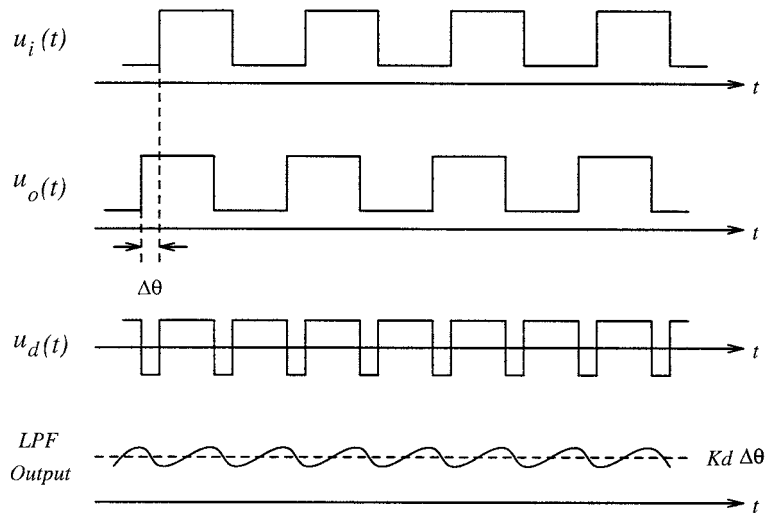

FIGURE 57.2 Waveforms in a PLL.

The output signal $u_d(t)$ of the PD consists of a dc component and a superimposed ac component. The latter is undesired and removed by the loop filter (LPF). Thus, the LPF generates an almost-dc control voltage for the VCO to oscillate at a frequency equal to the input frequency.

How the building blocks of the basic PLL work together will be explained in the following. First, the angular frequency ω_i of the input signal $u_i(t)$ is assumed equivalent to the central frequency ω_o of the VCO signal $u_o(t)$. Now, a small positive frequency step is applied to $u_i(t)$ at $t = t_o$ (shown in Fig. 57.2). $u_i(t)$ accumulates a phase faster than $u_o(t)$ of the VCO does. The PD then generates wider pulses increasingly, which results in a higher dc voltage at the LPF output to increase the VCO frequency. Depending on the type of the loop filter, the final phase error will be reduced to zero or to a finite value.

It is important to note from the descriptions in the above that the loop locks only after two conditions are satisfied: (1) ω_i and ω_o are equal and (2) the phase difference between the input $u_i(t)$ and the VCO output $u_o(t)$ settles to a steady-state value. If the phase error varies with time so fast that the loop is unlocked, the loop must keep on the transient process, which involves both *frequency acquisition* and *phase acquisition.*

To design a practical PLL system, it is required to know the status of the responses of the loop if (1) the input frequency is varied slowly (tracking process), (2) the input frequency is varied abruptly (lock-in process), and (3) the input and the output frequencies are not equal initially (acquisition process). Using linear PLL as an example, these responses will be shown in the following subsections.

Loop Order of the PLL

Second-Order Loop

The loop order of the PLL depends on the characteristics of the loop filter; therefore, the loop filter is a key component that affects the PLL dynamic behavior. Figure 57.3 shows three types of loop filters that are widely used. Figure 57.3(a) is a passive lead-lag filter; the associate transfer function $F(s)$ is given by

$$F(s) = \frac{1 + s\tau_2}{1 + s(\tau_1 + \tau_2)} \tag{57.2}$$

where $\tau_1 = R_1C$ and $\tau_2 = R_2C$. Figure 57.3(b) shows an active lead-lag filter; its transfer function is

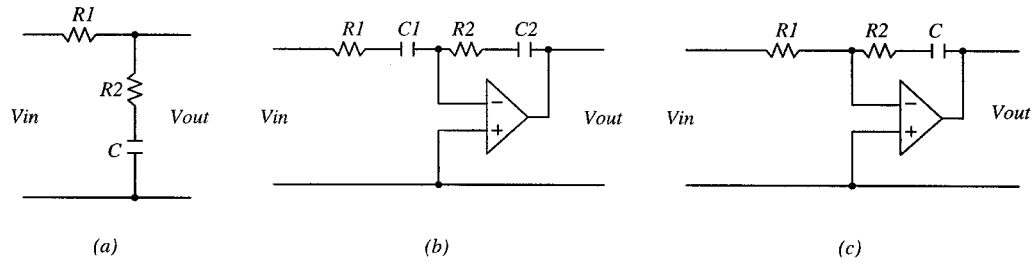

FIGURE 57.3 (a) Passive lead-lag filter, (b) active lead-lag filter, and (c) active PI filter.

$$F(s) = k_a \frac{1+s\tau_2}{1+s\tau_1} \tag{57.3}$$

where $\tau_1 = R_1C_1, \tau_2 = R_2C_2$ and $k_a = -\frac{C_1}{C}$. A PI filter is shown in Fig. 57.3(c), where PI stands for *Proportional and Integral* action. The transfer function is given by

$$F(s) = \frac{1+s\tau_2}{s\tau_1} \tag{57.4}$$

where $\tau_1 = R_1C$ and $\tau_2 = R_2C$. Their Bode diagrams are shown in Fig. 57.4 respectively. High-order filters could be used in some applications, but additional filter poles introduce a phase shift. High-order systems are not trivial generally to maintain a stable system.

Figure 57.5 shows the linear block diagram of the PLL. According to control theory, the closed loop transfer function of PLL can be derived as

$$H(s) \triangleq \frac{\theta_o(s)}{\theta_i(s)} = \frac{k_d k_o F(s)}{s + k_d k_o F(s)} \tag{57.5}$$

where k_d with units V/rad is called the phase-detector gain, k_o is the VCO gain factor and has units rad/s-V. In addition to the phase transfer function, a phase-error transfer function $H_e(s)$ is defined as follows:

$$H_e(s) \triangleq \frac{\theta_e(s)}{\theta_i(s)} = \frac{s}{s + k_d k_o F(s)} \tag{57.6}$$

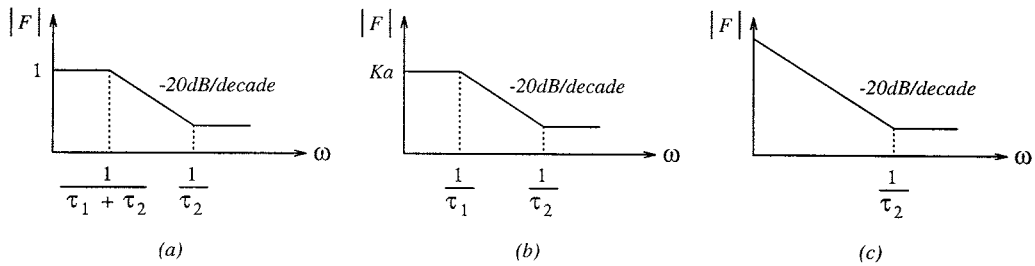

FIGURE 57.4 Bode diagrams of (a) passive lead-lag filter, (b) active lead-lag filter, and (c) active PI filter.

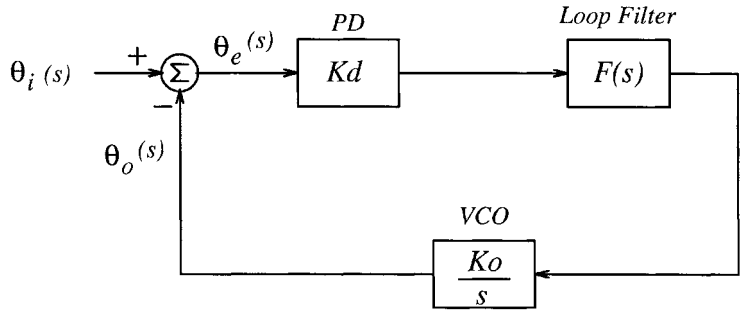

FIGURE 57.5 Linear model of PLL.

The transfer functions of the loop filters shown in Fig. 57.3 are substituted for $F(s)$ in Eq. 57.5 in order to analyze the phase transfer function. We obtain the phase transfer functions as follows:

For the passive lead-lag filter,

$$H(s) = \frac{k_d k_o \dfrac{1+s\tau_2}{\tau_1+\tau_2}}{s^2 + s\dfrac{1+k_d k_o \tau_2}{\tau_1+\tau_2} + \dfrac{k_d k_o}{\tau_1+\tau_2}} = \frac{\omega_n\left(2\zeta - \dfrac{\omega_n}{k_d k_o}\right)s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{57.7}$$

For the active lead-lag filter,

$$H(s) = \frac{k_d k_a k_o \dfrac{1+s\tau_2}{\tau_1}}{s^2 + s\dfrac{1+k_d k_a k_o \tau_2}{\tau_1} + \dfrac{k_d k_a k_o}{\tau_1}} = \frac{\omega_n\left(2\zeta - \dfrac{\omega_n}{k_d k_o k_a}\right)s + \omega}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{57.8}$$

For the active PI filter,

$$H(s) = \frac{k_d k_o \dfrac{1+s\tau_2}{\tau_1}}{s^2 + s\dfrac{k_d k_o \tau_2}{\tau_1} + \dfrac{k_d k_o}{\tau_1}} = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{57.9}$$

where ω_n is the *natural frequency* and ξ is the *damping factor*. These two parameters are important to characterize a PLL. If the condition $k_d k_o \gg \omega_n$ or $k_d k_o k_o \gg \omega_n$ is true, this PLL system is called a *high-gain loop*. If the reverse is true, the system is a *low-gain loop*. Most practical PLLs are high-gain loops for good tracking performance. For a high-gain loop, Eqs. 57.7 to 57.9 become approximately

$$H(s) \approx \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{57.10}$$

Similarly, assuming a high-gain loop, the approximate expression of the phase-error transfer function $H_e(s)$ for all three loop filter types becomes

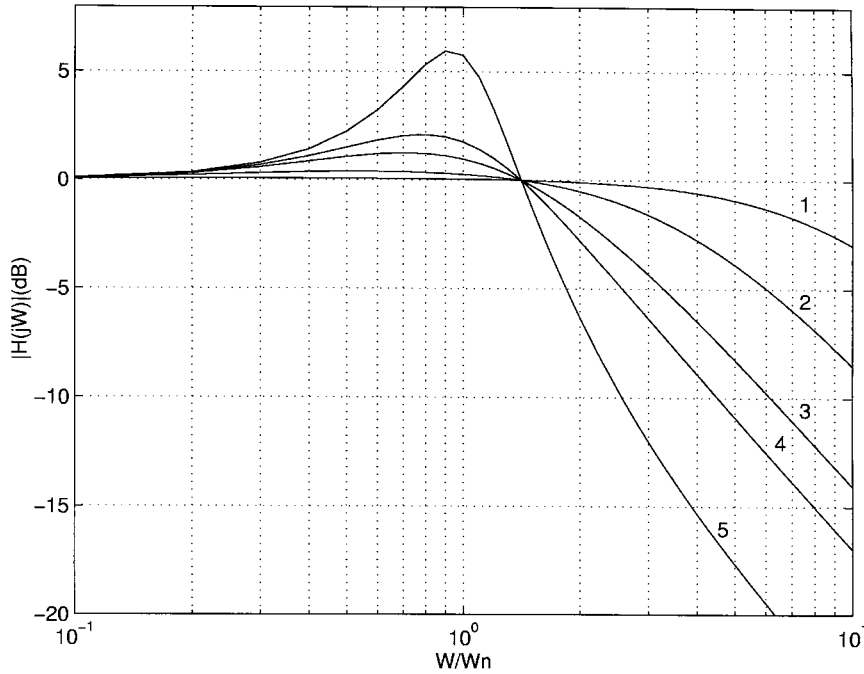

FIGURE 57.6 Frequency responses of the phase transfer function $H(j\omega)$ for different damping factors. Trace 1: ζ = 5, Trace 2: ζ = 2, Trace 3: ζ = 1, Trace 4: 5 = 0.707, Trace 5: 3 = 0.3.

$$H_e(s) \approx \frac{s^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{57.11}$$

Because the highest power of s in the denominator of the transfer function is 2, the loop is known as the second-order loop.

The magnitude of the frequency responses of $H_e(s)$ for a high-gain loop with several values of damping factor are plotted in Fig. 57.6. It shows that the loop performs a low-pass filtering on the input phase signal. That is, the second-order PLL is able to track both phase and frequency modulations of the input signal as long as the modulation frequency remains within the frequency band roughly between zero and ω_n.

The magnitude of the frequency responses of $H_e(s)$ are plotted in Fig. 57.7. A high-pass characteristic is derived. It indicates that the second-order PLL tracks the low-frequency phase error but cannot track high-frequency phase error.

The transfer function $H(s)$ has a –3dB frequency, ω_{-3db}. ω_{-3db} stands for the closed-loop bandwidth of the PLL. The relationship between ω_{-3db} and ω_n is presented here to provide a comparison with the familiar concept of bandwidth. In the high-gain loop case, by setting $|H(j\omega)| = \frac{1}{\sqrt{2}}$ and solving for ω, we find that

$$\omega_{-3db} = \omega_n \left[2\zeta^2 + 1 + \sqrt{\left(2\zeta^2 + 1\right)^2} \right]^{\frac{1}{2}} \tag{57.12}$$

The relationship between ω_{-3db} and ω_n for different damping factors is plotted in Fig. 57.8.[4]

Other-Order Loop

The second-order PLL with a lead-lag loop filter is commonly used because the lead-lag filter has two time constants to determine the natural frequency and the damping factor independently. Therefore, a

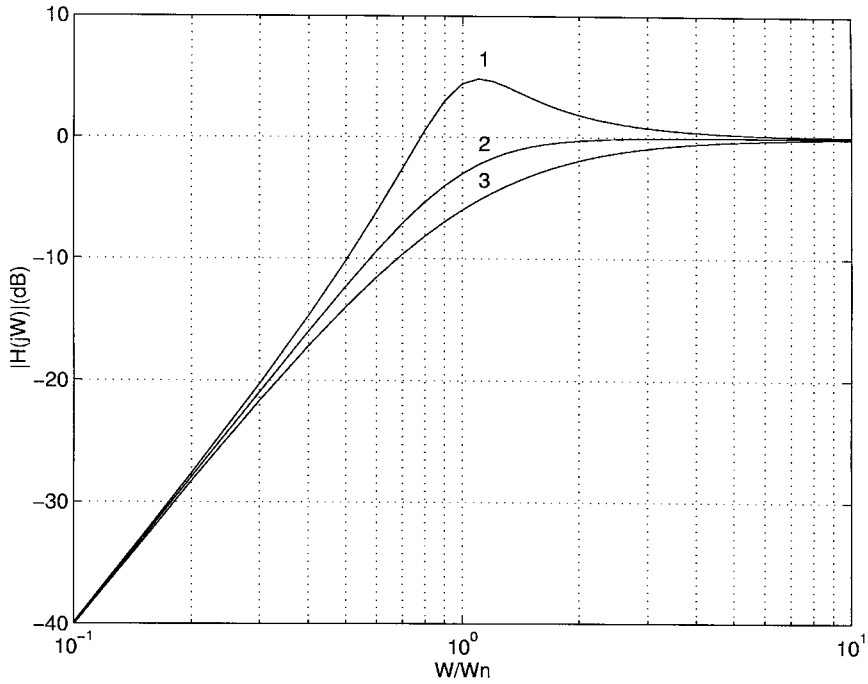

FIGURE 57.7 Frequency responses of the phase-error transfer function $H_e(j\omega)$ for different damping factors. Trace 1: $\zeta = 0.3$, Trace 2: $\zeta = 0.707$, Trace 3: $\zeta = 1$.

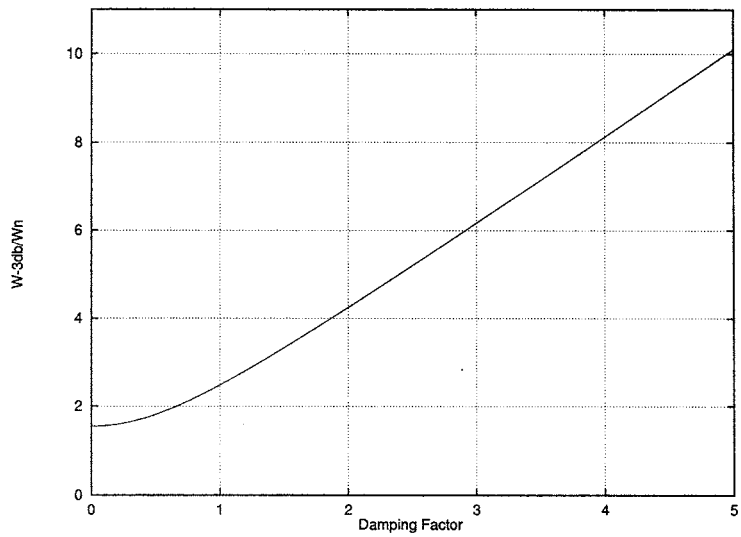

FIGURE 57.8 ω_{-3db} bandwidth of a second-order loop versus different damping factors.

high dc loop gain for good tracking, while maintaining an overdamped PLL system, can be achieved. No loop filter and single pole loop filter cases are discussed briefly in the following for completeness.

If the loop filter is left out, a first-order loop is obtained. As shown in Fig. 57.5, set $F(s) = 1$ and the closed-loop transfer function can be derived as

$$H(s) = \frac{k}{s+k} \tag{57.13}$$

where $k = k_d k_o$. If it is necessary to design a high dc gain loop for fast tracking, then the bandwidth of the PLL must be wide enough because the dc loop gain k is the only parameter available, which is not suitable for noise suppression. Therefore, fast tracking and narrow bandwidth are incompatible in a first-order loop.

Another commonly used loop filter is the passive lag filter. The transfer function is

$$F(s) = \frac{1}{1+s\tau} \tag{57.14}$$

The closed-loop transfer function can be derived as

$$H(s) = \frac{\frac{k_d k_o}{\tau}}{s^2 + \frac{1}{\tau}s + \frac{k_d k_o}{\tau}} = \frac{\tau\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{57.15}$$

where $\omega_n = \sqrt{\frac{k_d k_o}{\tau}}$ and $\zeta = \frac{1}{2\sqrt{\tau k_d k_o}}$. Although there are two parameters (τ and $k = k_o k_d$) available, three loop parameters must be determined (ω_n, ξ,k). That is if it is necessary to have a large dc loop gain and a narrow bandwidth, the loop will be severely underdamped and the transient response will be poor.

A high-order filter is used for critical applications because it provides better noise filtering. However, it is difficult to design a high-order loop due to some problems such as loop stability.

Tracking Process

The linear model of a PLL shown in Fig. 57.5 is suitable for analyzing the tracking performance of a PLL that is initially locked, but with small phase error. If the phase error changes so abruptly that the PLL loses lock, a large phase error will be induced, even if it happens only momentarily. The unlock condition is a non-linear process that cannot be analyzed by a linear model. The acquisition process will be described later.

At first, consider a step phase error applied to the input. The input phase signal is $\theta_i(t) = \Delta\theta u(t)$, the Laplace transform of the input is $\theta_i(s) = \frac{\Delta\theta}{s}$, which is substituted into Eq. 57.11 to get

$$\theta_e(s) = \frac{\Delta\theta}{s} \frac{s^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{57.16}$$

According to the final value theorem of the Laplace transform,

$$\lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) = 0$$

In other words, the loop will eventually track on the step phase change without steady-state phase error.

Applying a step change of frequency $\Delta\omega$ to the input, the input phase change is a ramp (i.e., $\theta_i(t) = \Delta\omega t$); therefore, $\theta_i(s) = \frac{\Delta\omega}{s^2}$. Substituting $\theta_i(s)$ in Eq. 57.6 and applying the final value theorem, one obtains

$$\begin{aligned} \theta_v &= \lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) \\ &= \lim_{s\to 0} \frac{\Delta\omega}{s + k_d k_o F(s)} \end{aligned} \tag{57.17}$$

$$= \frac{\Delta\omega}{k_d k_o F(0)}$$

$$= \frac{\Delta\omega}{k_v}$$

θ_v is called the *velocity error* or *static phase error.*[4] Because the input frequency almost never agrees exactly with the VCO free-running frequency, there is a frequency difference $\Delta\omega$ between the two. From Eq. 57.17, if the PLL has a high dc loop gain, (i.e., $k_d k_o F(0) \gg \Delta\omega$), the steady-state phase error to a step frequency error input approaches zero. This is the reason why a high-gain loop has a good tracking performance. Now the advantage of a second-order loop using an active loop filter of high dc gain is evident. The active lead-lag loop filter with a high dc gain will make the steady-state phase error approach zero and the noise bandwidth narrow simultaneously, which is impossible in a first-order loop.

If the input frequency is changed linearly with time at a rate of $\Delta\dot{\omega}$, which is $\theta_i(t) = \frac{1}{2}\,\Delta\dot{\omega}\,t^2$, so $\theta_i(s) = \frac{\Delta\dot{\omega}}{s^3}$. According to a high-gain loop and applying the final value theorem of Laplace transform, then

$$\begin{aligned} \theta_a &= \lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) \\ &= \frac{\Delta\dot{\omega}}{\omega_n^2} \end{aligned} \tag{57.18}$$

θ_a is called an *acceleration error* (sometimes called *dynamic tracking error* or *dynamic lag*).[4]

In some applications, PLL needs to track an accelerating phase error without static tracking error. The expression of the static phase error when frequency ramp is applied

$$\theta_e(s) = \lim_{s\to 0} \frac{\Delta\omega}{s\left(s + k_d k_o F(s)\right)} \tag{57.19}$$

For θ_e to be zero, it is necessary to make $F(s)$ be a form of $\frac{G(s)}{s^2}$, where $G(0) \neq 0$. $\frac{G(s)}{s^2}$ implies that the loop filter has two cascade integrators. This is a third-order loop. In order to eliminate the static acceleration error, a third-order loop is very useful for some special applications, such as satellites and missiles systems.

Based on Eq. 57.18, a large natural frequency ω_n is used to reduce the static tracking phase error in a second-order loop; however, a wide natural frequency has an undesired noise filtering performance. In contrast, the zero tracking phase error for a frequency ramp error is concordant with a small loop bandwidth in a third-order loop.

The preceding analysis on tracking process is under the assumption that the phase error is relatively small and the loop is linear. If the phase error is large enough to make the loop drop out of lock, the linear assumption is invalid. For a sinusoidal-characteristic phase detector, the exact phase expression of Eq. 57.17 should be

$$\sin\theta_v = \frac{\Delta\omega}{k_v} \tag{57.20}$$

The sine function has solutions when $\Delta\omega \le k_v$. Therefore, there is no solution if $\Delta\omega > k_v$. This is the case when the loop loses lock and the output of the phase detector will be beat notes signal rather than a dc control voltage. Therefore, k_v can be used to define the *hold range* of the PLL; that is

$$\Delta\omega_H = \pm k_v = k_o k_d F(0) \tag{57.21}$$

The hold range is the frequency range in which a PLL is able to maintain lock *statically*. Namely, if input frequency offset exceeds the hold range statically, the steady-state phase error would drop out of the linear range of the phase detector and the loop loses lock. The hold range expressed in Eq. 57.21 is not correct when some other components in PLL are saturated earlier than the phase detector. k_v is a function of k_o, k_d, and $F(0)$. The dc gain $F(0)$ of the loop filter depends on the filter type. Then hold range $\Delta\omega_H$ can be $k_o k_d$, $k_o k_d k_a$, and ∞ for passive lead-lag filter, active lead-lag filter, and active PI filter, respectively. When the PI filter is used, the real hold range is actually determined by the control range of the VCO.

Considering the dynamic phase error θ_a in a second-order loop, the exact expression for a sinusoidal characteristic phase detector is

$$\sin\theta_a = \frac{\Delta\dot{\omega}}{\omega_n^2} \tag{57.22}$$

which implies that the maximum change rate of the input frequency is ω_n^2. If the rate exceeds ω_n^2, the loop will fall out of lock.

Lock-in Process

The *lock-in* process is defined as PLL locks within one single beat note between the input and the output (VCO output) frequency. The maximum frequency difference between the input and the output that the PLL can lock within one single beat note is called the *lock-in range* of the PLL.

Figure 57.9 is the case in which a frequency offset $\Delta\omega$ is less than the lock-in range. Then, PLL will lock within one single beat note between ω_i and ω_o, and the lock-in process happens. In Fig. 57.10(b), the frequency offset $\Delta\omega$ between input (ω_i) and output (ω_o) is larger than the lock-in range; hence, the lock-in process will not take place, at least not instantaneously.

The magnitude of the lock-in range can be derived approximately in the following. Suppose the PLL is unlocked initially. The input frequency ω_i is $\omega_o + \Delta\omega$. If the input signal $v_i(t)$ is a sine wave and given by

$$v_i(t) = A_i \sin(\omega_o t + \Delta\omega t) \tag{57.23}$$

and the VCO output signal $v_o(t)$ is usually a square wave written as a Walsh function[5]

$$v_o(t) = A_o W(\omega_o t) \tag{57.24}$$

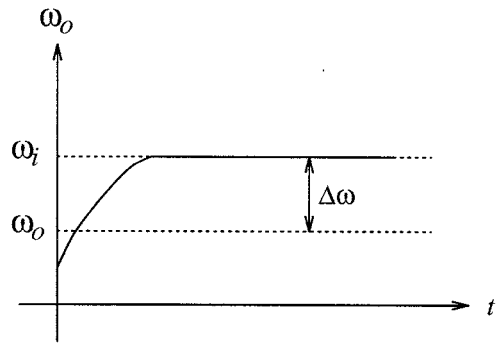

FIGURE 57.9 Lock-in process of the PLL.

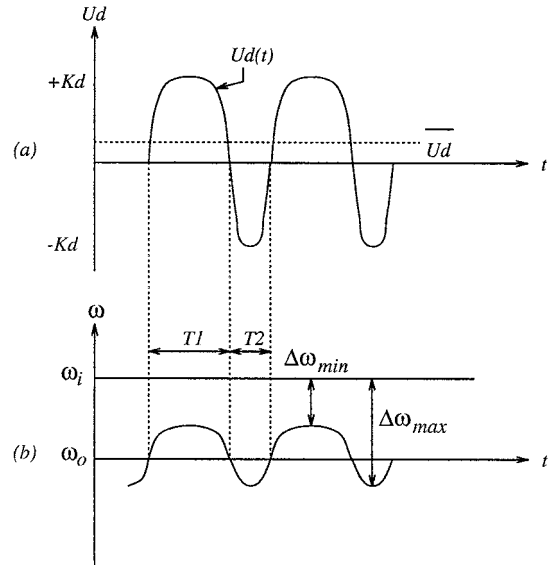

FIGURE 57.10 Pull-in process of the PLL.

$v_o(t)$ can be replaced by the Fourier Series,

$$v_o(t) = A_o\left[\frac{4}{\pi}\cos(\omega_o t) + \frac{4}{3\pi}\cos(3\omega_o t) + \ldots\right] \tag{57.25}$$

So, the phase detector output v_d is

$$\begin{aligned} v_d(t) = v_i(t)v_o(t) &= A_i A_o\left[\frac{2}{\pi}\sin(\Delta\omega t) + \ldots\right] \\ &= k_d \sin(\Delta\omega t) + \textit{high-frequency terms} \end{aligned} \tag{57.26}$$

The high-frequency components can be filtered out by the loop filter. The output of the loop filter is given by

$$v_f(t) \approx k_d \left|F(\Delta\omega)\right| \sin(\Delta\omega t) \tag{57.27}$$

The peak frequency deviation based on Eq. 57.27 is equal to $k_d k_o |F(\Delta\omega)|$. If the peak deviation is larger than the frequency error between ω_i and ω_o, the lock-in process will take place. Hence, the lock-in range is given by

$$\Delta\omega_L = k_d k_o \left|F(\Delta\omega_L)\right| \tag{57.28}$$

The lock-in range is always larger than the corner frequency $\frac{1}{\tau_1}$ and $\frac{1}{\tau_2}$ of the loop filter in practical cases. An approximation of the loop filter gain $F(\Delta\omega_L)$ is shown as follows:

For the passive lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1 + \tau_2}$$

For the active lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx k_a \frac{\tau_2}{\tau_1}$$

For the active PI filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1}$$

τ_2 is usually much smaller than τ_1, and the $F(\Delta\omega_L)$ can be further approximated as follows:

For the passive lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1}$$

For the active lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx k_a \frac{\tau_2}{\tau_1}$$

For the active PI filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1}$$

Substituting the above equations into Eq. 57.28 and assuming a high-gain loop,

$$\Delta\omega_L = 2\zeta\omega_n \tag{57.29}$$

can be obtained for all three types of loop filters shown in Fig. 57.3.

Acquisition Process

Suppose that the PLL does not lock initially, and the input frequency is $\omega_i = \omega_o + \Delta\omega$, where ω_o is the initial frequency of VCO. If the frequency error $\Delta\omega$ is larger than the lock-in range, the lock-in process will not happen. Consequently, the output signal $u_d(t)$ of the phase detector shown in Fig. 57.10(a) is a sine wave that has a frequency $\Delta\omega$. The ac phase detector output signal $u_d(t)$ passes through the loop filter. Then the output $u_f(t)$ of the loop filter modulates the VCO frequency. As shown in Fig. 57.10(b), when ω_o increases, the frequency difference between ω_i and ω_o becomes smaller and vice versa.Therefore,

the phase detector output $u_d(t)$ becomes asymmetric. That is, the duration of positve half-periods of the phase detector output is larger than the negative ones. The average value $\overline{u_d(t)}$ of the phase detector output therefore goes to slightly positive. Then the frequency of VCO will be pulled up until it reaches the input frequency. This phenomenon is called a *pull-in process.*

Because the pull-in process is a non-linear behavior, the mathematical analysis is quite complicated. According to the results in Ref. 1, the pull-in range and the pull-in time depend on the type of loop filter. For an active lead-lag filter with a high-gain loop, the pull-in range is

$$\Delta\omega_P \approx \frac{4\sqrt{2}}{\pi}\sqrt{\zeta\omega_n k_o k_d} \tag{57.30}$$

and the pull-in time is

$$T_P \approx \frac{\pi^2}{16}\frac{\Delta\omega_0^2 k_a}{\zeta\omega_n^3} \tag{57.31}$$

where $\Delta\omega 0$ is the initial frequency error. Equations 57.30 and 57.31 will be modified for different types of phase detectors.[1]

Aided Acquisition

The PLL bandwidth is always too narrow to lock a signal of large frequency error. Furthermore, the frequency acquisition is slow and impractical. Therefore, there are aided frequency-acquisition techniques to solve this problem, such as the frequency-locked loop (FLL) and bandwidth-widening methods.

The frequency-locked loop, which is very similar to a PLL, is composed of a frequency discriminator, a loop filter, and a VCO. PLL is a coherent mechanism to recover a signal buried in noise. FLL, in contrast, is a non-coherent scheme that cannot distinguish between signal and noise. Therefore, an FLL can only be useful to provide signal frequency, which usually implies that the input signal power must exceed the noise.

The major difference between PLL and FLL is the phase detector and the frequency discriminator. The frequency discriminator is the frequency detector in the FLL. It generates a voltage proportional to the frequency difference between the input and the VCO. The frequency difference will be driven to zero in a negative feedback fashion. If a linear frequency detector is employed, it can be shown that the frequency-acquisition time is proportional to the logarithm of the frequency error.[6] In the literature, some frequency detectors like the quadricorrelator,[7] balance quadricorrelator,[8] rotational frequency detector,[9] and frequency delimiter[10] are disclosed.

Delay-Locked Loop

Two major approaches for adjustable timing elements are VCO and voltage-controlled delay line (VCDL). Figure 57.11 shows a typical delay-locked loop (DLL)[11,12] that replaces the VCO of a PLL with a VCDL. The input signal is delayed by an integer multiple of the signal period because the phase error is zero when the phase difference between V_{in} and V_o approaches a multiple of the signal periods. The VCDL usually consists of a number of cascaded gain stages with variable delay. Delay lines, unlike ring oscillators, cannot generate a signal; therefore, it is difficult to make frequency multiplication in a DLL.

In a VCO, the output "frequency" is proportional to the input control voltage. The phase transfer function contains a pole, which is $H(s) = \frac{k_o}{s}$ (k_o is the VCO gain). In a VCDL, the output "phase" is proportional to the control voltage, and the phase transfer function is $H(s) = k_{VCDL}$. So, the DLL can be

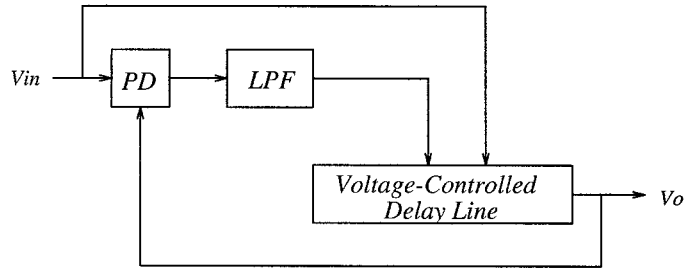

FIGURE 57.11 DLL block diagram.

easily stabilized with a simple first-order loop filter. Consequently, DLLs have much more relaxed tradeoffs among gain, bandwidth, and stability. This is one of the two important advantages over PLLs. Another advantage is that delay lines typically introduce much less jitter than a VCO.[13] Because a delay chain is not configured as a ring oscillator, there is no jitter accumulation because the noise does not contribute to the starting point of the next clock cycle.

Charge-Pump Phase-Locked Loop

A charge-pump PLL usually consists of four major blocks as shown in Fig. 57.12. The phase detector is a purely phase-frequency detector. The charge-pump circuit converts the digital signals UP, DN, and null (neither up nor down) generated by the phase detector into a corresponding charge-pump current I_p, $-I_p$, and zero. The loop filter is usually a passive RC circuit converting the charge-pump current into an analog voltage to control the VCO. So, the purpose of the "charge-pump" is to convert the logic state of the phase-frequency detector output into an analog signal suitable for controlling the voltage-controlled oscillator. The linear model of a charge-pump PLL is shown in Fig. 57.13. The k_d is the equivalent gain of a charge-pump circuit and a loop filter, which is shown in Fig. 57.14. If the loop bandwidth is much smaller than the input frequency, the detailed behavior within a single cycle can be ignored. Then, the state of a PLL can be assumed to be only changed by a small amount during each input cycle. Actually, the "average" behavior over many cycles is interesting. Then, the average current charging the capacitor is given by

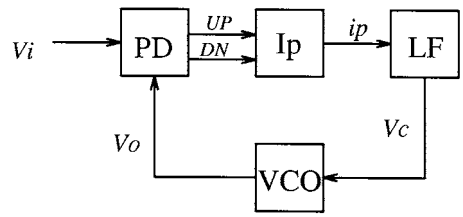

FIGURE 57.12 Charge-pump PLL diagram.

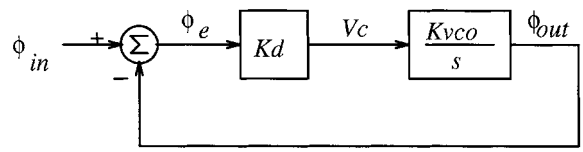

FIGURE 57.13 The linear model of charge-pump PLL.

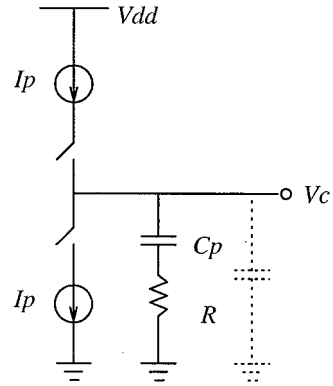

FIGURE 57.14 The schematic of a loop filter

$$\begin{aligned} I_{avg} &= \frac{Q}{T} = \frac{I\Delta t}{T} \\ &= \frac{I\left(\frac{\phi e}{2\pi}\right)T}{T} \\ &= \frac{I\phi_e}{2\pi} \end{aligned} \tag{57.32}$$

And the average k_d in Fig. 57.13 is

$$k_d \triangleq \frac{v_c}{\phi_e} = \frac{I}{2\pi}\left(R + \frac{1}{C_p s}\right) \tag{57.33}$$

The closed-loop transfer function can be obtained as

$$\begin{aligned} H(s) \triangleq \frac{\phi_{out}}{\phi_{in}} &= \frac{k_d \frac{k_{vco}}{s}}{1 + \frac{k_d k_{vco}}{s}} \\ &= \frac{\frac{I}{2\pi C_p}\left(RC_p s + 1\right)k_{vco}}{s^2 + \frac{I}{2\pi}k_{vco}Rs + \frac{Ik_{vco}}{2\pi C_p}} \end{aligned} \tag{57.34}$$

Generally, a second-order system is characterized by the natural frequency $f_n = \frac{\omega_n}{2\pi}$ and the damping factor ζ. So,

$$\begin{aligned} \omega_n &= \sqrt{\frac{I}{2\pi C_p}k_{vco}}\ rad\ \sec \\ \zeta &= \frac{RC_p}{2}\omega_n \end{aligned} \tag{57.35}$$

For the stability consideration, there is a limitation of a normalized natural frequency F_N:[14]

$$F_N \triangleq \frac{f_n}{f_i} < \frac{\sqrt{1+\zeta^2}-\zeta}{\pi} \tag{57.36}$$

In the single-ended charge pump, the resistor added in series with the capacitor shown in Fig. 57.14 can introduce "ripple" in the control voltage V_c even when the loop is locked.[15] The ripple control voltage modulates the VCO frequency and results in phase noise. This effect is especially undesired in frequency synthesizers. In order to suppress the ripple, a second-order loop filter, as shown in Fig. 57.14 with a shunt capacitor in dotted lines, is used. This configuration introduces a third pole in the PLL. Stability issues must be taken care of. Gardner[15] provides criteria for the stability of the third-order PLL.

An important property of any PLL is the static phase error that arises from a frequency offset $\Delta\omega$ between the input signal and the free-running frequency of the VCO. According to the analysis of Ref. 15, the static phase error is

$$\theta_v = \frac{2\pi\Delta\omega}{k_o I_p F(0)} rad \tag{57.37}$$

To eliminate the static phase error in conventional PLLs, an active loop filter with a high dc gain ($F(0)$ is large) is preferred. But the charge-pump PLL allows zero static phase error without the need for a large dc gain of the loop filter. This effect arises from the input open circuit during the "null" state (charge-pump current is zero). Real circuits will impose some resistive loading R_s in parallel to the loop filter. Therefore, the static phase error, from Eq. 57.37 will be

$$\theta_v = \frac{2\pi\Delta w}{k_o I_p R_s} rad \tag{57.38}$$

The shunt resistive loading most likely comes from the input of a VCO control terminal. Compared with the static phase error of a conventional PLL as expressed in Eq. 57.17, the same performance can be obtained from a charge-pump PLL without a high dc-gain loop filter.[16]

PLL Noise Performance

In high-speed data recovery applications, better performance of the VCO and the overall phase-locked loop itself is desired. The random variations of the sampling clock, so-called jitter, is the critical performance parameter.

Jitter sources of PLL, when using a ring voltage-controlled oscillator, mainly come from the input and the VCO itself. The ring oscillator jitter is associated with the power supply noise, the substrate noise, $1/f$ noise, and the thermal noise. The former two noise sources can be reduced by fully differential circuit structure. $1/f$ noise, on the other hand, can be rejected by the tracking capability of the PLL. Therefore, the thermal noise is the worst noise source. From the analysis in Ref. 17, the one-state RMS timing jitter error of the ring oscillator normalized to the time delay per stage can be shown as

$$\frac{\Delta\tau_{rms}}{t_d} \approx \sqrt{\frac{2KT}{C_L}}\left(\sqrt{1+\frac{2}{3}a_v}\right)\frac{1}{V_{pp}} \tag{57.39}$$

where C_L is the load capacitance, $\sqrt{1+\frac{2}{3}a_v}$ is called the noise contribution factor ς, a_v is the small-signal gain of the delay cell, and Vpp is the VCO output swing. From Eq. 57.39, for a fixed output bandwidth, higher gain contributes larger noise.

Because the ring oscillator is a feedback architecture, the noise contribution of a single delay cell may be amplified and filtered by the following stage. To consider two successive stages, Eq. 57.39 can be rearranged as:[17]

$$\frac{\Delta\tau_{rms}}{t_d} \approx \sqrt{\frac{2KT}{C_L}} \frac{1}{\left(V_{gs} - V_t\right)} \varsigma \tag{57.40}$$

Therefore, the cycle-to-cycle jitter of the ring oscillator in a PLL can be predicted[17] by

$$\overline{\left(\Delta\tau_N\right)^2} = \frac{KT}{I_{ss}} \frac{a_v \varsigma^2}{\left(V_{gs} - V_t\right)} T_o \tag{57.41}$$

where I_{ss} is the current of the delay cell, and T_o is the output period of the VCO. Based on Eq. 57.41, designing a low jitter VCO, $(V_{gs} - V_t)$ should be as large as possible. For fixed delay and fixed current, a lower gain of each stage is better for jitter performance, but the loop gain must satisfy the Barkhausen criterion. From the viewpoint of VCO jitter, a wide bandwidth of the PLL can correct the timing error of the VCO rapidly.[13] If the bandwidth is too wide, the input noise jitter may be so large that it dominates the jitter performance of the PLL. Actually, this is a tradeoff.

For a phase-locked loop design, the natural frequency and the damping factor are the key parameters to be determined by designers. If the signal-to-noise ratio $(\text{SNR})_i$ is defined, then the output signal-to-noise ratio $(\text{SNR})_o$ can be obtained:[4]

$$\left(\text{SNR}\right)_o = \left(\text{SNR}\right)_i \frac{B_i}{2B_L} \tag{57.42}$$

where B_i is the bandwidth of the prefilter and B_L is the noise bandwidth. Hence, the B_L can be derived using Eq. 57.42. And the relationship of B_L with ω_n and ζ is

$$B_L = \frac{\omega_n}{2}\left(\zeta + \frac{1}{4\zeta}\right) \tag{57.43}$$

Therefore, the ω_n and ζ can be designed to satisfy the $(\text{SNR})_o$ requirement.

Besides the system and circuit designs, jitter can be reduced in the board level design. Board jitter can be alleviated by better layout and noise decoupling schemes like such as appending proper decouple and bypass capacitances.

PLL Design Considerations

A PLL design starts with specifying the key parameters such as natural frequency ω_n, lock-in range $\Delta\omega_L$, damping factor ζ, and the frequency control range which depend significantly on applications. Design procedures based on a practical example will be described as follows:

Step 1. Specify the damping factor ζ. The damping factor of the PLL determines the responses of phase or frequency error steps applied to the input. ζ should be considered to achieve fast response, small overshoot, and minimum noise bandwidth B_L. If ζ is very small, large overshoot will occur and the overshoot causes phase jitter.[18] If ζ is too large, the response will become sluggish.

Step 2. Specify the lock-in range $\Delta\omega_L$ or the noise bandwidth B_L. As shown in Eqs. 57.29 and 57.43, the natural frequency ω_n depends on $\Delta\omega_L$and ζ (or B_L and ζ). If the noise is not the key

issue of the PLL, one can ignore the noise bandwidth and specify the lock-in range. Where noise is of concern, one should specify B_L first, and keep the lock-in range of the PLL.

Step 3. Calculate the ω_n according to Step 2. If the lock-in range has been specified, Eq. 57.29 indicates that

$$\omega_n = \frac{\Delta\omega_L}{2\zeta} \tag{57.44}$$

If the noise bandwidth has been specified, Eq. 57.43 indicates the natural frequency as

$$\omega_n = \frac{2B_L}{\zeta + \frac{1}{4}\zeta} \tag{57.45}$$

Step 4. Determine the VCO gain factor k_o and the phase detector gain k_d. k_o and k_d are both characterized by circuit architectures and they must achieve the requirement of the lock-in range specified in Step 2. For example, if k_o or k_d is too small, the PLL will fail to achieve the desired lock-in range.

Step 5. Choose the loop filter. Different types of loop filters are available, as shown in Fig. 57.3. Eqs. 57.7 to 57.9, ω_n and ζ (specified above) are used to derive the time constants of the loop filter.

57.3 Building Blocks of the PLL Circuit

Voltage-Controlled Oscillators

The function of a voltage-controlled oscillator (VCO) is to generate a stable and periodic waveform whose frequency can be varied by an applied control voltage. The relationship between the control voltage and the oscillation frequency depends upon the circuit architecture. A linear characteristic is generally preferred because of its wider applications. As a general classification, VCOs can be roughly categorized into two types by the output waveforms: (1) *harmonic oscillators* that generate nearly sinusoidal outputs, and (2) *relaxation oscillators* that provide square or triangle outputs. In general, a harmonic oscillator is composed of an amplifier that provides an adequate gain and a frequency-selective network that feeds a certain output frequency range back to the input. LC-tank oscillators and crystal oscillators belong to this type.

Relaxation oscillators are the most commonly used oscillator configuration in monolithic IC design because they can operate in a wide frequency range with a minimum number of external components. According to the mechanism of the oscillator topology employed, relaxation oscillators can be further categorized into three types: (1) grounded capacitor VCO,[19] (2) emitter-coupled VCO, and (3) delay-based ring VCO.[20] The operation of the first two oscillators is similar in the sense that time duration spent in each state is determined by the timing components and charge/discharge currents. The delay-based ring VCO operates quite differently since the timing relies on the delay in each of the gain stages that are connected in a ring configuration.

Generally, harmonic oscillators have the following advantages: (1) superior frequency stability, which includes the frequency stability with temperature, power supply, and noise; and (2) good frequency accuracy control, because the oscillation frequency is determined by a tank circuit or a crystal.

Nevertheless, harmonic oscillators are not compatible with monolithic IC technology and their frequency turning range is limited. On the contrary, relaxation oscillators are easy to implement in monolithic ICs. Since frequency is normally proportional to a controlled-current or -voltage and inversely proportional to timing capacitors, the frequency of oscillation can be varied linearly over a very wide

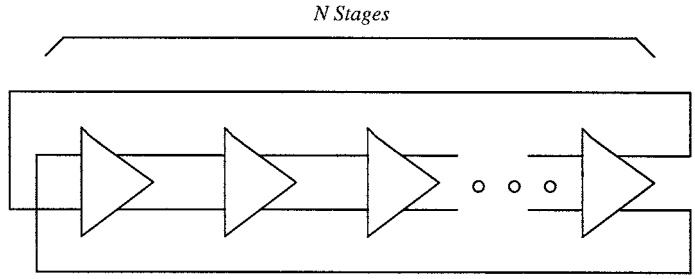

FIGURE 57.15 Ring oscillator.

range. Coming from the ease of frequency tuning, the drawbacks of such oscillators are poor frequency stability and frequency inaccuracy.

Recently, the ring oscillator has received considerable attentions in high-frequency PLL applications for clock synchronization and timing recovery. Since they can provide high-frequency oscillation with simple digital-like circuits that are compatible with digital technology, they are suitable for VLSI implementations.

In order to achieve high rejection of power supply and substrate noises, both the signal path and the control path of a VCO must be fully differential. A common ring oscillator topology in monolithic PLLs is shown in Figure 57.15. The loop oscillates with a period equal to $2NT_d$ where T_d is the delay of each stage. The oscillation can be obtained when the total phase shift is zero and the loop gain is greater or equal to unity at a certain frequency. To vary the frequency of oscillation, the effective number of stages or the delay of each stage must be changed. The first approach is called "delay interpolating" VCO,[20] where a shorter delay path and a longer delay path are used in parallel. The total delay is tuned by increasing the gain of one path and decreasing the other, and the total delay is a weighted sum of the two delay paths. The second approach is to vary the delay time of each stage to adjust the oscillation frequency. The delay of each stage is tuned by varying the capacitance or the resistance seen at the output node of each stage. Because the tuning range of the capacitor is small and the maximum oscillation frequency is limited by the minimum value of the load capacitor, it makes the "resistive tuning" a better alternative technique. The resistive tuning method provides a large, uniform frequency tuning range and lends itself easily to differential control. In Figure 57.16(a), the on-resistance of the triode PMOS loads are adjusted by V_{cont}. The more V_{cont} decreases, the more the delay of the stage drops; because the time constant at the output node decreased, the small-signal gain decreases too. The circuit eventually fails to oscillate when the loop gain at the oscillation frequency is less than unity. In Fig. 57.16(b), the delay of the gain stage is tuned by adjusting the tail current, but the small-signal gain remains constant. So, the circuit is better than Fig. 57.16(a). As shown in Fig. 57.16(c),[21] the PMOS current source with a pair of cross-coupled diode loads provides a differential load impedance that is independent of common-mode voltage. This makes the cell delay insensitive to common-mode noise. Figure 57.16(d) is a poor delay cell for a ring oscillator because the tuning range is very small.

The minimum number of stages that can be used while maintaining reliable operation is an important issue in a ring oscillator design. When the number of stages decreases, the required phase shift and dc gain per stage increases. Two-stage bipolar ring oscillators can be designed reliably,[22] but CMOS implementations cannot. Thus, CMOS ring oscillators typically utilize three or more stages.

Phase and Frequency Detectors

The phase detector type has influence on the dynamic range of PLLs. Hold range, lock-in range, and pull-in range are analyzed in Section 57.2, based on the multiplier phase detector. Most other types of phase detectors have a greater linear output span and a larger maximum output swing than a sinusoidal characteristic phase detector. A larger tracking range and a larger lock limit are available if the linear output

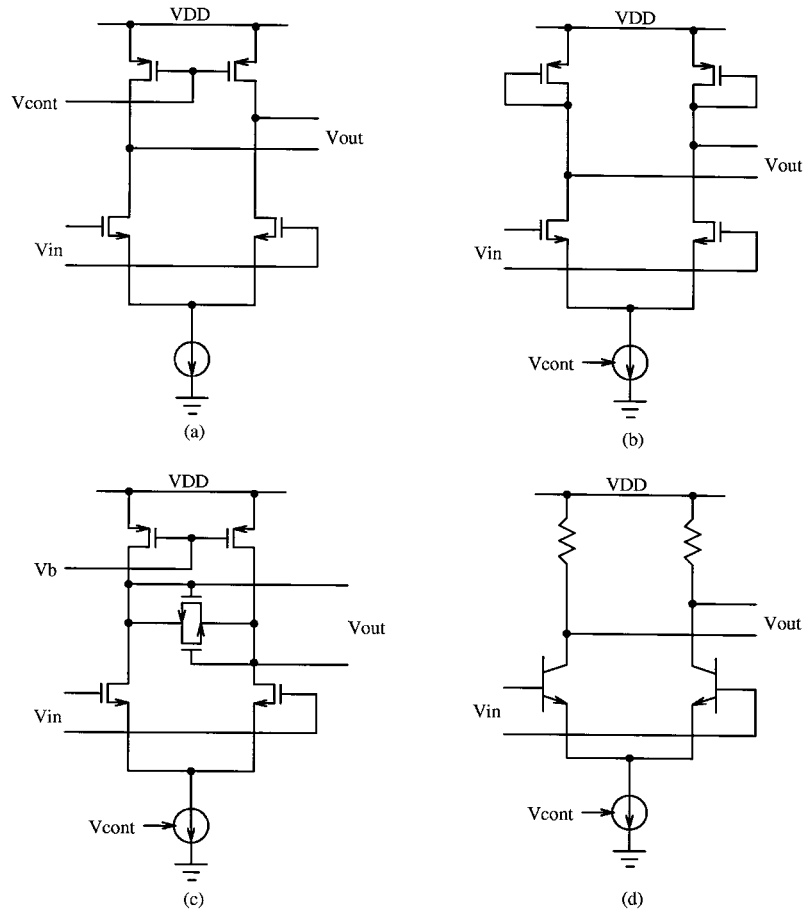

FIGURE 57.16 The gain stages using resistive tuning.

range of the PD increases. The three widely used phase detectors are XOR PD, edge-triggered JK-flipflop, and PFD (phase-frequency detector). The characteristics of these phase detectors are plotted in Fig. 57.17.

The XOR phase detector can maintain phase tracking when the phase error θ_e is confined in the range of

$$\frac{-\pi}{2} < \theta_e < \frac{\pi}{2}$$

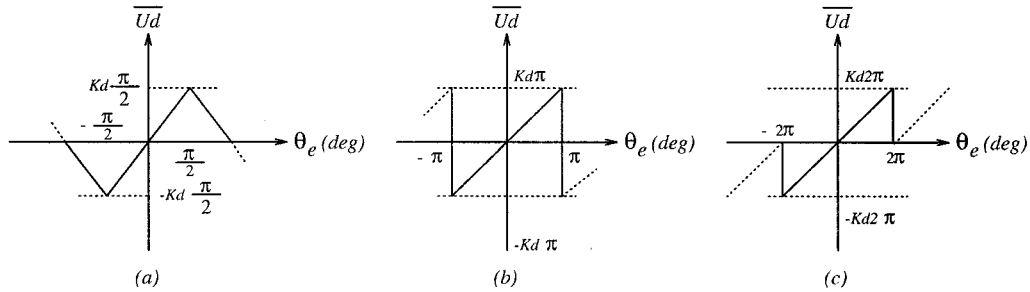

FIGURE 57.17 Phase detector characteristics of (a) XOR, (b) JK-flipflop, and (c) PFD.

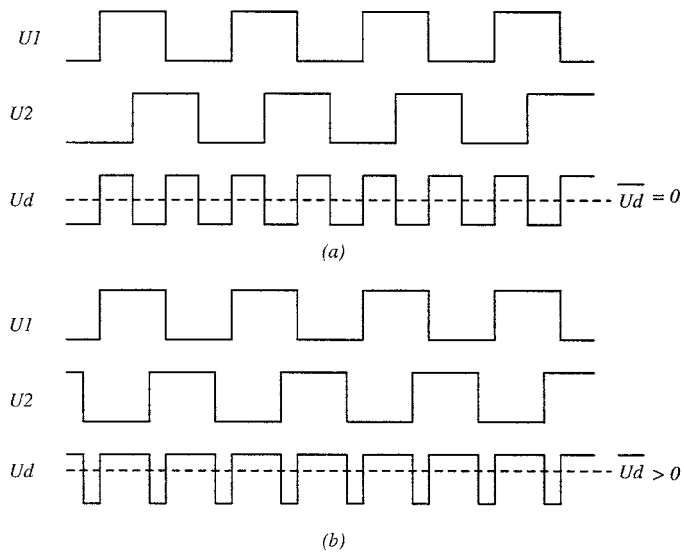

FIGURE 57.18 Waveforms of the signals for the XOR phase detector: (a) waveforms at zero phase error, and (b) waveforms at positive phase error.

as shown in Fig. 57.17(a). The zero phase error takes place when the input signal and the VCO output are quadrature in phase as shown in Fig. 57.18(a). As the phase difference deviates from $\frac{\pi}{2}$, the output duty cycle is no longer 50%, which provides a dc value proportional to the phase difference as shown in Fig. 57.18(b). But the XOR phase detector has a steady-state phase error if the input signal or the VCO output are asymmetric.

The JK-flipflop phase detector shown in Fig. 57.19, also called a two-state PD, is barely influenced by the asymmetric waveform because it is edge-triggered. The zero phase error happens when the input signal and the VCO output are out-of phase as illustrated in Fig. 57.19(a). As shown in Fig. 57.17(b), the JK-flipflop phase detector can maintain phase tracking when the phase error is within the range of

$$-\pi < \theta_e < \pi$$

Here, a positive edge appearing at the "J" input triggers the flipflop into "high" state (Q = 1), and the rising edge of u_2 drives Q to zero. Figure 57.19(b) shows the output waveforms of the JK-flipflop phase detector for $\theta_e > 0$.

The PFD output depends not only on the phase error, but also on the frequency error. The characteristic is shown in Fig. 57.17(c). When the phase error is greater than 2π, the PFD works as a frequency detector. The operation of a typical PFD is as follows, and the waveforms are shown in Fig. 57.20. If the frequency of input A, ω_A, is less than the frequency of input B, ω_B, then the PFD produces positive pulses at Q_A, while Q_B remains at zero. Conversely, if $\omega_A > \omega_B$, the positive pulses appear at Q_B while $Q_A = 0$. If $\omega_A = \omega_B$, then the PFD generates pulses at either $Q_A$or Q_B with a width equal to the phase difference between the two inputs. The outputs $Q_A$and Q_B are usually called the "up" and "down" signals, respectively. If the input signal fails, which usually happens at the NRZ data recovery applications during missing or extra transmissions, the output of the PFD would stick on the high state (or low state). This condition may cause the VCO to oscillate fast or slow abruptly, which results in noise jitter or even losing lock. This problem can be remedied by additional control logic circuits to make the PFD output toggle back and forth between the two logic levels with 50% duty cycle,[18] the loop is interpreted as zero phase error. The "rotational FD" described by Messerschmitt can also solve this issue.[9] The output of a PFD can be converted to a dc control voltage by driving a three-state charge-pump, as described in Section 57.2.

57.4 PLL Applications

Clock and Data Recovery

In data transmission systems such as optical communications, telecommunications, disk drive systems, and local networks, data is transmitted on baseband or passband. In most of these applications, only data signals are transmitted by the transmitter; clock signals are not transmitted in order to save hardware cost. Therefore, the receiver should have some scheme to extract the clock information from the received data stream and regenerate transmitted data using the recovery clock. This scheme is called *timing recovery* or *clock recovery.*

To recover the data correctly, the receiver must generate a synchronous clock from the input data stream, and the recovered clock must synchronize with the bit rate (the baud of data). The PLL can be used to recover the clock from the data stream, but there are some special design considerations. For example, because of the random nature of data, the choice of phase-frequency detectors is restricted. In particular, a three-state PD is not proper; because of missing data transitions, the PD will interpret the VCO frequency to be higher than the data frequency, and the PD output stays on "down" state to make the PLL lose lock, as shown in Fig. 57.21. Thus, the choice of phase-frequency detector for random binary data requires a careful examination of their responses when some transitions are absent. One useful method is the rotational frequency detector described in Ref. 9. The random data also causes the PLL to introduce undesired phase variation in the recovered clock; this is called *timing jitter* and is an important issue of the clock recovery.

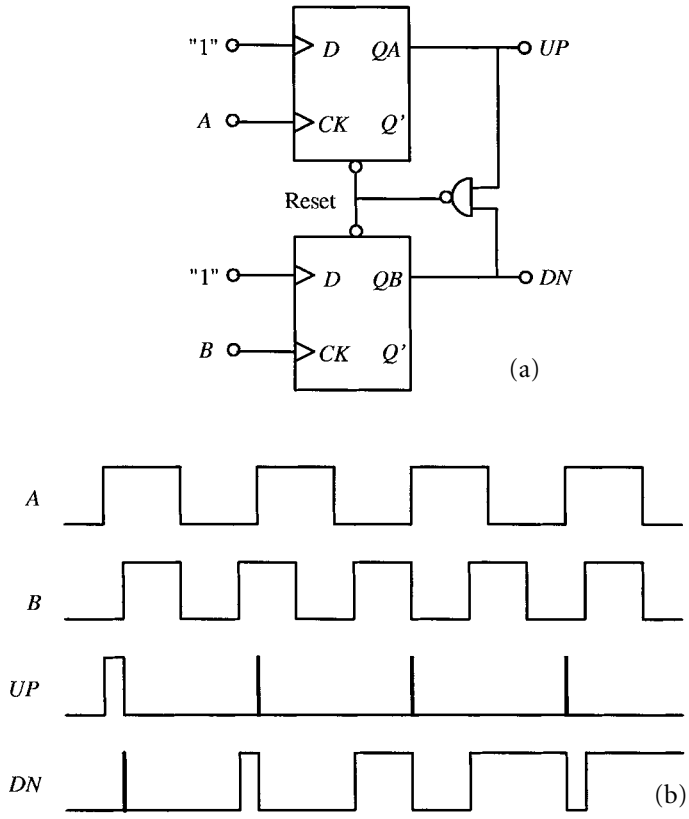

FIGURE 57.20 (a) PFD diagram and (b) input and output waveforms of PFD.

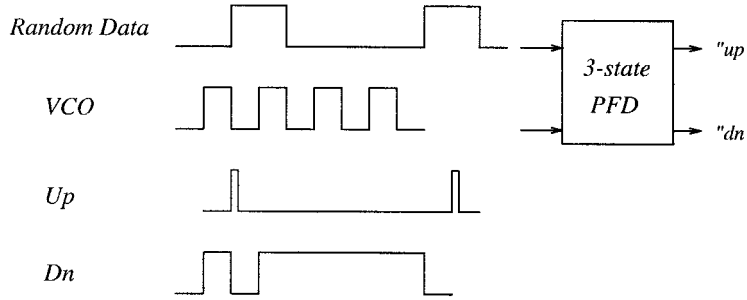

FIGURE 57.21 Response of a three-state PD to random data.

Data Format

Binary data is usually transmitted in a NRZ (Non-Return-to-Zero) format, as shown in Fig. 57.22(a), because of the consideration of bandwidth efficiency. In NRZ format, each bit has a duration of T_B (bit period). The signal does not go to zero between adjacent pulses representing 1's. It can be shown[23] in that the corresponding spectrum has no line component at $f_B = \frac{1}{T_B}$; most of the spectrum of this signal lines below $\frac{f_B}{2}$. The term "non-return-to-zero" distinguishes from another data type called "return-to-zero" (RZ), as shown in Fig. 57.22(b), in which the signal goes to zero between consecutive bits. Therefore,

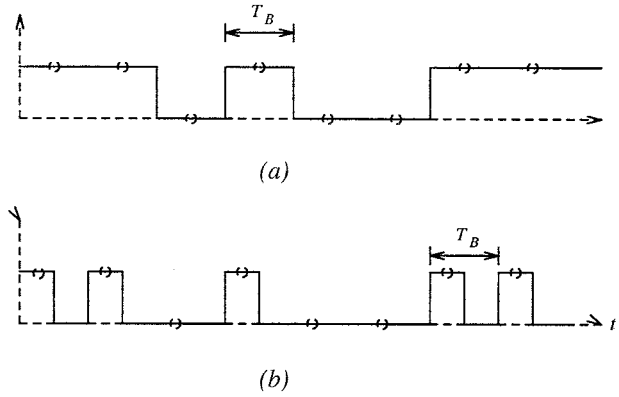

FIGURE 57.22 (a) NRZ data and (b) RZ data.

the spectrum of RZ data has a frequency component at f_B. For a given bit rate, RZ data needs wider transmitting bandwidth; therefore, NRZ data is preferable when channel or circuits bandwidth is a concern.

Due to the lack of a spectral component at the bit rate of NRZ format, a clock recovery circuit may lock to spurious signals or fail to lock at all. Thus, a non-linear process at NRZ data is essential to create a frequency component at the baud rate.

Data Conversion

One way to recover a clock from NRZ data is to convert it to RZ-like data that has a frequency component at bit rate, and then recover clock from data using a PLL. Transition detection is one of the methods to convert NRZ data to RZ-like data. As illustrated in Fig. 57.23(a), the edge detection requires a mechanism to sense both positive and negative data transitions. In Fig. 57.23(b), NRZ data is delayed and compared with itself by an exclusive-OR gate; therefore, the transition edges are detected. In Fig. 57.24, the NRZ data V_i is first differentiated to generate pulses corresponding to each transition. These pulses are made to be all positive by squaring the differentiated signal $\dot{v}_i$. The result is the signal V_i' that looks just like RZ data, where pulses are spaced at an interval of T_B.

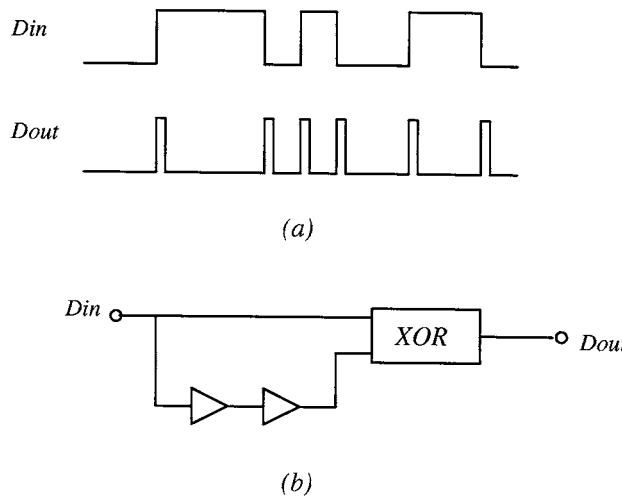

FIGURE 57.23 Edge detection of NRZ data.

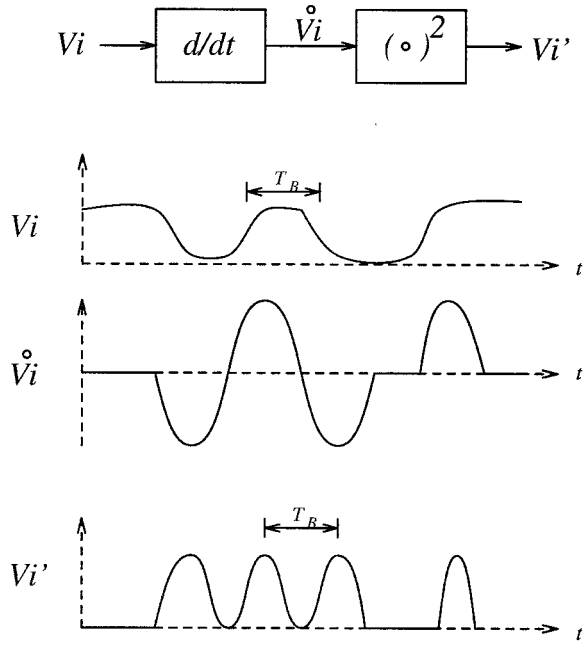

FIGURE 57.24 Converting NRZ to RZ-like signal.

Clock Recovery Architecture

Based on different PLL topologies, there are several clock recovery approaches. Here, the early-late and the edge-detector based methods are described.

Figure 57.25 shows the block diagram of the early-late method. If the input lags the VCO output, Fig. 57.26 shows the waveforms for this case. In Fig. 57.26, the early integrator integrates the input signal for the early-half period of the clock signal and holds it for remainder of the clock signal. On the other hand, the late integrator integrates the input signal for the late-half period of the clock signal and holds it for the next early-half period. The average difference between the absolute values of the late hold and the early hold voltage generated from a low-pass filter gives the control signal to adjust the frequency of the VCO. As mentioned above, this method is popular for rectangular pulses. However, there are some drawbacks to this method. Since this method relies on the shape of pulses, a static phase error can be introduced if the pulse shape is not symmetric. In high-speed applications, this approach requires a fast settling integrator that limits the operating speed of the clock recovery circuit and the acquisition time cannot be easily controlled.

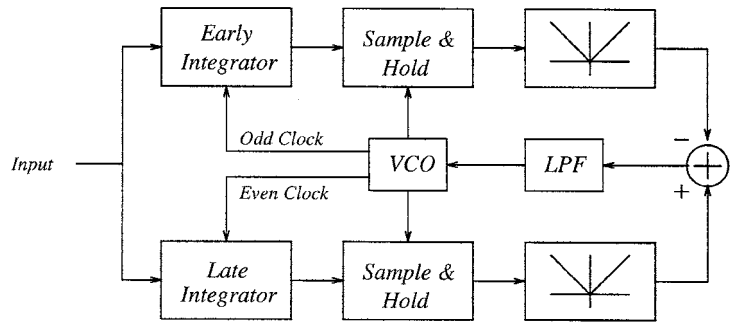

FIGURE 57.25 Early-late block diagram.

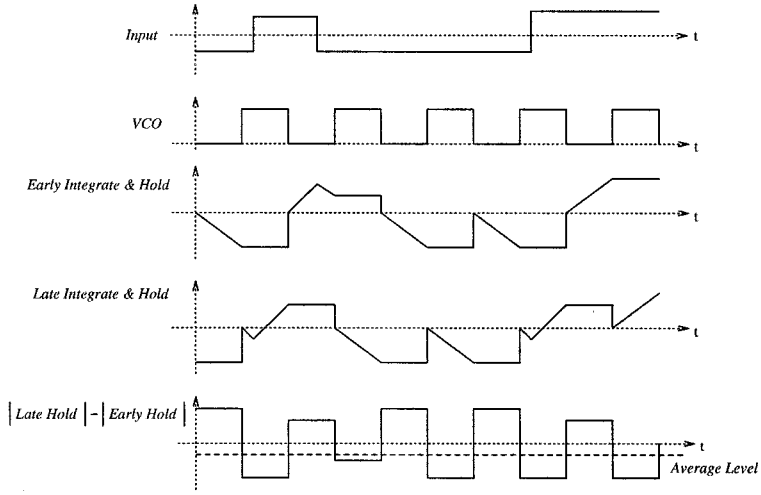

FIGURE 57.26 Clock waveforms for early-late architecture.

The most widely used technique for clock recovery in high-performance, wide-band data transmission applications is the edge-detection based method. The edge-detection method is used to convert data format such that the PLL can lock the correct band frequency. More details were given in the previous subsection. There are many variations of this method, depending on the exact implementation of each PLL loop component. The "quadricorrelator" introduced by Richman[7] and modified by Bellisio[24] is a frequency-difference discriminator and has been implemented in a clock recovery architecture. Figure 57.27 is a phase-recovery locked loop using edge-detection method and quadricorrelator to recover timing information from NRZ data.[25] As shown in Fig. 57.27, the quadricorrelator follows the edge-detector with a combination of three loops sharing the same VCO. Loop I and II form a frequency-locked loop that contains the quadricorrelator for frequency detection. Loop III is a typical phase-locked loop for phase alignment. The phase- and frequency-locked loops share the same VCO; the interaction between two loops is a very important issue. As described in Ref. 25, when $\omega_1 \approx \omega_2$, the dc feedback signal produced by loop I and II approaches zero, and loop III dominates the loop performance. A composite frequency- and phase-locked loop is a good method to achieve fast acquisition and a narrow PLL loop bandwidth

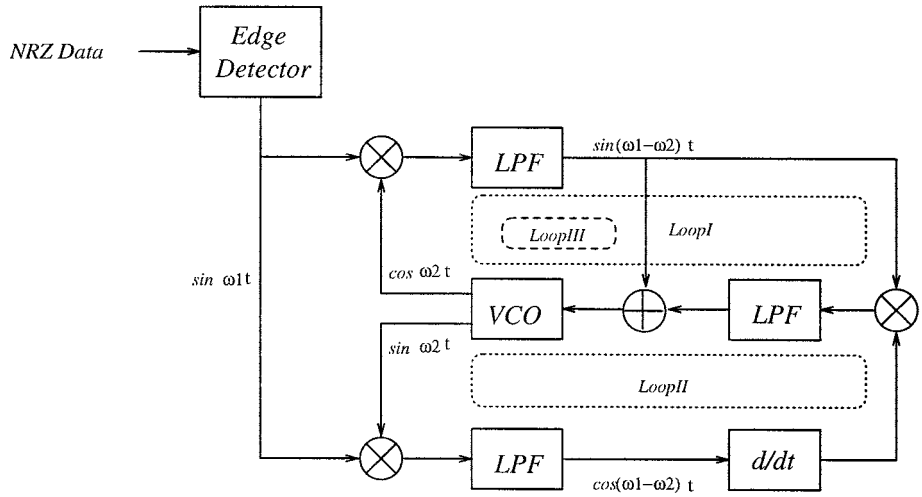

FIGURE 57.27 Quadricorrelator.

to minimize the VCO drift. Nevertheless, because the wide band frequency-locked loop can respond to noise and spurious components, it is essential to disable the frequency-locked loop when the frequency error gets into the lock-in range of the PLL to minimize the interaction. More clock recovery architectures are described in Refs. 18, 20, 22, 26–28.

Frequency Synthesizer

A frequency synthesizer generates any of a number of frequencies by locking a VCO to an accurate frequency source such as a crystal oscillator. For example, RF systems usually require a high-frequency local oscillator whose frequency can be changed in small and precise steps. The ability to multiply a reference frequency makes PLLs attractive for synthesizing frequencies.

The basic configuration used for frequency synthesis is shown in Fig. 57.28(a). This system is capable of generating an integer multiple frequency of a reference frequency. A quartz crystal is usually used as the reference clock source because of its low jitter characteristic. Due to the limited speed of a CMOS device, it is difficult to generate frequency directly in the range of GH_z or more. To generate higher frequencies, prescalers are used; they are implemented with other IC technologies such as ECL. Figure 57.28(b) shows a synthesizer structure using a prescaler V; the output frequency becomes

$$f_{out} = \frac{NVf_i}{M} \tag{57.46}$$

Because the scaling factor V is much greater than one, obviously, it is no longer possible to generate any desired integer multiple of the reference frequency. This drawback can be circumvented by using a so-called dual-modulus prescaler, as shown in Fig. 57.29. A dual-modulus prescaler is a divider whose division can be switched from one value to another by a control signal. The following shows that the dual-modulus prescaler makes it possible to generate a number of output frequencies that are spaced only by one reference frequency. The VCO output is divided by V/V+1 dual-modulus prescaler. The

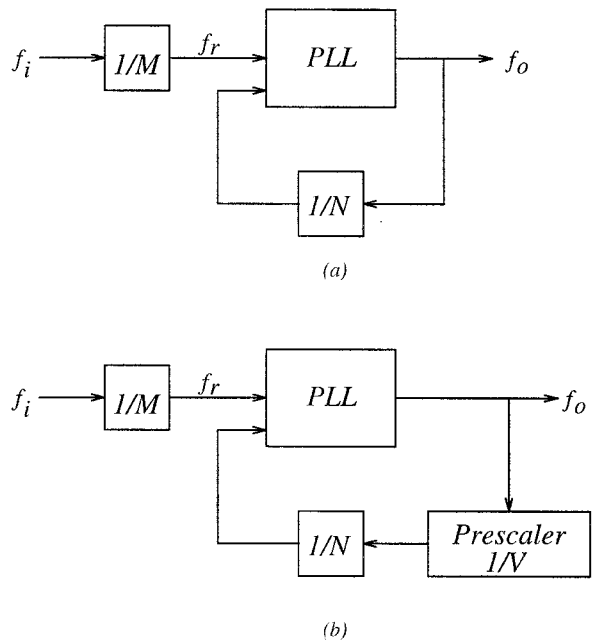

FIGURE 57.28 Frequency-synthesizer block diagrams: (a) basic frequency-synthesizer system; (b) system extends the upper frequency range by using an additional high-speed prescaler.

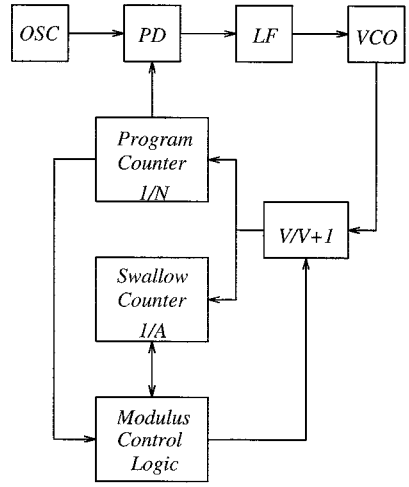

FIGURE 57.29 The block diagram of dual-modulus frequency synthesizer.

output of the prescaler is fed into a "program counter" $\frac{1}{N}$ and a "swallow counter" $\frac{1}{A}$. The dual-modulus prescaler is set to divide by V+1 initially. After "A" pulses out of the prescaler, the swallow counter is full and changes the prescaler modulus to V. After additional "N-A" pulses out of the prescaler, the program counter changes the prescaler modulus back to V+1, restarts the swallow counter, and the cycle is repeated. In this way, the VCO frequency is equal to $(V+1)A + V(N-A) = VN + A$ times the reference frequency. Note that N must be larger than A. If this is not the case, the program counter would be full earlier than $\frac{1}{A}$, and both counters would be reset. Therefore, the dual-modulus prescaler would never be switched from $V+1$ to V. For example, if V = 64, then A must be in the range of 0 to 63 such that $N_{min} = 64$. The smallest realizable division ratio is

$$\left(N_{tot}\right)_{min} = N_{min} V = 4096 \tag{57.47}$$

The synthesizer of Fig. 57.29 is able to generate all integer multiples of the reference frequency, starting from $N_{tot} = 4096$. For extending the upper frequency range of frequency synthesizers, but still allowing the synthesis of lower frequency, the four-modulus prescaler is a solution.[1]

Based on the above discussions, the synthesized frequency is an integer multiple of a reference frequency. In RF applications, the reference frequency is usually larger than the channel spacing for loop dynamic performance considerations, in which the wider loop bandwidth for a given channel spacing allows faster settling time and reduces the phase jitter requirements to be imposed on the VCO. Therefore, a "fractional" scaling factor is needed. Fractional division ratios of any complexity can be realized. For example, a ratio of 3.7 is obtained if a counter is forced to divide by 4 in seven cycles of each group of ten cycles and by 3 in the remaining three cycles. On the average, this counter effectively divides the input frequency by 3.7.

Continuous-Time Filters

John M. Khoury
Lucent Technologies

58.1 Introduction

Modern Very Large Scale Integrated (VLSI) circuits realize complex mixed analog-digital systems on a monolithic semiconductor chip. These systems generally incorporate signal processing operations that can be performed either in the digital domain using digital signal processing (DSP) techniques or in the analog domain with analog signal processing (ASP) circuits. ASP techniques fall into two basic categories: continuous-time or sampled-data. The selection of DSP, continuous-time ASP, or sampled-data ASP approaches is highly dependent on the system requirements; however, continuous-time filters are generally preferable in applications that require low power, high-frequency operation, and moderate dynamic range.

Fully integrated continuous-time filters have found wide application in many VLSI systems that include modems, telephone circuits, disk drive read channels, video processing circuits, and others. The applications usually fall into one of the three basic configurations shown in Fig. 58.1. In the top two views, the continuous-time filter provides anti-aliasing and smoothing functions for sample-data signal processing operations that are either performed with switched-capacitor (SC), switched-current (SI), or DSP filters. Generally, for these applications, the precise signal processing functions are kept in the sampled-data domain. The continuous-time filter can then have non-stringent frequency response specifications provided that the ratio of half the sampling rate to the band edge is large for the sampled-data filter. Often for lower power operation or extremely high frequency operation, the entire signal processing is performed with the continuous-time ASP as shown in the bottom of Fig. 58.1.

When designing a system, the natural question arises as to which is the best approach for the performing the core signal processing operations: DSP or ASP. In general, DSP is usually the obvious choice if the application has the following attributes: (1) frequency response specifications that must be repeatable to within fractions of decibels (dB) over all manufacturing processes, (2) band edges are in the 100-kHz range and below, (3) dynamic range requirements exceed 80 dB, and (4) a high degree of programmability or coefficient adaptation is needed.

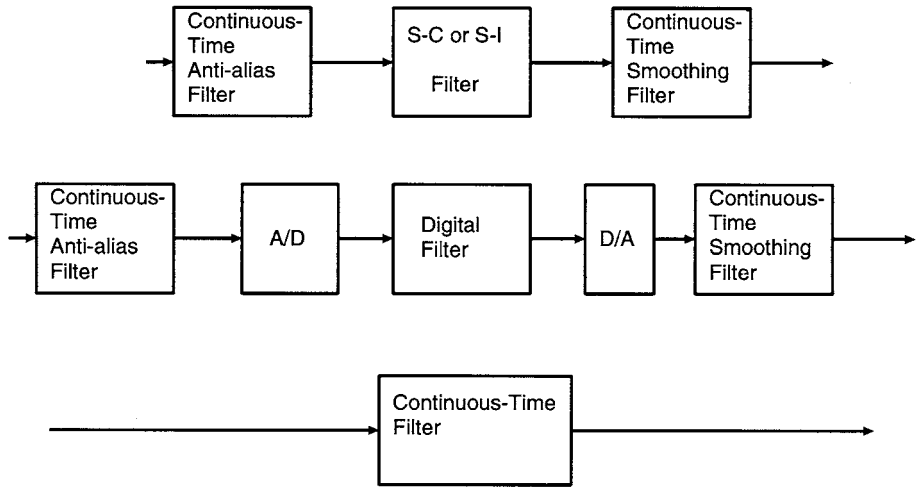

FIGURE 58.1 General uses of continuous-time filter.

ASP typically has a clear advantage when the critical frequencies in the filter exceed several hundred kHz. In today's 0.35-μm CMOS technologies, SC filters are generally limited to sampling rates below 100 MHz; hence, filter passbands will typically be below 25 MHz. SI filters have similar limitations. Continuous-time filters are then the only viable alterntive for passbands in the 10's of MHz and higher.

Continuous-time filters may be designed for the entire frequency range from audio to above 100 MHz. When used in audio and above audio applications, continuous-time filters can achieve the lowest possible power of all the filtering techniques; dynamic ranges above 90 dB can be obtained and linearity above 80 dB is possible with certain continuous-time design approaches.[1-4] Higher frequency continuous-time filters can also be designed to achieve excellent linearity.[5] In the 10- to 150-MHz range, continuous-time filters usually will achieve linearity and dynamic range performance in the 60-dB range and cutoff frequency accuracy in the range of a few percent.[6-11] Integrated continuous-time filters to date have not achieved the performance required in the high-frequency, high-Q, and high-linearity wireless application. The fundamental limitations of thermal noise present in all integrated continuous-time, SC, and SI filters severely limits the achievable dynamic range under high-Q conditions.[12]

Integrated continuous-time filters differ from discrete active filters and SC or SI filters in that a frequency tuning circuit is almost always required to obtain accurate frequency response characteristics.[1,7,9,10,13-15] In VLSI chips, the capacitor values can vary by ±15% for linear capacitors such as double-poly or metal-metal capacitors. Similarly, the resistance element, whether it is a diffused resistor, polysilicon resistor, or transistor will vary widely with processing and temperature. The combined effect often results in RC products that vary by as much as ±50%. In continuous-time filter applications such as anti-aliasing or reconstruction functions, such variation is often acceptable. However, to achieve corner frequency accuracy of a few percent, a tuning circuit is required. In addition to frequency tuning/scaling the filter, circuits to tune the quality factor of the filter are sometimes employed.[6,8,11,16-18]

The following sections in this chapter cover the state-variable implementation of continuous-time filters, the design of VLSI integrators, and the design of highly linear continuous-time filters. The chapter concludes with the design of tuning circuits.

58.2 State-Variable Synthesis Techniques

In the 1960s, considerable research was performed in the area of active filter design. At that time, the focus was on discrete circuit implementations that operated with single-ended circuitry. Although many creative and theoretically appealing approaches were invented and used commercially for discrete designs,

only a few of the circuit topologies are well suited to VLSI implementations. An extensive discussion of active filter realizations can be found in Ref. 19.

Of all the possible active filter topologies possible, the *state-variable filter* is the most general in form and most widely used in VLSI continuous-time filters today. The key advantage of state-variable filters is that they require only two basic building blocks: (1) integrators and (2) weighted summers. In VLSI solutions, the integrators are realized with on-chip capacitors, an active element such as an operational amplifier (op-amp), and a resistive element or transconductance amplifier. Signal summation is performed in the voltage or current domains, depending on the technique used.

The topology of state-variable filters can take on many varied forms. In the most general case, a linear system with N state variables would consist of N integrators with signal coupling between any and all integrators. In practice, coupling between integrators is limited to make the design realizable. In the biquadratic (biquad) filter structure, the N-th order filter is realized as a cascade of second-order circuits, followed by a first-order circuit, if N is odd. The biquad approach is widely used for its simplicity, ease of design, and ease of debugging.[19]

An alternate form of state-variable filters, called the "leapfrog" topology, is realized by simulating the equations that govern RLC ladder filters.[19] In the leapfrog topology, only the state variables (i.e., integrators) that are adjacent to one another are coupled. Leapfrog filters are more difficult to design, but they generally offer improved passband magnitude response accuracy and better dynamic range performance than the cascade of biquads.

Biquadratic Filters

The biquad structure realizes the filtering function as a cascade of second-order filters. The structure decouples the poles of the system and can ease the overall design approach.

The general equation governing the biquadratic filter is

$$V_{out}(s) = K \frac{s^2 + \frac{\omega_{oz}}{Q_z} s + \omega_{oz}^2}{s^2 + \frac{\omega_{op}}{Q_p} s + \omega_{op}^2} V_{in}(s) \tag{58.1}$$

where $V_{out}(s)$ and $V_{in}(s)$ are the output and input signals of the biquad, respectively, K is a gain constant, ω_p and ω_z are the frequencies of the poles and zeros, and Q_p and Q_z are the quality factors of the poles and zeroes, respectively. Although many methods of realizing this transfer function are possible, the state-variable approach uses a loop of two integrators connected with negative feedback to realize the poles. Damping around one (or both) integrator(s) makes the corresponding integrator lossy and implements the pole quality factor, Q_p. The zeroes of the biquad can be achieved by (1) creating an output signal $V_{out}(s)$ that is the weighted summation of the two integrator outputs, as well as the input signal, $V_{in}(s)$, or (2) by summing scaled values of the input signal into both integrators as well as directly to the output. The block diagram of the generalized biquad, shown in Fig. 58.2, places the zeroes and adjusts the overall gain of the filter with the K_1, K_2, and K_3 constants. The block diagram of Fig. 58.2 can be easily converted to an integrated VLSI filtering technique with a one-for-one substitution of the integrators and weighted summers with the corresponding VLSI circuits. Integrated implementations will be discussed in the sections on G_m-*C*, G_m-*OTA-C*, and *MOSFET-C* filters.

If the high-order transfer function is of the form:

$$H(s) = \frac{N(s)}{D(s)} \tag{58.2}$$

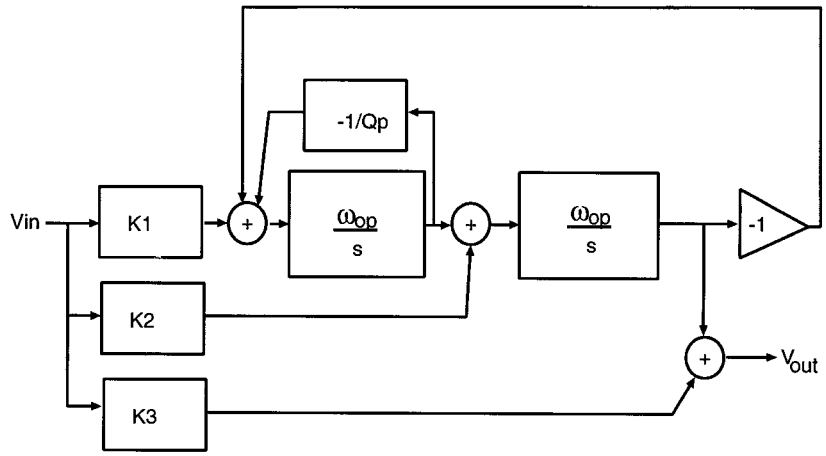

FIGURE 58.2 Biquad block diagram.

then $H(s)$ can be factored into second-order sections where the numerators and denominators of these biquads are at most second order, as in Eq. 58.1. Issues of how to arrange the cascade of second-order functions and how to pair the poles and zeroes can greatly affect the filter's performance in terms of signal swing, dynamic range, and dc offset accumulation. A few simple rules of how to realize a cascaded filter are enumerated here.

1. **Factor into Biquadratic Terms:** Split the numerator, $N(s)$, and the denominator, $D(s)$, into products of second-order functions. If either $N(s)$, or $D(s)$ is odd-order, a first-order term will be necessary. The transfer function is then in the following form:

$$H(s) = \frac{N_1(s)N_2(s)N_3(s)\ldots}{D_1(s)D_2(s)D_3(s)\ldots} \tag{58.3}$$

2. **Pair Poles and Zeroes:** Convert Eq. 58.3 into a product of second-order transfer functions, $H_A(s)$ $H_B(s)$ $H_C(s)$ …, by pairing each $N_i(s)$ with a $D_j(s)$ in such a way that $|H_A(j\omega)|$, $|H_B(j\omega)|$, $|H_C(j\omega)|$, etc. has as flat a magnitude response over the passband as possible. In this way, the signal at the various points in the cascade of the filter will be large and hence less susceptible to interference. Interference could be due to the thermal noise of the active and passive circuits, power supply noise, and crosstalk from digital circuits on-chip.

   To make $|H_A(j\omega)|$, $|H_B(j\omega)|$, $|H_C(j\omega)|$, etc. as flat as possible over the passband, pair the zeroes of $N_i(s)$ as close in frequency and Q as the poles of $D_j(s)$. This method minimizes the variation caused by $|N_i(j\omega)|/|D_j(j\omega)|$ because the effects of the pole and zero pairs tend to partially cancel.
3. **Choose Cascade Order:** The next decision is to order the biquads (and maybe a first-order term). Many practical factors influence the optimum ordering. A few examples are:
   a. Order the cascade to equalize signal swing as much as possible throughout the filter to maximize dynamic range.
   b. Choose the first biquad to be lowpass or bandpass to reject high-frequency noise, eliminating overload in the remaining stages.
   c. If the offset at the filter output is critical, the last stage should be a highpass or bandpass to block the dc of previous stages.
   d. Avoid high-Q biquads at the last stage because these biquads have higher fundamental noise and worse sensitivity to power supply noise than low-Q stages.[12]

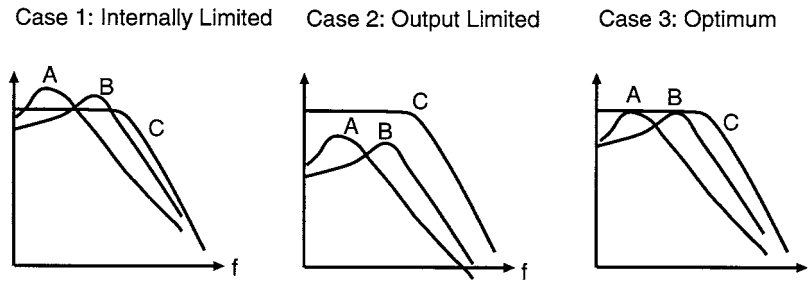

FIGURE 58.3 Dynamic range scaling.

e. In general, do not place allpass stages at the end of the cascade because these have wideband noise. It is usually best to place allpass stages near the beginning of the filter.
f. If several highpass or bandpass stages are available, one can place them at the beginning, middle, and end of the filter. This will prevent input dc offset from overloading the filter, will prevent internal offsets of the filter itself from accumulating (and hence decreasing available signal swing), and will provide a filter output that has low dc offset.
g. The effect of thermal noise at the filter output varies with ordering; therefore, several decibels (dB) of SNR can often be gained with biquad reordering.

4. **Dynamic Range Optimization:** Dynamic range optimization is simply the scaling of gains within the filter to make sure that the overload levels of the integrators (or summers) are equalized so that all elements will saturate at the same signal level.

If the frequency spectrum of the input signal is known, then dynamic range scaling of the filter's should be performed with this signal. The maximum amplitude input signal should be provided and the gains scaled until all integrator and summer outputs are at their maximum level. Note that gain scaling should be performed so as not to modify any loop gains in the filter; otherwise, the transfer function would be altered.

If the frequency spectrum of the input signal is unknown, the typical approach is to assume the input signal is a single sinusoid. The filter is then dynamic range scaled so that for the maximum amplitude input sinusoid, all integrator and summer outputs have the same maximum value for any possible sinusoidal frequency. Usually, the frequency of the input sinusoid is swept over the filter's passband and the maximum levels are then gain scaled. Pictorially this can be seen in Fig. 58.3. Here, the filter consists of a cascade of three biquads: A, B, C. The frequency response to each biquad output is shown. In case 1, the signal will clip at the output of biquads A and B first; whereas in case 2, the output, C, will saturate first. It is only in case 3 — where the maximum gains have been equalized — that clipping occurs in all three biquads at the same level.

Dynamic range scaling must be performed not only at the output of each biquad, but also at the output of the internal integrator. As an example, consider the classical Tow-Thomas biquad in Fig. 58.4. The derivation of this biquad from the block diagram in Fig. 58.2 should be self-evident. The frequency response shows that the internal node V_x will clip at a lower input amplitude level than the output. The signal amplitude at node V_x must be reduced by a factor F. The reduction in gain can be achieved by lowering the impedance in the feedback loop of the first integrator by F. However, to maintain constant loop gain around the two integrator loop, the input resistor of the second integrator must become R/F. The result of this dynamic range scaling is shown in Fig. 58.5.

Leapfrog Filters

The leapfrog filter topology uses active integrators and weighted summers to simulate all the equations governing RLC ladder filters.[19] The question naturally arises as to why passive *ladder* filters should be chosen. First, a wealth of knowledge and design tables exist for these filters. Designers can easily use

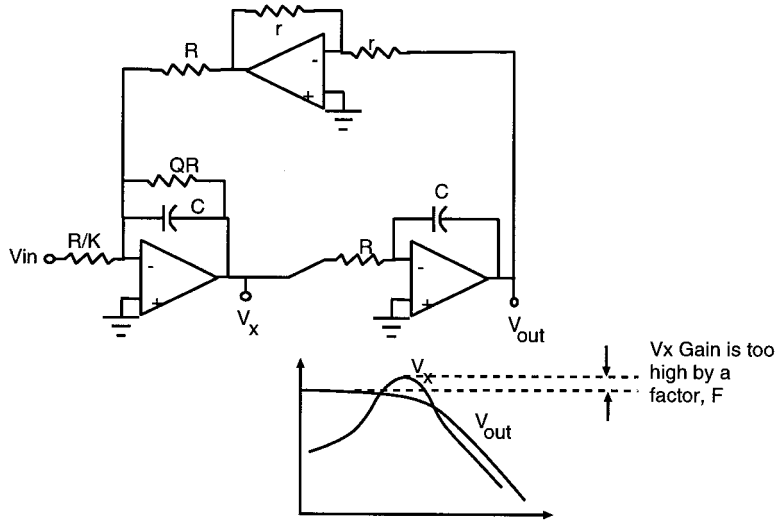

FIGURE 58.4 Tow-Thomas biquad prior to dynamic range scaling.

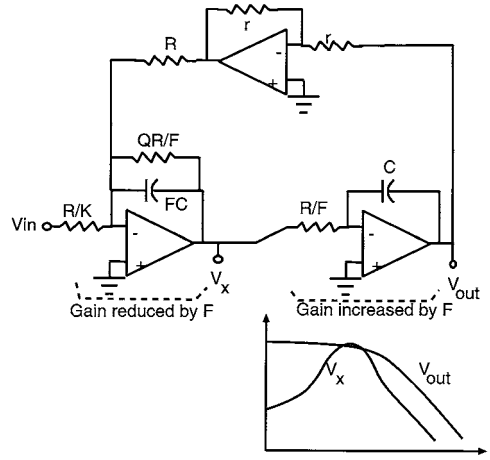

FIGURE 58.5 Tow-Thomas biquad after dynamic range scaling.

tabulated data to design classical ladder filters that implement Butterworth, Chebychev, Bessel, etc. responses. With a few simple steps, these ladders can be transformed into an active leapfrog topology with element values.[19] The second and more important reason to simulate ladder filters is that *in the passband*, the sensitivity of the filter's magnitude response to element value variation is extremely low. This low sensitivity is not true in the stopband, nor is it true for the phase response of the filter. Since leapfrog filters simulate all the equations governing the ladder filter, these sensitivity advantages carry over to the active realization. Finally, filters that are relatively insensitive to component errors *usually* have lower thermal noise. In most applications, leapfrog filters will have superior performance relative to biquadratic filters in terms of noise and passband magnitude response accuracy. Snelgrove and Sedra[20] analyzed biquad filters, leapfrog filters, and filters optimized for noise and magnitude response sensitivity. The leapfrog filters achieved performance close to the optimized design, but the biquad approach showed significantly degraded performance.

The design of leapfrog filters can be found in Ref. 19. Here, we will show by example the design of these filters. Consider the third-order lowpass doubly terminated ladder shown in Fig. 58.6. Since the

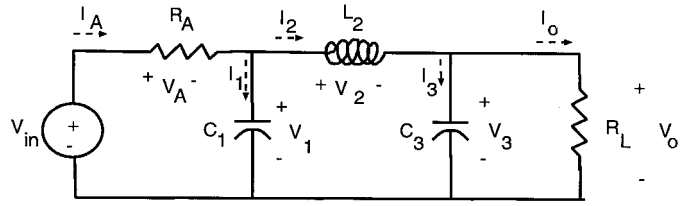

FIGURE 58.6 Third-order doubly terminated lowpass LC ladder filter.

active filter must simulate all equations governing the ladder, the first step is to write all the equations. The two-terminal branch relationships are:

$$I_A = \frac{V_A}{R_A}, \quad V_1 = \frac{I_1}{sC_1}, \quad I_2 = \frac{V_2}{sL_2}, \quad V_3 = \frac{I_3}{sC_3}, \quad I_O = \frac{V_O}{R_L} \tag{58.4}$$

The KVL equations are:

$$V_A = V_{in} - V_1, \quad V_2 = V_1 - V_3, \quad V_O = V_3 \tag{58.5}$$

The KCL equations are:

$$I_1 = I_A - I_2, \quad I_3 = I_2 - I_O \tag{58.6}$$

As can be seen in Eqs. 58.4 to 58.6, some variables are currents while others are voltages. In the implementations, usually all signal variables are either voltages or currents. Here, voltage signals will be assumed. To convert the current signals in Eqs. 58.4 to 58.6 to voltages, all currents can be scaled by a resistance r of arbitrary value (e.g., 1 Ω). After the scaling by r, Eqs. 58.4 to 58.6 become:

$$\begin{gathered} rI_A = \frac{rV_A}{R_A}, \quad V_1 = \frac{rI_1}{srC_1}, \quad rI_2 = \frac{V_2}{sL_2/r}, \quad V_3 = \frac{rI_3}{srC_3}, \quad rI_O = \frac{rV_o}{R_L}, \\ V_A = V_{in} - V_1, \quad V_2 = V_1 - V_3, \quad V_O = V_3, \quad rI_1 = rI_A - rI_2, \quad rI_3 = rI_2 - rI_O \end{gathered} \tag{58.7}$$

Using Eq. 58.7, the signal flow graph (SFG) shown in Fig. 58.7 can be obtained. Arrows flowing into a circle represent summation, and the values next to the arrows indicate a scaling operation. In the SFG, the KVL equations are implemented with the top two summation circles, while the KCL equations are

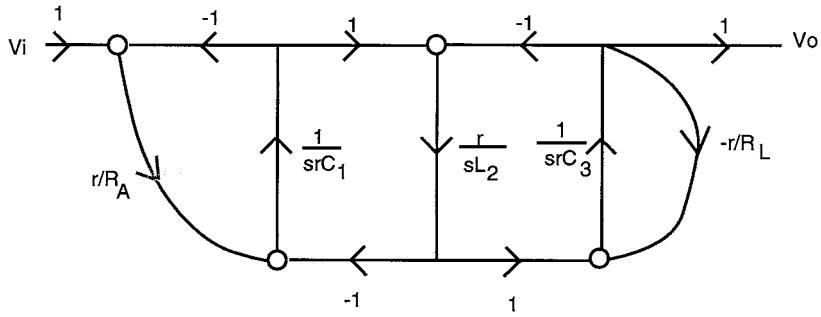

FIGURE 58.7 Signal flow graph representation of LC ladder filter.

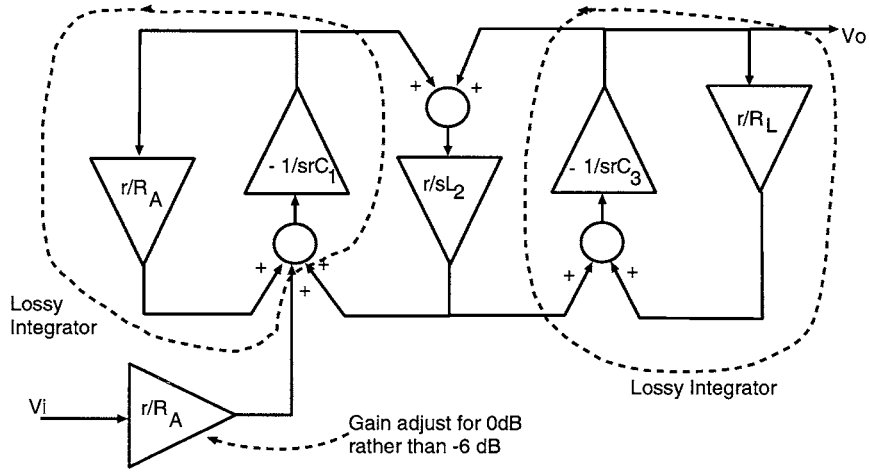

FIGURE 58.8 Leapfrog filter with gain scaling extracted.

on the bottom side. If one were to implement this SFG directly, the gain of the filter would be less than 0 dB (e.g., –6 dB for an equally terminated ladder). In fact, the gain would be the same as the original RLC ladder. By replicating the gain block, r/R_A, as shown in Fig. 58.8 an additional degree of freedom is obtained to implement arbitrary filter gains. Dotted lines are used to indicate that the integrators on the end of the filter are damped, while the inner integrator is lossless. In the realization of high-order ladder filters, the internal integrators will always be lossless, while the outside ones will be lossy due to the ladder terminations.

Highpass and bandpass leapfrog filters can be realized directly from the lowpass LC ladder with the use of the classical lowpass-to-highpass or lowpass-to-bandpass transformations.[19] For illustrative purposes, the bandpass case is considered here. Starting from a lowpass prototype with frequency domain variable *s,* a bandpass filter with bandwidth *BW* and center frequency ω_o can be realized in the frequency domain variable *p* with the following transformation:

$$s = \frac{p^2 + \omega_o^2}{pBW} \tag{58.8}$$

Applying the transformation element by element to a third-order lowpass ladder, one obtains the bandpass ladder shown in Fig. 58.9. An SFG can be generated directly from the bandpass ladder and the active filter realized. Alternatively, the lowpass-to-bandpass transformation can be applied directly to the lowpass active filter of Fig. 58.8, resulting in the bandpass active filter in Fig. 58.10. Notice that each integrator has been replaced with a bandpass biquad and that the biquads corresponding to the terminations are damped.

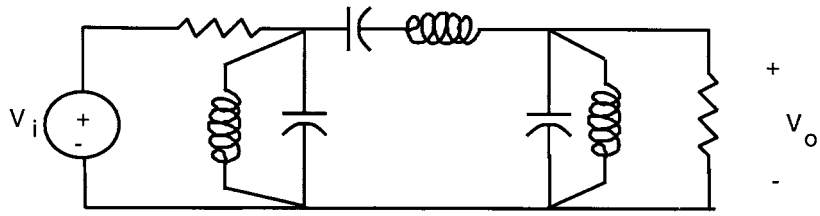

FIGURE 58.9 Bandpass ladder filter.

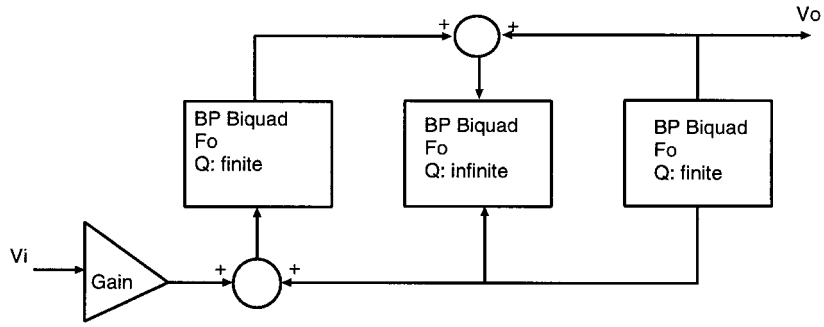

FIGURE 58.10 Bandpass leapfrog filter realization.

Designers proficient in the use of SFGs can readily transform the active leapfrog realization to include zeroes in the transfer function.

58.3 Realization of VLSI Integrators

Once the state-variable topology has been created, the VLSI filter realization is determined by the approach used for the integrator. This section describes the most common types of VLSI integrators and their corresponding summing circuits. The three most common types of implementations are the G_m-*C*, G_m-*OTA-C* and *MOSFET-C* filters. G_m-*C* filters are generally recognized to offer the highest possible frequency operation at the lowest power; however, the structures are sensitive to parasitic capacitances and generally have higher noise and offset than other techniques. G_m-*OTA-C* filters are far less parasitic sensitive than G_m-*C* designs, but at the cost of higher power. Finally, *MOSFET-C* filters generally are the most parasitic insensitive, and have the least noise and offset; however, the frequency of operation is *usually* the lowest of the three approaches. In BiCMOS technology where extremely wideband op-amps can be made, *MOSFET-C* techniques possess bandwidth capabilities approaching that of G_m-*C* and G_m-*OTA-C* filters.

G_m-*C* Integrators and Filters

G_m-*C* filters implement integrators with a transconductance amplifier loaded by a capacitor. As shown in Fig. 58.11 a differential transconductance amplifier (also called a transconductor) takes an input voltage, V_{ind}, and produces at its output a current $I_{out} = G_m V_{ind}$. This output current is integrated by the capacitor to produce the output voltage signal, V_{out}. The transfer function of the G_m-*C* integrator is

$$H(s) = \frac{G_m}{sC} = \frac{\omega_o}{s} \tag{58.9}$$

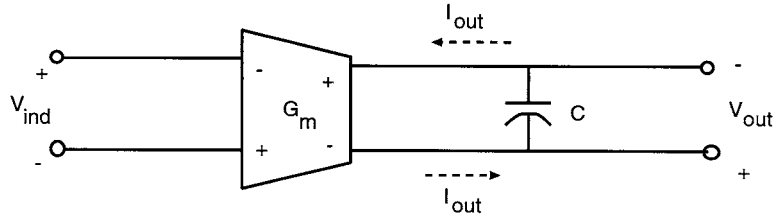

FIGURE 58.11 G_m-*C* integrator.

where ω_o is the unity-gain frequency of the integrator. The ideal integrator has infinite dc gain, a unity-gain frequency of ω_o, and a phase shift of –90° for all frequencies. Capacitors in VLSI technology are usually high quality, so all stringent integrator requirements fall on the transconductor design. Since the transconductor is a voltage-to-current ($V \rightarrow I$) converter, it should have: (1) high input impedance to accurately sense the input voltage signal, (2) high output impedance so the output signal appears as a current source, (3) high dc gain, (4) wide bandwidth so as not to create phase and magnitude errors in the integrator response, (5) large signal handling capability at the input and output for good dynamic range, and (6) a well-defined and tunable $V \rightarrow I$ mechanism to be used for frequency scaling the filter to remove process and temperature variations. In CMOS or BiCMOS technology, achieving high input impedance is simple due to the gate terminal of the MOSFET. Designing for high output impedance can be achieved with cascoding and with the use of regulated cascodes[21]; however, there is a tradeoff between high bandwidth and high output impedance. The most difficult aspect of G_m cell design is making the $V \rightarrow I$ mechanism tunable simultaneously achieving good linearity in the presence of large input signal swings.

Building state-variable filters with G_m-C filters follows directly from the block diagrams or SFGs. Signal summation is performed in the current domain by placing transconductor outputs in parallel. Consider the SFG in Fig. 58.12. The bandpass G_m-C filter is readily implemented as in Fig. 58.13. The loop of two

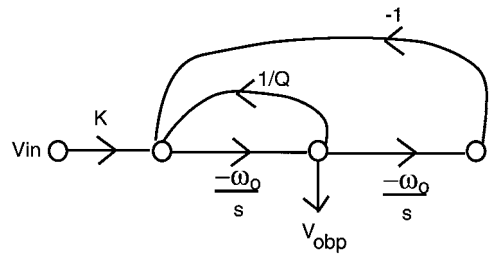

FIGURE 58.12 Signal flow graph representation of a state-variable biquad.

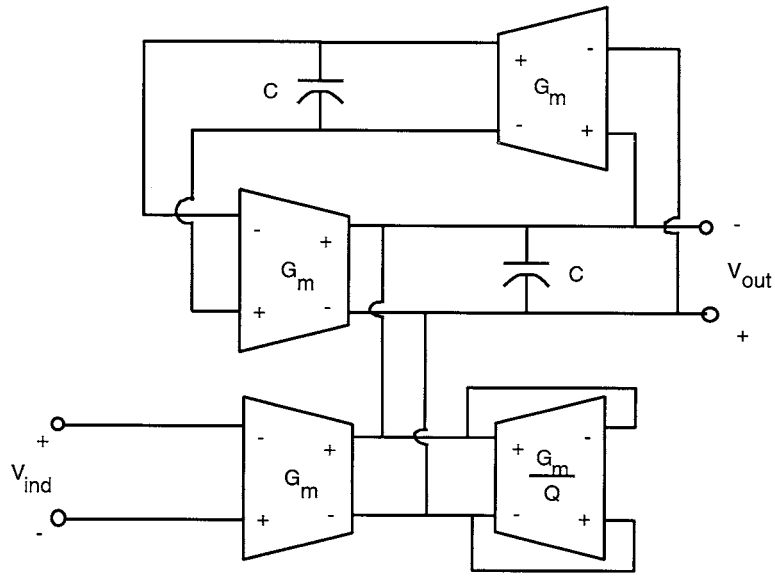

FIGURE 58.13 G_m-C realization of a bandpass biquad.

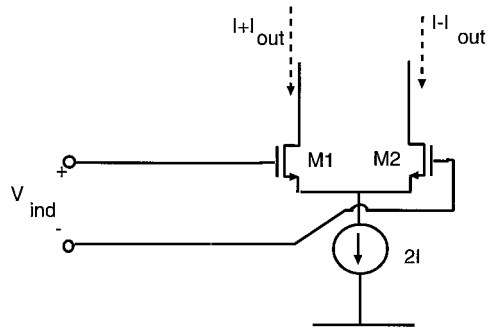

FIGURE 58.14 An MOS differential pair used as a $V \rightarrow I$ converter.

integrators is on the top of the figure, biquad damping is performed with the G_m/Q transconductor, and input signal scaling and summation are achieved with the remaining G_m cell. The G_m/Q transconductor connected in the negative feedback configuration on itself implements a resistor of value Q/G_m.

The key aspect in the design of G_m-C filters is the transconductor design and more specifically, the $V \rightarrow I$ converter. In the simplest case, the $V \rightarrow I$ converter can be a simple MOS differential pair, as shown in Fig. 58.14. The large signal differential output current, I_{outd}, is given by[22]:

$$I_{outd} = 2I_{out} = \mu_n \frac{C_{ox} W}{2L} V_{ind} \sqrt{\left(\frac{4I}{\mu_n C_{ox} W/(2L)} \right) - \left(V_{ind} \right)^2} \tag{58.10}$$

I_{outd} is a non-linear function of the input V_{ind}. The transconductance of the differential pair, $G_m = dI_{outd}/dV_{ind}$, is maximum at $V_{ind} = 0$ and falls off for increased signal swing. The maximum G_m is:

$$G_m = \sqrt{2I\mu_n C_{ox} W/L} = g_{m1} = g_{m2} \tag{58.11}$$

The transconductance can be tuned with the tail current $2I$ to frequency scale the G_m-C filter; however, the tuning range is small since G_m only varies as the square root of the current. In general, if the targeted filter application requires no programmability and the critical frequencies are nominally fixed, then roughly a 2:1 tuning range is needed to accommodate process and temperature variations. The tail current would then require a 4:1 variation, greatly impacting power dissipation. The more significant disadvantage of this $V \rightarrow I$ converter is its small linear input range. It can be shown that the linear differential input voltage range is much smaller than $\pm\sqrt{2}(V_{gs1,2-bias} - V_T)$, where $V_{gs1,2-bias}$ is the bias level of M1 and M2 for $V_{ind} = 0$. To maximize the linear input range $V_{gs1,2-bias}$ must be kept large by using small W/L ratios. Even with use of small W/L ratios, the input range is typically limited to less than ±200 mV for linearity of 40 to 60 dB.

Many linearization techniques have been invented using MOSFETs in the saturation and triode regions, as well as BiCMOS solutions. A few approaches are discussed here. In the basic MOS differential pair, the output current, I_{outd}, increases with V_{ind}; however, the rate of increase drops off at higher input amplitude levels. One solution is to have another source of current that is added to the transconductor's output. If that current is zero for low levels of V_{ind}, but increases with V_{ind}, the net effect is to linearize the overall G_m cell. Rather than adding a current, we can instead subtract a current from the G_m stages output. The amount to be subtracted would be maximum for $V_{ind} = 0$ and would drop to zero for large differential input signals. This technique uses an additional differential pair, as shown in Fig. 58.15.[10] Transistors M3 and M4 operate at lower current than M1 and M2 and are biased such that $(V_{gs3,4-bias} - V_T) \ll (V_{gs3,4-bias} - V_T)$. Detailed design equations for the sizing of M1-M4, I1, and I2 can be found in

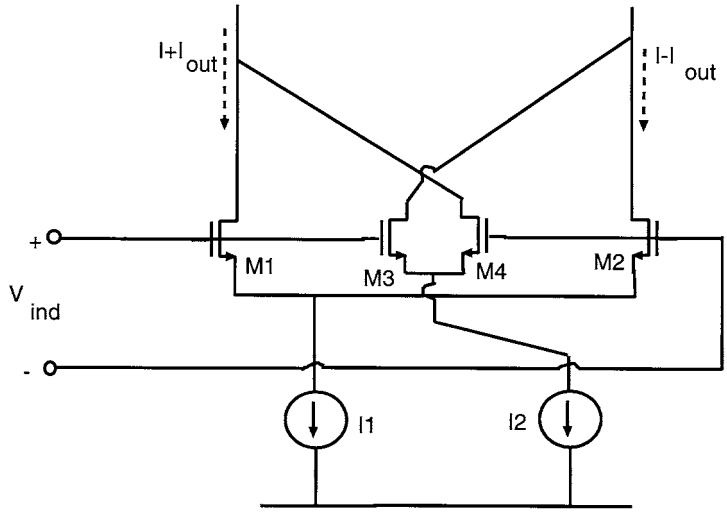

FIGURE 58.15 A cross-coupled linearized MOS $V \rightarrow I$ converter.

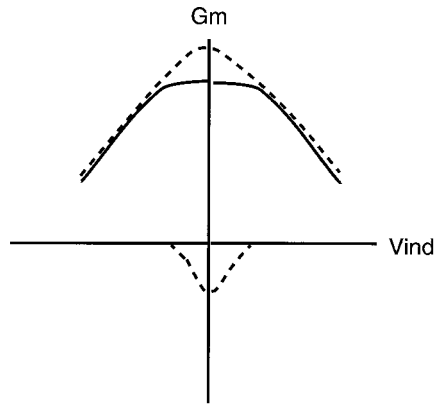

FIGURE 58.16 Individual differential pair G_m (dotted curves) and combined G_m (solid curve).

Ref. 10. The current through M3 and M4 will saturate at lower input voltages than the drain currents of M1 and M2. The concept is more clearly understood with Fig. 58.16. The dotted lines show the transconductance of the individual differential pairs versus input differential signal. The dotted lines for positive G_m correspond to the transistors M1 and M2, while the negative G_m refers to M3 and M4. Adding the G_m curves, the solid curve is obtained. Notice now that the transconductance curve is flat for small V_{ind}. It is possible to add the outputs of multiple differential pairs with slightly different non-linearities to broaden the region over which G_m is constant. A related approach is given in Ref. 23.

A classical linearization method is to use a differential pair with source degeneration. However, in most technologies, the resistor used for degeneration would vary with temperature and processing and be nominally fixed in value. To afford tunability, the degeneration resistor can be replaced with a MOSFET, M3, operating in the triode region, as shown in the G_m cell of Fig. 58.17.[24] M1 and M2 act as source followers and the transconductor's signal currect, I_{out}, is ideally the drain current of M3. The drain current of M3 can be expanded in a Taylor series for the case of zero drain-to-source voltage and obtains the following from the "3/2 Power" model[25] of the MOSFET:

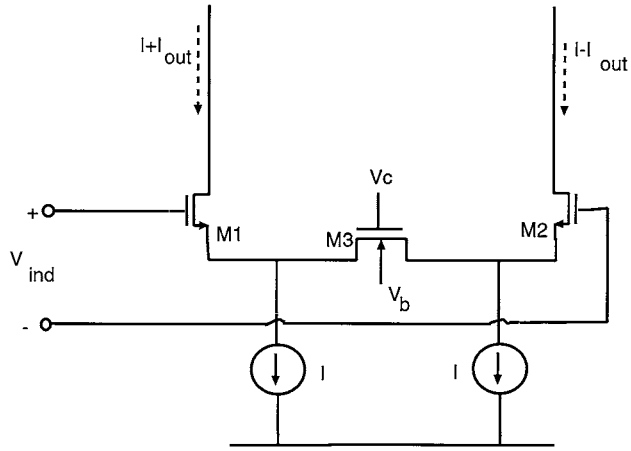

FIGURE 58.17 Source degenerated MOS $V \rightarrow I$ converter.

$$I = \left(W/L\right)\mu C_{ox}\left[\left(V_C - V_Q - V_T\right)\left(V_D - V_S\right) + \sum_{i=2}^{\infty} a_i\left(V_D^i - V_S^i\right)\right] \tag{58.12}$$

where V_Q is the bias level of the source and drain with respect to the body, V_S and V_D are the voltages on the source and drain terminals, respectively, and the a_i are constants. Notice that if the source and drain voltages are balanced around a common-mode voltage V_Q, such that $V_D = V_Q + V_{ind}/2$ and $V_S = V_Q - V_{ind}/2$, then as can be seen from Eq. 58.12,

$$I = \left(W/L\right)\mu C_{ox}\left[\left(V_C - V_Q - V_T\right)V_{ind} + \sum_{i>1,odd}^{\infty} a_i V_{ind}^i\right] \approx \left(W/L\right)\mu C_{ox}\left(V_C - V_Q - V_T\right)V_{ind} \tag{58.13}$$

For many applications, the remaining odd-order non-linearity is low enough (e.g., –65 dB) to be inconsequential. For applications requiring superior linearity, cross-coupled triode degenerated differential pairs can be used to theoretically cancel all high-order non-linearities.[24,26] Based on Eq. 58.13 the transconductance of the G_m cell is:

$$G_m = \left(W/L\right)\mu C_{ox}\left(V_C - V_Q - V_T\right) \tag{58.14}$$

assuming M1 and M2 are ideal source followers. As desired, the G_m is tunable with the control voltage, V_C, connected to the gate of M3. The linear input range can in practice be on the order of ± 1.0 *V*, provided that M3 remains in the triode region. The maximum input signal is thus equal to

$$V_{ind\text{–max}} = 2\left(V_C - V_Q - V_T\right) \tag{58.15}$$

The maximum input signal swing is a function of the tuning control voltage, V_C; consequently, the dynamic range is tightly coupled to the tuning range. In some situations where a programmable filter is required, multiple transistors can replace M3 and the triode devices can either be connected to V_C, or

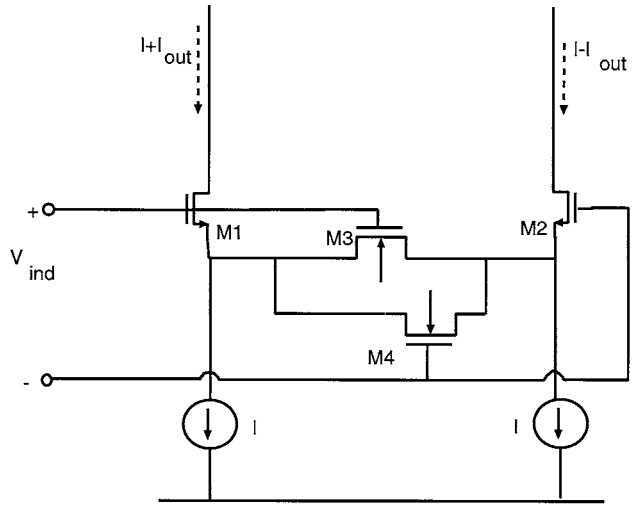

FIGURE 58.18 G_m cell operating in triode and saturation.

switched off to implement ranges in the filter.[7] In contrast to the transconductors in Figs. 58.14 and 58.15, power dissipation is unaffected by tuning. Finally, source followers M1 and M2 must be extremely low impedance (i.e., have high g_m) to drive the resistance of M3. Either large *W/L* devices can be used for M1 and M2, or negative feedback can be used around M1 and M2 to reduce their impedance at their source terminals.[5,27]

As an alternative to requiring low impedance source followers, the G_m cell shown in Fig. 58.18 can be used.[9] For small input signals, M3 and M4 operate in the triode region as in the previous design; however, the effective control voltage to tune the devices is set to the gate-to-source bias level of M1 and M2. For large positive input differential signals, more current flows in M1, increasing the V_{GS} of M1. If M3 and M4 had fixed gate voltages, the current through them would drop off, resulting in lower G_m as in the design of Fig. 58.17. However, the gate voltage of M3 increases under this input condition and helps to maintain a constant G_m. By scaling M1 and M2 to M3 and M4 (e.g., to a ratio of about 7:1) the linear range can be expanded. The linear range is also larger than that of Fig. 58.17 because M3 and M4 can operate in both the triode and saturation regions.

All transconductor designs discussed to this point have achieved an expanded linear range as a function of device matching or use of balanced input differential signals. Since matching and signal balancing can never be perfect, the achievable linearity is a strong function of layout and processing. In contrast, the transconductor of Fig. 58.19 achieves high linearity by maintaining constant drain-to-source voltage across triode devices M1 and M2.[8,28,29] Using the basic triode equation for a MOSFET,

$$I = \frac{1}{2}\mu_n C_{ox}\frac{W}{L}\left[2\left(V_{gs} - V_t\right)V_{DS} - V_{DS}^2\right] \tag{58.16}$$

one can see that if the drain-to-source voltage is held constant, the relationship between V_{GS} and I is linear, except for an offset. Cascode devices Q1 and Q2 in Fig. 58.19 are used to hold $V_{DS1} = V_{DS2} = I_d R_d$, resulting in a linear transconductance of

$$g_m = \mu_n C_{ox}\frac{W}{L}R_d I_d \tag{58.17}$$

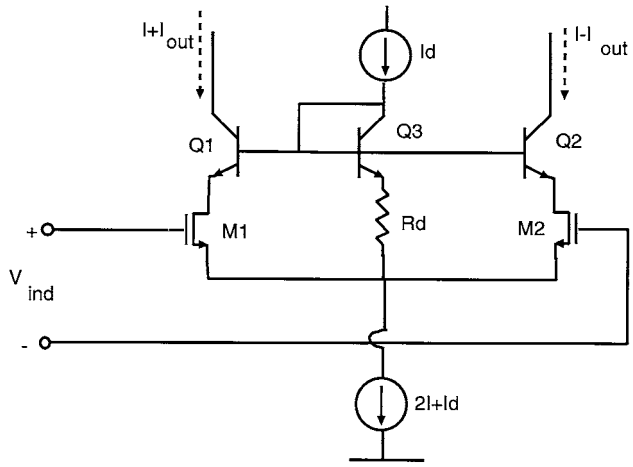

FIGURE 58.19 $V \rightarrow I$ converter with differential pair operating in triode with constant drain-to-source voltage.

The G_m cell is easily tuned with the collector current of Q3, I_d. Q1-Q3 could be replaced with MOSFETs; however, since the transconductance of bipolar devices is higher than MOSPETs, the BiCMOS solution provides superior cascoding to hold the drain-to-source voltages of M1 and M2 constant.

Many alternative linearization schemes exist for the $V \rightarrow I$ converters in CMOS, BiCMOS, and bipolar technology.[5,17,23,30-32] Invariably, nearly all the techniques require matching of transistors and/or balanced signals to achieve optimal linearity performance. Also, many of the techniques, particularly the MOSFET-based transconductors, rely on simplified large signal models (e.g., square law) of the transistors to model and cancel the non-linearity. In reality, more complex transistor equations, as found in Ref. 33, are needed to better predict performance. Ultimately, only experimental results over many process lots must be used for guaranteeing a specified linearity.

Once the $V \rightarrow I$ converter design has been determined, the entire G_m amplifier or integrator can be assembled using known op-amp structures. The design in Fig. 58.20 uses the $V \rightarrow I$ converter of Fig. 58.17 with a folded-cascode output stage. The cascoding raises the output impedance of the amplifier and

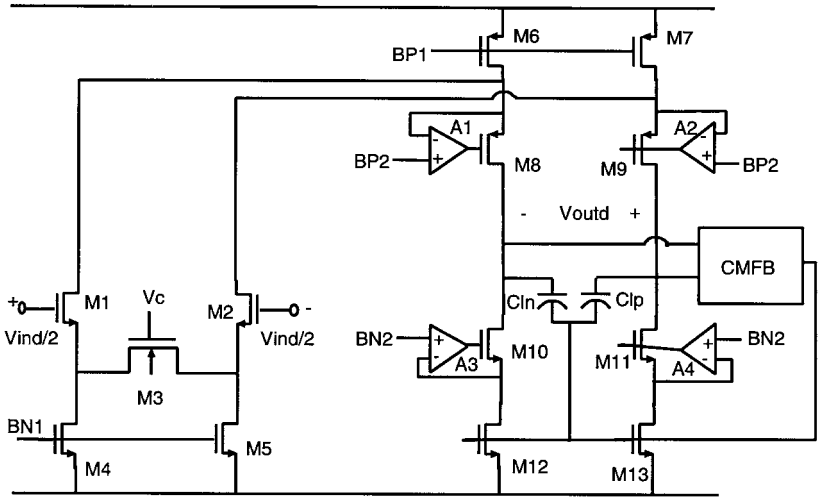

FIGURE 58.20 Folded cascode MOS G_m-C integrator.

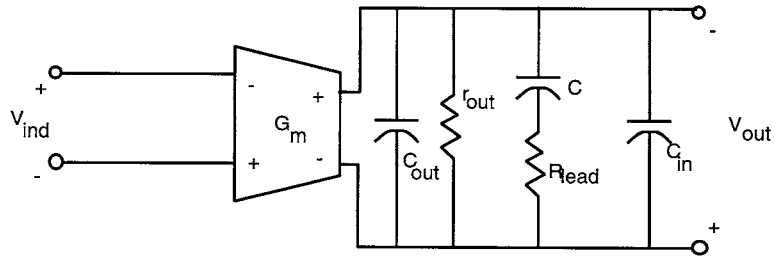

FIGURE 58.21 Non-idealities modeled in the G_m-C integrator.

optionally A1 through A4 create regulated cascodes to raise the output impedance further.[21] The nominally equal capacitors C_{lp} and C_{ln} serve two functions. For differential-mode output signals, the capacitors integrate the output current. For common-mode signals, they provide high frequency common-mode feedback (CMFB) via the gates of M12 and M13, while low frequency CMFB is poerformed with standard techniques.[34] Folding the cascode structure permits larger output voltage swings and equal input and output common-mode voltage levels. Use of folding as opposed to an unfolded cascode (i.e., telescopic structure) will generally result in increased input-referred noise and offset due to the addition of transistors M6 and M7.

G_m-C Integrator Frequency Response Errors

The G_m-C integrator will have magnitude and phase errors due to parasitic capacitances and resistances. Consider the non-ideal integrator shown in Fig. 58.21. C is the integrating capacitance, c_{in} is the parasitic capacitance due to wire routing and the input of the next stage, and c_{out} and r_{out} are the parasitic output capacitance and resistance of the transconductor, respectively. R_{lead} is a series resistance that is sometimes added to provide phase lead for correction of parasitic effects. Assuming that the G_m amplifier has a dc level of G_{mo}, a parasitic pole at ω_p and a parasitic zero at ω_z, the transfer function of the non-ideal integrator can be derived as:

$$H_a(s) = \frac{G_{mo}\left(1 + s/\omega_z\right)}{\left(1 + s/\omega_p\right)} \frac{r_{out}}{1 + sr_{out}\left(C + c_{out} + c_{in}\right)} \tag{58.18}$$

The ideal integrator has infinite dc gain, a rolloff of 6 dB/octave, a unity-gain frequency of $\omega_o = G_{mo}/C$ and a phase of 90° for all frequencies. Parasitics generally have a much stronger effect on the integrator's phase response than the magnitude response. The integrator phase errors in turn are the largest source of filter magnitude response errors. In general, the integrator phase accuracy at ω_o is most critical. The G_m-C integrator's phase error as a function of frequency is:

$$\phi_{I-error}(\omega) \approx \pi/2 + \left(\omega/\omega_z\right) - \left(\omega/\omega_p\right) - \arctan\left[G_{mo}r_{out}\left(\omega/\omega_{ox}\right)\right] \tag{58.19}$$

where ω_{ox} is the actual as opposed to the ideal unity-gain frequency. As an example, consider a G_m-C integrator with a unity-gain frequency of 20 MHz, C = 1 pF, $G_{m\sigma}$ = 125.7 μS, and r_{out} = 1 MΩ. If the transconductor has a parasitic pole at 300 MHz, but no parasitic zero, the resulting phase error at 20 MHz is –3.4°. Depending on the application, such an error may be acceptable. Two methods exist for correcting the phase error. The simplest approach is to add a zero to the transfer function to create phase lead of +3.4° at 20 MHz, resulting in zero net phase error at ω_o. The small value resistor, R_{lead}, in Fig. 58.21 is used for this purpose. Phase lead can also be created within the G_m amplifier with known feedforward techniques. If the accuracy of the phase is critical, tunable phase lead or lag can be performed.[6,8,11,16]

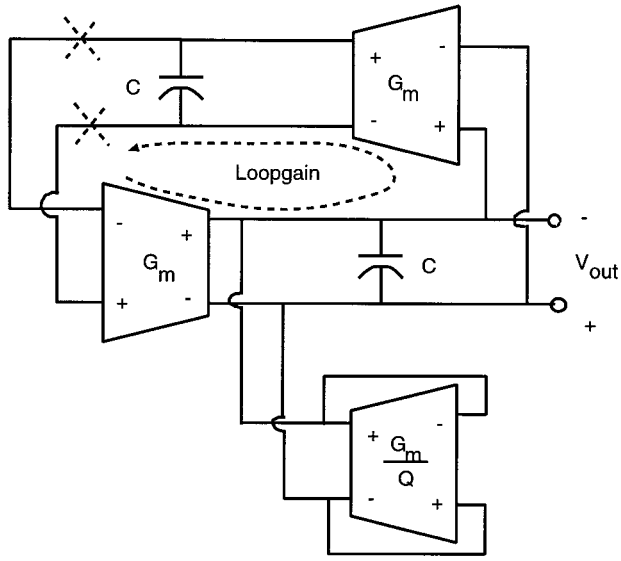

FIGURE 58.22 Integrator phase error impact on biquad filter Q.

The natural question arises as to what integrator phase accuracy is required. Although the requirement is dependent on the filter topology, and transfer function, a good estimate can be determined by considering the damped loop of two integrators shown in Fig. 58.22. This loop of integrators is found in cascade of biquad filters and leapfrog filters and is therefore quite general. The system poles are determined by the loop gain transfer function, $T(s)$,

$$T(s)=\left[\frac{G_m}{sC}\right]\left[\frac{G_m}{sC+G_m/Q}\right]=\left[\frac{1}{s/\omega_o}\right]\left[\frac{1}{s/\omega_o+1/Q}\right] \tag{58.20}$$

Under Ideal conditions and assuming a high value of Q, the loop gain phase shift is

$$\phi(\omega)\approx\frac{\omega_o}{\omega Q} \tag{58.21}$$

Notice that as Q increases, the net phase shift around the loop approaches zero; thus making any integrator phase errors a large source of damping errors. Consider two examples. First, the continuous-time filter used in hard disk drive read channels often has a Bessel response where all the poles are low Q. Assuming $Q \approx 2$, the nominal phase shift around the integrator loop, $\phi(\omega_o) \approx 26.6°$, is quite large. If the total integrator phase error is to be kept $<0.1\phi$, then each integrator phase error must be $<1°$. In contrast, for a bandpass response that might be found in wireless systems with $Q = 100$, the nominal loop phase is $\phi(\omega_o) \approx 0.57°$, and each integrator phase error must be kept $<0.03°$. The low-Q integrator requirements can be met with fixed or tunable phase lead networks, whereas the high-Q applications will require phase tuning (Q tuning) circuits. Although this discussion has centered around G_m-C filters, the results are equally applicable to G_m-*OTA*-C and *MOSFET*-C filters.

G_m-*OTA*-C Filters

The G_m-C integrator of Fig. 58.11 achieves high frequency operation because the circuit configuration is open loop; however, the requirement for high impedance at the output nodes of the G_m amplifier is

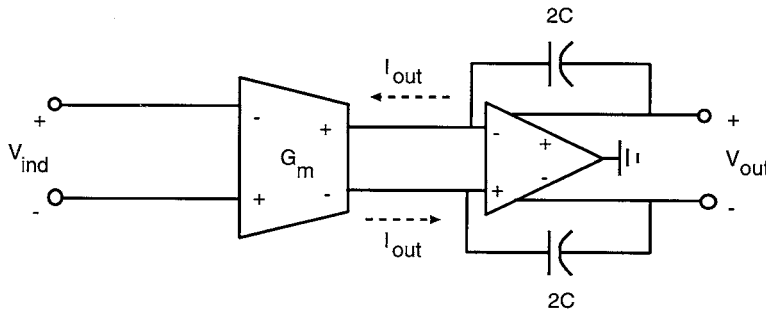

FIGURE 58.23 Fully balanced G_m-*OTA*-*C* integrator.

generally difficult to meet. Use of cascodes in the output stage is required, but the signal swing and resulting linearity often suffer. The second difficulty is that any parasitic capacitance due to routing or the input impedance of the next stage will lower the unity-gain frequency of the integrator. A portion of the parasitic capacitance is the non-linear diode capacitance of the drain diffusions. As the signal frequency increases, more current flows into these non-linear capacitors, reducing the overall linearity of the integrator.

The G_m-*OTA*-*C* integrator of Fig. 58.23 adds an operational transconductance amplifier (*OTA*) connected with negative feedback via the integration capacitors at the output of the G_m amplifier. For this configuration, the G_m amplifier drives into a virtual short-circuit and hence requires no signal swing. Parasitic capacitances at the output of the G_m amplifier are held at virtual ground and the capacitances at the output of the *OTA* are driven by a low impedance, so in both cases, their impact on the integrator's frequency response and linearity is negligible. Although the parasitic capacitances do not shift the ω_o of the integrator, high-frequency parasitic poles are created that can cause phase errors near ω_o. For this reason, the G_m-*OTA*-*C* approach operates at a lower frequency than the G_m filtering technique.

The dc gain of the G_m-*OTA*-*C* integrator is

$$\frac{V_{out}(s)}{V_{ind}(s)} = G_{mo} r_{out} A_o \tag{58.22}$$

where G_{mo} is the dc transconductance of the transconductor, r_{out} is its output resistance, and A_o is the dc voltage gain of the *OTA*. The G_m-*OTA*-*C* integrator has two stages of gain, and the increase in gain relative to the G_m-*C* approach by the factor A_o results in a more ideal integrator characteristic at low frequency. Since two gain stages are used, cascoding is often eliminated or simplified so the improvement in the G_m-*OTA*-*C* integrator's dc gain over that of the G_m-*C* integrator may be less dramatic. Elimination of cascoding simplifies the circuit design, often results in reduced power dissipation, and enables lower voltage operation.

Signal summation in G_m-*OTA*-*C* filters is performed in the current domain at the summing node of the *OTA*. Instead of one G_m amplfier as in Fig. 58.23, the outputs of multiple transconductors with different values of G_m can be paralleled and drive the *OTA* summing node to obtain weighted summation and integration.

Many G_m-*OTA*-*C* integrator designs exist, but the one in Fig. 58.24 is a good example.[8] The transconductor consists of M1-M4, Q1, and Q2. The $V \rightarrow I$ mechanism is realized with triode operated devices, M1 and M2, that have constant drain-to-source voltages. Varying the base voltage of transistors Q1 and Q2 tunes the $V \rightarrow I$ converter. Unlike the $V \rightarrow I$ converter in Fig. 58.19, devices M1 and M2 are connected to ground rather than to a current source to improve the headroom in the G_m amplifier. The input common-mode voltage level at the gates of M1 and M2 must be well controlled so the drain current bias levels are fixed. M3 and M4 serve as simple current sources and their gate voltages are varied by a CMFB

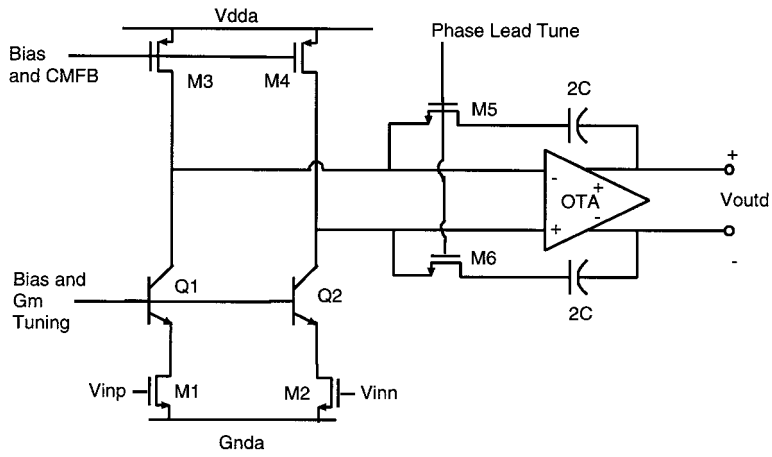

FIGURE 58.24 A BiCMOS G_m-*OTA*-*C* integrator with tunable phase lead.

circuit (not shown) to control the output common-mode voltage of the G_m stage. The second stage consists of the *OTA*, integrating capacitors, and phase lead transistors, M5 and M6. M5 and M6 operate in triode with a zero drain-to-source bias voltage and act as resistors. Their role is to provide phase lead in much the same way as the R_{lead} resistor does in the G_m-*C* design of Fig. 58.21. Here, the use of transistors instead of a fixed resistor permits the amount of phase lead to be adjusted for process and temperature variations. The phase lead tuning circuit in Ref. 8 is a dc control loop and does not use the more complex *Q* tuning techniques given in Refs. 6, 11, 16, and 18.

The *OTA* design can take the form of standard op-amp topologies. In Ref. 8 a simple one-stage BiCMOS design with cascoding was used, as shown in Fig. 58.25. CMFB control via the gates of M2 and M4 is required to control the average output voltages of V_{outp} and V_{outn}. Notice that although the G_m-*OTA*-*C* integrator requires two basic amplifiers (e.g., a G_m and an *OTA* amplifier), the amplifiers can often be simpler than the single G_m amplifier required in G_m-*C* filters. The power and bandwidth penalties of the G_m-*OTA*-*C* technique may therefore be less negative than at first view.

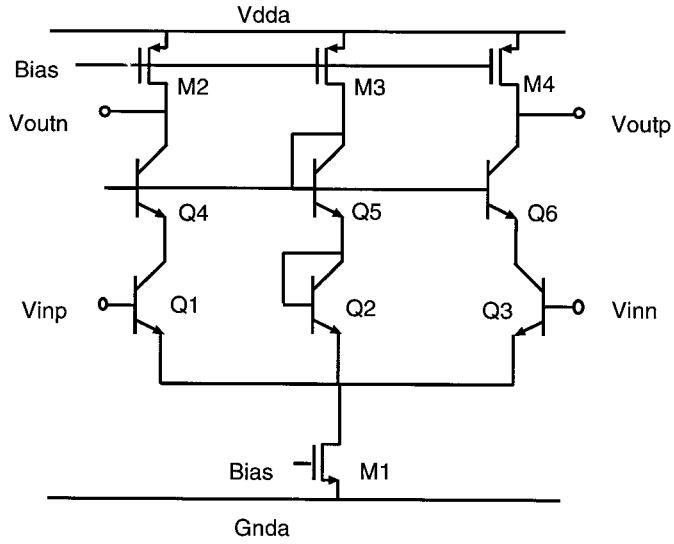

FIGURE 58.25 *OTA* for G_m-*OTA*-*C* integrator of Fig. 58.24.

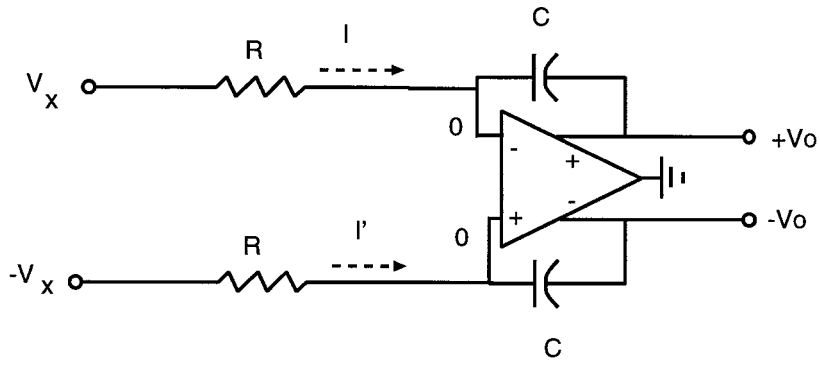

FIGURE 58.26 Balanced active RC integrator.

MOSFET-C Filters

MOSFET-C and G_m-*OTA-C* filters are similar, except that passive $V \rightarrow I$ devices are used to produce currents for summing into the *OTA* or op-amp in the *MOSFET-C* case, rather than an active $V \rightarrow I$ converter as in the G_m-*OTA-C* approach. Using two equal resistors for $V \rightarrow I$ conversion results in the fully balanced classical active-RC integrator of Fig. 58.26. For balanced inputs signals, V_x and $-V_x$, that have a common-mode level of zero, the input terminals of the op-amp are fixed at zero volts. The op-amp provides balanced outputs, $V_o(t)$ and $-V_o(t)$, that are derived to be:

$$V_o(t) - -V_o(t) = \frac{-1}{C}\int_{-\infty}^{t}\left[I(\tau) - I'(\tau)\right]d\tau \tag{58.23}$$

Therefore,

$$V_o(t) = \frac{-1}{RC}\int_{-\infty}^{t} V_x(\tau)\,d\tau \tag{58.24}$$

Obviously, using fixed resistors does not permit frequency scaling the integrator to remove temperature and process variations. If one replaces the resistors with MOSFETs operating in the triode region with zero drain-to-source bias, the *MOSFET-C* integrator shown in Fig. 58.27 results. Although each MOSFET is non-linear, operating with the fully balanced structure and assuming perfect matching of devices, the even-order non-linearities will cancel. Odd-order non-linearities are not canceled; however, they are low enough for many applications. Using Eq. 58.12 the output of the *MOSFET-C* integrator can be derived[35] as:

$$V_o(t) \approx \frac{-(W/L)\mu C_{ox}(V_C - V_Q - V_T)}{C}\int_{-\infty}^{t} V_x(\tau)\,d\tau \tag{58.25}$$

V_Q is the input common-mode bias level of the signals V_x and $-V_x$. The approximation results from the assumption that the odd-order non-linearities can be neglected. Notice that the op-amp input terminals are at voltage V_y, as opposed to zero. V_y will have a bias level of V_Q, but V_y will vary with the input signal V_x with a square-law characteristic.[36] For practical circuits, V_y will vary by a couple of hundred millivolts, resulting in modest input common-mode range requirements for the amplifier.

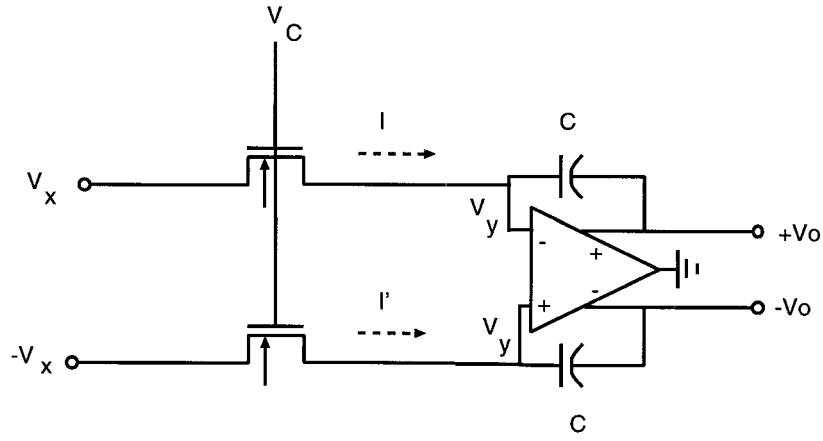

FIGURE 58.27 The *MOSFET-C* integrator.

The derivation of the *MOSFET-C* integrator linear input/output characteristic assumes that both transistors remain in the triode region. Such a requirement results in a coupling of the minimum permissible tuning voltage, V_{C-min} and the maximum input signal swing, V_{x-max}.

$$V_{x-max} = V_{C-min} - V_Q - V_T \tag{58.26}$$

Non-linearity cancellation in the *MOSFET–C* integrator depends on matched devices as well as fully balanced input signals. Since in a filter the signals that drive the integrator input come from a similar integrator stage, the op-amp used must have well-balanced outputs. If the signal balancing is imperfect in magnitude or if the signals are not exactly 180° out of phase, the even-order non-linearities will no longer be suppressed.[37] Magnitude errors of 1% and phase errors of 1° can be problematic.[37] The op-amp design must use a robust CMFB circuit consisting of an error amplifier and linear detector (i.e., two resistors) for the output common-mode detection, as described in Ref. 34. Many CMFB circuits that are adquate for differential switched-capacitor circuits do not provide adequate balancing for *MOSFET-C* filters.

Variations of the basic two-transistor fully balanced *MOSFET-C* integrator are possible.[26,38] In Ref. 38, the design of *MOSFET-C* filters with only single-ended output op-amps is described. In Ref. 26, the four-transistor *MOSFET-C* integrator shown in Fig. 58.28 in theory cancels even- *and odd*-order non-linearities.

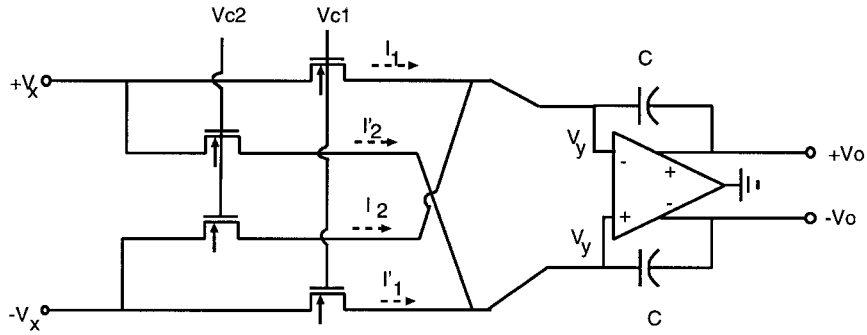

FIGURE 58.28 Four transistor *MOSFET-C* integrator.

Assuming perfectly matched transistors and constant mobility of carriers in the transistors,[33] the integrator output can be derived with Eq. 58.12 as:

$$V_o(t) = \frac{-(W/L)\mu C_{ox}(V_{C1} - V_{C2})}{C} \int_{-\infty}^{t} V_x(\tau)\, d\tau \tag{58.27}$$

Here, integrator tuning only depends on $V_{C1} - V_{C2}$, and is independent of the transistor threshold voltage, V_T, resulting in several advantages. First, in the basic two-transistor *MOSFET-C* integrator, body noise, V_B, can modulate the threshold voltage and couple into the integrator. The threshold voltage using the signal convention in the *MOSFET-C* integrator, is[33]:

$$V_T = V_{T0} + \gamma\left(\sqrt{V_Q - V_B + \phi_B} - \sqrt{\phi_B}\right) \tag{58.28}$$

where V_{T0} is the threshold voltage at zero source-to-body bias, and γ and ϕ_B are constants. Since the integrator's gain in the four-transistor *MOSFET-C* design is independent of V_T, immunity to body noise is achieved. The second advantage of the four-transistor *MOSFET-C* integrator is that very low integrator gains can be realized without loss of signal swing by making $V_{C1} - V_{C2}$ small, while simultaneously maximizing $V_{C1} + V_{C2}$. In contrast, to realize low gain, the basic *MOSFET-C* integrator requires $V_C - V_Q - V_T$ to be small, directly limiting the signal swing, as shown in Eq. 58.26. The primary disadvantage of the four-transistor *MOSFET-C* integrator is increased thermal noise and device sensitivity in comparison to the standard *MOSFET-C* circuit.[37] For most applications, the four-transistor integrator results in increased dynamic range (e.g., a few dB) and a larger tuning range.

Realizing *MOSFET-C* filters from SFGs, block diagrams, or classical active RC filters is straightforward. The *MOSFET-C* equivalent of the Tow-Thomas biquad (Fig. 58.4) is constructed as in Fig. 58.29. Each resistor in the active RC filter is replaced with a MOSFET, and the single-ended topology is converted to a balanced structure by mirroring all devices around the line of symmetry going between the op-amp input terminals and its output. Mirroring and use of a fully balanced structure is mandatory to obtain cancellation of even-order non-linearities in the triode-operated MOSFETs. Signal inversion is obtained by taking the opposite output terminal of the op-amp, so the inverting amplifier in the classical single-ended design is not required in the *MOSFET-C* approach. Weighted signal summation is achieved by

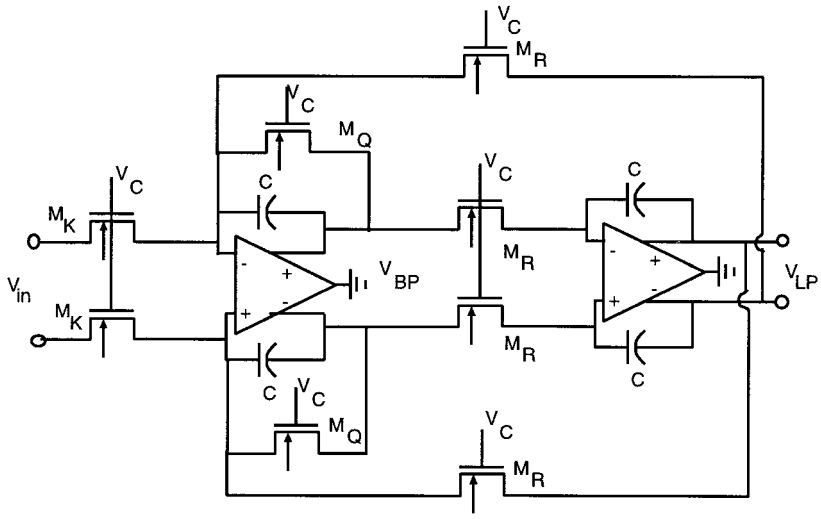

FIGURE 58.29 *MOSFET-C* version of Tow-Thomas biquad.

connecting multiple transistors to the op-amp summing node and scaling the relative W/*L* ratios of the devices. The gates of all MOSFETs are connected to a single control voltage, V_C, for frequency tuning the filter.

The frequency response of *MOSFET-C* filters can become distorted due to integrator gain and phase errors, as in the case of G_m-*C* and G_m-*OTA-C* filters. As before, phase errors are more problematical. Integrator phase errors in the *MOSFET-C* approach are due to the finite op-amp gain–bandwidth product as well as the distributed capacitance of the MOSFET. The triode-operated MOSFET acts as a linear tunable resistor for small signals; however, parasitic capacitance between the channel-to-gate terminal and from the channel-to-body terminal makes the transistor act as a uniformly distributed RC transmission line.[33,37] The transistor is then a lowpass filter between the integrator input and the op-amp summing node, creating phase lag in the integrator's response.

The channel resistance R_T and capacitance C_T of the MOSFET are given by

$$R_T = \frac{1}{\mu C_{ox}\left(W/L\right)\left[V_C - V_Q - V_T\right]} \tag{58.29}$$

$$C_T = WLC_{ox}\left(b+1\right) \tag{58.30}$$

where b is the backgate effect and is approximately 0.1. As discussed in Ref. 37, for most applications, the MOSFET can be modeled as a first-order lumped circuit resulting in the balanced small-signal *MOSFET-C* integrator model of Fig. 58.30. The transfer function of the integrator is then

$$\frac{V_o}{V_i} = \frac{-\omega_o}{s}\left[\frac{1}{1+\dfrac{s}{\omega_\tau}}\right] \tag{58.31}$$

where $\omega_o = 1/R_TC$ and $\omega_\tau = 1/R_TC_T$. Clearly, distributed capacitance adds extra phase lag. Note that ω_o is proportional to $1/L$, but ω_τ is proportional to $1/L^2$, where L is the channel length. Therefore, *MOSFET-C* filters will in general have worse distributed effects for *low* frequency filters because long channel lengths are used.

MOSFET-C integrator phase errors due to distributed effects and op-amp finite gain-bandwidth product can be compensated by introducing a high frequency zero by either adding a small series resistor to each integrating capacitor or by adding capacitor C_c in parallel with the MOSFETs, as shown in

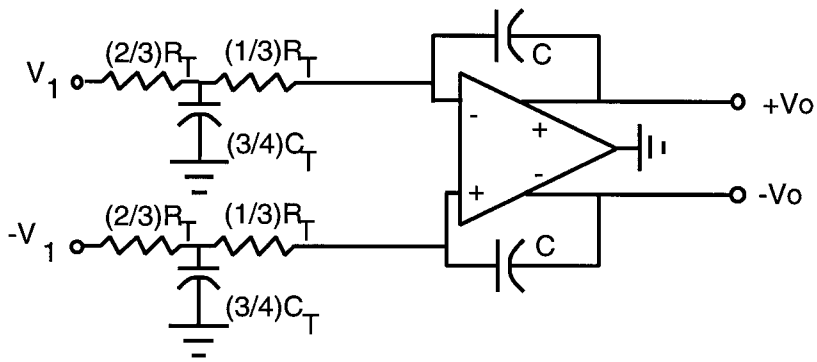

FIGURE 58.30 Small-signal model of *MOSFET-C* integrator with MOSFET channel capacitance.

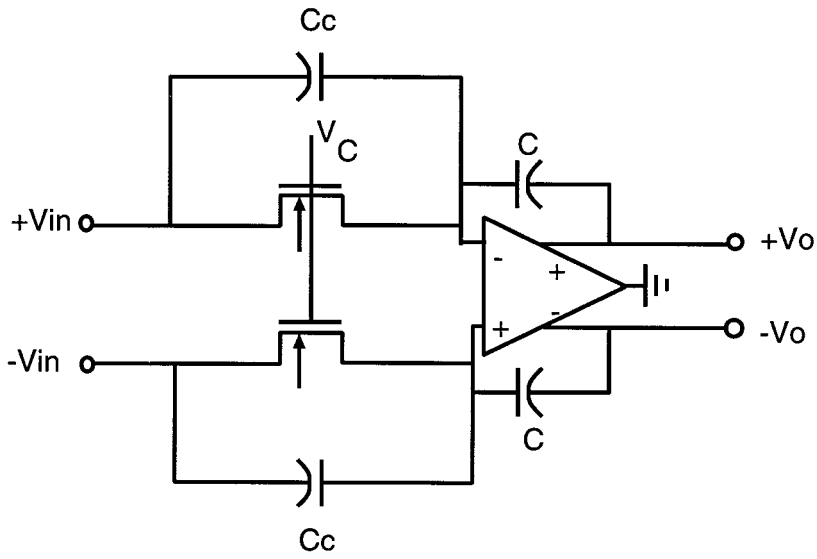

FIGURE 58.31 Phase compensated *MOSFET-C* integrator.

Fig. 58.31. Assuming an op-amp frequency response model of $A(s) = \omega_T/s$, C_c should be selected as follows to null the integrator phase error at the unity-gain frequency[37]:

$$C_c \approx \frac{C_T}{6} + \frac{\omega_o}{\omega_T} C \tag{58.32}$$

The use of a fixed phase compensation capacitor, such as C_c, or a fixed series resistor is often appropriate for low-quality factor filters, but not for high-Q filters (e.g., $Q > 10$).

Alternate Continuous-Time Filter Techniques

Although the vast majority of integrated continuous-time filters fall into the G_m-*C*, G_m-*OTA-C*, or *MOSFET-C* approaches, other techniques have been developed for applications requiring high linearity. The approaches described so far permit continuous frequency scaling of the filter and hence require MOS or bipolar transistors as variable resistors or transconductors. Since transistors are inherently non-linear, use of nominally matched devices, balanced signals, etc. must be employed to achieve overall linear operation. Practical issues generally limit the linearity to 60 dB for signal swings on the order of 1 V. To achieve linearity in the 80-dB range and higher, use of linear passive devices (e.g., resistors) has helped.[2-4,39,40]

The linearity of the *MOSFET-C* integrator can be vastly improved if less drain-to-source voltage is dropped across the MOSFETs for maximum input signals. Adding resistors in series with the input signals will improve linearity, but decrease the tuning range. With the addition of two transistors connected to a second control voltage V_{c2}, as in Fig. 58.32, the tuning range can be restored.[4] The majority of the input voltage is dropped across the resistors for excellent linearity, and the four transistors are used to simply steer signal current to ground or to the op-amp summing node. As V_{c2} is increased, more current is diverted to ground, leaving less for the summing node, so the integrator gain is reduced. This configuration has been used to achieve in excess of 90-dB linearity for digital audio applications.[4] In this technique, the integrator loop gain is low, restricting the signal bandwidth to levels significantly below standard *MOSFET-C* filters.

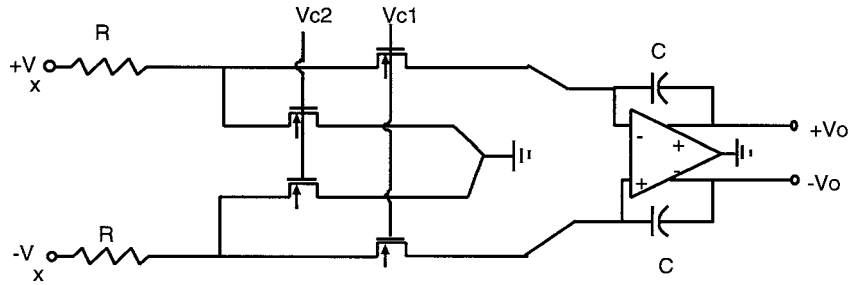

FIGURE 58.32 *R-MOSFET-C* integrator.

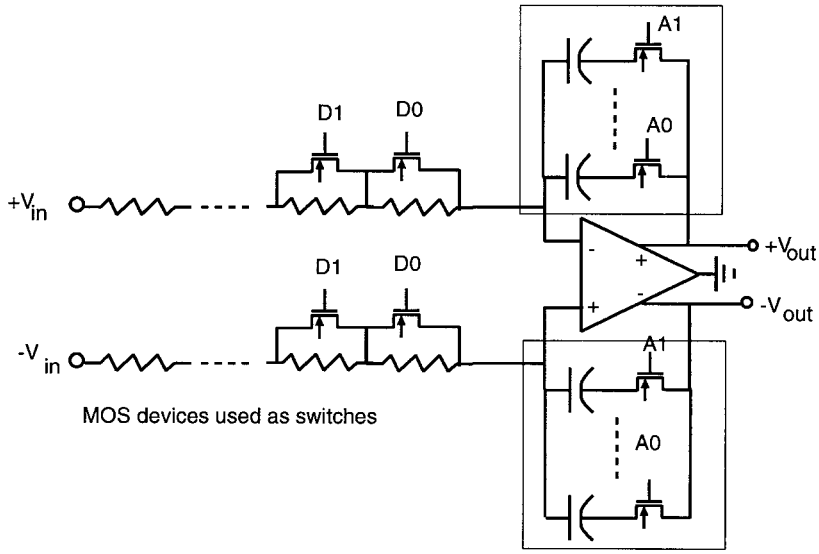

FIGURE 58.33 Programmable active RC integrator.

If continuous frequency scaling can be replaced with discretized tuning, then switchable active RC filters can be used to maximize linearity.[2,3,39,40] The basic concept, as shown in Fig. 58.33, is to build the integrator with linear resistors and capacitors. MOS switches are then used to program the values of capacitors and/or resistors. In the figure, a series connection of resistors is shown; however, parallel combinations are also feasible.[2] This technique has no inherent bandwidth restrictions, but in practice the MOS switches add parasitic capacitance that cause phase lag, disturbing the integrator's frequency response. A design tradeoff is then tuning resolution versus switch parasitics. To provide adequate tuning range to cover process and temperature variations (e.g., ±50%) and a minimization of switch parasitics, typically results in tuning resolution of ±2 to ±5%. Filter tuning can use microprocessor control[3] or a replica master integrator or delay circuit with up/down counters.[2,39,40] Finally, since the components are inherently linear, use of balanced structures is not mandatory and a larger class of classical active RC filters can be implemented on-chip. Single-amplifier biquad structures[19,40] then become attractive.

58.4 Filter Tuning Circuits

Integrated continuous-time filters require on-chip tuning circuits to control the corner or center frequencies in the face of process and temperature variations. Only in some non-critical applications, such as anti-alias or reconstruct filters, can the ±50% variation in filter time constants be tolerated. Filter

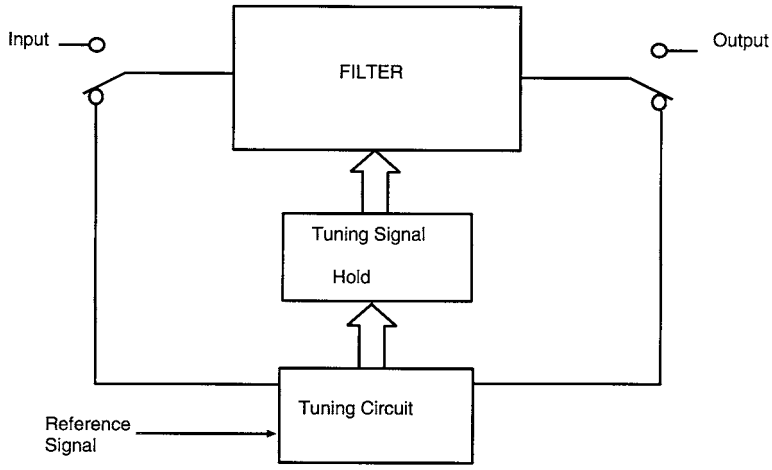

FIGURE 58.34 A direct-tuned filter.

tuning, or frequency scaling of the filter, can be accomplished with either direct or indirect tuning methods.

Direct Tuning

Direct tuning, illustrated conceptually in Fig. 58.34, is described in Ref. 41. The filter is periodically removed from the signal path and, after measurements are made with respect to a reference signal, the required adjustments are applied to the filter and held with analog or digital storage means. The filter is then returned to the signal path. The advantage of this approach is that the filter is measured directly and excellent accuracy is possible. Since many applications cannot tolerate interruption of the signal path, it is conceptually possible to use two filters[41]: one processes the signal while the other is tuned. However, the complexity and chip area overhead cause this alternative to be rarely used. Direct tuning is seldom used, but a production example does exist.[42]

Master-Slave Tuning

By far the most prevalent tuning method is the indirect or master-slave tuning technique. In this aproach, a master circuit that is made of the same components as the main filter is tuned with respect to a reference signal or component. The tuning signal that adjusts the master is also used to tune the slave or main filter. Since components in the master and slave circuits are on the same chip, they will match accurately. The time constants of the slave will then track the master over all process and temperature variations. If the master and slave components are placed closely in the layout, and good layout techniques are used, then matching of a few percent is possible.

One simple dc master-slave frequency tuning technique, shown in Fig. 58.35, uses a precision off-chip resistor. A small voltage V is applied to the MOSFET and $-V$ is applied to the resistor. The circuit converges when $I_1 = I_2$, so that $r_{ds} = 1/R_s$. The process and temperature variations of the MOSFET resistance are then removed; however, capacitor values in the filter will need trimming during manufacture. An ingenious variation[43] replaces the external precision resistor with an on-chip switched-capacitor equivalent resistance as shown in Fig. 58.36. If switched-capacitor C_s is clocked at a rate f_s, the charge transfer from the input voltage V to the summing node is equivalent to that which would be obtained with a resistor of value

$$R_{sc} = \frac{1}{f_s C_s} \tag{58.33}$$

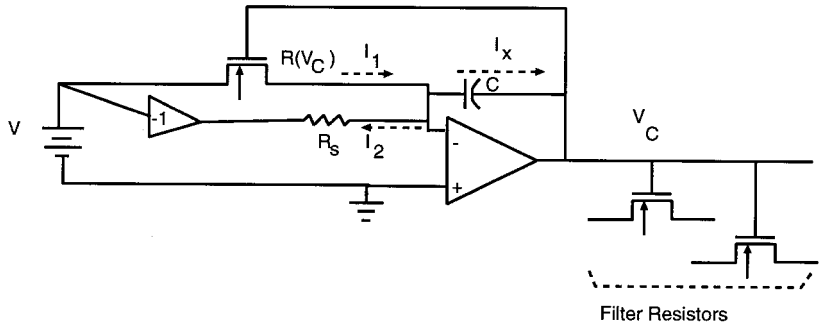

FIGURE 58.35 Reference resistor-based master-slave tuning circuit.

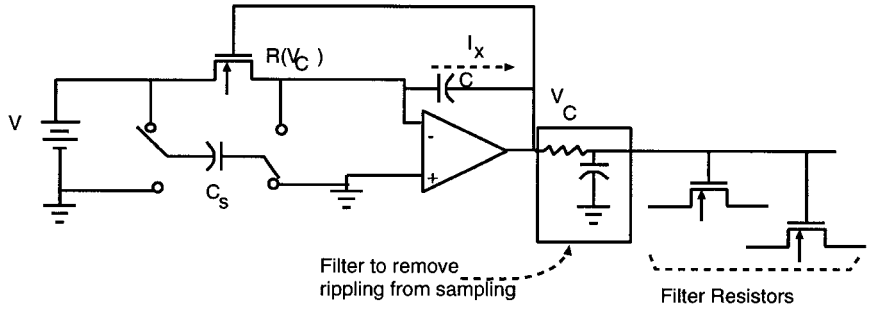

FIGURE 58.36 Switched-capacitor-based master-slave tuning circuit.

The average current flowing through the switched-capacitor will be forced equal to the drain current in the MOSFET due to the negative feedback resulting in $I_x = 0$. The voltage V_C that tunes the MOSFET in the master cell will then reach an average dc value with some ripple due to the switched-capacitor circuit operation. After additional filtering of V_C to remove the ripple, the tuning signal is routed to the slave filter. The slave filter will possess many time constants and critical frequencies. A critical frequency, f_x, will be determined by a MOSFET channel resistance r_{ds-x} and a capacitance, C_x. The tuning circuit then ensures that

$$f_x = f_s\left(\frac{r_{ds}}{r_{ds-x}}\right)\left(\frac{C_s}{C_x}\right) \tag{58.34}$$

The filter's critical frequency, f_x, is then accurate since it is determined by the clock reference, f_s, the ratio of the channel resistance of transistors, and the ratio of capacitors. Clearly, the switched-capacitor tuning technique has the benefit that it tunes time constants, not just resistance values. The master-slave dc tuning methods shown here are equally applicable to G_m-C and G_m-OTA-C filters.

Often, the master-slave tuning approach uses a phase-lock loop (PLL) and a master cell that is either a voltage-controlled filter (VCF) or a voltage-controlled oscillator (VCO). First, consider the case of a master VCF.[6,10] Many options exist for the design of the VCF, but a reasonable design uses a lowpass biquadratic filter. The transfer function of a lowpass biquad is given by

$$V_{o-lp}(s) = \frac{K\omega_o^2}{s^2 + \frac{\omega_o}{Q}s + \omega_o^2}V_{in}(s) \tag{58.35}$$

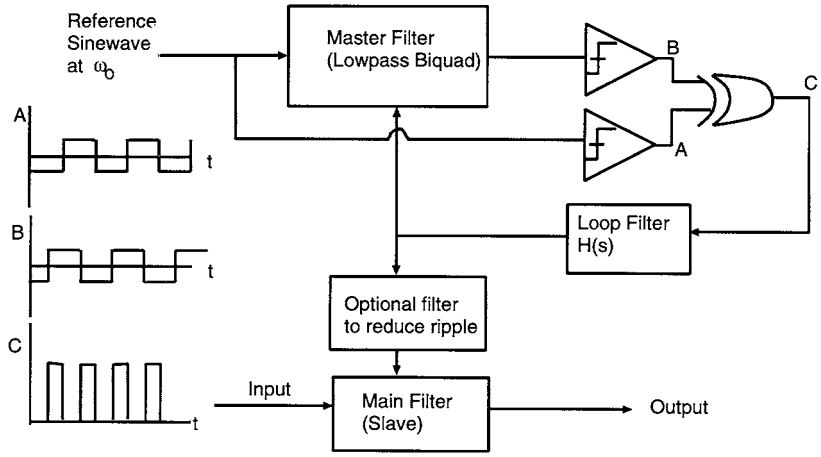

FIGURE 58.37 A VCF-based Master-slave tuning system.

where K is a gain constant. If a sinewave at frequency ω_o is applied to the filter's input, the phase of the output will be –90° with respect to the input, provided that the filter is accurately tuned. The PLL tuning circuit will adjust the RC products of the VCF until the phase shift is –90°. One embodiment of the VCF master-slave tuning method is shown in Fig. 58.37. The exclusive-OR (XOR) gate phase detector is preceded by two slicers that convert the filter's sinewave input and output signals to logic levels. The loop filter, $H(s)$, has a first-order lowpass response and the feedback loop forces the tuning voltage (or current) at the output of the loop filter to converge to a dc value, which simultaneously frequency tunes the master biquad and slave filter. Since the loop filter output will contain ripple, extra lowpass filtering can be applied outside the feedback loop so as not to compromise loop stability while eliminating the ripple on the tuning signal in the slave filter.

The tuning accuracy of this approach is directly linked to the loop gain of the PLL, which is derived as

$$\text{Loop gain} = K_D H(s) K_{VCF} = K_D H(s)\left(\frac{\partial \omega_o}{\partial V_C}\right)\left(\frac{-2Q}{\omega_o}\right) \tag{58.36}$$

K_D is the phase detector gain in volts/radian, K_{VCF} is the master filter's gain in radians/volt, V_C is the filter's tuning signal, and Q and ω_o are the quality factor and corner frequency of the master biquad, respectively. To maximize the tuning accuracy, the loop gain should be maximized. The gain is kept high by using a relatively high-Q master filter (e.g., $Q > 5$) and an integrator for the loop filter. Frequency tuning errors will occur if there are static phase errors in the PLL. Static phase errors will not cause PLL convergence difficulty; however, the relative phase of the biquad's input and output signals may differ from –90°. Static phase errors can occur due to delay mismatches in the slicers or rise and fall time asymmetries in the XOR phase detector.[6]

The PLL with VCF master-slave tuning approach is appealing because the master circuit is simply a biquad that closely resembles a portion of the slave filter. The only drawback is that this tuning method requires a sinusoidal reference signal that is not usually available in most system applications. Unfortunately, use of a commonly available square wave reference signal is unacceptable because the large harmonic content shifts the zero crossings at the master biquad's output, creating a systematic error in phase measurements, resulting in a fixed frequency tuning error. Triangular input signals work better since the harmonic content is lower.[6]

Since sinusoidal reference signals are rarely available, the more common PLL tuning approach uses a VCO in a classical PLL circuit.[44] Use of a master VCO with PLL has been widely applied to master-slave continuous-time filter tuning.[1,7,9,13,14,27] This master-slave tuning technique, depicted in Fig. 58.38, uses

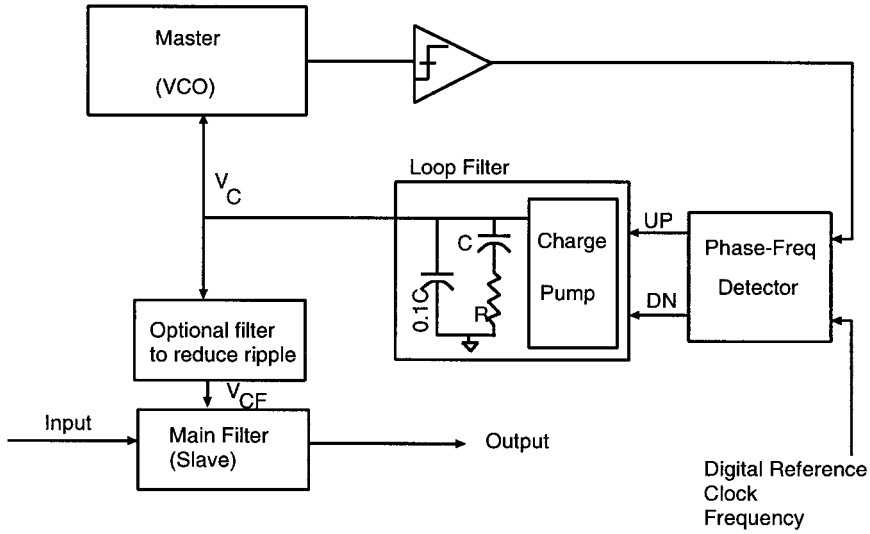

FIGURE 58.38 A VCO-based master-slave tuning system.

a master oscillator that is constructed with the same type of capacitors and resistors (or transconductors) used in the slave filter. The VCO produces a sinusoidal output, so a slicer converts the signal to a square wave for application to the digital phase-frequency detector. Some implementations use an XOR gate, but the phase-frequency detector enhances the capture range of the PLL and prevents harmonic locking.[44] In Fig. 58.38 the loop filter is implemented with a charge pump that has fixed source and sink current levels coupled to a resistor and capacitor in series to ground. The capacitor and charge pump form an integrator and the series resistor introduces a zero to stabilize the loop. As in the previous case, the output of the loop filter tunes both the master oscillator and the slave filter. However, unlike the PLL with VCF tuning method, the PLL will lock the VCO to *exactly* the same frequency as the input reference signal even if static phase errors occur. In this application, static phase errors between the input reference and the VCO output are inconsequential.

The primary drawback with the PLL and VCO master-slave tuning method is that the VCO design is difficult. Virtually any poorly designed VCO can be placed in the PLL and lock to the reference frequency; however, the issue is whether the control voltage, V_C, that is developed will correctly tune the slave filter. In other words, the voltage-to-frequency conversion curve for the VCO and the slave filter must be identical or at least they must match to better than about ±1% over the full range of tuning levels. Designing a slave filter that has a well-defined tuning voltage-to-corner frequency curve is relatively easy. In contrast, unless extreme care is taken in the VCO design, the amplitude of oscillation and hence VCO linearity can be coupled to the tuning signal level. The amplitude of oscillations in the VCO must be well controlled in the linear region so that the MOSFETs or transconductors in the master operate at the same levels as in the slave so that the voltage-to-frequency characteristics are nominally the same. This issue has been addressed in Ref. 7, but more work needs to be done.

Q Tuning Loops

Frequency tuning circuits hold the filter's time constants fixed over process and temperature variations or, equivalently, hold constant an integrator's unity-gain frequency. In contrast, Q tuning loops adjust an integrator's phase response to achieve –90° over all process and temperature conditions. Rather than directly tune the phase response of an integrator, the Q of a bandpass biquad can be adjusted instead[6,11,16] as shown in Fig. 58.39. If the integrators have phase lag, the Q will be enhanced; if they have phase lead, the Q will be reduced. The input-output relationship of the bandpass biquad is

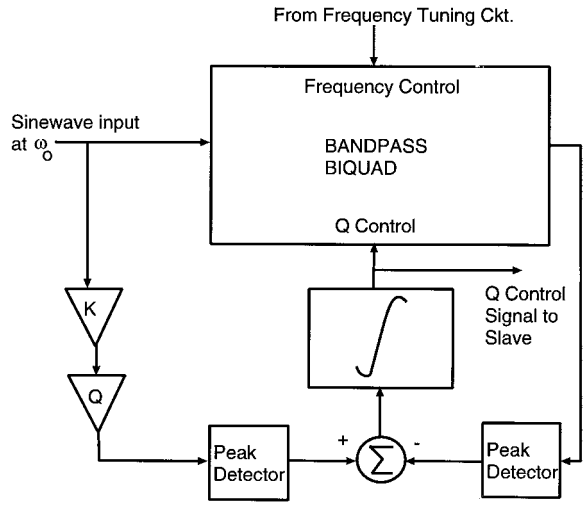

FIGURE 58.39 A master-slave Q tuning loop.

$$V_{o-bp}(s) = \frac{K\omega_o s}{s^2 + \frac{\omega_o}{Q}s + \omega_o^2} V_{in}(s) \tag{58.37}$$

If a sinusoid of frequency ω_o is applied to the biquad input and the biquad is properly frequency scaled by a tuning loop (not shown), then the sinusoid at the biquad output will have an amplitude *KQ*. Since *K* will be defined by well-matched components, the output amplitude error can be directly attributed to errors in *Q*. By subtracting the amplitude of the biquad's input and output and integrating, the *Q* error can be driven to zero with the negative feedback shown. Amplitude measurements can use r.m.s.-type detectors or peak amplitude detecting circuits, as shown in the figure. Many variations of Q tuning loops exist.[6,11,16,18]

Master-slave Q tuning loops should be used with caution for two reasons. First, if the tuning loop incorrectly adjusts the integrator's phase response, even momentarily during a transient, the slave filter can break into oscillation. Second, integrator phase errors are in large part due to parasitic capacitances. For the master-slave Q tuning to be successful, parasitics in the master and slave must match and track, suggesting that meticulous attention to layout detail is required. Additionally, excellent modeling and extraction of the parasitics from the layout are necessary to precisely design these circuits.

58.5 Conclusion

Integrated continuous-time filters are now found in a variety VLSI chips spanning the frequency range from a few kHz for ultra-low power hearing aid applications to over 150 MHz for the hard disk drive read channel application. The continuous-time filtering techniques described in this chapter have become integral parts of production quality chips and now represent well-established analog filter design practices.

Switched-Capacitor Filters

Andrea Baschirotto
Università di Pavia

59.1 Introduction

The accuracy of the absolute value of integrated passive devices (R and C) is very poor. As a consequence, the frequency response accuracy of integrated active-RC filters is poor and they are not feasible when high-accuracy performance is needed. A possible solution for the implementation of analog filters with accurate frequency response was given by the switched-capacitor (SC) technique since the late 1970s.[1,2] Their popularity has further increased since they can be realized with the same standard CMOS technology used for digital circuits. In this way, fully integrated low-cost high-flexibility mixed-mode systems have become possible. The main reasons of the large popularity of SC networks can be summarized as follows:

1. The basic requirements of SC filters fit the popular MOS technology features. In fact, the infinite input impedance of the operational amplifier (op-amp) is obtained using a MOS input device;

MOS transconductance amplifiers can be used since only-capacitive load is present; precise switches are realized with MOS transistor; and capacitors are available in the MOS process.

2. SC filter performance accuracy is based on the matching of integrated capacitors (and not on their absolute values). In a standard CMOS process, the capacitor matching error can be less than 0.2%. As a consequence, SC systems guarantee very accurate frequency response without component trimming. For the same reason, temperature and aging coefficients track reducing performance sensitivity to temperature and aging variations.
3. It is possible to realize SC filters with long time constants without using large capacitors and resistors. This means a chip area saving, with respect to active-RC filter implementations.
4. SC systems operate with closed-loop structures; this allows one to process large swing signals and to achieve large dynamic range.

On the other hand, the major drawbacks of the SC technique can be summarized in the following points:

1. To process a fully analog signal, an SC filter has to be preceded by an anti-aliasing filter and followed by a smoothing filter, which complicate the overall system and increase power and die size.
2. The op-amps embedded in an SC filter have to perform a large dc-gain and a large unity-gain bandwidth, much larger than the bandwidth of the signal to be processed. This limits the maximum signal bandwidth.
3. The power of noise of all the sources in the SC filter is folded in the band [0–Fs/2]. Thus, their nose power density is increased by the factor (Fs/2)/Fb, where Fs is the sampling frequency and Fb is the noise bandwidth at the source.

From its first proposals, the SC technique has been deeply developed. Many different circuits solutions have been realized with the SC technique not only in analog filtering, but also in analog equalizers, analog-to-digital and digital-to-analog conversion (including in particular the oversampled SD converters), Sample&Hold, Track&Hold, etc.

In this chapter, an overview of the main aspects of the SC technique is given, leaving to the reader to study the large literature for details more related to his necessity. A few advanced solutions feasible for future SC systems are given in the last section.

59.2 Sampled-Data Analog Filters

An SC filter is a continuous-amplitude, sampled-data system. This means that the amplitude of the signals can assume any value within the possible range in a continuous manner. On the other hand, these values are assumed at certain time instants and then they are held for the entire sampling period. Thus, the resulting waveforms are not continuous in time but look like a staircase.

In an SC filter, the continuous-time input signal is firstly sampled at sampling frequency Fs and then processed through the SC network. This sampling operation results in a particular feature of the frequency response of the SC system. In the following, the aspects relative to the sampling action are illustrated from an intuitive point of view, while a more rigorous description can be found in Ref. 3.

The sampling operation extracts from the continuous-time waveform the values of the input signal at the instant k·Ts (k = 1,2,3, …), where Ts is the sampling period (Ts = 1/Fs). This is shown in Fig. 59.1 for a single-input sinewave at $fo = 0.16 \cdot Fs$ (i.e., with $fo < Fs/2$).

If the input sinewave is at $Fs + fo$, the input sequence of analog samples is exactly equal to that previously obtained with *fo* as input frequency (see Fig. 59.2). Both sequences should then be processed in exactly the same way by the SC network, and the overall filter output sequence should then result to be again identical. The two input sinewaves result then to be indistinguishable after the sampling action. This effect is called *aliasing*. It can be demonstrated that a sinewave at frequency *fo* in the range [0–Fs/2] is aliased by the components at frequency f_{al} given by:

$$f_{al} = k \cdot Fs \pm fo \qquad (k = 1, 2, 3, \ldots) \tag{59.1}$$

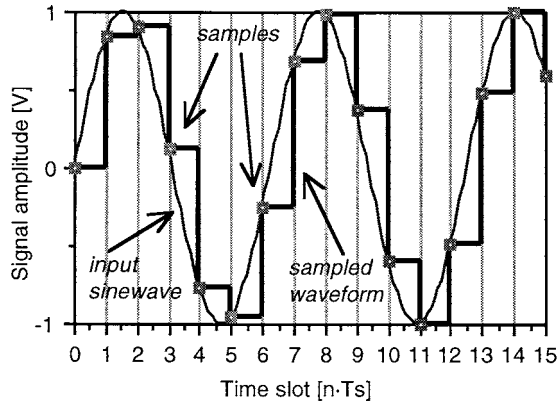

FIGURE 59.1 Sampling of the input signal.

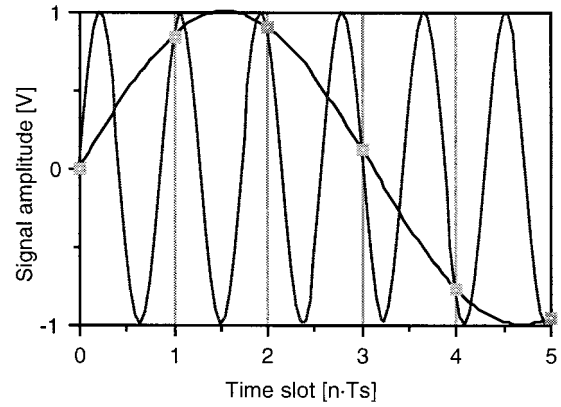

FIGURE 59.2 Aliasing between fo and FS + fo.

As a consequence, in order to avoid frequency aliasing (which means signal corruption), the input signal band of a sample data system must be limited to the [0–Fs/2] range. The range [0–Fs/2] is called *baseband* and the above limitation is an expression of the Nyquist theorem.

After the sampling, the SC network processes the sequence of samples, independently of how they have been produced. Since all the frequencies given in Eq. 59.1 produce the same sequence of samples, the gain for all of them is the same. This concept results in the fact that the transfer function of a sampled-data system is periodical with period equal to Fs, and it is symmetrical in its period. For instance, in Fig. 59.3 the frequency response amplitude for a lowpass filter is shown for frequencies higher than Fs.

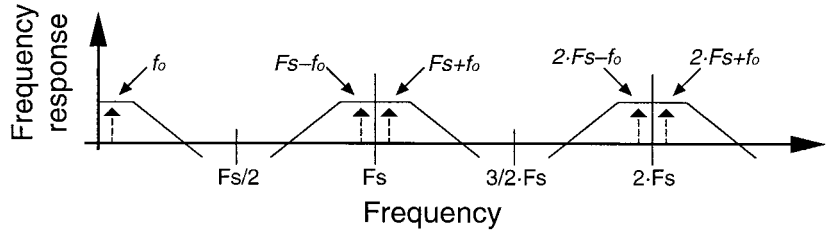

FIGURE 59.3 Periodicity of the sampled-data system transfer function.

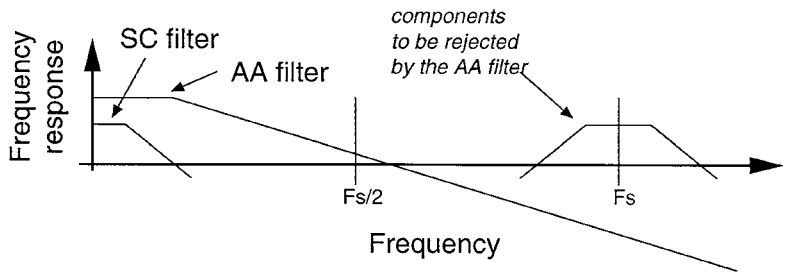

FIGURE 59.4 Transfer functions of swtiched-capacitor and anti-aliasing filters.

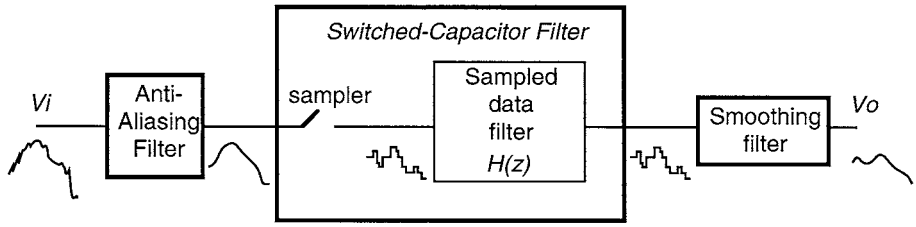

FIGURE 59.5 Overall SC filtering structure.

As stated above, in order to avoid the aliasing effect to corrupt the signal, it is necessary to limit the input signal bandwidth. This function is performed by the anti-aliasing (AA) filter, which is placed in front of the SC filter and operates in the continuous-time domain. From a practical point of view, the poles of the SC filter are typically much smaller than Fs/2, and only in the passband is the frequency response required to be accurate. On the other hand, the AA filter transfer function is not required to be accurate. Thus, the AA filter is usually implemented with active-RC filters (see Fig. 59.4).

At the output of the SC network, a staircase signal is produced. If a continuous-time output waveform is needed, a continuous-time smoothing filter must be added. The overall SC filter processing chain then results as shown in Fig. 59.5. Of course, in some cases, the input signal spectrum is already limited to Fs/2 and then the AAF filter is not necessary; while in other cases, the final smoothing filter is no longer necessary, like when the SC filter is used in front of a sampled-data system (like an ADC, for instance).

59.3 The Principle of the SC Technique

The principle of the SC technique consists in simulating the resistor behavior with a switched-capacitor structure. In the structure of Fig. 59.6, where an ideal op-amp is used, the resistor Req is connected between Vi and a zero-impedance zero-voltage node (as a virtual ground is). This means that a continuous-time current I flows from Vi, through Req, into the virtual ground. This current is equal to:

$$I = Vi/Req \qquad (59.2)$$

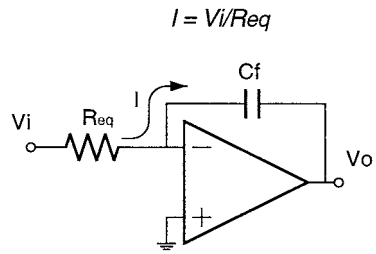

FIGURE 59.6 Basic RC integrator.

The alternative SC structure is shown in Fig. 59.7(a). It is composed of an input sampling capacitor CS (connected through four switches to the input signal VI, to the op-amp input node, and to two ground nodes), an op-amp, and a feedback (integrating) capacitor Cf. The clock phases driving the switches are shown in Fig. 59.7(b). A switch is closed (conductive) when its driving phase is high. It is

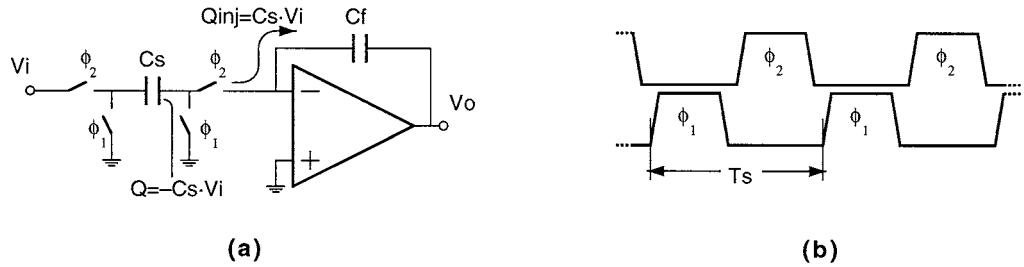

FIGURE 59.7 Basic SC integrator.

necessary that the two clock phases are non-overlapping, in order to connect each capacitor plate to only one low-impedance node for each time slot.

During phase ϕ1, capacitor Cs is discharged. During phase ϕ2, Cs is connected between Vi and the virtual ground. So, a charge Q = –Cs·Vi is collected on its right-hand plate. Due to the charge conservation law applied at the virtual ground node, this charge collection corresponds to an injection in virtual ground of the same amount of charge but with the opposite sign, given by:

$$Qinj = Cs \cdot Vi \tag{59.3}$$

Notice that this charge injection is independent of the component in the op-amp feedback path. This charge injection occurs every clock period. Observing this effect for a long time slot T, the total charge injection Qtot is given by:

$$Qtot = Cs \cdot Vi \cdot \frac{T}{Ts} \tag{59.4}$$

This corresponds to a mean current (Imean) equal to:

$$Imean = \frac{Qtot}{T} = Cs \cdot \frac{Vi}{Ts} \tag{59.5}$$

Equating Eq. 59.2 with Eq. 59.5, the following relationship holds:

$$Req = \frac{Ts}{Cs} \tag{59.6}$$

This means that the structure composed of Cs and the four switches operated at Fs is equivalent to a resistor Req. This approximation is valid for Vi equal to a dc-value, as it is the case of the proposed example, and it is still valid for Vi *slowly variable with respect to the clock period*; otherwise, the quantitiative average operation of Eq. 59.5 is no longer valid. The limits of the approximation between a resistor and an SC structure as expressed in Eq. 59.6 implies fundamental differences in the exact design of SC filters when derived from active-RC filters in a one-to-one correspondence.

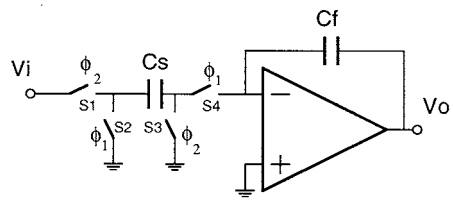
The synthesis of active filters is based on the use of some elementary blocks interconnected in different ways, depending on the type of adopted design philosophy. The different strategies and approaches for designing analog filters are well known from the continuous-time domain and they are also used in the case of SC filters, although the sampled-data nature of the SC filters can be profitably used either for simplifying or improving the design itself. In any case, basic building blocks are used to compose high-order filters.

In the following, the main basic blocks are described. They implement first-order (active integrators, undamped and damped, summers) and second-order (biquads) transfer functions in the *z*-domain (*z* is the state variable in the sampled data domain).

59.4 First-Order SC Stages

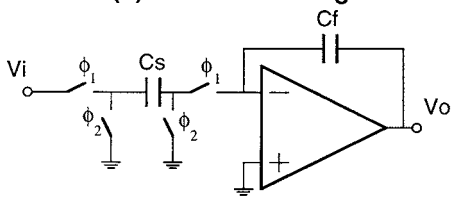
The Active SC Integrators

In Fig. 59.8(a-c), the standard integrators normally used in SC designs are shown. For each integrator, the transfer function in the z-domain is reported, assuming that the input signal is sampled during phase $\phi 1$ and is held to this value until the end of phase $\phi 2$, while the output is read during phase $\phi 2$.



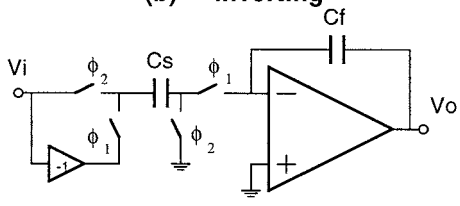
(a) - non-inverting

$$H_a(z) = \frac{V_o(z)}{V_i(z)} = \frac{Cs}{Cf} \cdot \frac{z^{-1}}{1 - z^{-1}} \tag{59.7a}$$



(b) - inverting

$$H_b(z) = \frac{V_o(z)}{V_i(z)} = -\frac{Cs}{Cf} \cdot \frac{1}{1 - z^{-1}} \tag{59.7b}$$



(c) - bilinear

$$H_c(z) = \frac{V_o(z)}{V_i(z)} = 2 \cdot \frac{Cs}{Cf} \cdot \frac{1 + z^{-1}}{1 - z^{-1}} \tag{59.7c}$$

FIGURE 59.8 SC integrators.

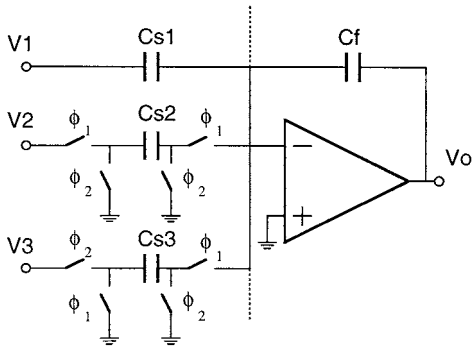
The third integrator is called bilinear since it implements the bilinear mapping of the s-to-z transformation (s is the state variable in the continuous-time domain).

In all the above transfer functions, only capacitor ratios appear. For this reason, the SC filter transfer functions are sensitive only to the capacitor ratios (i.e., to the capacitor matching) and are independent of absolute capacitor value. This is a remarkable advantage of all SC netowrks.

An important feature of all these integrators is their insensitivity to parasitic capacitance. This can be verified by observing that any parasitic capacitance connected to the capacitor left-hand plate is not connected to the virtual ground and therefore does not contribute to the amount of injected charge. On the other hand, the stray capacitance connected to the capacitor right-hand armature could contribute to the charge transfer, but this capacitance is switched between two nodes (ground and virtual ground) at the same potential and thus no charge injection results.

The Summing Integrator

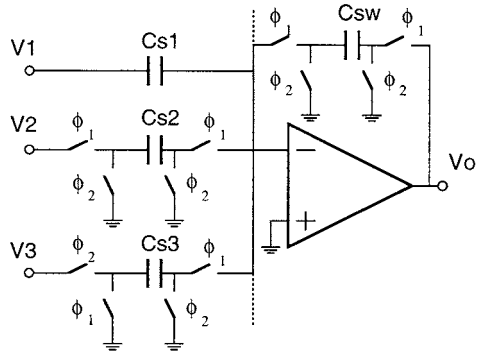
The SC operation is based on charge transfer. It is therefore easy to make weighted sum of multiple inputs by connecting different input branches to the same virtual ground. This concept is shown in the summing integrator of Fig. 59.9. The transfer function from the three input signals to the output is given in Eq. 59.8.



$$Vo = \frac{Cs1 \cdot \left(1 - z^{-1}\right) \cdot V1 - Cs2 \cdot V2 + Cs3 \cdot z^{-1} \cdot V3}{Cf \cdot \left(1 - z^{-1}\right)} \quad (59.8)$$

FIGURE 59.9 The SC summing integrator.

If the integrating feedback capacitor (Cf) is replaced by a feedback switched-capacitor (Csw), the structure does not maintain memory of its past evolution and a simple summing amplifier is obtained. The resulting structure is shown in Fig. 59.10, with the corresponding transfer function given in Eq. 59.9. This is the basic building block for the construction of SC filters implementing FIR frequency response.[4]

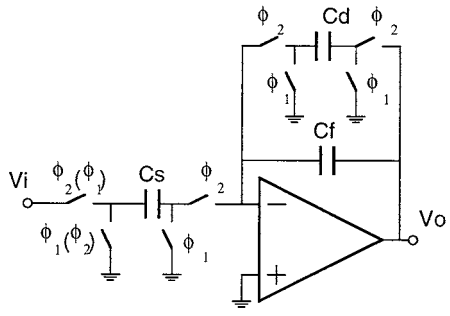


$$Vo = \frac{1}{Csw} \cdot \left(Cs1 \cdot \left(1 - z^{-1}\right) \cdot V1 - Cs2 \cdot V2 + Cs3 \cdot z^{-1} \cdot V3\right) \quad (59.9)$$

FIGURE 59.10 The SC summing amplifier.

The Active Damped SC Integrator

A damped integrator can be realized by connecting a damping switched capacitor (Cd) in parallel to the integrating capacitor (Cf), as shown in Fig. 59.11. Both inverting and non-inverting circuits are possible, depending on the type of input sampling structure. Equation 59.10a is valid for the clock phases out of parentheses, while Eq. 59.10b is valid for the clock phases within parentheses.



$$H_1(z) = \frac{Cd \cdot z^{-1}}{\left(Cd + Cf\right) - Cf \cdot z^{-1}} \quad (59.10a)$$

$$H_2(z) = -\frac{Cd}{\left(Cd + Cf\right) - Cf \cdot z^{-1}} \quad (59.10b)$$

FIGURE 59.11 Damped SC integrator.

A Design Example

As an example, the design of a damped SC integrator (Fig. 59.11) is given. A possible design approach is to derive the capacitor values of the SC structure from the R and C values in the equivalent continuous-time protptype, which is shown in Fig. 59.12, by the relationship of Eq. 59.6. It results that: Cs = Ts/Rs, and Cd = Ts/Rd. For instance, to have the pole frequency at 10 kHz with unitary dc-gain, a possible solution is: Rs = Rd = 159. 15 kΩ, and Cf = 10 pF. Using Fs = 1 MHz, it is obtained that Cs = Cd = 0.628 pF.

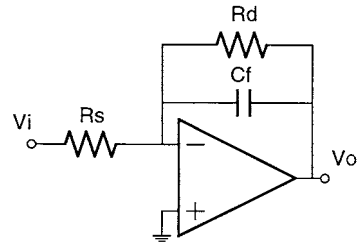


FIGURE 59.12 Continuous-time damped RC integrator.

The frequency response of the continuous-time and the SC damped integrator are shown in Fig. 59.13(a). Line I refers to the damped integrator of Fig. 59.11. Line II refers to a damped integrator with bilinear input branch (see Fig. 59.8(c)), while line III refers to the active-RC integrator of Fig. 59.12. In the passband, the frequency responses track very well. By increasing the input frequency, a difference becomes evident (as stated by the fact that Eq. 59.6 is valid for slowly variant signals). This is more pronounced if the frequency response is plotted up to 2·Fs (see Fig. 59.13(b)), where the periodic behavior of the sampled-data system frequency response is evident. Moreover, the key point of a sampled-data filter is the fact that the frequency response fixes the ratio between sampling-frequency and pole-frequency, i.e., with the above capacitor values, the pole frequency (fp) is 10 kHz for Fs = 1 MHz, while it decreases to 1 kHz if Fs = 100 kHz is used (i.e., the ratio fp/Fs remains constant). For this reason, the frequency response is plotted as a function of the normalized frequency f/Fs.

A limited stopband attenuation results for line I. This attenuation is improved using the bilinear input branch which implements a zero at Fs/2. This does not affect the frequency response in the passband, while a larger attenuation is obtained in the stopband (line II).

For the SC networks, the frequency response depends on capacitor ratios. Thus, the above extracted capacitor values can be normalized to the lowest one (which will be the unit capacitance). For this first-order cell example, the normalized capacitor values are: Cf = 15.92, and Cs = Cd = 1. The chosen value of the unit capacitance will not change the transfer function, while it will affect other filter features like die size, power consumption, and output noise.

From a general point of view, using Cf much larger than Cd corresponds to having a small damping impedance, as is the case in high-Q filters. This results in a large capacitor spread. On the other hand, to have a small time constant requires Cs much smaller than Cf; and also in this case, a large capacitor spread occurs. Since the unit capacitance cannot be smaller than a minimum technological value (to

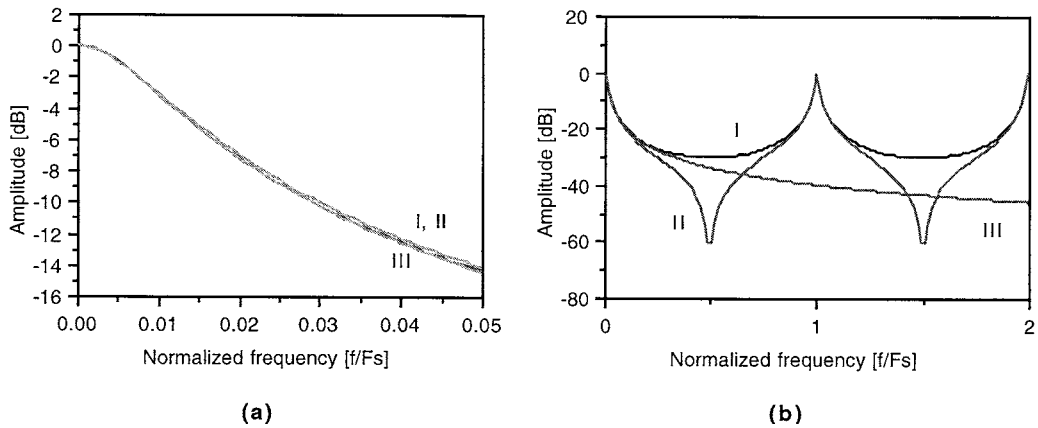

FIGURE 59.13 Frequency response comparison for different integrators.

achieve a certain matching accuracy), a large capacitor spread means to have a large capacitor to be driven and thus a large power to the op-amp to operate. In addition, a large chip area is needed. Thus, in order to avoid large capacitor spread, possible solutions will be proposed in the follwing.

59.5 Second-Order SC Circuit

The general expression of a second-order (biquadratic) z-transfer function can be written in the form:

$$H(z)=\frac{\gamma+\varepsilon\cdot z^{-1}+\delta\cdot z^{-2}}{1+\alpha\cdot z^{-1}+\beta\cdot z^{-2}} \tag{59.11}$$

The denominator coefficients (α, β) fix the pole frequency and quality factor, while the numerator coefficients (γ, ε, δ) define the types of filter frequency response. Several SC biquadratic cells have been proposed in literature to implement the above transfer function. In the following two of them are presented: the Fleischer & Laker one and another one useful for high sampling frequency.

The Fleischer & Laker Biquad

A popular biquadratic cell, proposed by Fleischer & Laker,[5] is shown in Fig. 59.14 in its most general form. The cell is composed by:

- an input branch (capacitor G, H, I, and J) which allows to select the zero positions, and therefore the kind of frequency response;
- a resonating loop (capacitor A, B, C, and D in conjuntion with the damping capacitors E, and F) which sets the pole frequency and the pole quality factor. The two damping capacitors are not usually adopted together. In general E-capacitor is used for high-Q filters, while F-capacitor is preferred for low-Q circuits.

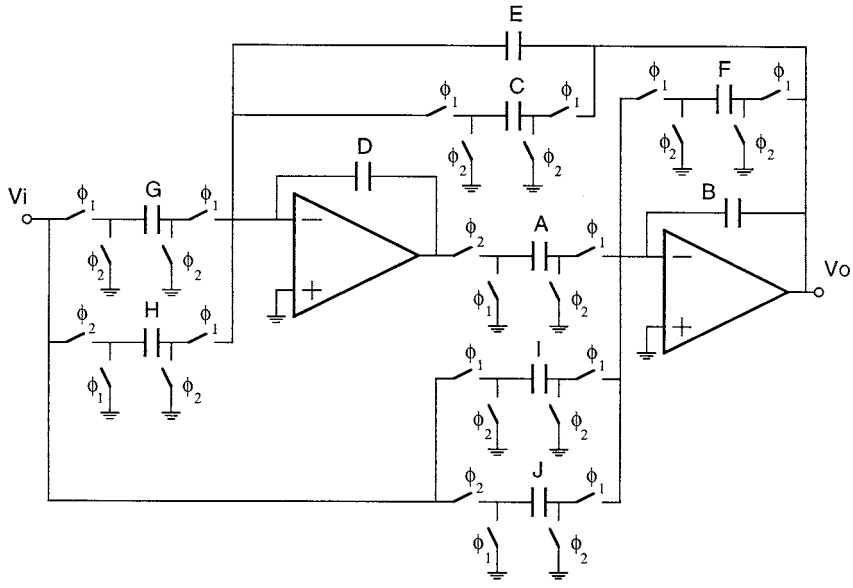

FIGURE 59.14 Fleischer & Laker biquadratic cell.

The transfer function of the Fleischer & Laker biquad cell can be written as:

$$H(z)=\frac{Vo}{Vi}=-\frac{D\cdot I+\left(A\cdot G-D\cdot\left(I+J\right)\right)z^{-1}+\left(J\cdot D-A\cdot H\right)z^{-2}}{D\cdot\left(B+F\right)-\left(D\cdot\left(2\cdot B+F\right)-A\cdot\left(C+E\right)\right)z^{-1}+\left(D\cdot B-A\cdot E\right)z^{-2}} \tag{59.12}$$

This cell allows one to synthetize any kind of transfer function by using parasitic insensitive structures, which ensures performance accuracy. The key observation related to this biquad cell is that the first op-amp operates in cascade to the second one; therefore, its settling is longer than the second one is.

Design Methodology

At the first order, the SC circuits can be derived from continuous-time circuits implementing the desired frequency response, by a proper substitution of each resistor with the equivalent SC structures, as shown for the first-order cell. An alternative approach is to optimize the transfer function in the *z*-domain, and to numerically fit the desired transfer function with the transfer function implemented by the second-order cell. A third possibility is to adapt the *s*-domain transfer function to the *z*-domain signal processing of the SC structures. This procedure will be used in the following.

Consider the case of a given transfer function in *s*-domain, for instance, when an approximation table (Butterworth, Chebichev, Bessel, etc.) is used. The *s*-domain transfer function to be implemented is written as:

$$H(s)=\frac{a_2\cdot s^2+a_1\cdot s+a_0}{s^2+b_1\cdot s+b_0} \tag{59.13}$$

This *s*-domain transfer function is transformed into a *z*-domain transfer function through the use of the bilinear *s*-to-*z* transformation:

$$s=\frac{2}{Ts}\cdot\frac{1-z^{-1}}{1+z^{-1}} \tag{59.14}$$

This transformation produces a warping of the frequency of interest. To avoid this error, a characteristic frequency for the given design (i.e., the frequencies ω_i of interest for the final filter mask) should be 'prewarped' according to the relationship between the angular frequencies in the *s*-domain (Ω_i) and in the *z*-domain (ω_i):

$$\Omega_i=\frac{2}{Ts}\cdot\tan\left(\frac{\omega_i\,Ts}{2}\right) \tag{59.15}$$

as it is indicated in Fig. 59.15 for a bandpass-type response.

The characteristic frequency can be the –3dB frequency for a low-pass filter. The H'(s) that will satisfy the 'prewarped' filter mask will be automatically transformed by Eq. 59.14 into a *z*-domain transfer function whose frequency response satisfies the desired filter mask in the ω-domain. Obviously, if $\omega_i\cdot Ts \ll 1$, no predistortion is needed, being $\Omega_i \approx \omega_i$. Assuming that $\omega_{i\cdot Ts} \ll 1$, H′(s) ≈H(s) and Eq. 59.14 is substituted directly into Eq. 59.13; the resulting coefficients of terms z^{-i} in the denominator are then equated to the corresponding ones in Eq. 59.12. Assuming A = B = D = 1, the capacitor values for the E-type and F-type can be extracted as follows:

$$\mathrm{F}=0 \qquad E=\frac{b_1Ts}{1+\frac{b_1Ts}{2}+\frac{b_0Ts^2}{4}} \qquad C=\frac{b_0Ts^2}{1+\frac{b_1Ts}{2}+\frac{b_0Ts^2}{4}} \tag{59.16a}$$

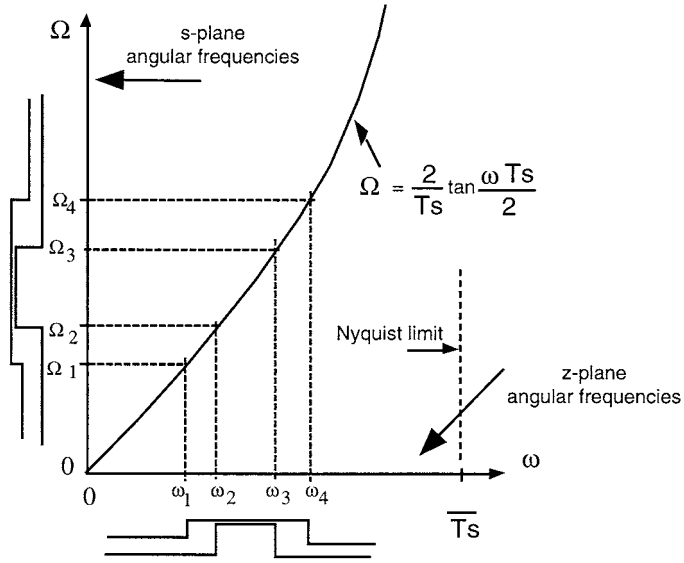

FIGURE 59.15 Bilinear mapping between continuous-time (Ω) and sampled-data (ω) frequency.

$$\mathrm{E}=0 \qquad E=\frac{b_1 Ts}{1-\frac{b_1 Ts}{2}+\frac{b_0 Ts^2}{4}} \qquad C=\frac{b_0 Ts^2}{1-\frac{b_1 Ts}{2}+\frac{b_0 Ts^2}{4}} \tag{59.16b}$$

When the bilinear transform is used, a second-order numerator is obtained, which can be written as given in Eq. 59.17, where simple solutions for the input capacitors are also given.

$$\text{Lowpass} \qquad K\left(1+z^{-1}\right)^2 \qquad I=J=IKI \qquad G=4IKI;\ H=0 \tag{59.17a}$$

$$\text{Bandpass} \qquad K\left(1+z^{-1}\right)\cdot\left(1-z^{-1}\right) \qquad I=G=H=IKI;\quad J=0 \tag{59.17b}$$

$$\text{Highpass} \qquad K\left(1-z^{-1}\right)^2 \qquad I=J=IKI \qquad G=H=0 \tag{59.17c}$$

Design Example

As design example for the second-order cell, a bandpass response with Q = 5, *fo* = 20 kHz, and *Fs* = 1 MHz is considered (i.e., *fo*/*Fs* = 0.02). The transfer functions in the *s*-domain and in the *z*-domain (using bilinear transformation) are the following:

$$H(s)=\frac{s}{s^2+\frac{2\cdot\pi\cdot fo}{Q}\cdot s+\left(2\cdot\pi\cdot fo\right)^2}=\frac{2.5133\cdot 10^4\cdot s}{s^2+2.5133\cdot 10^4\cdot s+1.5791\cdot 10^{10}} \tag{59.18}$$

$$H(z)=\frac{z^{-2}-1}{z^{-2}-1.9719\cdot z^{-1}+0.98755} \tag{59.19}$$

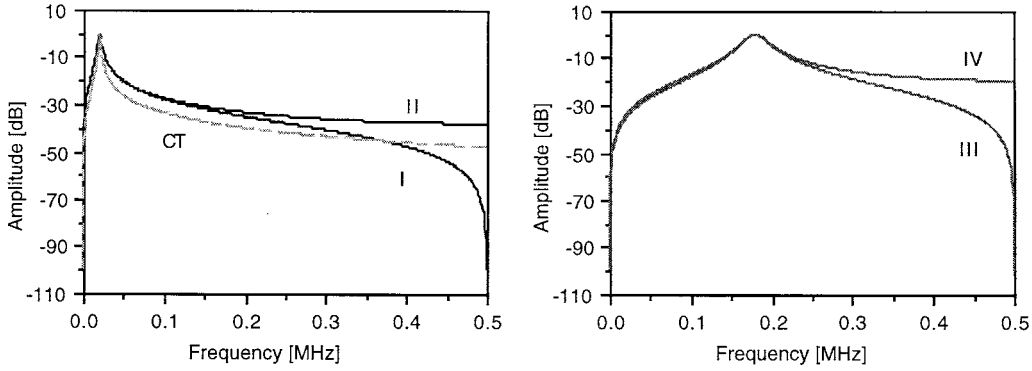

FIGURE 59.16 Frequency responses for different designs.

No frequency has been prewarped, since, applying Eq. 59.15 to *fo*, the prewarped pole frequency should result 19.765 kHz, with a negligible deviation of about 0.1%.

For the bandpass response, using the bilinear *s*-to-*z* mapping, the zero positions are at $\{z = 1, z = -1\}$. The frequency response is shown in Fig. 59.16 with line I. The normalized capacitance value, obtained equating the transfer function of Eq. 59.19 with the transfer function of the biquadratic cell of Eq. 59.12, are given in Table 59.1, for the E-type and F-type structures, in column I. A very large capacitor spread (>78) is needed. This results in large die area, and large power consumption. The capacitor spread could be reduced with a slight modification of the transfer function to the one given in the following:

$$H(z) = \frac{z^{-1} - 1}{z^{-2} - 1.9719 \cdot z^{-1} + 0.98755} \tag{59.20}$$

With respect to the bilinear transformation of Eq. 59.9, in this case, the zero at dc is maintained, while the zero at Nyquist frequency (at Fs/2, i.e., at z = –1) is eliminated. The normalized capacitor values are indicated again in Table 59.1, in Column II. It can be seen that a large reduction of the capacitor spread is obtained (from 80 to 8, for the E-type). The obtained frequency response is reported in Fig. 59.16 with line II. In the passband no significant changes occur; on the other hand in the stopband, the maximum signal attenuation is about –35 dB. In some applications, this solution is acceptable, also in consideration of the considerable capacitor spread reduction. For this reason, if not strictly necessary, the zero at Fs/2 can be eliminated. However reducing the factor fo/Fs results in reducing the stopband attenuation. For instance, for *fo* = 200 kHz (i.e., *fo*/Fs = 0.2), the frequency response with and without the Nyquist zero are reported in Fig. 59.16 with line III and IV, respectively. In this case, the stopband attenuation is reduced to –22 dB and therefore the Nyquist zero could be strongly needed. The relative normalized capacitor values are indicated in Table 59.1 in Column III (with zeros at $\{z = 1, z = -1\}$), and in Column IV (with zeros at $z = 1$).

A Biquadratic Cell for High Sampling Frequency

In the previous biquadratic cell, the two op-amps operate in cascade during the same clock phase. This requires that the second op-amp in cascade wait for the complete settling of the first op-amp to complete its settling. This, of course, reduces the maximum achievable sampling frequency, or, alternatively for a given sampling frequency increases the required power consumption since op-amps with larger bandwidth are needed. In order to avoid this aspect, the biquad shown in Fig. 59.17 can be used. In this scheme, the two op-amps settle in different clock phase and thus they have the full clock phase time slot to settle.

The transfer function of the biquadratic cell is given in Eq. 59.21. As it can be seen a limitation occurs in the possible transfer function, since the term in z^{-2} is not present.

High-Order Filters

The previous first- and second-order cells can be used to build up high-order filters. The main architectures are taken from the theory for the active RC filters. Some of the most significant ones are: ladder[6] (with good amplitude response robustness with respect to component spread), cascade of first- and second-order cells (with good phase response robustness with respect to component spread), follow-the-leader feedback (for low-noise systems, like reconstruction filters in oversampled DAC).

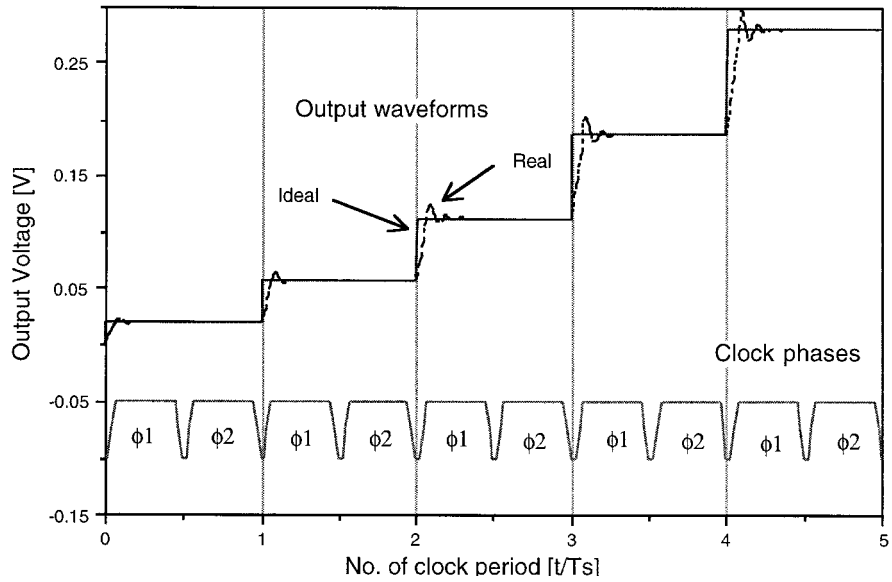

FIGURE 59.18 Output waveform evolution.

59.6 Implementation Aspects

The arguments presented so far have to be implemented in actual integrated circuits. Such implementations have to minimize the effects of the non-idealities of the actual blocks, which are capacitors, switches, and op-amps. The capacitor behavior is quite stable, apart from capacitance non-linearities which affect the circuit performance only as a second-order effect.

On the other hand, switches and op-amps must be properly designed to operate in the SC system. The switches must guarantee a minimum conductance to ensure a complete charge transfer within the available timeslot. For the same reason, the op-amps must ensure large-dc gain, large unity-gain bandwidth, and large slew rate. For instance, in Fig. 59.18, the ideal output waveform of an SC network is shown with a solid line, while the more realistic actual waveform is illustrated with the dotted line. The output sample is updated during phase $\phi 1$, while it is held (at the value achieved at the end of phase $\phi 1$ during phase $\phi 2$. In phase $\phi 1$, the output value moves from its initial to its final value. The slowness of this movement is affected by switch conductance, op-amp slew rate, and op-amp bandwidth.

The transient response of the system can be studied using the linear model of Fig. 59.19, where the conductive switches are replaced by their on-resistance Ron and the impulsive charge injection is replaced by a voltage step. The assumption of a complete linear system should allow one to exactly study the system evolution. In this case, the circuit time-constants depend on input branch ($\tau_{in} = 2 \cdot Ron \cdot Cs$), op-amp frequency response, and feedback factor.

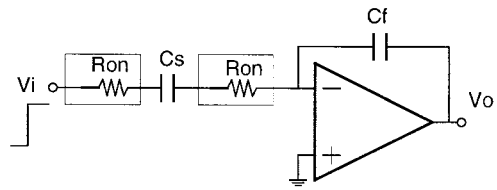

FIGURE 59.19 Linear model for transient analysis.

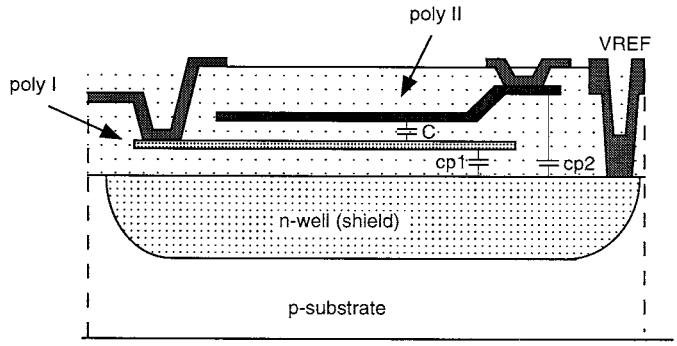

FIGURE 59.20 Poly1-poly2 capacitor cross-section.

Non-linear analysis is, however, necessary when op-amp slew rate occurs. This analysis is difficult to carry out and optimum performance can be achieved using computer simulations. Usually, for typical device models, 10% of the available timeslot (i.e., Ts/2) is used for slew rate, while 40% is used for linear settling.

Integrated Capacitors

Integrated capacitors in CMOS technology for SC circuits are mainly realized using poly1-poly2 structure, whose cross-section is shown in Fig. 59.20. This capacitor implementation guarantees linear behavior over a large signal swing. The main drawbacks of integrated capacitors are related to their absolute and relative inaccuracy, and to their associated parasitic capacitance.

The absolute value of integrated capacitors can change ±30% from their nominal values. However, the matching between equal capacitors can be on the order of 0.2%, provided that proper layout solutions are adopted (in close proximity, with guard rings, with common centroid structure). The matching of two capacitors of different value C can be expressed with the standard deviation of their ratio σ_C, which is correlated with the standard deviation of the ratio between two identical capacitors σ_{C1} by Eq. 59.22.[7]

$$\sigma_C = \frac{\sigma_{C1}}{\sqrt{C/C1}} \tag{59.22}$$

This model can be used to evaluate the robustness of the SC system performance with respect to random capacitor variations using a Monte Carlo analysis.

The plates of poly1-poly2 capacitor of value C present a parasitic capacitance toward the substrate, as shown in Fig. 59.18. Typically, this capacitance is about 10% of C for the bottom plate (cp1 = C/10), and it is 1% of C for the top plate (cp2 = C/100). In order to reduce the effect of these parasitic capacitances in the transfer function of the SC systems, it is useful to connect the top plate to the op-amp input node, and the bottom plate to low impedance nodes (op-amp output nodes or voltage sources). In addition, in Fig. 59.20, an n-well, biased with a clean voltage VREF; is placed under the poly1-poly2 capacitor in order to reduce noise coupling from the substrate, through parasitic capacitance.

MOS Switches

The typical situation during sampling operation is shown in Fig. 59.21(a) (this is the input branch of the integrator of Fig. 59.7(a)). The input signal Vi is sampled on the sampling capacitor Cs in order to have Vc = Vi.

FIGURE 59.21 (a) ideal sampling structure, (b) sampling structure with NMOS switches.

In Fig. 59.21(b), the switches are replaced by a single-nMOS device which operates in the triode region with an approximately zero voltage drop between drain and source. The switch on-resistance Ron can be expressed as:

$$Ron = \frac{1}{\mu n \cdot Cox \cdot \frac{W}{L} \cdot \left(V_{gs} - V_{th}\right)} = \frac{1}{\mu n \cdot Cox \cdot \frac{W}{L} \cdot \left(V_G - Vi - V_{th}\right)} \tag{59.23}$$

where V_G is the amplitude of the clock driving phase, μn is the electron mobility, Cox is the oxide capacitance, and W and L are the width and length of the MOS device. Using V_{DD} = 5 V (i.e., V_G = 5 V), the dependence of Ron on the input voltage is plotted in Fig. 59.22(a). This means that if Ron is required by the capacitor value be lower than a given value (to implement a low Ron·Cs time constant), a limitation in the possible input swing is given. For instance, if the maximum possible Ron is 2.5 kΩ, the maximum input signal swing is [0 V–3.5 V].

To avoid this limitation, a complementary switch can be used. It consists of an NMOS and a PMOS device in parallel, as shown in Fig. 59.23. The PMOS switch presents a Ron behavior complementary to that of the NMOS, as plotted in Fig. 59.22(b). The complete switch Ron is then given by the parallel of the two contributions which is sufficiently low for all the signal swing.

Using this solution requires one to distribute double clock lines controlling the NMOS and the PMOS. This could be critical for SC filters operating at high-sampling frequency, also in consideration of the synchronization of the two phases and of the digital noise from the distributed clocks which could reduce the dynamic range.

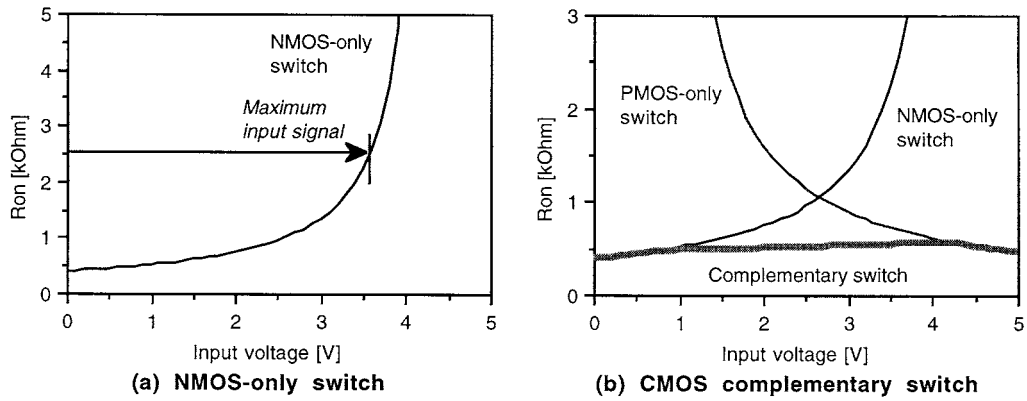

FIGURE 59.22 Switch on-resistance.

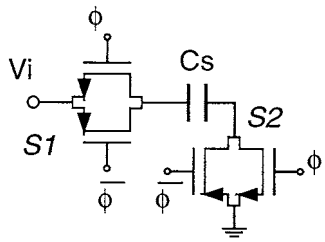

FIGURE 59.23 Sampling structure with complementary switches.

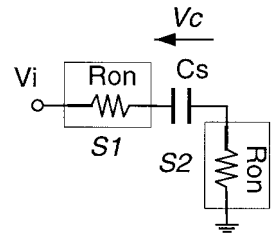

FIGURE 59.24 Sampling operation linear model.

Once a minimum conductance is guaranteed, the structure can be studied using the linear model for the MOS devices S1 and S2 which operate in the triode region, resulting in the circuit of Fig. 59.24. In this case, Vc follows Vi, through an exponential law with a time constant τ_{in} = Cs·2·Ron. Typically, at least 6·τ_{in} must be guaranteed in the sampling timeslot to ensure sufficient accuracy. For a given sampling capacitance value, this is achieved using switches with sufficiently low on-resistance and no voltage drop across its nodes. Large on-resistance results in a long time constant and incomplete settling, while a voltage drop results in an incorrect final value. MOS technology allows the implementation of analog switches satisfying both the previous requirements.

Transconductance Amplifier

The SC technique appears the natural application of available CMOS technology design features. This is true also for the case of the op-amp design. In fact, SC circuits require an infinite input op-amp impedance, as in the case of op-amp using a MOS input device. On the other hand, CMOS op-amps are particularly efficient when the load impedance is not resistive and low, but only capacitive, as in the case of SC circuits. In addition, SC circuits allow one to process a full swing (rail-to-rail) signal and this is possible for CMOS op-amps. The main requirements to be satisfied by the op-amp remain the bandwidth, the slew rate, and the dc-gain.

The bandwidth and the slew rate must be sufficiently large to guarantee accurate settling for all the signal steps. The op-amp gain must be sufficiently large to ensure a complete charge transfer. A tradeoff between large dc-gain (achieved with low-current and/or multistage structure) and large bandwidth (obtained at high-current and/or simple structure) must be optimized. For this case, the use of mixed technology (like BiCMOS) could help the proper design optimization.

59.7 Performance Limitations

The arguments described thus far are valid assuming an ideal behavior of the devices in the SC network (i.e., op-amp, switches, and capacitor). However, in actual realization, each of them presents non-idealities which reduce the performance accuracy of the complete SC circuit. The main limitations and their effects are described in the following. Finally, considerations about noise in SC systems conclude this section.

Limitation Due to the Switches

As described before, CMOS switches satisfy both low on-resistance and zero voltage-drop requirements. However, they introduce some performance limitations due to their intrinsic CMOS realization. The cross-section of an NMOS switch in its on-state is shown in Fig. 59.25. The connection between its nodes N1 and N2 is guaranteed by the presence of the channel, made up of the charge Qch. The amount of charge Qch can be written as:

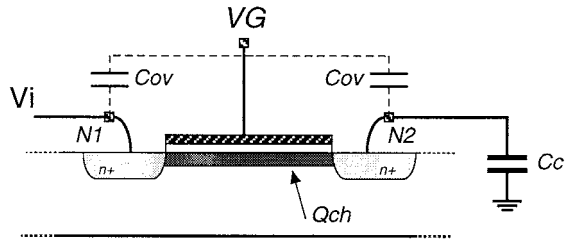

FIGURE 59.25 Switch charge profile of an NMOS switch in the on-state.

$$Qch = \left(W \cdot L\right) \cdot Cox \cdot \left(V_G - Vi - V_{TH}\right) \tag{59.24}$$

where Vi is the channel (input) voltage. Both nodes N1 and N2 are at voltage Vi (no voltage drop between the switch nodes). In addition, the gate oxide which guarantees infinite MOS input impedance constitutes a capacitive connection between gate and both source and drain. This situation results in two non-ideal effects: charge injection and clock feedthrough.

Charge Injection

At the switch turn-off, the charge Qch given in Eq. 59.24 is removed from the channel and it is shared between the two nodes connected to the switch, with a partition depending on the node impedance level.

The charge k·Qch is injected in N2 and collected on a capacitor Cc. A voltage variation nVc across the capacitor arises, which is given by:

$$\Delta Vc = k \cdot \frac{Qch}{Cc} \tag{59.25}$$

For all the switches of a typical SC integrator, as shown in Fig. 59.26(a), this effect is important. For instance, for the switch S4 connected to the op-amp virtual ground, the charge injection into the virtual ground is collected in the feedback capacitor and it is processed as an input signal. The amount of this charge injection depends on different parameters (see Eq. 59.24 and Eq. 59.25). Charge Qch depends on switch size W, which however cannot be reduced beyond a certain level; otherwise, the switch on-resistance should increase. Thus, a tradeoff between charge injection and on-resistance is present. In addition, charge Qch depends on the voltage Vi which the switch is connected to. For the switches S2, S3, and S4, the injected charge is proportional to (V_G – Vgnd) and is always fixed; as a consequence, it can be considered like an offset. On the other hand, for the switch S1 connected to the signal swing, the channel charge Qch is dependent on (V_G – Vi), i.e., on the signal amplitude and thus also the charge injection is signal dependent. This creates an additional signal distortion.

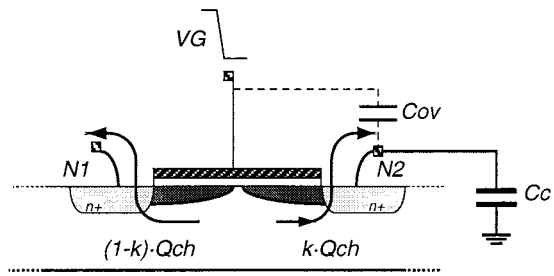

FIGURE 59.26 Charge displacement during turn-off.

Possible solutions for the reduction of the charge injection are: use of dummy switches, use of slowly variable clock phase, use of differential structures, use of delayed clock phases,[8] and use of signal-dependent charge pump.[9]

Dummy switches operate with complementary phases in order to sink the charge rejected by the original switches. The use of differential structures reduces the offset charge injection to the mismatch of the two differential paths. For the signal-dependent charge injection, the delayed phases of Fig. 59.26(b) are applied to the integrator of Fig. 59.26(a). This clock phasing is based on the concept that at the turn-off, S3 is open before S1. In such a way, when S1 opens, the impedance toward Cs is infinite and no signal-dependent charge injection occurs into Cs.

Clock Feedthrough

The clock feedthrough is the amount of signal that is injected in the sampling capacitor Cc from the clock phase through the MOS overlap capacitor (Cov) path, shown in Fig. 59.27, which is then proportional to the area of the switches. Using large switches, to reduce on-resistance, results in large charge injection and large clock feedthrough. This error is typically constant (it depends from capacitance partition) and therefore it can be greatly reduced by using differential structures. The voltage error ΔVc across a capacitance Cc due to the feedthrough of the clock amplitude ($V_{DD} - V_{SS}$) can be written as:

$$\Delta Vc = \left(V_{DD} - V_{SS}\right) \cdot \frac{Cov}{Cov + Cc} \tag{59.26}$$

Limitation Due to the Op-amp

The operation of SC networks is based on the availability of a "good" virtual ground which ensures a complete charge transfer from the sampling capacitors to the feedback capacitor. Whenever this charge transfer is uncompleted, the SC network performance derives from its nominal behavior. The main non-ideality causes from the op-amp are: finite dc-gain, finite bandwidth, finite slew-rate, and gain non-linearity.

Finite Op-amp dc-Gain Effects[10,11]

The op-amp finite gain results in a deviation of output voltage at the end of the sampling period from the ideal one, as shown in Fig. 59.28(a). This output sample deviation can be translated in the SC system performance deviation. For the finite gain effect, an analysis which correlates the op-amp gain Ao with SC network performance deviation, can be carried out under the hypothesis that the op-amp bandwidth is sufficiently large to settle within the available timeslot.

For the case of the summing amplifier of Fig. 59.10, it can be demonstrated that the effect of the finite op-amp dc-gain (AO) is only in an overall gain error. For this reason SC FIR filters (based on this scheme) exhibit a low sensitivity to op-amp finite dc-gain. On the other hand, for the case of SC integrators, the

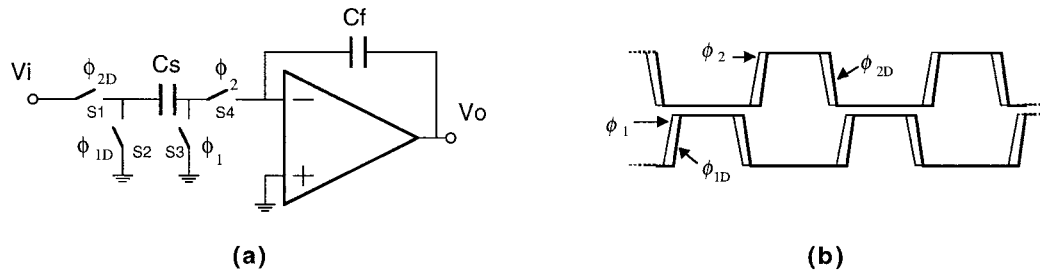

FIGURE 59.27 Clocking scheme for signal-dependent charge injection reduction.

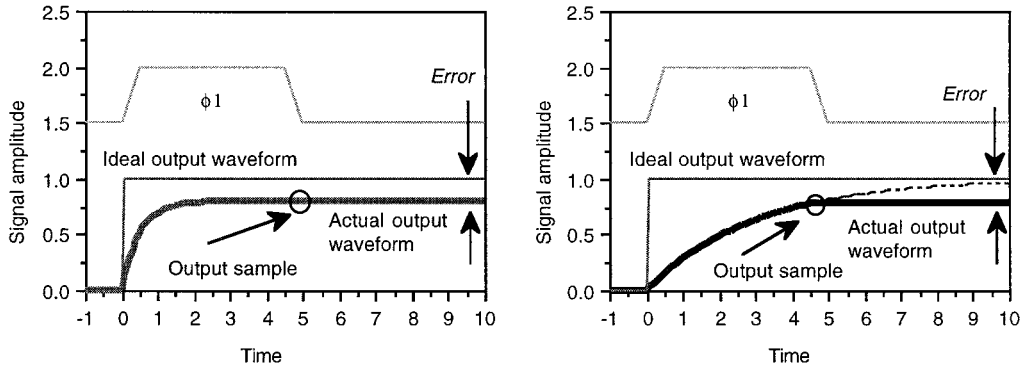

FIGURE 59.28 Op-amp induced errors.

finite gain effect results in pole and gain deviation. For instance, the transfer function of the integrator of Fig. 59.8(a) becomes:

$$H_a(z)=\frac{V_o(z)}{V_i(z)}=\frac{Cs}{Cf}\cdot\frac{z^{-1}}{1+\frac{1}{Ao}\cdot\left(1+\frac{Cs}{Cf}\right)-\left(1+\frac{1}{Ao}\right)\cdot z^{-1}} \tag{59.27}$$

For a biquadratic cell, the op-amp finite gain results in pole frequency, pole quality factor deviations. The actual frequency and quality factor of the pole (f_oA and Q_A) are correlated to their nominal values (fo and Q) by the relationship:

$$f_{oA}=\frac{Ao}{1+Ao}\cdot f_o \qquad Q_A=\frac{1}{\frac{1}{Q}+\frac{2}{Ao}}\approx\left(1-\frac{2\cdot Q}{Ao}\right)\cdot Q \tag{59.28}$$

Finite Bandwidth and Slew-Rate[10,11]

Also, op-amp finite bandwidth and slew-rate result in incomplete charge transfer, which still corresponds with deviation of the output sample with respect to its nominal value. For the case of only finite bandwidth, the effect is shown in Fig. 59.28(b). An analysis similar to that of the finite gain for the finite bandwidth and slew-rate effect is not easily extracted. This is due to the fact that incomplete settling is caused by the correlation of a linear effect (e.g., the finite bandwidth) and a non-linear effect (e.g., the slew rate). In addition, this case is worsened by the fact that in some structures, several op-amps are connected in cascade and then each op-amp (a part of the first one) has to wait for the operation conclusion of the preceding one.

Op-amp Gain Non-linearity

Since the SC structure allows one to process large swing signals, for this signal swing, the op-amp has to perform constant gain. When the op-amp gain is not constant for all the necessary output swing, distortion arises. An analysis can be carried out for the case of the integrator of Fig. 59.8(a).[12] Assuming an op-amp input (vi)-to-output (vo) relationship expressed in the form:

$$vo=a_1\cdot vi+a_2\cdot vi^2+a_3\cdot vi^3+\ldots \tag{59.29}$$

The resulting harmonic components (for $\omega o \cdot Ts \ll 1$) are given by:

$$HD2 = \frac{a_2}{2 \cdot a_1^3 \beta} \quad V_o \sqrt{1 + \left(\frac{Vo}{2 \cdot Vi} \right)^2} \tag{59.30a}$$

$$HD3 = \frac{a_3}{2 \cdot a_1^4 \beta} \quad V_o^2 \sqrt{1 + \left(\frac{Vo}{3 \cdot Vi} \right)} \tag{59.30b}$$

The distortion can then be reduced or making constant low-gain (i.e., reducing a_2 and a_3) or using a very large op-amp gain (i.e., increasing a_1). This second case is usually the adopted strategy.

Noise in SC Systems[13,14]

In SC circuits, the main noise sources are in the switches (thermal noise) and in the op-amp (thermal noise and 1/*f* noise). These noise sources are processed by the SC structure as an input signal, i.e., they are sampled (with consequent folding) and transferred to the output with a given transfer function. As explained for the signal, the output frequency range of an SC filter is limited in the band [0–Fs/2]. This means that for any noise source its sampled noise band, independently on how large it is at the source before sampling, is limited in the [0–Fs/2] range. On the other hand, the total power of noise remains constant after sampling; this means that the power density of sampled noise is increased by the factor Fb/(Fs/2), where Fb is the noise band at its source. This can be seen for the switch noise in the following simple example. Consider the structure of Fig. 59.29, where the resistance represents the switch on-resistance. Its associated noise spectral density is given by $v_n^2 = 4kT \cdot Ron$ (where *k* is the Boltzmann's constant and T is the absolute temperature). The transfer function to the output node (the voltage over the capacitor) is $H(s) = \frac{1}{1 + s \cdot Ron \cdot Cs}$. The total output noise can be calculated from the expression:

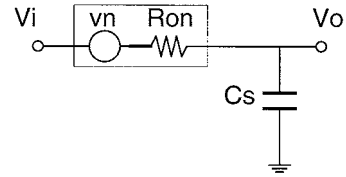

FIGURE 59.29 Sampling the noise on a capacitor.

$$n_o^2 = \int_0^\infty v_n^2 \cdot \left| H(s)^2 \right| \cdot df = \frac{kT}{Cs} \tag{59.31}$$

The total sampled noise is then given by *k*T/Cs, and presents a bandwidth of Fs/2. This means that the output noise power density is *k*T/Cs·2/Fs. (See Fig. 59.30.)

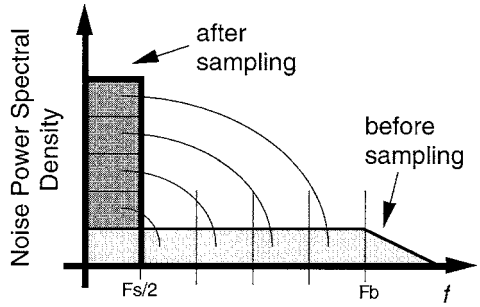

FIGURE 59.30 Folding of the noise power spectral density.

The same folding concept can be applied to the op-amp noise. For the op-amp 1/*f* noise, the corner frequency is usually lower than Fs/2. Therefore, the 1/f noise is not modified by the sampling. On the other hand, the white noise presents a bandwidth Fb larger than Fs/2. This means that this noise component is modified in a noise source of bandwidth Fs/2 and noise power density multiplied by the factor Fb/(Fs/2). When the noise sources are evaluated in this way, the output noise of an SC cell can be evaluated by summing the different components properly weighted by their transfer functions from their source position to the output node.

A few considerations follow for the noise performance of an SC cell. Switch noise is independent of Ron, since its dependence is cancelled in the bandwidth dependence. Thus, this noise source is dependent only on Cs. Noise reduction is achieved by increasing Cs. This, however, trades with the power increase necessary to drive the enlarged capacitance. Of course, even if Ron does not appear in the noise expression, as the capacitor is enlarged, the Ron must be adequately decreased in order to guarantee a proper sampling accuracy.

For the op-amp noise, the noise band is usually correlated with the signal bandwidth. Therefore, a good op-amp settling (achieved with a large signal bandwidth) is in contrast to low-noise performance (achieved with reduced noise bandwidth). Therefore, in low-noise systems, the bandwidth of the op-amp is designed to be the minimum that guarantees proper settling.

59.8 Compensation Technique (Performance Improvements)

SC systems usually operate with a two-phase clock in which the op-amp is 'really' active only during one phase, and during the other phase is 'sleeping.' Provided that the op-amp output node is not read during the second phase, this non-active phase could be used to improve the performance of the SC system, as shown in the following.[15] 1/f noise and offset can be reduced with Correlated Double Sampling (CDS) or the chopper technique. Similar structures are also able to compensate for the error due to a finite gain of the operational amplifier. On the other hand, proper structures are able to reduce the capacitor spread occurring in particular situations (high-Q or large time constant filters). Finally, the double-sampled-technique can be used to increase, by a factor of two, the sampling frequency of the SC system.

CDS Offset-Compensated SC Integrator

The extra phase available in a two-phase SC system can be used to reduce op-amp offset and 1/f noise effects at the output. A possible scheme is shown in Fig. 59.31,[16] and operates as follows. Capacitor Cof is used to sample, during $\phi 1$, the offset voltage Voff as it appears in the inverting node of the op-amp with close to unitary feedback. During $\phi 2$, the inverting node is still at a voltage very close to Voff, since

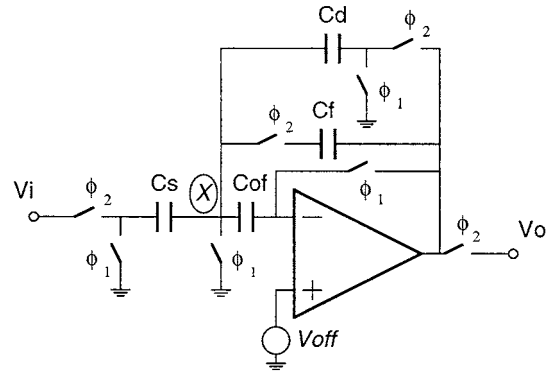

FIGURE 59.31 Offset-compensated SC integrator.

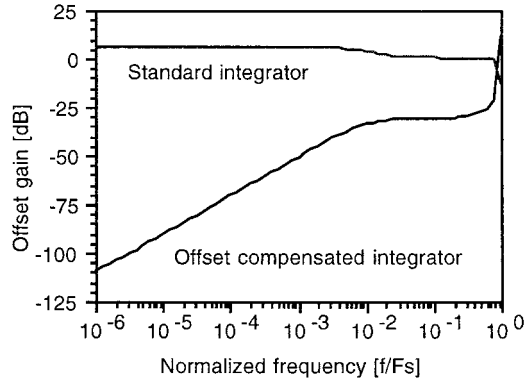

FIGURE 59.32 Offset-compensated SC integrator performance.

the bandwidth of Voff is assumed to be very small with respect to the sampling frequency. Capacitor Cof maintains the charge on its armatures and acts like a battery. Thus, node X is a good virtual ground, independent on the op-amp offset. In the same way, the output signal, read only during $\phi 2$, is offset independent. The effect of this technique can be simulated using the value of the first-order cell of the previous example (i.e., Cf = 15.92, and Cs = Cd = 1), and Cof = 1. The transfer function Vo/Voff is shown in Fig. 59.32. At low frequency, the Voff is highly rejected, while this is not the case of the standard (uncompensated) integrator. The main problem with this solution is due to the unity feedback operation of the structure during phase $\phi 1$. This requires the stability of the op-amp, which could require a very high power consumption.

Chopper Technique

An alternative solution to reduce offset 1/f noise at the output is given by the chopper technique. It consists of placing one SC mixer for frequency Fs/2 at the op-amp input and a similar one at the op-amp output. This action does not affect white noise. On the other hand, offset and 1/f noise are shifted to around Fs/2, not affecting the frequencies around dc, where the signal to be processed is supposed to be.

This concept is shown for a fully differential op-amp in Fig. 59.33. In Fig.59.34, the input-referred noise power spectral density (PSD) without and with chopper modulation is shown. The white noise level (wnl) is not affected by the chopper operation and remains constant. It will be modified by the folding of the high-frequency noise, as previously described.

This technique is particularly advantageous for SC systems since the mixer can be efficiently implemented with the SC technique as shown in Fig. 59.35.

Finite-Gain Compensated SC Integrator

In the op-amp design, a tradeoff between op-amp dc-gain and bandwidth exists. Therefore, when a large bandwidth is needed, a finite dc-gain necessarily occurs, reducing SC filter performance accuracy. To

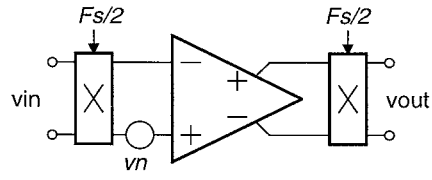

FIGURE 59.33 Op-amp with chopper.

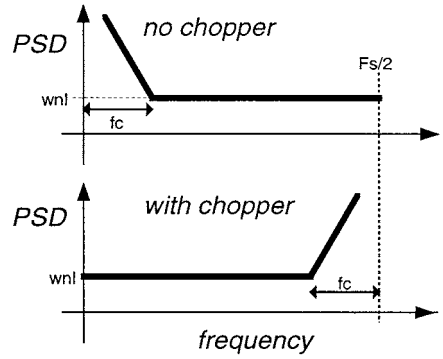

FIGURE 59.34 Input-referred noise power spectral density (PSD) without and with chopper technique.

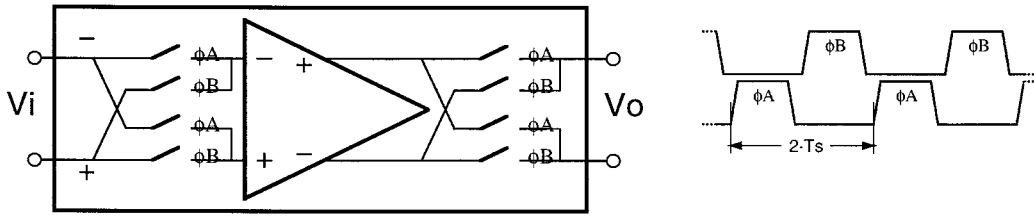

FIGURE 59.35 Op-amp with SC chopper configuration.

avoid this, the available extra phase can be used to self-calibrate the structure with respect to the error due to the op-amp finite gain. In the literature, several techniques have been proposed. The majority of them are based on the concept of using a preview of the future output samples to pre-charge a capacitor placed in series to the op-amp inverting input node in order to create a 'good' virtual ground (as for offset cancellation). The various approaches differ on how they get the preview and how they calibrate the new virtual ground. For the different cases, they can be effective for a large bandwidth,[17,18] for a small bandwidth,[19,20] or for a passband bandwidth.[21] As an example of this kind of compensation, one of the earliest proposed schemes is depicted in Fig. 59.36.

The op-amp finite gain makes the op-amp inverting input node different from the virtual ground ideal behavior and assume the value –Vo/Ao, where Vo is the output value and Ao is the op-amp dc-gain. In the scheme of Fig. 59.36, the future output sample is assumed to be close to the previous sample, sampled of Cg1. This limits the effectiveness of this scheme to signal frequencies f for which this

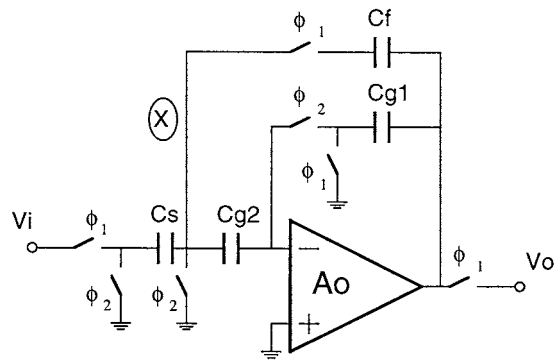

FIGURE 59.36 Finite-gain-compensated SC integrator.

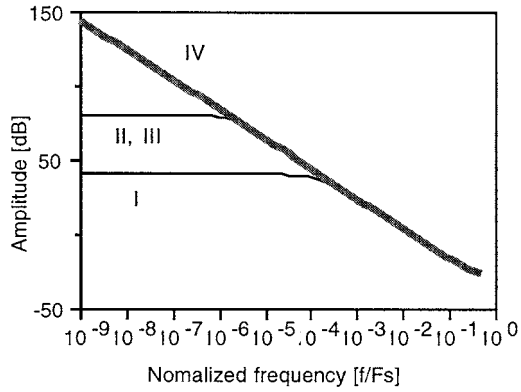

FIGURE 59.37 Finite-gain-compensated SC integrator performance.

assumption is valid (i.e., for *f*/Fs ≪ 1). The circuit operates as follows. During ϕ1, auxiliary capacitor Cg1 samples the output; while during ϕ2, Cg1 is used to precharge Cg2 to –Vo/Ao, generating a good virtual ground at node X.

In Fig. 59.37, the frequency response of different integrators are compared. Line I refers to an uncompensated integrator with Ao = 100; line II refers to the uncompensated integrator with Ao = 10,000. This line matches with line III, which corresponds to the compensated integrator with Ao = 100. Finally, line IV is the frequency response of the ideal integrator. From this comparison, the compensation effect is to achieve an op-amp gain Ao performance similar to those achieved with an op-amp gain Ao^2.

Alternative solution to the op-amp gain compensation are based on the use of a replica amplifier matched with the main one. Also in this way the effectiveness of the solution is to achieve performance accuracy relative to an op-amp dc-gain of Ao^2.

The Very-Long Time-Constant Integrator

In the design of Very-Long Time-Constant integrators using the scheme of Fig. 59.8(a), typical key points to be considered are:

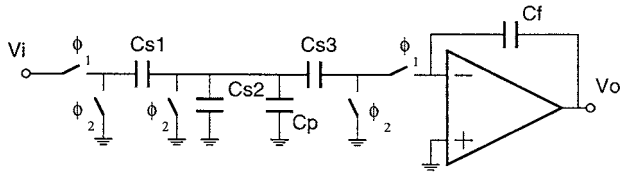
- The capacitor spread: if the pole frequency *fp* is very low with respect to the sampling frequency Fs, then the capacitor spread S = Cf/Cs of a standard integrator (Fig. 59.8(a)) will be very large. This results in large die area and reduce performance accuracy for poor matching.
- The sensitivity to the parasitic capacitances: proper structure can reduce capacitor spread. They, however, suffer from the presence of parasitic capacitance. Parasitic-insensitive or at least parasitic-compensated designs should then be considered.
- The offset of the operational amplifier: offset-compensated op-amps are needed when the op-amp offset contribution cannot be tolerated.

In the literature, several SC solutions have been proposed, more oriented toward reducing the capacitor spread than toward compensating either the parasitics or the op-amp offset.

A first solution is based on the use of a capacitive T-network in a standard SC integrator, as shown in Fig. 59.38.[22] The operation of the sampling T-structure is to realize a passive charge partition with the capacitors Cs1, and Cs2+Cs3. The final result is that only the charge on Cs3 is injected into the virtual ground. Therefore, the effect of this scheme is that Cs is replaced with the Cs_equiv, given by the expression:

$$Cs\_equiv = Cs3 \cdot \frac{Cs1}{Cs1 + Cs2 + Cs3} \tag{59.32}$$

The net gain of this approach is that, using Cs2 = $\sqrt{S}$·Cs1 = $\sqrt{S}$·Cs3, the capacitor spread is reduced to $\sqrt{S}$. For example, an integrator with Cs = 1 and Cf = 40, can be realized with Cs1 = 1, Cs2 = 6, Cs3 = 1, and Cf = 5, i.e., with the capacitor spread reduced to 6.

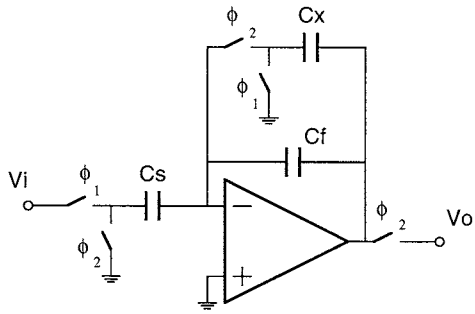


$$\frac{Vo}{Vi} = \frac{Cs1}{Cs1+Cs2+Cs3} \cdot \frac{Cs3}{Cf} \cdot \frac{1}{1-z^{-1}} \tag{59.33}$$

FIGURE 59.38 A T-network long-time-constant SC integrator.

The major problem of the circuit of Fig. 59.38 is due to the fact that the T-network is sensitive to the parasitic capacitance Cp (due to Cs1, Cs2, and Cs3) in the middle node of the T-network, which is added to Cs2, reducing frequency response accuracy.

A parasitic-insensitive circuit is the one proposed by Nararaj[23] and shown in Fig. 59.39. In this case, the transfer function is given by Eq. 59.34. Also, in this case, Cs = Cx = $\sqrt{S}$·Cf are usually adopted to reduce the standard spread from S to $\sqrt{S}$. However, for the Nagaraj integrator, the op-amp is used on both phases, disabling the possibility of using double-sampled structure.



$$\frac{Vo}{Vi} = \frac{Cf}{Cs} \cdot \frac{Cx}{Cf+Cx} \cdot \frac{1}{1-z^{-1}} \tag{59.34}$$

FIGURE 59.39 The Nagaraj's long-time-constant SC integrator.

It is also possible to combine a long-time-constant scheme with an offset-compensated scheme to obtain a long-time-constant offset-compensated SC integrator.[15]

Double-Sampling Technique

If the output value of the SC integrator of Fig. 59.8(b) is read only at the end of ϕ2, the requirement for the op-amp to settle can be relaxed. For the integrator of Fig. 59.8(b), the time available for the op-amp to settle is $T_s/2$. The equivalent double-sampled structure is shown in Fig. 59.40. The capacitor values for the two structures are the same, and thus they implement the same transfer function. The time evolution for the two structures are compared in Fig. 59.41. For the double-sampled SC integrator, the time available for the op-amp to settle is doubled.

This advantage can be used in two ways. First, when a high sampling frequency is required, if the op-amp cannot settle in Ts/2, the extra time allows it to reach the speed requirement (i.e., the double-sampling technique is used to increase the sampling frequency). Second, at low sampling frequency when the power consumption must be strongly reduced, a smaller bandwidth guaranteed by the op-amp reduces its power consumption.

The cost of the double-sampled structure is the doubling of all the switched capacitors. In addition, in the case of a small mismatch between the two parallel paths, mismatch energy could be present around Fs/4.[24]

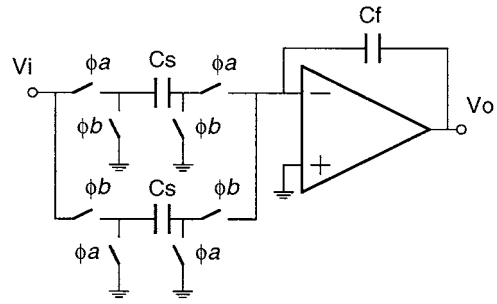


FIGURE 59.40 Double-sampled SC integrator.

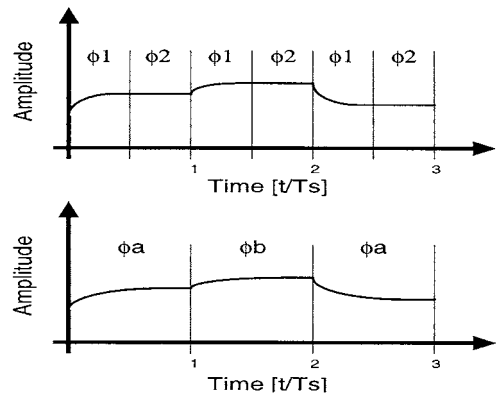

FIGURE 59.41 Double-sampled operation.

59.9 Advanced SC Filter Solutions

In this section, alternative solutions able to overcome some basic limitations to SC system performance improvement are proposed. They deal with the tradeoff between bandwidth-vs.-gain in the op-amp design for high-frequency SC filter, and the implementation of low-voltage SC filters.

Precise Op-amp Gain (POG) for High-Speed SC Structures[25,26]

Standard design of SC networks assumes operation with infinite gain and infinite bandwidth op-amps. However, in the op-amp design, a tradeoff exists between the speed and the gain. As a consequence with a high sampling frequency, the needed large bandwidth limits the op-amp gain to low values, thus limiting the achievable accuracy. Thus, standard design is less feasible for high-sampling frequency. A possible solution to this limitation is the Precise Op-amp Gain (POG) design approach, which consists of designing high-frequency SC networks, taking into account the precise gain value of the op-amps as a parameter in the capacitor design. The standard design op-amp tradeoff between *speed-and-gain* is then changed into the POG design tradeoff between *speed-and-gain precision*, which is more affordable in high-frequency op-amps.

If the op-amp dc-gain is Ao, the transfer function of the first-order cell shown in Fig. 59.42 is given by:

$$H_{POG}(z) = -\frac{Cs_{POG}}{\left(Cf_{POG} + Cd_{POG} + \dfrac{Cs_{POG} + Cf_{POG} + Cd_{POG}}{Ao}\right) - Cf_{POG}\left(1 + \dfrac{1}{Ao}\right)z^{-1}} \tag{59.35}$$

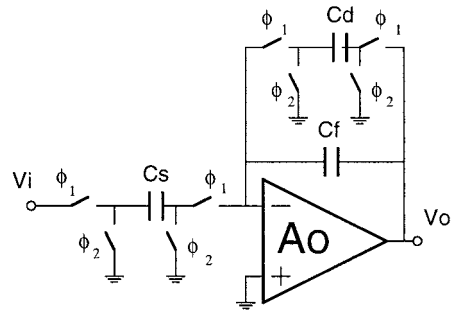

FIGURE 59.42 Dumped SC integrator.

This expression for Ao equal to infinite becomes the standard case t.f HST, which is given by:

$$H_{ST}(z) = -\frac{Cs}{(Cf + Cd) - Cf\ z^{-1}} \tag{59.36}$$

To obtain the same t.f., the POG capacitor values are obtained from the standard values as given in the following:

$$Cs_{POG} = Cs \qquad Cf_{POG} = Cf \cdot \left(1 + \frac{1}{Ao}\right) \qquad Cd_{POG} = Cd\left(1 + \frac{1}{Ao}\right) + \frac{Cs}{Ao} \tag{59.37}$$

The concept here applied to the SC integrator can be applied to higher-order SC filters. It can be demonstrated that using the POG approach with an op-amp nominal gain Ao and an actual gain in the range [Ao(1 – ε), Ao(1 + ε)] achieves the same response accuracy as the standard approach with an infinite op-amp nominal gain with an actual gain given by:

$$A_{eff} = \frac{(Ao+1)(1 \pm \varepsilon)}{\varepsilon} \approx \frac{Ao}{\varepsilon} \tag{59.38}$$

The value A_{eff} can then be defined as the effective gain of the POG approach. For example, for the op-amp with Ao = 100 and ε = 0.08, the same performance accuracy is achieved as when using standard design with op-amp gain A = 1250. This value of A_{eff} can then be used in Eq. 59.27 to evaluate filter performance accuracy.

Low-Voltage Switched-Capacitor Solutions

In the last few years, the interest in low-power, low-voltage integrated systems has consistently grown due to the increasing importance of portable equipment and to the reduction of the supply voltage of modern standard CMOS scaled-down technology ICs. For the design of SC filters operating at reduced supply voltages,[27,28] capacitor properties are quite stable. On the other hand, at low supply, it is difficult to properly operate the MOS switches and the op-amps. With the supply voltage reduction, the MOS switches' overdrive voltage is lowered, inhibiting proper operation of classical transmission gate (complementary switches). The switch conductance for different input voltages changes, depending on the supply voltage V_{DD}. In Fig. 59.22, the case for V_{DD} = 5 V was shown. In Fig. 59.43, the case for V_{DD} = 1 V is reported for comparison. In this case, there is a critical voltage region centered around $V_{DD}/2$ for which both switches are not conducting. In SC circuits, to achieve rail-to-rail swing, the output of the op-amp

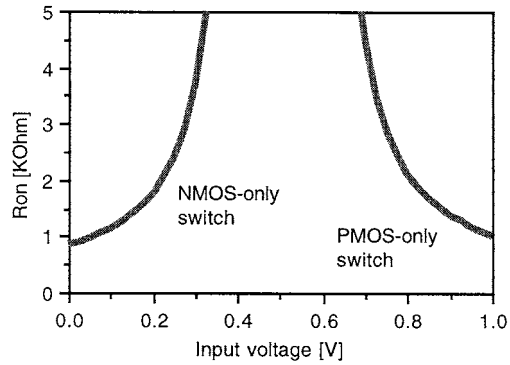

FIGURE 59.43 Switch Ron with V_{DD} = 1 V.

must necessarily cross this critical region, where the switches connected to the op-amp output node will not properly operate at V_{DD} = 1 V.

On the other hand, op-amp operation can be achieved with proper design using a supply voltage as low as $V_{TH}+2\cdot V_{OV}$, with some modifications at system level. Switches and op-amp sections may use different supply voltages. In fact, using voltage multiplier (a possible scheme is shown in Fig. 59.44[29]), it is possible to generate on-chip a voltage higher than the supply voltage. This "multiplied" voltage can then be used to power the entire SC circuit (op-amp and switches) or to drive only the switches.

If the higher supply is used to bias the op-amp and switches, standard design solutions can be implemented. In addition, the op-amp powered with a higher supply voltage can manage a larger signal swing, with a consequential larger dynamic range. However, in a scaled-down technology, the maximum acceptable electric field between gate and channel (for gate oxide breakdown) and between drain and source (for hot electron damage) must be reduced. This puts an absolute limit on the value of the multiplied supply voltage. In addition, the need to supply a dc-curent to the op-amp from the multiplied supply forces one must use an external capacitor, which is an additional cost.

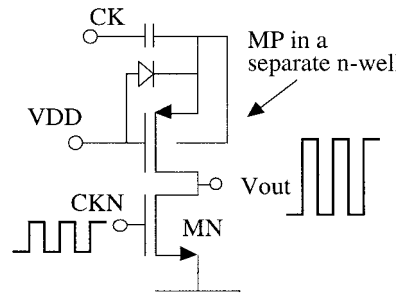

FIGURE 59.44 Charge-pump for on-chip voltage multiplication.

An alternative approach consists of using the multiplied supply to drive only the switches. In this case, the voltage multiplier does not supply any dc-current, thus avoiding any external capacitor. This solution, like the previous one, must not exceed the limit of the technology associated with the gate oxide breakdown. Nonetheless, this approach is largely used because it allows the filter to operate at high sampling frequency.

In order to avoid any kind of voltage multiplier, the Switched-OpAmp (SOA) approach was proposed[30,31] and is based on the following considerations:

1. The best condition for the switches driven with a low supply voltage is to be connected either to ground or to V_{DD}. Thus, to properly operate, S2, S3, and S4 in Fig. 59.8(a) have to be referred to ground or to V_{DD} (i.e., the op-amp input dc-voltage has to be either ground or V_{DD}). This allows one to minimize the required op-amp supply voltage. On the other hand, the op-amp dc output voltage has to be at $V_{DD}/2$ in order to have rail-to-rail output swing.
2. The switch S1 connected to the signal swing cannot operate properly for the full signal swing, as explained before.

The resulting SOA SC integrator is shown in Fig. 59.45. The SOA approach uses an op-amp, which can operate in a tri-state mode. In this way, the critical output switch S1 is no longer necessary and it can be eliminated, moving the critical problem to the op-amp design. The function of the eliminated

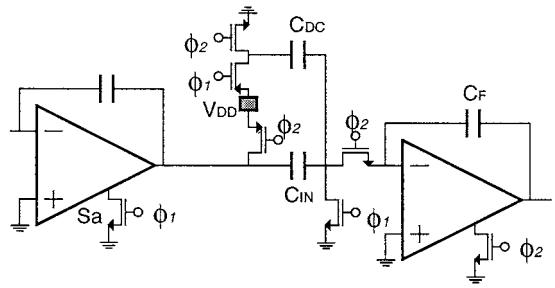

FIGURE 59.45 Switched-op-amp SC integrator.

critical switch S1 is implemented by turning on and off the op-amp through Sa, which is connected to ground.

The input dc-voltage is set to ground. Therefore, all the switches are connected to ground (and realized with a single NMOS device) or to V_{DD} (and realized with a PMOS device), and are driven with the maximum overdrive, given by $V_{DD} - V_{TH}$. Capacitor C_{DC} in Fig. 59.45 gives a fixed charge injection into virtual ground, producing a voltage level shift between input (V_{in_DC}) and output (V_{out_DC}) op-amp dc-voltage. Since V_{in_DC} is set to ground, using $C_{DC} = C_{IN}/2$ sets $V_{out\_DC} = V_{DD}/2$. C_{DC} has no effect on the signal transfer function given by:

$$H(z) = \frac{C_{IN} \cdot z^{-1/2}}{C_F \cdot (1 - z^{-1})} \tag{59.39}$$

A fully differential architecture of the scheme of Fig. 59.45 provides both signal polarities at each node, useful to build up high-order structures without any extra elements (e.g., inverting stage). In addition, any disturbance (offset or noise) injected by C_{DC} results in a common-mode signal, which is largely rejected by the fully differential operation.

The SOA approach suffers from the following problems:

1. SOA structure operates with an op-amp, which is turned on and off. Its turn-on time becomes the main limitation in the possible maximum sampling frequency.
2. In an SOA structure, the output signal is available only during one clock phase; while during the other clock phase, the output is set to zero (return-to-zero), as shown in Fig. 59.46. If the output signal is read as a continuous-time waveform, the return to zero has two effects: a loss of 6 dB in the transfer function, and an increased distortion due to the large output steps. On the other

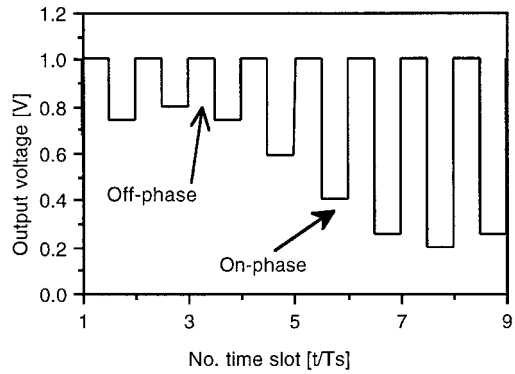

FIGURE 59.46 Switched-op-amp output waveform.

hand, when the SOA integrator is used in front of a sampled-data system (like an ADC), the output signal is sampled only when it is valid and both the above problems are cancelled.

A comparison between the three different low-voltage SC filter design approaches is given in Table 59.2.

TABLE 59.2 Comparison Between Different Low-voltage SC Designs

		Supply multiplier	Clock multiplier	Switched-op-amp
$V_{DDswith}$		V_{DDmult}	V_{DDmult}	V_{DD}
$V_{DDop\text{-}amp}$		V_{DDmult}	V_{DD}	V_{DD}

60.1 Introduction

Microprocessors are rapidly moving into deep submicron dimensions, gigahertz clock frequencies, and transistor counts in excess of 10 million transistors. This trend is being fueled by the ever-increasing demand for more powerful computers on one side and by rapid advances in process technology, architecture, and circuit design on the other side. At these small dimensions and high speeds, timing and signal integrity analyses play a critical role in ensuring that designs meet their performance and reliability goals.

Timing analysis is one of the most important verification steps in the design of a microprocessor because it ensures that the chip is meeting speed requirements. Timing analysis of multi-million transistor microprocessors is a very challenging task. This task is made even more challenging because in the deep submicron regime, transistor-level and interconnect-centric analyses become vital. Therefore, timing analysis must satisfy the two conflicting requirements of accurate low-level analysis (so that deep submicron designs can be handled) and efficient high-level abstraction (so that large designs can be handled).

The term *signal integrity* typically refers to analyses that check that signals to not assume unintended values due to circuit noise. *Circuit noise* is a broad term that applies to phenomena caused by unintended circuit behavior such as unintentional coupling between signals, degradation of voltage levels due to leakage currents and power supply voltage drops, etc. Circuit noise does not encompass physical noise effects (e.g., thermal noise) or manufacturing faults (e.g., stuck-at faults). Signal integrity is also becoming a very critical verification task. Among the various signal integrity-related issues, noise induced by coupling between adjacent wires is perhaps the most important one. With the scaling of process technologies, coupling capacitances between wires are become a larger fraction of the total wire capacitances.

Coupling capacitances are also larger because a larger number of metal layers are now available for routing, and more and more wires are running longer distances across the chip. As operating frequencies increase, noise induced on signal nets due to coupling is much greater. Noise-related functional failures are increasing as dynamic circuits become more prevalent, with circuit designers looking for increased performance at the cost of noise immunity.

Another important problem in submicron high-performance designs is the integrity of the power grid that distributes power from off-chip pads to the various gates and devices in the chip. Increased operating frequencies result in higher current demands from the power and ground lines, which in turn increases the voltage drops seen at the devices. Excessive voltage drops reduce circuit performance and inject noise into the circuit, which may lead to functional failures. Moreover, with reductions in supply voltages, problems caused by excessive voltage drops become more severe. The analysis of the power and ground distribution network to measure the voltage drops at the points where the gates and devices of the chip connect to the power grid is called *IR-drop* or *power grid analysis*.

In this chapter, we will briefly discuss the important issues in static timing analysis, noise analysis with particular emphasis on coupling noise, and IR-drop analysis methods. Additional information on these topics is available in the literature and the reader is encouraged to look through the list of references.

60.2 Static Timing Analysis

Static timing analysis (TA)[1-4] is a very powerful technique for verifying the timing correctness of a design. The power of this technique comes from the fact that it is pattern independent, implicitly verifies all signal propagation paths in the design, and is applicable to very large designs. Further, it lends itself easily to higher levels of abstraction, which makes it even more computationally feasible to perform full-chip timing analysis. The fundamental idea in static timing analysis is to find the *critical paths* in the design. Critical paths are those signal propagation paths that determine the maximum operating frequency of the design. It is easiest to think of critical paths as being those paths from the inputs to the outputs of the circuit that have the longest delay. Since the smallest clock period must be larger than the longest path delay, these paths dictate the operating frequency of the chip. In very simple terms, static TA determines these long paths using breadth-first search as follows. Starting at the inputs, the latest time at which signals arrive at a node in the circuit is determined from the arrival times at its fan-in nodes. This latest arrival time is then propagated toward the primary outputs. At each primary output, we obtain the latest possible arrival time of signals and the corresponding longest path. If the longest path does not meet the timing constraints imposed by the designer, then a violation is detected. Alternatively, if the longest path meets the timing constraints, then all other paths in the circuit will also satisfy the timing constraints. By propagating only the latest arrival time at a node, static TA does not have to explicitly enumerate all the paths in the design.

Historically, simulation-based or *dynamic timing analysis* techniques had been the most common timing analysis technique. However, with increasing complexity and size of recent microprocessor designs, static timing analysis has become an indispensable part of design verification and much more popular than dynamic approaches. Compared to dynamic approaches, static TA offers a number of advantages for verifying the timing correctness of a design. Dynamic approaches are pattern-dependent. Since the possible paths and their delays are dependent on the state of the circuit, the number of input patters that are required to verify all the paths in a circuit is exponential with the number of inputs. Hence, only a subset of paths can be verified with a fixed number of input patterns. Only moderately large circuits can be verified because of the computational cost and size limitations of transient simulators. Static TA, on the other hand, implicitly verifies all the longest paths in the design without requiring input patterns. Dynamic timing analysis is still heavily used to verify complex and critical circuitry such as PLLs, clock generators, and the like. Dynamic simulation is also used to generate timing models for block-level static timing analysis. Dynamic timing analysis technique rely on a circuit simulator (e.g., SPICE[5]) or on a fast timing simulator (e.g., ILLIADS,[6] ACES,[7] TimeMill[8]) for performing the simulations. Because

of the importance of static techniques in verifying the timing behavior of microprocessors, we will restrict the discussion below to the salient points of static TA.

DCC Partitioning

The first step in transistor-level static TA is to partition the circuit into *dc connected components* (DCCs), also called *channel-connected components*. A DCC is a set of nodes which are connected to each other through the source and drain terminals of transistors. The transistor-level representation and the DCC partitioning of a simple circuit is shown in Fig. 60.1. As seen in the diagram, a DCC is the same as the gate for typical cells such as inverters, NAND and NOR gates. For more complex structures such as latches, a single cell corresponds to multiple DCCs. The inputs of a DCC are the primary inputs of the circuit or the gate nodes of the devices that are part of the DCC. The outputs of a DCC are either primary outputs of the circuit or nodes that are connected to the gate nodes of devices in other DCCs. Since the gate current is zero and currents flow between source and drain terminals of MOS devices, a MOS circuit can be partitioned at the gates of transistors into components which can then be analyzed independently. This makes the analysis computationally feasible since instead of analyzing the entire circuit, we can analyze the DCCs one at a time. By partitioning a circuit into DCCs, we are ignoring the current conducted by the MOS parasitic capacitances that couple the source/drain and gate terminals. Since this current is typically small, the error is small. As mentioned above, DCC partitioning is required for transistor-level static TA. For higher levels of abstraction, such as gate-level static TA, the circuit has already been partitioned into gates, and their inputs are known. In such cases, one starts by constructing the timing graph as described in the next section.

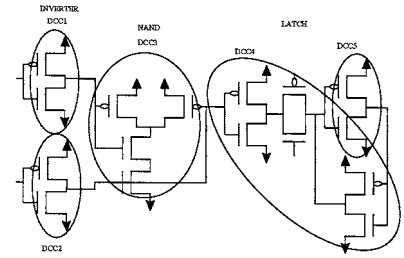

FIGURE 60.1 Transistor-level circuit partitioned into DCCs.

Timing Graph

The fundamental data structure in static TA is the *timing graph*. The timing graph is a graphical representation of the circuit, where each vertex in the graph corresponds to an input or an output node of the DCCs or gates of the circuit. Each edge or timing arc in the graph corresponds to a signal propagation from the input to the output of the DCC or gate. Each timing arc has a polarity defined by the type of transition at the input and output nodes. For example, there are two timing arcs from the input to the output of an inverter: one corresponds to the input rising and the output falling, and the other to the input falling and the output rising. Each timing arc in the graph is annotated with the propagation delay of the signal from the input to the output. The gate-level representation of a simple circuit is shown in Fig. 60.2(a) and the corresponding timing graph is shown in Fig. 60.2(b). The solid line timing arcs correspond to falling input transitions and rising output transitions, whereas the dotted line arcs represent rising input transitions and falling output transitions.

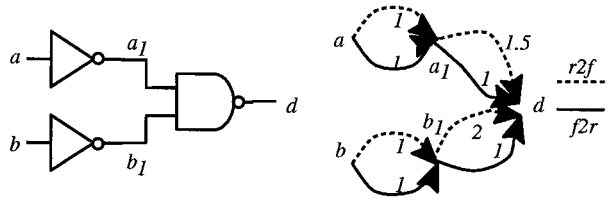

FIGURE 60.2 A simple digital circuit: (a) gate-level representation, and (b) timing graph.

Note that the timing graph may have cycles which correspond to feedback loops in the circuit. Combinational feedback loops are broken and there are several strategies to handle sequential loops (or cycles of latches).[5] In any event, the timing graph becomes acyclic and the vertices of the graph can be arranged in topological order.

Arrival Times

Given the times at which the signals at the primary inputs or *source nodes* of the circuit are stable, the minimum (earliest) and maximum (latest) arrival times of signals at all the nodes in the circuit can be calculated with a single breadth-first pass through the circuit in topological order. The early arrival time $a(v)$ is the smallest time by which signals arrive at node v and is given by

$$a(v) = \min_{u \in FI(v)} \left[a(u) + d_{uv} \right] \tag{60.1}$$

Similarly, the late arrival time $A(v)$ is the latest time by which signals arrive at node v and is given by

$$A(v) = \max_{u \in FI(v)} \left[A(u) + d_{uv} \right] \tag{60.2}$$

In the above equations, $FI(v)$ is the set of all fan-in nodes of v, i.e., all nodes that have an edge to v and d_{uv} is the delay of an edge from u to v. Equations 60.1 and 60.2 will compute the arrival times at a node v from the arrival times of its fan-in nodes and the delays of the timing arcs from the fan-in nodes to v. Since the timing graph is acyclic (or has been made acyclic), the vertices in the graph can be arranged in topological order (i.e., the DCCs and gates in the circuit can be *levelized*). A breadth-first pass through the timing graph using Eqs. 60.1 and 60.2 will yield the arrival times at all nodes in the circuit.

Considering the example of Fig. 60.2, let us assume that the arrival times at the primary inputs a and b are 0. From Eq. 60.2, the maximum arrival time for a rising signal at node a_1 is 1, and the maximum arrival time for a falling signal is also 1. In other words, $A_{a1,r} = A_{a1,f} = 1$, where the subscripts r and f denote the polarity of the signal. Similarly, we can compute the maximum arrival times at node b_1 as $A_{b1,r} = A_{b1,f} = 1$, and at node d as $A_{d,r} = 2$ and $A_{d,f} = 3$.

In addition to the arrival times, we also need to compute the *signal transition times* (or slopes) at the output nodes of the gates or DCCs. These transition times are required so that we can compute the delay across the fan-out gates. Note that there are many timing arcs that are incident at the output node and each gives rise to a different transition time. The transition time of the node is picked to be the transition time corresponding to the arc that causes the latest (earliest) arrival time at the node.

Required Times and Slacks

Constraints are placed on the arrival times of signals at the primary output nodes of a circuit based on performance or speed requirements. In addition to primary output nodes, timing constraints are automatically placed on the clocked elements inside the circuit (e.g., latches, gated clocks, domino logic gates, etc.). These timing constraints check that the circuit functions correctly and at-speed. Nodes in the circuit where timing checks are imposed are called *sink nodes*.

Timing checks at the sink nodes inject required times on the earliest and latest signal arrival times at these nodes. Given the required times at these nodes, the required times at all other nodes in the circuit can be calculated by processing the circuit in reverse topological order considering each node only once. The late required time $R(v)$ at a node v is the required time on the late arriving signal. In other words, it is the time by which signals are required to arrive at that node and is given by

$$R(v) = \max_{u \in FO(v)} \left[R(u) - d_{uv} \right] \tag{60.3}$$

Similarly, the early required time $r(v)$ is the required time on the early arriving signal. In other words, it is the time after which signals are required to arrive at node v and is given by

$$r(v) = \min_{u \in FO(v)} \left[r(u) - d_{uv} \right] \tag{60.4}$$

In these equations, $FO(v)$ is the set of fan-out nodes of v (i.e., the nodes to which there is a timing arc from node v) and d_{uv} is the delay of the timing arc from node u to node v. Note that $R(v)$ is the time *before* which a signal must arrive at a node, whereas $r(v)$ is the time *after* which the signal must arrive.

The difference between the late arrival time and the late required time at a node v is defined as the *late slack* at that node and is given by

$$S_l(v) = R(v) - A(v) \tag{60.5}$$

Similarly, the *early slack* at node v is defined by

$$S_e(v) = a(v) - r(v) \tag{60.6}$$

Note that the late and early slacks have been defined in such a way that a negative value denotes a constraint violation. The overall slack at a node is the smaller of the early and late slacks; that is,

$$S(v) = \min \; S_l(v), S_e(v) \tag{60.7}$$

Slacks can be calculated in the backward traversal along with the required times. If the slacks at all nodes in the circuit are positive, then the circuit does not violate any timing constraint. The nodes with the smallest slack value are called *critical nodes*. The most *critical path* is the sequence of critical nodes that connect the source and sink nodes.

Continuing with the example of Fig. 60.2, let the maximum required time at the output node d be 1. Then, the late required time for a rising signal at node a_1 is $R_{a1,r} = -0.5$ since the delay of the rising-to-falling timing arc from a_1 to d is 1.5. Similarly, the late required time for a falling signal at node a_1 is $R_{a1,f} = R_{d,r} - 1 = 0$. The required times at the other nodes in the circuit can be calculated to be: $R_{b1,r} = -1$, $R_{b1,f} = 0$, $R_{a,r} = -1$, $R_{a,f} = -1.5$, $R_{b,r} = -1$, and $R_{b,f} = -2$. The slack at each node is the difference between the required time and the arrival time and are as follows: $S_{d,r} = -1.5$, $S_{d,}$f $= -2$, $S_{a1,r} = -1.5$, $S_{a1,f} = -1$, $S_{b1,r} = -2$, $S_{b1,f} = -1$, $S_{a,r} = -1$, $S_{a,f} = -1.5$, $S_{b,r} = -1$, and $S_{b,f} = -2$. Thus, the critical path in this circuit is b falling — $b1$ rising — d falling, and the circuit slack is –2.

Clocked Circuits

As mentioned earlier, combinational circuits have timing checks imposed only at the circuit primary outputs. However, for circuits containing clocked elements such as latches, flip-flops, gated clocks, domino/precharge logic, etc., timing checks must also be enforced at various internal nodes in the circuit to ensure that the circuit operates correctly and at-speed. In circuits containing clocked elements, a separate recognition step is required to detect the clocked elements and to insert constraints. There are two main techniques for detecting clocked elements: pattern recognition and clock propagation.

In *pattern recognition*-based approaches, commonly used sequential elements are recognized using simple topological rules. For example. back-to-back inverters in the netlist are often an indication of a latch. For more complex topologies, the detection is accomplished using templates supplied by the user. Portions of a circuit are typically recognized in the graph of the original circuit by employing subgraph isomorphism algorithms.[9] Once a subcircuit has been recognized, timing constraints are automatically

inserted. Another application of pattern-based subcircuit recognition is to determine logical relationships between signals. For example, in pass-gate multiplexors, the data select lines are typically one-hot. This relationship cannot be obtained from the transistor-level circuit representation without recognizing the subcircuit and imposing the logical relationships for that subcircuit. The logical relationship can then be used by timing analysis tools. However, purely pattern recognition-based approaches can be restrictive and may necessitate a large number of templates from the user for proper functioning.

In *clock propagation*-based approaches, the recognition is performed automatically by propagating clock signals along the timing graph and determining how these clock signals interact with data signals at various nodes in the circuit. The primary input clocks are identified by the user and are marked as (simple) clock nodes. Starting from the primary clock inputs and traversing the timing arcs in the timing graph, the type of the nodes are determined based on simple rules. These rules are illustrated in Fig. 60.3,

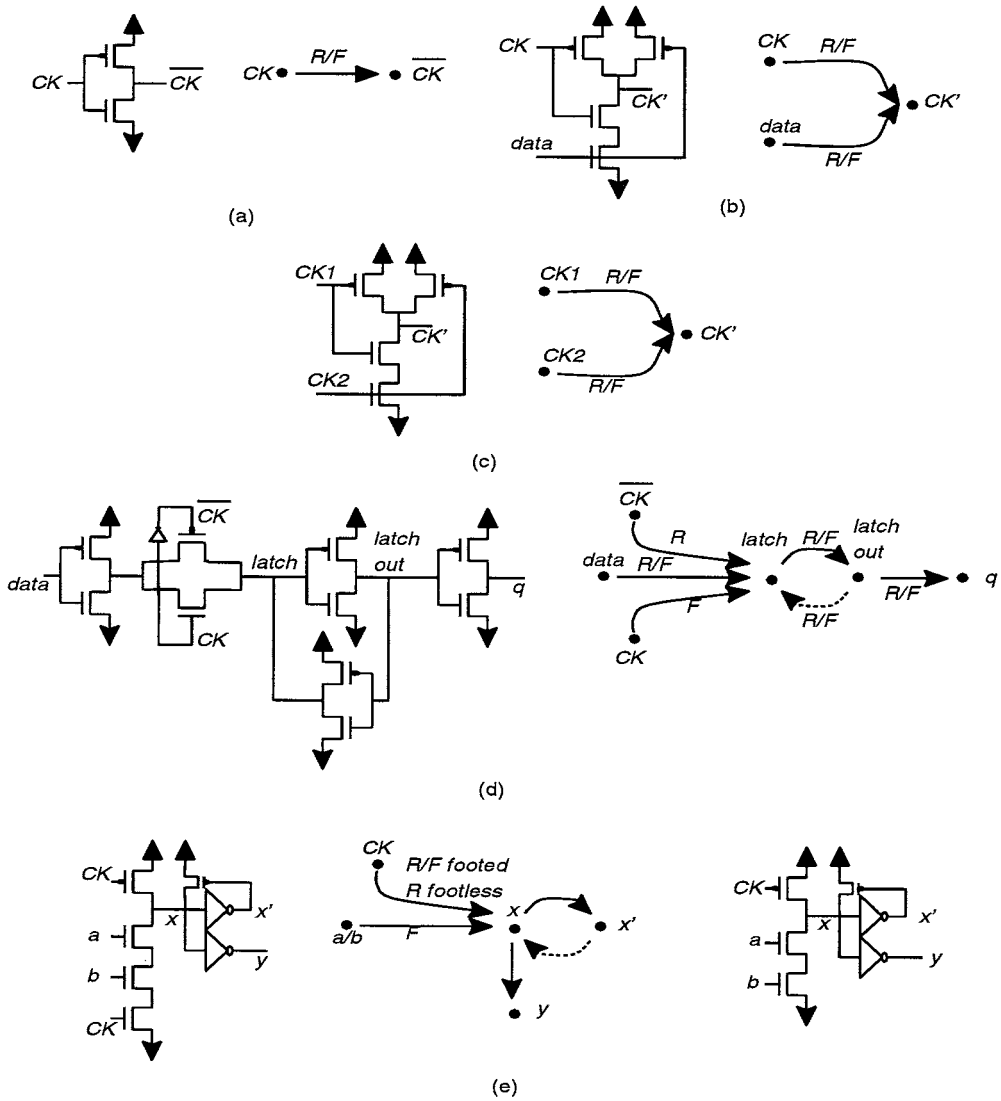

FIGURE 60.3 Sequential element detection: (a) simple clock, (b) gated clock, (c) merged clock, (d) latch node, and (e) footed and footless domino gates. Broken arcs are shown as dotted lines. Each arc is marked with the type of output transition(s) it can cause (e.g., R/F: rise and fall, R: rise only, and F: fall only).

where we show the transistor-level subcircuits and the corresponding timing subgraphs for some common sequential elements.

- A node that has only one clock signal incident on it and no feedback is classified as a *simple clock node* (Fig. 60.3(a)).
- A node that has one clock and one or more data signals incident on it, but no feedback, is classified as a *gated clock node* (Fig. 60.3(b)).
- A node that has multiple clock signals (and zero or more data signals) incident on it and no feedback is classified as a *merged clock node* (Fig. 60.3(c)).
- A node that has at least one clock and zero or more data signals incident on it and has a feedback of length two (i.e., back-to-back timing arcs) is classified as a *latch node* (Fig. 60.3(d)). The other node in the two node feedback is called the *latch output node*. A latch node is of type data. The timing arc(s) from the latch output node to the latch is (are) broken.
  Latches can be of two types: *level-sensitive* and *edge-triggered*. To distinguish between edge-triggered and level-sensitive latches, various rules may be applied. These rules are usually design-specific and will not be discussed here. It is assumed that all latches are level-sensitive unless the user has marked certain latches to be edge-triggered.

  Note that the domino gates of Fig. 60.3(e) also satisfy the conditions for a latch node. For a latch node, both data and clock signals cause rising and falling transitions at the latch node. For domino gates, data inputs *a* and *b* cause only falling transitions at the *domino node x*. This condition can be used to distinguish domino nodes from latch nodes. Footed and footless domino gates can be distinguished from each other by looking at the clock transitions on the domino node. Since the footed gate has the clocked nMOS transistor at the "foot" of the evaluate tree, the clock signal at *CK* causes both rising and falling transitions at node *x*. In the footless domino gate, *CK* causes only a rising transition at node *x*.

Clock propagation stops when a node has been classified as a data node. This type of detection can be easily performed with a simple breadth-first search on the timing graph.

Once the sequential elements have been recognized, timing constraints must be inserted to ensure that the circuit functions correctly and at-speed.[10] These are described below and illustrated in Figs. 60.4 and 60.5.

- *Simple clocks*: In this case, no timing checks are necessary. The arrival times and slopes at the simple clock node are obtained just as in normal data node.
- *Gated clocks*: The basic purpose of a gated clock is to enable or disable clock transitions at the input of the gate from propagating to the output of the gate. This is done by setting the value of the data input. For example, in the gated clock of Fig. 60.3(b), setting the data input to 1 will allow the clock waveform to propagate to the output, whereas setting the data input to 0 will disable transitions at the gate output. To make sure that this is indeed the behavior of the gated clock, the timing constraints should be such that transitions at the data input node(s) do not create transitions at the output node. For the gated NAND clock of Fig. 60.3(b), we have to ensure that the data can transition (high or low) only when the clock is low, i.e., data can transition after the clock turns low (short path constraint) and before the clock turns high (long path constraint). This is shown in Fig. 60.4(a). In addition to imposing this timing constraint, we also break the timing arc from the data node to the gated clock node since data transitions cannot create output clock transitions.
- *Merged clocks*: Merged clocks are difficult to handle in static TA since the output clock waveform may have a different clock period compared to the input clocks. Moreover, the output clock waveform depends on the logical operation performed by the gate. To avoid these problems, static TA tools typically ask the user to provide the waveform at the merged clock node and the merged clock node is treated as a (simple) clock input node with that waveform. Users can obtain the clock waveform at the merged clock node by using dynamic simulation with the input clock waveforms.

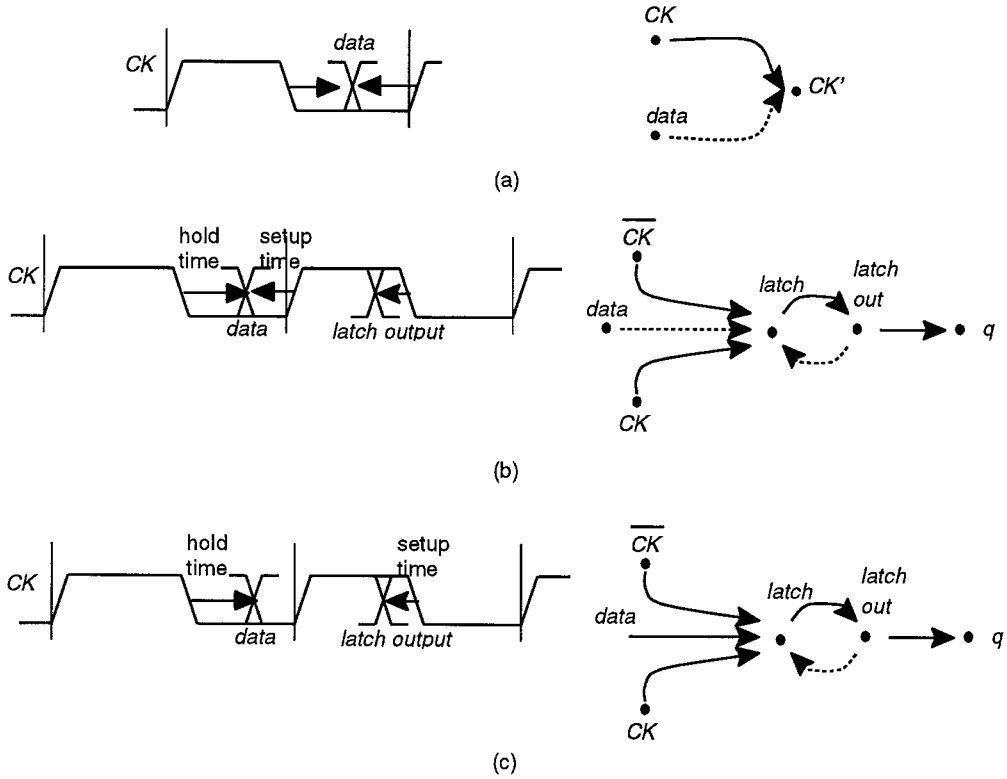

FIGURE 60.4 Timing constraints and timing graph modifications for sequential elements: (a) gated clock, (b) edge-triggered latch, and (c) level-sensitive latch. Broken arcs are shown as dotted lines.

- *Edge-triggered latches*: An edge-triggered latch has two types of constraints: *set-up constraint* and *hold constraint*. The set-up constraint requires that the data input node should be ready (i.e., the rising and falling signals should have stabilized) before the latch turns on. In the latch shown in Fig. 60.3(d), the latch is turned on by the rising edge of the clock. Hence, the data should arrive some time before the rising edge of the clock (this time margin is typically referred to as the *set-up time* of the latch). This constraint imposes a required time on the latest (or maximum) arrival time at the data input of the latch and is therefore a long path constraint. This is shown in Fig. 60.4(b). The hold constraint ensures that data meant for the current clock cycle does not accidentally appear during the on-phase of the previous clock cycle. Looking at Fig. 60.4(b), this implies that the data should appear some time after the falling edge of the clock (this time margin is called the *hold time* of the latch). The hold time imposes a required time on the early (or minimum) arrival time at the data input node and is therefore a short path constraint. As the name implies, in edge-triggered latches, the on-edge of the clock causes data to be stored in the latch (i.e., causes transitions at the latch node). Since the data input is ready before the clock turns on, the latest arrival time at the latch node will be determined only by the clock signal. To make sure that this is indeed the behavior of the latch, the timing arc from the data input node to the latch node is broken, as shown in Fig. 60.4(b). One additional set of timing constraints is imposed for an edge-triggered latch. Since data is stored at the latch (or latch output) node, we must ensure that the data gets stored before the latch turns off. In other words, signals should arrive at the latch output node before the off-edge of the clock.
- *Level-sensitive latches*: In the case of level-sensitive latches, the data need not be ready before the latch turns on, as is the case for edge-triggered latches. In fact, the data can arrive after the on-edge of the clock — this is called *cycle stealing* or *time borrowing*. The only constraint in this case

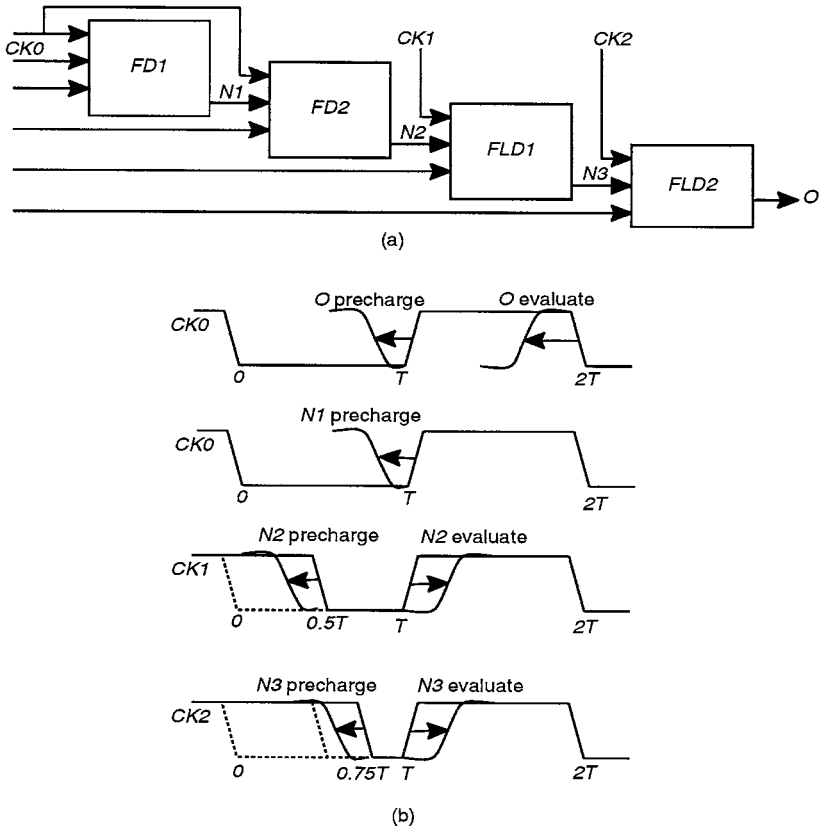

FIGURE 60.5 Domino circuit: (a) block diagram, and (b) clock waveforms and precharge and evaluate constraints. Note precharge implies the phase of operation (clock); the signals are falling.

is that the data gets latched before the clock turns off. Hence, the set-up constraint for a level-sensitive latch is that signals should arrive at the latch output node (not the latch node itself) before the falling edge of the clock, as shown in Fig. 60.4(c). The hold constraint is the same as before; it ensures that data meant for the current clock cycle arrives only after the latch was turned off in the previous clock cycle. This is also shown in Fig. 60.4(c). Since the latest arriving signal at the latch node may come from either the data or the clock node, timing arcs are not broken for a level-sensitive latch. Since data can flow through the latch, level-sensitive latches are also referred to as *transparent latches*.

- *Domino gates*: Domino circuits have two distinct phases of operation: *precharge* and *evaluate*.[11] Looking at the domino gate of Fig. 60.3(e), we see that in the precharge phase, the clock signal is low and the domino node x is precharged to a high value and the output node y is pre-discharged to a low value. During the evaluate phase, the clock is high and if the values of the gate inputs establish a path to ground, domino node x is discharged and output node y turns high. The difference between *footed* and *footless domino gates* is the clocked nMOS transistor at the "foot" of the nMOS evaluate tree. To demonstrate the timing constraints imposed on domino circuits, consider the domino circuit block diagram and the clock waveforms shown in Fig. 60.5. The footed domino blocks are labeled *FD*1 and *FD*2, and the footless blocks are labeled *FLD*1 and *FLD*2. From Fig. 60.5(b), note that all three clocks have the same period $2T$, but the falling edge of *CK*2 is $0.25T$ after the falling edge of *CK*1 which in turn is $0.5T$ after the falling edge of *CK*0. Therefore, the precharge phase for *FD*1 and *FD*2 is T, for *FLD*1 is $0.5T$, and for *FLD*2 is $0.25T$. The various timing constraints for domino circuits are illustrated in Fig. 60.5 and discussed below.

1. We want the output O to evaluate (rise) before the clock starts falling and to precharge (fall) before the clock starts rising.
2. Consider node $N1$, which is an output of $FD1$ and an input of $FD2$. $N1$ starts precharging (falling) when $CK0$ falls, and the constraint on it is that it should finish precharging before $CK0$ starts rising.
3. Next, consider node $N2$, which is an input to $FLD1$ clocked by $CK1$. Since this block is footless, $N2$ should be low during the precharge phase to avoid short-circuit current. $N2$ starts precharging (falling) when $CK0$ starts falling and should finish falling before $CK1$ starts falling. Note that the falling edges of $CK0$ and $CK1$ are $0.5T$ apart, and the precharge constraint is on the late or maximum arrival time of $N2$ (long path constraint). Also, $N2$ should start rising only after $CK1$ has finished rising. This is a constraint on the early or minimum arrival time of $N2$ (short path constraint). In this example, $N2$ starts rising with the rising edge of $CK0$ and, since all the clock waveforms rise at the same time, the short path constraint will be satisfied trivially.
4. Finally, consider node $N3$. Since $N3$ is an input of $FLD2$, it must satisfy the short-circuit current constraints. $N3$ starts precharging (falling) when $CK1$ starts falling and it should fall completely before $CK2$ starts falling. Since the two clock edges are $0.25T$ apart, the precharge constraint on $N3$ is tighter than the one on $N2$. As before, the short path constraint on $N3$ is satisfied trivially.

The above discussion highlights the various types of timing constraints that must be automatically inserted by the static TA tool.

Note that each relative timing constraint between two signals is actually composed of two constraints. For example, if signal d must rise before clock CK rises, then (1) there is a required time on the late or maximum rising arrival time at node d (i.e., $A_{d,r} < A_{CK,r}$), and (2) there is a required time on the early or minimum rising arrival time at the clock node CK (i.e., $a_{CK,r} < a_{d,r}$). There is one other point to be noted. Set-up and hold constraints are fundamentally different in nature. If a hold constraint is violated, then the circuit will not function at any frequency. In other words, hold constraints are *functional constraints*. Set-up constraints, on the other hand, are *performance constraints*. If a set-up constraint is violated, the circuit will not function at the specified frequency, but it will function at a lower frequency (lower speed of operation). For domino circuits, precharge constraints are functional constraints, whereas evaluate constraints are performance constraints.

Transistor-Level Delay Modeling

In transistor-level static TA, delays of timing arcs have to be computed on the fly using transistor-level delay estimation techniques. There are many different transistor-level delay models which provide different tradeoffs between speed and accuracy. Before reviewing some of the more popular delay models, we define some notations. We will refer to the delay of a timing arc as being its *propagation delay* (i.e., the time difference between the output and the input completing half their transitions). For a falling output, the fall times is defined as the time to transition from 90% to 10% of the swing; similarly, for a rising output, the rise time is defined as the time to transition from 10% to 90% of the swing. The transition time at the output of the timing arc is defined to be either the rise time or the fall time. In many of the delay models discussed below, the transition time at the input of a timing arc is required to find the delay across the timing arc. At any node in the circuit, there is a transition time corresponding to each timing arc that is incident on that node. Since for long path static TA, we find the latest arriving signal at a node and propagate that arrival time forward, the transition time at a node is defined to be the output transition time of the timing arc which produced the latest arrival time at the node. Similarly, for short path analysis, we find the transition time as the output transition time of the timing arc that produced the earliest arrival time at the node.

Analytical closed-form formulae for the delay and output transition times are useful for static TA because of their efficiency. One such model was proposed in Hedenstierna et al.,[12] where the propagation

delay across an inverter is expressed as a function of the input transition time s_{in}, the output load C_L, and the size and threshold voltages of the NMOS and PMOS transistors. For example, the inverter delay for a rising input and falling output is given by

$$t_d = k_0 \frac{C_L}{\beta_n} + s_{in}\left(k_1 + k_2 V_{tn}\right) \tag{60.8}$$

where β_n is the NMOS transconductance (proportional to the width of the device), V_{tn} is the NMOS threshold voltage, and k_0, k_1, and k_2 are constants. The formula for the rising delay is the same, with PMOS device parameters being used. The output transition time is considered to be a multiple of the propagation delay and can be calibrated to a particular technology. More accurate analytical formulae for the propagation delay and output transition time for an inverter gate have been reported in the literature.[13,14] These methods consider more complex circuit behavior such as short-circuit current (both NMOS and PMOS transistors in the inverter are conducting) and the effect of MOS parasitic capacitances that directly couple the input and outputs of the inverter. More accurate models of the drain current and parasitic capacitances of the transistor are also used. The main shortcoming of all these delay models is that they are based on an inverter primitive; therefore, arbitrary CMOS gates seen in the circuit must be mapped to an equivalent inverter.[15] This process often introduces large errors.

A simpler delay model is based on replacing transistors by linear resistances and using closed-form expressions to compute propagation delays.[16,17] The first step in this type of delay modeling is to determine the charging/discharging path from the power supply rail to the output node that contains the switching transistor. Next, each transistor along this path is modeled as an effective resistance and the MOS diffusion capacitances are modeled as lumped capacitances at the transistor source and drain terminals. Finally, the Elmore time constant[18] of the path is obtained by starting at the power supply rail and adding the product of each transistor resistance and the sum of all downstream capacitances between the transistor and the output node. The accuracy of this method is largely dependent on the accuracy of the effective resistance and capacitance models. The effective resistance of a MOS transistor is a function of its width, the input transition time, and the output capacitance load. It is also a function of the position of the transistor in the charging/discharging path. The position variable can have three values: *trigger* (when the input at the gate of the transistor is switching), *blocking* (when the transistor is not switching and it lies between the trigger and the output node), and *support* (when the transistor is not switching and lies between the trigger and the power supply rail). The simplest way to incorporate these effects into the resistance model is to create a table of the resistance values (using circuit simulation) for various values of the transistor width, the input transition, and the output load. During delay modeling, the resistance value of a transistor is obtained by interpolation from the calibration table. Since the position is a discrete variable, a different table must be stored for each position variable. The effective MOS parasitic capacitances are functions of the transistor width and can also be modeled using a table look-up approach. The main drawbacks of this approach are the lack of accuracy in modeling a transistor as a linear resistance and capacitance, as well as not considering the effect of parallel charging/discharging paths and complementary paths. In our experience, this approach typically gives 10–20% accuracy with respect to SPICE for standard gates (inverters, NANDs, NORs, etc.); for complex gates, the error can be greater. These methods do not compute the transition time or slope at the output of the DCC. The transition time at the output node is considered to be a multiple of the propagation delay. Note that the propagation delay across a gate can be negative; this is the case, for example, if there is a slow transition at the input of a strong but lightly loaded gate. As a result, the transition time would become negative, giving a large error compared to the correct value.

Yet another method of modeling the delay from an input to an output of a DCC (or gate) is based on running a circuit simulator such as SPICE,[5] or a fast timing simulator such as ILLIADS[6] or ACES.[7] Since the waveform at the switching input is known, the main challenge in this method is to determine the assertions (whether an input should be set to a high or low value) for the side inputs which gives rise to

a transition at the output of the DCC.[19] For example, let us consider a rising transition at the input causing a falling transition at the output. In this case, a valid assertion is one that satisfies the following two conditions: (1) before the transition, there should be no conducting path between the output node and *Gnd*, and (2) after the transition, there should be at least one conducting path between the output node and *Gnd* and no conducting path between the output node and V_{dd}. The sensitization condition for a rising output transition is exactly symmetrical. The valid assertions are usually determined using a binary decision diagram.[20] For a particular input-output transition, there may be many valid assertions; these valid assertions may have different delay values since the primary charging/discharging path may be different or different node capacitances in the side paths may be charged/discharged. To find the assertion that causes the worst-case (or best-case) delay, one may resort to explicit simulations of all the valid assertions or employ other heuristics to prune out certain assertions. The main advantage of this type of delay modeling is that very accurate delay and transition time estimates can be obtained since the underlying simulator is accurate. The added accuracy is obtained at the cost of additional runtime.

Since static timing analyzers typically use simple delay models for efficiency reasons, the top few critical paths of the circuit should be verified using circuit simulation.[21,22]

Interconnects and Static TA

As is well known, interconnects are playing a major role in determining the performance of current microprocessors, and this trend is expected to continue in the next generation of processors.[23] The effect of interconnects on circuit and system performance should be considered in an accurate and efficient manner during static timing analysis. To illustrate interconnect modeling techniques, we will use the example shown in Fig. 60.6(a) of a wire connecting a driving inverter to three receiving inverters.

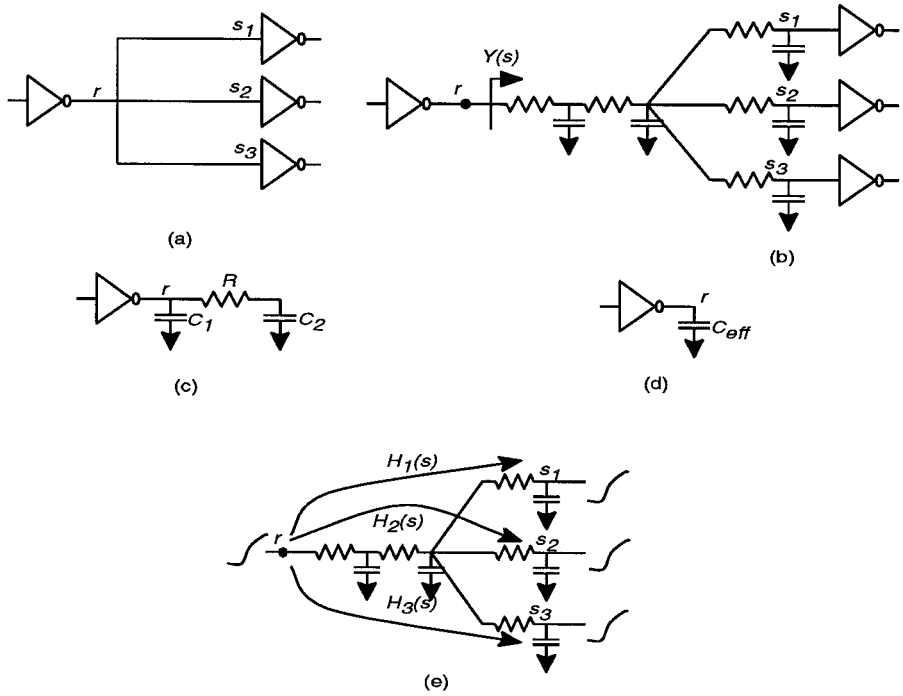

FIGURE 60.6 Handling interconnects in static TA: (a) a typical interconnect, (b) distributed RC model of interconnect, (c) reduced π-model to represent the loading of the interconnect, (d) effective capacitance loading, and (e) propagation of waveform from root to sinks.

The simplest interconnect model is to lump all the interconnect and receiver gate capacitances at the output of the driver gate. This approximation may greatly overestimate the delay across the driver gate since, in reality, all of the downstream capacitances are not "seen" by the driver gate because of resistive shielding due to line resistances. A more accurate model of the wire as a distributed RC line is shown in Fig. 60.6(b). This is the wire model output by most commercial RC extraction tools. In Fig. 60.6(b), node *r* is called the *root* of the interconnect and is driven by the driver gate, and the other end points of the wire at the inputs of the receiver gate are called *sinks* of the interconnect and are labeled s_1, s_2, and s_3. Interconnects have two main effects: (1) the interconnect resistance and capacitance determines the effective load seen by the driving gate and therefore its delay, and (2) due to non-zero wire resistances, there is a non-zero delay from the root to the sinks of the interconnect — this is called the *time-of-flight delay*.

To model the effect of the interconnect on the driver delay, we first replace the metal wire with a π-model load as shown in Fig. 60.6(c).[24] This is done by finding the first three moments of the admittance $Y(s)$ of the interconnect at node *r*. It can be shown that the admittance is given by $Y(s) = m_1 s + m_2 s^2 + m_3 s^3 + \ldots$. Next, we obtain the admittance of the π-load as $\hat{Y}(s) = s(C_1 + C_2) - s^2RC^2_2 + s^3R^2C^3_2 + \ldots$, where R, C_1, and C_2 are the parameters of the π-load model. To obtain the parameters of the π-load, we equate the first three moments of $Y(s)$ and $\hat{Y}(s)$. This gives us the following equations for the parameters of the π-load model:

$$C_2 = \frac{m_2^2}{m_3}, \quad C_1 = m_1 - \frac{m_2^2}{m_3}, \quad \text{and} \quad R = -\frac{m_3^2}{m_2^3} \tag{60.9}$$

Now, if we are using a transistor-level delay model or a pre-characterized gate-level delay model that can only handle purely capacitive loading and not π-model loads, we have to determine an effective capacitance C_{eff} that will accurately model the π-load. The basic idea of this method[25,26] is to equate the average current drawn by the π-model load to the average current drawn by the C_{eff} load. Since the average current drawn by any load is dependent on the transition time at the output of the gate and the transition time is itself a function of the load, we have to iterate to converge to the correct value of C_{eff}. Once the effective capacitance has been obtained, the delay across the driver gate and the waveform at node *r* can be obtained.

The waveform at the root node is then propagated to the sink nodes s_1, s_2, s_3 across the transfer functions $H_1(s)$, $H_2(s)$, and $H_3(s)$, respectively. This procedure is illustrated in Fig. 60.6(e). If the driver waveform can be simplified as a ramp, the output waveforms at the sink nodes can be computed easily using reduced-order modeling techniques like AWE[27] and the time-of-flight delay between the root node and the sink nodes can be calculated.

Process Variations and Static TA

Unavoidable variations and disturbances present in IC manufacturing processes cause variations in device parameters and circuit performances. Moreover, variations in the environmental conditions (of such parameters are temperature, supply voltages, etc.) also cause variations in circuit performances.[28] As a result, static TA should consider the effect of process and environmental variations. Typically, statistical process and environmental variations are considered by performing analysis at two process corners: *best-case* corner and *worst-case* corner. These process corners are typically represented as different device model parameter sets, and as the name implies, are for the fastest and slowest devices. For gate-level static TA, gate characterization is first performed at these two corners yielding two different gate delay models. Then, static TA is performed with the best-case and worst-case gate delay models. Long path constraints (e.g., latch set-up and performance or speech constraints) are checked with the worst-case models and short path constraints (e.g., latch hold constraints) are checked with the best-case models.

Timing Abstraction

Transistor-level timing analysis is very important in high-performance microprocessor design and verification since a large part of the design is hand-crafted and cannot be pre-characterized. Analysis at the transistor level is also important to accurately consider interconnect effects such as gate loading, charge-sharing, and clock skew. However, full-chip transistor-level analysis of large microprocessor designs is computationally infeasible, making timing abstraction a necessity.

Gate-Level Static TA

A straightforward extension of transistor-level static TA is to the gate level. At this level of abstraction, the circuit has been partitioned into gates, and the inputs and outputs of each gate have been identified. Moreover, the timing arcs from the inputs to the outputs of a gate are typically pre-characterized. The gates are characterized by applying a ramp voltage source at the input of the gate and an explicit load capacitance at the output of the gate. Then, the transition time of the ramp and the value of the load capacitance is varied, and circuit simulation (e.g., SPICE) is used to compute the propagation delays and output transition times for the various settings. These data points can be stored in a table or abstracted in the form of a curve-fitted equation. A popular curve-fitting approach is the *k*-factor equations,[26] where the delay t_d and output transition time t_{out} are expressed as non-linear functions of the input transition time s_{in} and the capacitive output load C_L:

$$t_d = \left(k_1 + k_2 C_L\right) s_{in} + k_3 C_L^2 + k_4 C_L + k_5 \tag{60.10}$$

$$t_{out} = \left(k_1' + k_2' C_L\right) s_{in} + k_3' C_L^2 + k_4' C_L + k_5'. \tag{60.11}$$

The various coefficients in the *k*-factor equations are obtained by curve fitting the data. Several modifications, including more complex equations and dividing the plane into a number of regions and having equations for each region, have been proposed.

The main advantage of gate-level static TA is that costly on-the-fly delay and output transition time calculations can be replaced by efficient equation evaluations or table look-ups. This is also a disadvantage since it requires that all the timing arcs in the design are pre-characterized. This may be a problem when parts of the design are not complete and the delays for some timing arcs are not available. This problem can be avoided if the design flow ensures that at early stages of a design, estimated delays are specified for all timing arcs which are then replaced by characterized numbers when the design gets completed. To apply gate-level TA to designs that contain a large amount of custom circuits, timing rules must be developed for the custom circuits also. Gate-level static TA is still at a fairly low level of abstraction and the effects of interconnects and clock skew can be considered. Moreover, at the gate level, the latches and flip-flops of the design are visible and so timing constraints can be inserted directly at those nodes.

Black-Box Modeling

At the next higher level of abstraction, gates are grouped together into blocks and the entire design (or chip) now consists of these blocks or "boxes." Each box contains combinational gates as well as sequential elements such as latches as shown in Fig. 60.7(a). Timing checks inside the block can be verified using static TA at the transistor or gate level. At the chip level, the internal nodes of the box are no longer visible and its timing behavior must be abstracted at the input, output, and clock pins of the box. In black-box modeling, we assume that the first and last latch along any path from input to output of the box are edge-triggered latches; in other words, cycle stealing is not allowed across these latches (cycle stealing may be allowed across other transparent latches inside the box). The first latch along a path from input to output is called an *input latch* and the last latch is called an *output latch*. With this assumption, there can be two types of paths to the outputs of the box. First, paths that originate at box inputs and end at box outputs without traversing through any latches. These paths are represented as input-output arcs in the block-box with the path delays annotated on the arcs. Second, there are paths that originate

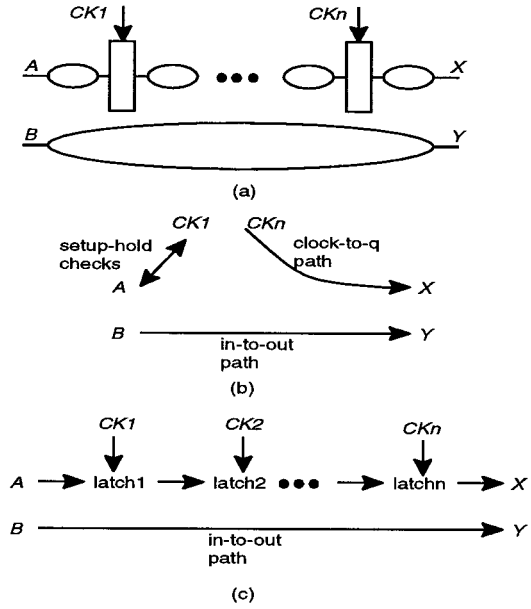

FIGURE 60.7 High-level timing abstraction: (a) a block containing combinational and sequential elements, (b) black-box model, and (c) gray-box model.

at the clock pins of the output edge-triggered latches and end at the box outputs.These paths are represented as clock-to-input arcs in the black-box and the paths delays are annotated on the arcs. Finally, the set-up and hold time constraints of the input latches are translated to constraints between the box inputs and clock pins. These constraints will be checked at the chip-level static TA. The constraints and the arcs are shown in Fig. 60.7(b). Note that the timing checkpoints inside a block have been verified for a particular set of clocks when the black-box model is generated. Since these timing checkpoints are no longer available at the chip level, a black-box model is valid only for a particular frequency. If a different clock frequency (or different clock waveforms) is used, then the black-box model must be regenerated.

Gray-Box Modeling

Gray-box modeling removes the edge-triggered latch restrictions of black-box modeling. All latches inside the box are allowed to be level-sensitive and therefore have to be visible at the top level so that the constraints can be checked and cycle-stealing is allowed through these latches. As shown in Fig. 60.7(c), the gray-box model consists of timing arcs from the box inputs to the input latches, from latches to latches, and from the output latches to the box outputs. The clock pins of each of the latches are also visible at the chip level, and so the set-up and hold timing constraints for each latch in the box is checked at the chip level. In addition to these timing arcs, there can also be direct input-output timing arcs. Note that since the timing checkpoints internal to the box are available at the chip level, the gray-box model is frequently independent — unlike the black-box model.

False Paths

To find the critical paths in the circuit, static TA propagates the arrival times from the timing inputs to the timing outputs. Then, it propagates the required times from the outputs back to the inputs and computes the slacks along the way. During propagation, static TA does not consider the logical functionality of the circuit. As a result, some of the paths that it reports to the user may be such that they cannot be activated by any input vector. Such paths are called false paths.[29-31] An example of a false path is shown in Fig. 60.8(a). For x to propagate to a, we must set $y = 1$, which is the non-controlling value of the NAND gate. Similarly, for a to propagate to b, we set $z = 1$. Now, since $y = z = 1$, $e = 0$ (the controlling

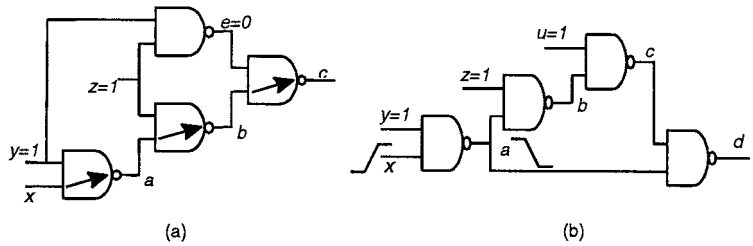

FIGURE 60.8 False path examples: (a) static false path, and (b) dynamic false path.

value for a NAND gate), and there can be no signal propagation from b to c. Therefore, there can be no propagation from x to c (i.e., $x - a - b - c$ is a false path). False paths that arise due to logical correlations are called *static false paths* to distinguish them from dynamic false paths, which are caused by temporal correlations.

A simple example of a *dynamic false path* is shown in Fig. 60.8(b). Suppose we want to find the critical path from node x to the output d. It is clear that there are two such paths, $x - a - d$ and $x - a - b - c - d$, of which the latter has a larger delay. In order to sensitize the longer path $x - a - b - c - d$, we would set the other inputs of the circuit to the non-controlling values of the gates (i.e., $y = z = u = 1$). If there is a rising transition on node x, there will be a falling transition on nodes a and c. However, because of the propagation delay from a to c, node a will fall well before node c. As soon as node a falls, it will set the primary output d to be 1 (since the controlling value of a NAND gate is 0). Because node a always reaches the controlling value before node c, it is not possible for a transition at node c to reach the output. In other words, the path x rising – a falling – b rising – c falling – d rising is a dynamic false path. Note that if we add some combinational logic between the output of the first NAND gate and the input of the last NAND gate to slow the signal a down, then the transition on c could propagate to the output. The example shown above is for purposes of illustration only and may appear contrived. However, dynamic false paths are very common in carry-lookahead adders.[32]

Finding false paths in a combinational circuit is an NP-complete problem. There are a number of heuristic approaches that find the longest paths in a circuit while determining and ignoring the false paths.[29-31] Timing analysis techniques that can avoid false paths specified by the user have also been reported.[33,34]

60.3 Noise Analysis

In digital circuits, nodes that are not switching are at the nominal values of the supply (logic 1) and ground (logic 0) rails. In a digital system, noise is defined as a deviation of these node voltages from their stable high or low values. Digital noise should be distinguished from physical noise sources that are common in analog circuits (e.g., shot noise, thermal noise, flicker noise, and burst noise).[35] Since noise causes a deviation in the stable logic voltages of a node, it can be classified into four categories: (1) *high undershoot* noise reduces the voltage of a node that is supposed to be at logic 1; (2) *high overshoot* noise which increases the voltage of a logic 1 node above the supply level (V_{dd}); (3) *low overshoot* noise increases the voltage of a node that is supposed to be at logic 0; and (4) *low undershoot* noise which reduces the voltage of a logic 0 node below the ground level (*Gnd*).

Sources of Digital Noise

The most common sources of noise in digital circuits are crosstalk noise, power supply noise, leakage noise and charge-sharing noise.[36]

Crosstalk Noise

Crosstalk noise is the noise voltage induced on a net that is at a stable logic value due to interconnect capacitive coupling with a switching net. The net or wire that is supposed to be at a stable value is called the *victim net*. The switching nets that induce noise on the victim net are called *aggressor nets*. Crosstalk noise is the most common source of noise in deep submicron digital designs because, as interconnect wires get scaled, coupling capacitances become a larger fraction of the total wire capacitances.[23] The ratio of the width to the thickness of metal wires reduces with scaling, resulting in a larger fraction of the total capacitance of the wire being contributed by coupling capacitances. Several examples of functional failures caused by crosstalk noise are given in the next section.

Power Supply Noise

This refers to noise on the power supply and ground nets of a design that is passed onto the signal nets by conducting transistors. Typically, the power supply noise has two components. The first is produced by IR-drop on the power and ground nets due to the current demands of the various gates in the chip (discussed in the next section). The second component of the power supply noise comes from the RLC response of the chip and package to current demands that peak at the beginning of a clock cycle. The first component of power supply noise can be reduced by making the wires that comprise the power and ground network wider and denser. The second component of the noise can be reduced by placing on-chip decoupling capacitors.[37]

Charge-Sharing Noise

Charge-sharing noise is the noise induced at a dynamic node due to charge redistribution between that node and the internal nodes of the gate.[32] To illustrate charge-sharing noise, let us again consider the two-input domino NAND gate of Fig. 60.9(a). Let us assume that during the first evaluate phase shown in Fig. 60.9(b), both nodes x and x_1 are discharged. Then, during the next precharge phase, let us assume that the input a is low. Node x will be precharged by the PMOS transistor *MP*, but x_1 will not and will remain at its low value. Now, suppose *CK* turns high, signaling the beginning of another evaluate phase. If during this evaluate phase, a is high but b is low, nodes x and x_1 will share charge resulting in the waveforms shown in Fig. 60.9(b): x will be pulled low and x_1 will be pulled high. If the voltage on x is reduced by a large amount, the output inverter may switch and cause the output node y to be wrongly set to a logic high value. Charge-sharing in a domino gate is avoided by precharging the internal nodes in the NMOS evaluate tree during the precharge phase of the clock. This is done by adding an anti-charge sharing device such as *MNc* in Fig. 60.9(c) which is gated by the clock signal.

Leakage Noise

Leakage noise is due to two main sources: *subthreshold conduction* and *substrate noise*. Subthreshold leakage current[32] is the current that flows in MOS transistors even when they are not conducting (off).

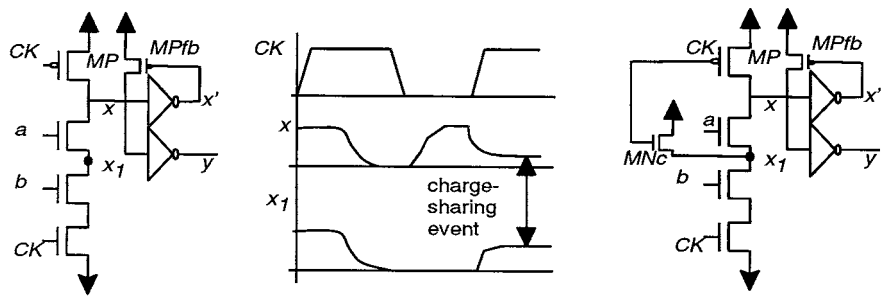

FIGURE 60.9 Example of charge-sharing noise: (a) a two-input domino NAND gate, (b) waveforms for charge-sharing event, and (c) anti charge-sharing device.

This current is a strong function of the threshold voltage of the device and the operating temperature. Subthreshold leakage is an important design parameter in portable devices since battery life is directly dependent on the average leakage current of the chip. Subthreshold conduction is also an important noise mechanism in dynamic circuits where, for a part of the clock cycle, a node does not have a strong conducting path to power or ground and the logic value is stored as a charge on that node. For example, suppose that the inputs *a* and *b* in the two-input domino NAND gate of Fig. 60.9(a) are low during the evaluate phase of the clock. Due to subthreshold leakage current in the NMOS evaluate transistors, the charge on node *x* may be drained away, leading to a degradation in its voltage and a wrong value at the output node *y*. The purpose of the half latch device *MPfb* is to replenish the charge that may be lost due to the leakage current.

Another source of leakage noise is minority carrier back injection into the substrate due to bootstrapping. In the context of mixed analog-digital designs, this is often referred to as *substrate noise*.[38] Substrate noise is often reduced by having guard bands, which are diffusion regions around the active region of a transistor tied to supply voltages so that the minority carriers can be collected.

Crosstalk Noise Failures

In this section, we provide some examples of functional failures caused by crosstalk noise. Functional failures result when induced noise voltages cause an erroneous state to be stored at a memory element (e.g., at a latch node or a dynamic node). Consider the simple latch circuit of Fig. 60.10(a) and let us

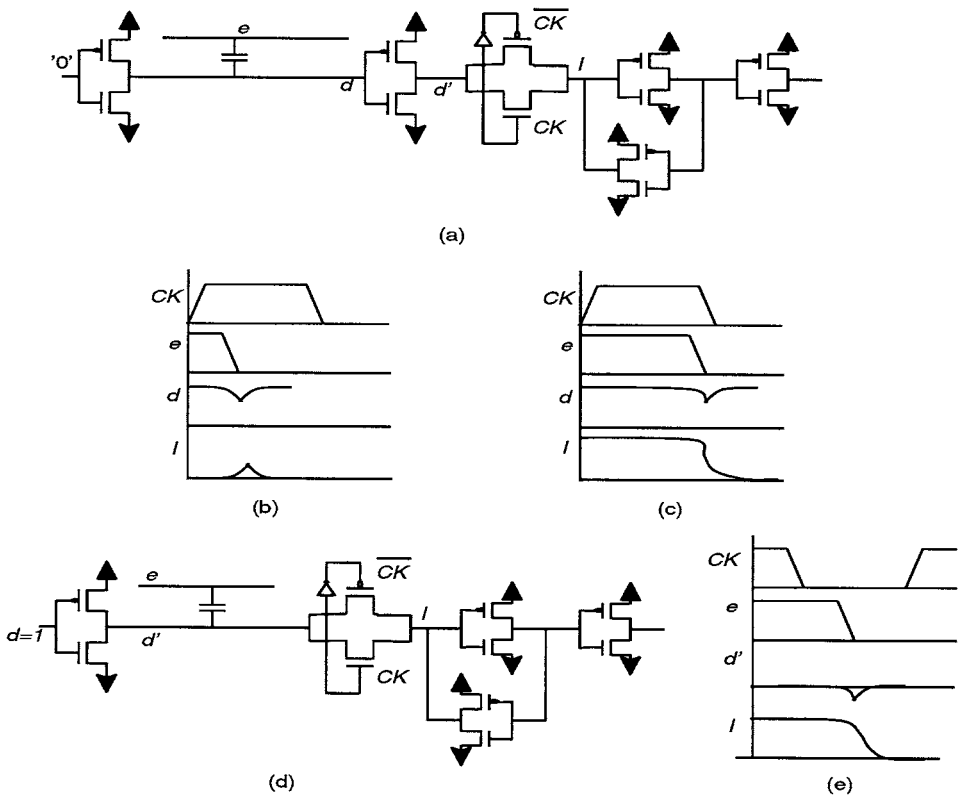

FIGURE 60.10 Crosstalk noise-induced functional failures: (a) latch circuit; (b) high undershoot noise on *d* does not cause functional failure in (b) but does cause failure in (c); (d) same latch circuit with noise induced on an internal node; and (e) low undershoot noise causing a failure.

assume that the data input *d* is a stable high value and the latch *l* has a stable low value. If the net corresponding to node *d* is coupled to another net *e* and there is a high to low transition on net *e*, net *d* will be pulled low. When *e* has finished switching, *d* will be pulled back to a high value by the PMOS transistor driving net *d* and the noise on *d* will dissipate. Thus, the transition on net *e* will cause a noise pulse on *d*. If the amplitude of this noise pulse is large enough, the latch node *l* will be pulled high. Depending on the conditions under which the noise is injected, it may or may not cause a wrong value to be stored at the latch node. For example, let us consider the situation depicted in Fig. 60.10(b), where *CK* is high and the latch is open. If the noise pulse on *d* appears near the middle of the clock phase, then the latch node will be pulled high; but as the noise on *d* dissipates, latch node *l* will return to its correct value because the latch is open. However, if the noise pulse on *d* appears near the end of the clock phase as shown in Fig. 60.10(c), the latch may turn off before the noise on *d* dissipates, the latch node may not recover, and a wrong value will be stored. A similar unrecoverable error may occur if noise appears on the clock net turning the latch on when it was meant to be off. This might cause a wrong value to be latched.

Now, let us consider the latch circuit of Fig. 60.10(d) where the wire between the input inverter and the pass gate of the latch is long and subject to coupling capacitances. Suppose the latch is turned off (*CK* is low), the data input is high so that the node *d′* is low, and a high value is stored at the latch node. If net *e* transitions from a high to a low value, a low undershoot noise will be introduced on *d′*. If this noise is sufficiently large, the NMOS pass transistor will turn on even through its gate voltage is zero (since its gate-source voltage will become greater than its threshold voltage). This will discharge the latch node *l*, resulting in a functional failure.

In order to push performance, domino circuits are becoming more and more prevalent.[88] These circuits trade performance for noise immunity and are susceptible to functional noise failures. A noise-related functional failure in domino circuits is shown in Fig. 60.11. Again, let us consider the two-input domino NAND gate shown in Fig. 60.11(a). Let us assume that during the evaluate phase, *a* is held to a low value by the driving inverter, but *b* is high. Then, *x* should remain charged and *y* should remain low. If an unrelated net *d* switches high, and there is sufficient coupling between signals *a* and *d*, then a low overshoot noise pulse will be induced on node *a*. If the pulse is large enough, a path to ground will be created and node *x* will be discharged. As shown in Fig. 60.11(b), this will erroneously set the output node of the domino gate to a high value. When the noise on *a* dissipates, it will return to a low value, but *x* and *y* are not able to recover from the noise event, causing a functional failure.

As the examples above demonstrate, functional failures due to digital noise cause circuits to malfunction. Noise analysis is becoming an important failure mechanism in deep submicron designs because of several technology and design trends. First, larger die sizes and greater functionality in modern chips result in longer wires, which makes the circuit more susceptible to coupling noise. Second, scaling of interconnect geometries has resulted in increased coupling between adjacent wire.[23] Third, the drive for faster performance has increased the use of faster non-restoring logic families such as domino logic.

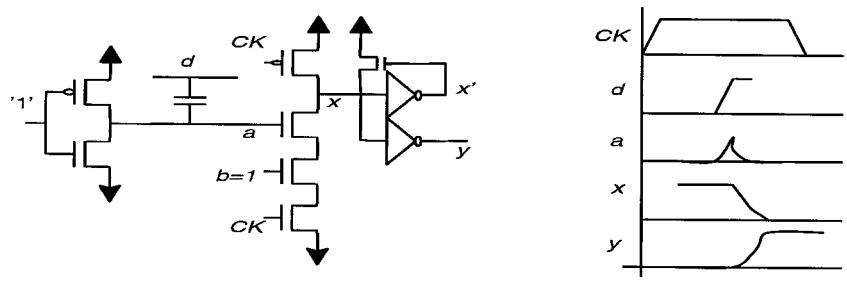

FIGURE 60.11 Functional failure in domino gates: (a) two-input NAND gate, and (b) voltage waveforms when input noise causes a functional failure.

These circuit families have faster switching speeds at the expense of reduced noise immunity. False switching events at the inputs of these gates are catastrophic since precharged nodes may be discharged and these nodes cannot recover their original state when the noise dissipates. Fourth, lower supply voltage levels reduce the magnitudes of the noise margins of circuits. Finally, in state-of-the-art microprocessors, many functional units located in different parts of the chip are operating in parallel and this causes a lot of switching activity in long wires that run across different parts of the chip. All of these factors make noise analysis a very important task to verify the proper functioning of digital designs.

Modeling of Interconnect and Gates for Noise Analysis

Let us consider the example of Fig. 60.12(a) where three wires are running in parallel and are capacitively coupled to each other. Suppose that we are interested in finding the noise that is induced on the middle net by the adjacent nets switching. The middle net is called the *victim net* and the two neighboring nets are called *aggressors*. Consider the situation when the victim net is held to a stable logic zero value by the victim driver and both the aggressor nets are switching high. Due to the coupling between the nets, a low overshoot noise will be induced on the victim net as shown in Fig. 60.12(a). If the noise pulse is large and wide enough, the victim receiver may switch and cause a wrong value at the output of the inverter.

The circuit-level models for this system are explained below and shown in Fig. 60.12(b).

1. The (net) complex consisting of the victim and aggressor nets is modeled as a coupled distributed RC network. The coupled RC lines are typically output by a parasitic extraction tool.
2. The non-linear victim driver is holding the victim net to a stable value. We model the non-linear driver as a linear holding resistance. For example, if the victim driver holds the output to logic 0 (logic 1), we determine an effective NMOS (PMOS) resistance. The value of the holding resistance for a gate can be obtained by pre-characterization using SPICE.
3. The aggressor driver is modeled as a Thevenin voltage source in series with a switching resistance. The Thevenin voltage source is modeled as a shifted ramp, where the ramp starts switching at time t_0 and the transition time is Δt. The switching resistance is denoted by R_s.
4. The victim receiver is modeled as a capacitor of value equal to the input capacitance of the gate.

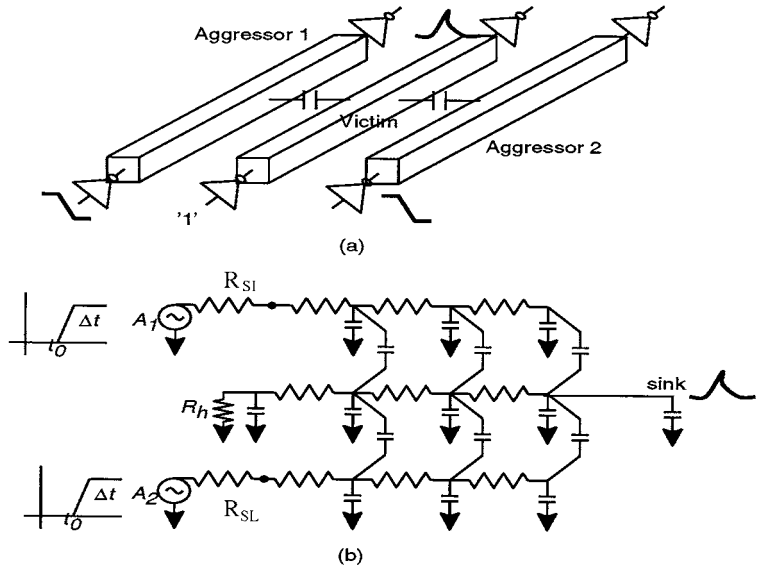

FIGURE 60.12 (a) A noise pulse induced on the victim net by capacitive coupling to adjacent aggressor nets, and (b) linearized model for analysis.

These models convert the non-linear circuit into a linear circuit. The multiple sources in this linear circuit can now be analyzed using *linear superposition*. For each aggressor, we get a noise pulse at the sink(s) of the victim net, while shorting the other aggressors. These noise pulses have different amplitudes and widths; the amplitude and width of the *composite noise waveform* is obtained by aligning these noise pulses so that their peaks line up. This is a conservative assumption to simulate the worst-case noise situation.

Input and Output Noise Models

As mentioned earlier, noise creates circuit failures when it propagates to a charge-storage node and causes a wrong value to be stored at the node. Propagating noise across non-linear gates[39] makes the noise analysis problem complex. In this discussion, a more conservative simple model will be discussed. With each input terminal of a victim receiver gate, we associate a noise rejection curve.[40] This is a curve of the noise amplitude versus the noise width that produces a predefined amount of noise at the output. If we assume a triangular noise pulse at the input of the victim receiver, the noise rejection curve defines the amplitude-width combination that produces a fixed amount of noise at the output of the receiver. A sample noise rejection curve is shown in Fig. 60.13. As the width becomes very large, the noise amplitude tends toward the dc noise margin of the gate. Due to the lowpass nature of a digital gate, very sharp noise pulses are filtered out and do not cause any appreciable noise at the output. When the noise pulse at the sink(s) of the victim net have been obtained, the pulse amplitude and width are compared against the noise rejection curve to determine if a noise failure occurs.

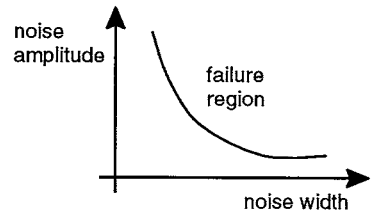

FIGURE 60.13 A typical noise rejection curve.

Since we do not propagate noise across gates, noise injected into the victim net at the output of the victim driver must model the maximum amount of noise that may be produced at the output of a gate. The output noise model is a dc noise that is equal to the predefined amount of output noise that was used to determine the input noise rejection curve above. Contributions from other dc noise sources such as IR-drop noise may be added to the output noise. If we assume that there is no resistive dc path to ground, this output noise appears unchanged at the sink(s) of the victim net.

Linear Circuit Analysis

The linear circuit that models the net complex to be analyzed can be quite large since the victim and aggressor nets are modeled as a large number of RC segments and the victim net can be coupled to many aggressor nets. Moreover, there are a large number of nets to be analyzed. Since general circuit simulation tools such as SPICE can be extremely time-consuming for these networks, fast linear circuit simulation tools such as RICE[41] can be used to solve these large net complexes. RICE uses reduced-order modeling and asymptotic waveform evaluation (AWE) techniques[27] to speed up the analysis while maintaining sufficient accuracy. Techniques that overcome the stability problems in AWE, such as Pade via Lancszos (PVL),[42] Arnoldi-based techniques,[43] congruence transform-based techniques (PACT),[44] or combinations (PRIMA),[45] have been proposed recently.

Interaction with Timing Analysis

Calculation of crosstalk noise interacts tightly with timing analysis since timing analysis lets us determine which of the aggressor nets can switch at the same time. This reduces the pessimism of assuming that for a victim net, all the nets it is coupled to can switch simultaneously and induce noise on it. Timing analysis defines timing windows by the earliest and latest arrival times for all signals. This is shown in Fig. 60.14 for three aggressors $A1$, $A2$, and $A3$ of a particular victim net of interest. Based upon these timing windows, we can define five different scenarios for noise analysis where different aggressors can

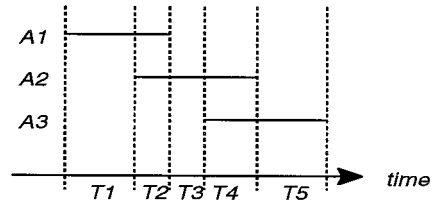

FIGURE 60.14 Effect of timing windows on aggressor selection for noise analysis.

switch simultaneously. For example, in interval $T1$, only $A1$ can switch; in $T2$, $A1$, and $A2$ can switch; in $T3$, only $A2$ can switch; and so on. Note that in this case, all three aggressors can never switch at the same time. Without considering the timing windows provided by timing analysis, we would have overestimated the noise by assuming that all three aggressors could switch at the same time.

Fast Noise Calculation Techniques

Any state-of-the-art microprocessors will have many nets to be analyzed, but typically only a small fraction of the nets will be susceptible to noise problems. This motivates the use of extremely fast techniques that provably overestimate the noise at the sinks of a net. If a net passes the noise test under this quick analysis, then it does not need to be analyzed any further; if a net fails the noise test, then it can be analyzed using more accurate techniques. In this sense, these fast techniques can be considered to be *noise filters*. If these noise filters produce sufficiently accurate noise estimates, then the expectation is that a large number of nets would be screened out quickly. This combination of fast and detailed analysis techniques would therefore speed up the overall analysis process significantly. Note that noise filters must be provably pessimistic and that multiple noise filters with less and less pessimism can be used one after the other to successively screen out nets.

Let us consider the net complex shown in Fig. 60.15(a), where we have modeled the net as distributed RC lines, the victim driver as a linear holding resistance, and the aggressors as voltage ramps and linear

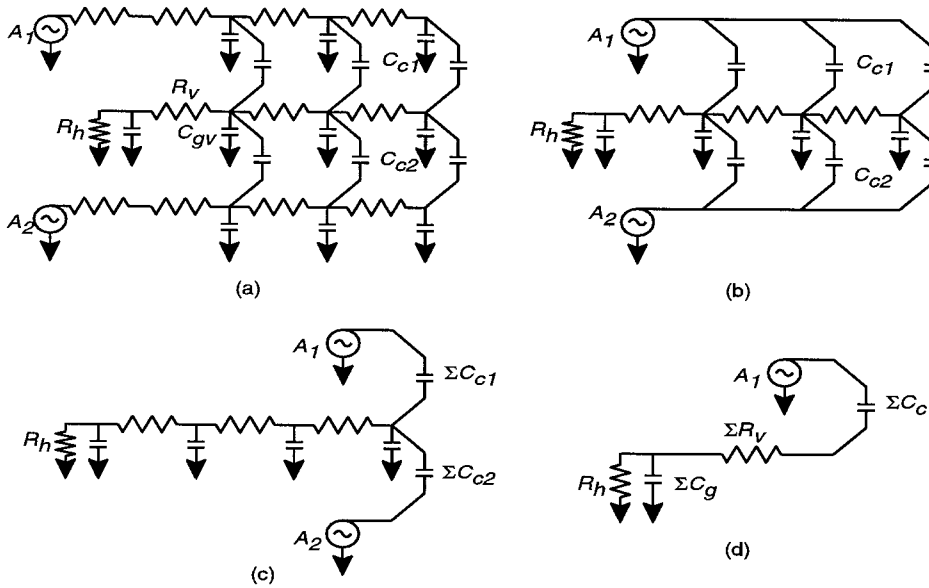

FIGURE 60.15 Noise filters: (a) original net complex with distributed RC models for aggressors and victims, (b) aggressor lines have only coupling capacitances to victim, (c) aggressors are directly coupled to sink of victim, and (d) single (strongest) aggressor and all grounded capacitors of victim moved away from sink.

resistances. The grounded capacitances of the victim net is denoted as C_{gv}, and the coupling capacitances to the two aggressors are denoted as C_{c1} and C_{c2}. In Figs. 60.15(b-d), we show the steps through which we can obtain a circuit which will provide a provably pessimistic estimate of the noise waveform. In Fig. 60.15(b), we have removed the resistances of the aggressor nets. This is pessimistic because, in reality, the aggressor waveform slows down as it proceeds along the net. By replacing it with a faster waveform, more noise will be induced on the victim net. In Fig. 60.15(c), the aggressor waveforms are capacitively coupled directly into the sink net; for each aggressor, the coupling capacitance is equal to the sum of all the coupling capacitances between itself and the victim net. Since the aggressor is directly coupled to the sink net, this transformation will result in more induced noise. In Fig. 60.15(d), we have made two modifications; first, we replaced the different aggressors by one capacitively coupled aggressor and, second, we moved all the grounded capacitors on the victim net away from the sink node. The composite aggressor is just the fastest aggressor (i.e., the aggressor that has the smallest transition time) and it is coupled to the victim net by a capacitor whose value is equal to the sum of all the coupling capacitances in the victim net. To simplify the victim net, we sum all the grounded capacitors and insert it at the root of the victim net and sum all the net resistances. By moving the grounded (good) capacitors away from the sink net, we increase the amount of coupled noise. This simple network can now be analyzed very quickly to compute the (pessimistic) noise pulse at the sink.

An efficient method to compute the peak noise amplitude at the sink of the victim net is described by Devgan.[46] Under infinite ramp aggressor inputs, the maximum noise amplitude is the final value of the coupled noise. For typical interconnect topologies, these analytical computations are simple and quick.

Noise, Circuit Delays, and Timing Analysis

Circuit noise, especially crosstalk noise, significantly affects switching delays. Let us consider the example of Fig. 60.16(a), where we are concerned about the propagation delay from *A* to *C*. In the absence of any coupling capacitances, the rising waveform at *C* is shown by the dotted line of Fig. 60.16(b). However, if net 2 is switching in the opposite direction (node *E* is rising as in Fig. 60.16(b)), then additional charge is pumped into net 1 due to the coupling capacitors causing the signals at nodes B_1 and B_2 to slow down. This in turn causes the inverter to switch later and causes the propagation delay from *A* to *C* to be much larger, as shown in the diagram. Note that if net 2 switched in the same direction as net 1, then the delay from *A* to *C* would be reduced. This implies that delays across gates and wires depend on the switching activity on adjacent coupled nets. Since coupling capacitances are a large fraction of the total capacitance of wires, this dependence will be significant and timing analysis should account for this behavior. Using the same terminology as crosstalk noise analysis, we call the net whose delay is of primary interest (net 1 in the above example) the *victim net* and all the nets that are coupled to it are called *aggressor nets.*

A model that is commonly used to approximate the effect of coupling capacitors on circuit delays is to replace each coupling capacitor by a grounded capacitor of twice the value. This model is accurate

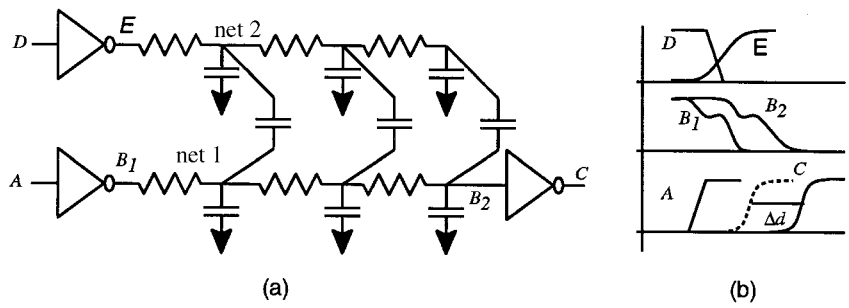

FIGURE 60.16 Effect of noise on circuit delays: (a) victim and aggressor nets, and (b) typical waveforms.

only when the victim and aggressor nets are identical and the waveforms on the two nets are identical, but switching in opposite directions. For some cases, doubling the coupling capacitance may be pessimistic, but in many cases it is not — the effective capacitance is much more than twice the coupling capacitance. Note that the effect on the propagation delay due to coupling will be strongly dependent on how the aggressor waveforms are aligned with respect to each other and to the victim waveform. Hence, one of the main issues in finding the effect of noise on delay is to determine the aggressor alignments that cause the worst propagation delay.

A more accurate model for considering the effect of noise on delay is described by Dartu et al.[47] In this approach, the gates are replaced by linearized models (e.g., the Thevenin model of the gate consists of a shifted ramp voltage source in series with a resistance). Once the circuit has been linearized, the principle of linear superposition is applied. The voltage waveform at the sink of the victim net is first obtained by assuming that all aggressors are "quiet." Then the victim net is assumed to be quiet and each aggressor is switched one at a time and the resultant noise waveforms at the victim sink node is recorded. These noise waveforms are offset with respect to each other because of the difference in the delays between the aggressors to the victim sink node. Next, the aggressor noise waveforms are shifted such that the peaks get lined up and a composite noise waveform is obtained by adding the individual noise waveforms. The remaining issue is to align the composite noise waveform with the noise-free victim waveform to obtain the worst delay. This process is described in Fig. 60.17, where we show the original noise-free waveform V_{orig} and the (composite) noise waveform V_{noise} at the victim sink node. Then, the worst case is to align the noise such that its peak is at the time when $V_{orig} = 0.5V_{dd} - V_N$, where V_N is the peak noise.[47,48] The final waveform at C is marked V_{final}.

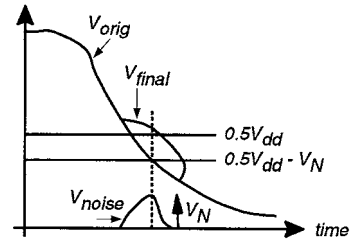

FIGURE 60.17 Aligning the composite noise waveform with the original waveform to produce worst-case delay.

The impact of noise on delays and the impact of timing windows on noise analysis implies that one has to iterate between timing and noise analysis. There is no guarantee that this process will converge; in fact, one can come up with examples when the process diverges. This is one of the open issues in noise analysis.

60.4 Power Grid Analysis

The power distribution network distributes power and ground voltages to all the gates and devices in the design. As the devices and gates switch, the power and ground lines conduct current and due to the resistance of the lines, there is an unavoidable voltage drop at the point of distribution. This voltage drop is called *IR-drop*. As device densities and switching currents increase, larger currents flow in the power distribution network causing larger IR-drops. Excessive voltage drops in the power grid reduce switching speeds of devices (since it directly affects the current drive of devices) and noise margins (since the effective rail-to-rail voltage is lower). Moreover, as explained in the previous section, IR-drops inject dc noise into circuits which may lead to functional or performance failures. Higher average current densities lead to undesirable wear-and-tear of metal wires due to electromigration.[49] Considering all these issues, a robust power distribution network is vital in meeting performance and reliability goals in high-performance microprocessors. This will achieve good voltage regulation at all the consumption points in the chip, notwithstanding the fluctuations in the power demand across the chip. In this section, we give a brief overview of various issues involved in power grid analysis.

Problem Characteristics

The most important characteristic of the power grid analysis problem is that it is a global problem. In other words, the voltage drop in a certain part of the chip is related to the currents being drawn from that as well as other parts of the chip. For example, if the same power line is distributing power to several

functional units in a certain part of the chip, the voltage drop in one functional unit depends on the currents being drawn by the other functional units. In fact, as more and more of the functional units switch together, the IR-drop in all the functional units will increase because the current supply demand on the power line is more.

Since IR-drop analysis is a global problem and since power distribution networks are typically very large, a critical issue is the large size of the network. For a state-of-the-art microprocessor, a number of nodes in the power grid is on the order of millions. An accurate IR-drop analysis would simulate the non-linear devices in the chip, together with the non-ideal power grid, making the size of the network even more unmanageable. In order to keep IR-drop analysis computationally feasible, the simulation is done in two steps. First, the non-linear devices are simulated assuming perfect supply voltages, and the power and ground currents drawn by the devices are recorded (these are called *current signatures*). Next, these devices are modeled as independent time-varying current sources for simulating the power grid and the voltage drops at the consumption points (where transistors are connected to power and ground rails) are measured. Since voltage drops are typically less than 10% of the power supply voltage, the error incurred by ignoring the interaction between the device currents and the actual supply voltage is usually small. The linear power and ground network is still very large and hierarchy has to be exploited to reduce the size of the analyzed network. Hierarchy will be discussed in more detail later.

Yet another characteristic of the IR-drop analysis problem is that it is dependent on the activity in the chip, which in turn is dependent on the vectors that are supplied. An important problem in IR-drop analysis is to determine what this input pattern should be. For IR-drop analysis, patterns that produce maximum instantaneous currents are required. This topic has been addressed by a few papers,[50-52] but will not be discussed here. However, the fact that vectors are important means that transient analysis of the power grid is required. Since each solution of the network is expensive and since many simulations are necessary, dynamic IR-drop analysis is very expensive. The speed and memory issues related to linear system solution techniques becomes important in the context of transient analysis. An important issue in transient analysis is related to the capacitances (both parasitic and intentional decoupling) in the power grid. Since capacitors prevent instantaneous changes in node voltages, IR-drop analysis without considering capacitors will be more pessimistic. A pessimistic analysis can be done by ignoring all power grid capacitances, but a more accurate analysis with capacitances may require additional computation time for solving the network.

Yet another issue is raised by the vector dependence. As mentioned earlier, the non-linear simulation to determine the currents drawn from the power grid is done separately (from the linear network) using the supplied vectors. Since the number of transistors in the whole chip is huge, simultaneous simulation of the whole chip may be infeasible because of limitations in non-linear transient simulation tools (e.g., SPICE or fast timing simulators). This necessitates partitioning the chip into blocks (typically corresponds to functional units, like floating point unit, integer unit, etc.) and performing the simulation one block at a time. In order to preserve the correlation among the different blocks, the blocks must be simulated with the same underlying set of chip-wide vectors. To determine the vectors for a block, a logic simulation of the chip is done, and the signals at the inputs of the block are monitored and used as inputs for the block simulation.

Since dynamic IR-drop analysis is typically expensive (especially since many vectors are required), techniques to reduce the number of simulations are often used. A commonly used technique is to compress the current signatures from the different clock cycles into a single cycle. The easiest way to accomplish this is to find the maximum envelope of the multi-cycle current signature. To find the maximum envelope over N cycles, the single-cycle current signature is computed using

$$i_{sc}(t) = \max i_{orig}(t + kT),\ 1 \le k \le N,\ 0 \le t \le T \tag{60.12}$$

where $i_{sc}(t)$ is the single-cycle, $i_{orig}(t)$ is the original current signature, and T is the clock period. Since this method does not preserve the correlation among different current sources (sinks), it may be overly pessimistic.

A final characteristic of IR-drop analysis is related to the way in which the analysis is typically done. Typically, the analysis is done at the very last stages of the design when the layout of the power network is available. However, IR-drop problems that could be revealed at this stage are very expensive or even impossible to fix. IR-drop analysis that is applicable to all stages of a microprocessor design has been addressed by Dharchoudhury et al.[53]

Power Grid Modeling

The power and ground grids can be extracted by a parasitic extractor to obtain an R-only or an RC network. Extraction implies that the layout of the power grid is available. To insert the transistor current sources at the proper nodes in the power grid, the extractor should preserve the names and locations of transistors. Power grid capacitances come from metal wire capacitances (coupling and grounded), device capacitances, and decoupling capacitors inserted in the power grid to reduce voltage fluctuations. Several interesting issues are raised in the modeling of power grid capacitances. The power or ground net is coupled to other signal nets and since these nets are switching, the effective grounded capacitance is difficult to compute. The same is true for capacitances of MOS devices connected to the power grid. Making the problem worse, the MOS capacitances are voltage dependent. These issues have not been completely addressed as yet. Typically, one resorts to worst-case analysis by ignoring coupling capacitances to signal nets and MOS device capacitances, but considering only the grounded capacitances of the power grid and the decoupling capacitors.

There are three other issues related to power grid modeling. First, for electromigration purposes, via arrays should be extracted as resistance arrays so that current crowding can be modeled. Electromigration problems are primarily seen in the vias and if the via array is modeled as a single resistance, such problems could be masked. Second, the inductance of the package pins also creates a voltage drop in the power grid. This drop is created by the time-varying current in the pins ($v = Ldi/dt$). This effect is typically handled by adding a fixed amount of drop on top of the on-chip IR-drop estimate. Third, a word of caution about network reduction or crunching. Most commercial extraction tools have options to reduce the size of an extracted network. This reduction is typically performed using reduced-order modeling techniques with interconnect delay being the target. This reduction is intended for signal nets and is done so that errors in the interconnect delay is kept below a certain threshold. For IR-drop analysis, such crunching should not be done since we are not interested in the delay. Moreover, during the reduction the nodes at which transistors hook up to the power grid could be removed.

Block Current Signatures

As mentioned above, accurate modeling of the current signatures of the devices that are connected to the power grid is important. At a certain point in the design cycle of a microprocessor, different blocks may be at different stages of completion. This implies that multiple current signature models should be available so that all the blocks in the design can be modeled at various stages in the design.[53]

The most accurate model is to provide transient current signatures for all the devices that are connected to the supply or ground grid. This assumes that the transistor-level representation of the entire block is available. The transient current signatures are obtained by transistor-level simulation (typically with a fast transient simulator) with user-specified input vectors. As mentioned earlier, in order to maintain correlation with other blocks, the input vectors for each block must be derived from a common chip-wide input vector set. At the chip-level, the vectors are usually hot loops (i.e., the vectors try to turn on as many blocks as possible). The block-level inputs for the transistor-level simulation are obtained by monitoring the signal values at the block inputs during a logic simulation of the entire chip with the hot loop vectors.

At the other end of the spectrum, the least accurate current model for a block is an area-based dc current signature. This is employed at early stages of analysis when the block design is not complete. The average current consumption per unit area of the block can be computed from the average power consumption

specification for the chip and the normal supply voltage value. Since the peak current can be larger than the average current, some multiple of the average per-unit-area current is multiplied by the block area to compute the current consumption for the block.

An intermediate current model can be derived from a full-chip gate-level power estimation tool. Given a set of input vectors, this tool computes the average power consumed by each block over a cycle. From the average power consumption, an average current can be computed for each cycle. Again, to account for the difference between the peak and average currents, the average current can be multiplied by a constant factor. Hence, one obtains a multi-cycle dc current signature for the block in this model.

Matrix Solution Techniques

The large size of power grids places very stringent demands on the linear system solver, making it the most important part of an IR-drop analysis tool. The power grids in typical state-of-the-art microprocessors usually contain multiple layers of metal (processes with up to six layers of metal are currently available) and the grid is usually designed as a mesh. Therefore, the network cannot usually be reduced significantly using a tree-link type of transformation. In older-generation microprocessors, the power network was often "routed" and therefore more amenable to tree-link type reductions. In networks of this type, significant reduction in the size can typically be obtained.[54]

In general, matrix solution techniques can be categorized into two major types: direct and iterative.[55] The size and structure of the conductance matrix of the power grid is important in determining the type of linear solution technique that should be used. Typically, the power grid contains millions of nodes, but the conductance matrix is very sparse (typically, less than five entries per row or column of the matrix). Since it is a conductance matrix, the matrix will also be symmetric positive definite — for a purely resistive grid, the conductance matrix may be ill-conditioned.

Iterative solution techniques apply well to sparse systems, but their convergence can be slowed down by ill-conditioning. Convergence can usually be improved by applying pre-conditioners. Another important advantage of iterative methods is that they do not suffer from size limitations as much as direct techniques. Iterative techniques usually need to store the sparse matrix and a few iteration vectors during the solution. The disadvantage of iterative techniques is in transient solution. If constant time steps are used during transient simulation, the conductance matrix remains the same from one time point to another and only the right-hand side vector changes. Iterative techniques depend on the right-hand side and so a fresh solution is required for each time point during transient simulation. The solution from previous time points cannot be reused. The most widely used iterative solution technique for IR-drop analysis is the conjugate gradient solution technique. Typically, a pre-conditioner such as incomplete Cholesky pre-conditioning is also used in conjunction with the conjugate gradient scheme.

Direct techniques rely on first factoring the matrix and then using these factors with the right-hand side vector to find the solution. Since the matrix is symmetric positive definite, one can apply specialized direct techniques such as Cholesky factorization. The main advantage of direct techniques in the context of IR-drop analysis is in transient analysis. As explained earlier, transient simulation with constant time steps will result in the linear solution of a fixed matrix. Direct techniques can factor this matrix once and the factors can be reused with different right-hand side vectors to give some efficiency. The main disadvantage of direct techniques is memory usage to store the factors of the conductance matrix. Although the conductance matrix is sparse, its factors are not and this means that the memory usage will be $O(n^2)$, were n is the size of the matrix.

Exploiting Hierarchy

From the discussions above, it is clear that IR-drop analysis of large microprocessor designs can be limited by size restrictions. The most effective way to reduce the size is to exploit the hierarchy in the design. In this discussion, we will assume a two-level hierarchy consisting of the chip and its constituent blocks. This hierarchy in the blocks also partitions the entire power distribution grid into two parts: the global

grid and the intra-block grid. The global grid distributes power from the chip pads to tap points in the various blocks (these are called block ports) and the intra-block grid distributes power from these tap points to the transistors in the block. This partitioning allows us to apply hierarchical analysis. First, the intra-block power grid can be analyzed to find the voltages at the transistor tap points. This analysis assumes that the voltages at the block ports are equal to ideal supply (V_{dd}) or ground (0). The intra-block analysis must also determine a macromodel for the block which is then used for analyzing the global grid. A block admittance macromodel will consist of a current source at each port and an admittance matrix relating the currents and voltages among the ports. The size of the admittance matrix will be equal to the number of ports and each entry will model the effect of the voltage at one port to the current at some other port. In other words, the off-diagonal entries in the admittance matrix will model current redistribution between the ports of the block. Note that, in general, the admittance matrix will be dense and have p^2 entries if p is the number of ports. If n is the number of nodes in the intra-block grid, this block would have contributed a sparse submatrix of size n to the global grid during flat analysis. For hierarchical analysis, this block contributes a dense submatrix of size p. If $p << n$, hierarchical analysis will be more efficient than a flat analysis, both in terms of computational time and memory usage.

For exact equivalence with flat analysis, the admittance between every pair of ports must be modeled, resulting in a dense admittance matrix for the block. This will reduce the sparsity of the global conductance matrix and adversely affect solution speed. However, if a block is large, the effective resistance between two ports that are far away will be very large and so the corresponding entry in the admittance matrix can be zeroed with very little loss in accuracy. In fact, the simplest block model will consist of current sources at the ports and a diagonal admittance matrix. For chip-level analysis, the error from this assumption can be kept small if the blocks themselves are small. There is one other source of error in hierarchical analysis and that is the dependence of the block currents on the port voltages. Again, if the voltage drops to the blocks are small (as it will be in a well-designed grid), the error due to this assumption will be small.

61.1 Introduction

The task of verifying that a microprocessor implementation conforms to its specification across various levels of design hierarchy is a major part of the microprocessor design process. Design verification is a complex process which involves a number of levels of abstraction (e.g., architectural, RTL, and gate), several aspects of design (e.g., timing, speed, functionality, and power), as well as different design styles.[22] With the high complexity of present-day microprocessors, the percentage of the design cycle time required for verification is often greater than 50%.

The increasing complexity of designs has led to a number of approaches being used for verification. Simulation and formal verification are widely recognized as being at opposite ends of the design verification spectrum, as shown in Fig. 61.1.[6] Simulation is the process of stimulating a software model of the design in an enviornment that models the actual hardware system. The values of internal and output signals are obtained for a given set of inputs and are compared with expected results to determine whether

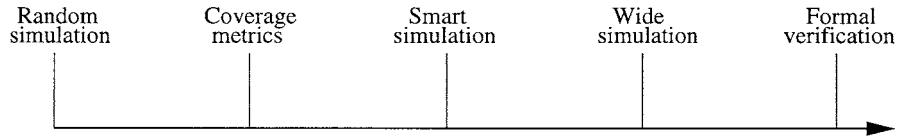

FIGURE 61.1 The spectrum of design verification techniques, which range from simulation to formal verification. (From Ref. 6. With permission.)

the design is behaving as specified. Formal verification, on the other hand, uses mathematical formulae on an abstracted version of the design to *prove* that the design is correct or that particular aspects of the design are correct.

Formal verification includes equivalence checking, model checking, and theorem proving. Equivalence checking verifies whether one description of a design is functionally equivalent to another. Model checking verifies that specified properties of a design are true, that is, that certain aspects of the design always work as intended. In theorem proving, the entire design is expressed as a set of mathematical assumptions. Theorems are expressed using these assumptions and are then proven. Formal verification is particularly useful at lower levels of abstraction, for example, to verify that a gate-level model matches its RTL specification. Formal verification is becoming popular as a means of achieving 100% coverage, at least for specific areas of the design, and is described more fully elsewhere in this book.

There are several problems inherent in applying formal verification to large microprocessor designs. While equivalence checking ensures that no functional errors are inserted from one design iteration to the next, it does not guarantee that the design meets the designer's specifications. Model checking is useful to check consistency with specifications; however, the assertions to be verified must be manually written in most cases. The size of the circuit or state machine that can be formally verified is severely limited due to the problem of state-space explosion. Last, formal techniques cannot be used for performance validation because timing-dependent circuits, such as oscillators, rely on analog behavior that is not handled by mathematical representations.

Simulation is therefore the primary commercial design verification methodology in use, especially for large microprocessor designs. Simulation is performed at various levels in the design hierarchy, including at the register transfer, gate, transistor, and electrical levels, and is used for both functional verification and performance analysis. Timing simulation is becoming critical for ultra-deep submicron designs because the problems of power grid IR-drops, interconnect delays, clock skews, and electromigration intensify with shrinking process geometries and adversely affect circuit performance.[23] Timing verification involves performing 2-D or 3-D parasitic RC extraction on the layout, followed by back-annotating the capacitance values obtained onto the netlist. A combination of static and dynamic timing analyses is performed to find critical paths in the circuit. Static analysis involves analyzing delays using a structural model of the circuit, while dynamic analysis uses vectors to simulate the design to locate critical paths.[23] Accurate measurements of the critical path delays can then be obtained using SPICE. Techniques for timing verification are described elsewhere in this book.

Pseudo-random vector generation is the most popular form of generating instruction sequences for functional simulation. Random test generators provide the ability to generate test programs that lead to multiple simultaneous events, which would be extremely time-consuming to write by hand.[18] Furthermore, the amount of computation required to generate random instruction sequences is low. However, random simulation often requires a very long time to achieve a suitable level of confidence in the design. This has given rise to the use of a number of semiformal metrics to estimate and improve simulation coverage. These methods combine the advantages of simulation and formal verification to achieve a higher coverage, while avoiding the scaling and methodology problems inherent in formal verification. In this chapter, we focus on the tools and techniques used to generate instruction sequences for a simulation-based verification environment.

The chapter is organized as follows. We begin with a description of the design verification environment in Section 61.2. Random and biased-random instruction generation, which lie at the simulation end of the spectrum, are discussed in Section 61.3. Section 61.4 describes three popular correctness checking methods that are used to determine the success or failure of a simulation run. Coverage metrics, which are used to estimate simulation coverage, are presented in Section 61.5. In Section 61.6, we move to the middle of the design verification spectrum and discuss *smart simulation*, which is used to generate vectors satisfying semiformal metrics. *Wide simulation*, which refers to the use of formal assertions to derive vectors for simulation is described in Section 61.7. Having covered the spectrum of semiformal verification methods, we conclude with a description of hardware emulation in Section 61.8. Emulation uses dynamically configured hardware to implement a design, which can be simulated at high speeds.

61.2 Design Verification Environment

In this section, we present a design verification environment that is representative of many commercial verification methodologies. This environment is illustrated in Fig. 61.2, and the typical levels of design abstraction are shown in Fig. 61.3. We describe the different parts of the environment and the role each part plays in the verification process.

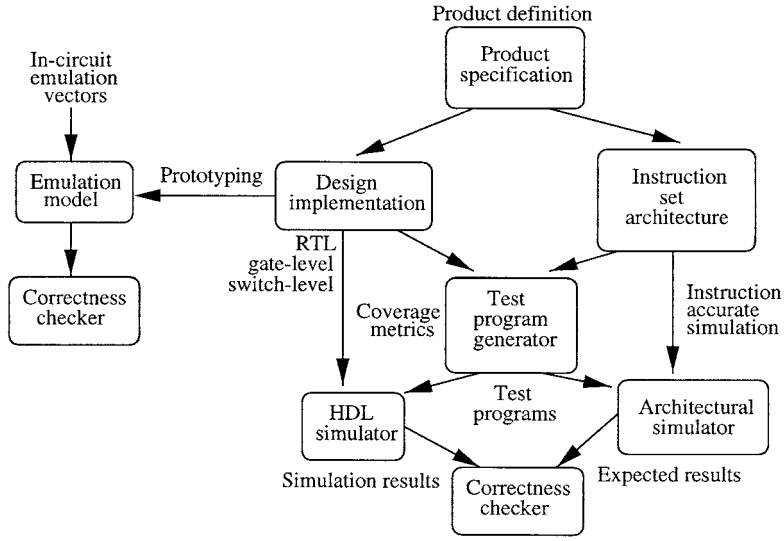

FIGURE 61.2 A representative design verification environment and verification process flow.

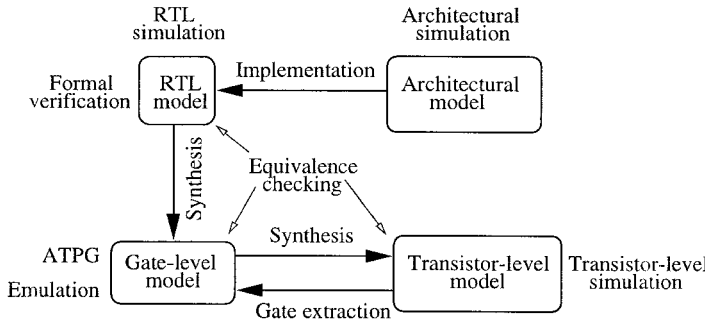

FIGURE 61.3 Different levels of design abstraction.

Architectural Model

A high-level specification of the microprocessor is first derived from the product requirements and from the requirement of compatibility with previous generations. An architectural simulation model and an RTL model are then implemented based on the product specification. The architectural model, often written in C or C++, includes the programmer-visible registers and the capability to simulate the execution of an instruction sequence. This model emphasizes simulation speed and correctness over implementation detail and therefore does not represent pipeline stages, parallel functional units, or caches. This model is instruction accurate but not clock cycle accurate.[22] A typical architectural model executes over 100 times faster than a detailed RTL model.[18]

RTL Model

The RTL model, implemented in a hardware description language (HDL) such as VHDL or Verilog, is more detailed than the architectural model. Data is stored in register variables, and transformations are represented by arithmetic and logical operators. Details of pipeline implementation are included. The RTL model is used to synthesize a gate-level model of the design, which may be used to formally verify equivalence between the RTL and transistor-level implementations or for automatic test pattern generation (ATPG) for manufacturing tests. Circuit extraction can also be performed to derive a gate-level model from the transistor-level implementation. In many methodologies, the RTL represents the *golden model* to which other models must conform. Equivalence checking is commonly used to verify the equivalence of RTL, gate-level, and transistor-level implementations.

Test Program Generator

The combination of simulation and formal methods is an emerging paradigm in design verification. A test program generator may therefore use a combination of random, hand-crafted, and deterministic instruction sequences generated to satisfy certain semiformal measures of coverage. These measures include the coverage of statements in the HDL description and coverage of transitions between control states in the design's behavior. The RTL model is simulated with these test vectors using an HDL simulator, and the results are compared with those obtained from the architectural simulation. Since the design specification (architectural-level) and design implementation (RTL or gate-level) are at different levels of abstraction, there can be no cycle-equivalent comparison. Instead, comparisons are made at special checkpoints, such as at the completion of a set of instructions.[12] Sections 61.3, 61.6, and 61.7 discuss the most popular techniques used for test generation.

HDL Simulator

HDL simulation consists of two stages. In the *compile* stage, the design is checked for errors in syntax or semantics and is converted to an intermediate representation. The design representation is then reduced to a collection of signals and processes. In the *execute* stage, the model is simulated by initializing values on signals and executing the sequential statements belonging to the various processes. This can be achieved in two ways: *event-driven* simulation and *cycle-based* simulation. Event-driven simulation is based on determining changes (events) in the value of each signal in a clock cycle and may incorporate various timing models. A process is first simulated by assigning a change in value to one or more of its inputs. The process is then executed, and new values for other signals are calculated. If an event occurs on another signal, other processes that are sensitive to that signal are executed. Events are processed in the order of the time at which they are expected to occur according to the timing model used. In this manner, all events occurring in a clock cycle are calculated. Cycle-based simulators, on the other hand, limit calculations by determining simulation results only at clock edges and ignoring inter-phase timing. Cycle-based simulators focus only on the design functionality by performing zero-delay, two-valued simulation (memory elements are assumed to be initialized to known values) and they offer an improvement

in speed of up to 10X while utilizing a fifth of the memory required for event-driven simulation. However, cycle-based simulators are inefficient in verifying asynchronous designs, and event-driven simulators must be used to derive initializing sequences and for timing calculations. Simulation techniques used at various levels of design abstraction are discussed more fully in this book.

Emulation Model

Hardware emulation is a means of embedding a dynamically configured prototype of the design in its final environment. This hardware prototype, known as the *emulation model*, is derived from the gate-level implementation of the design. The prototype can execute both random vectors and software application programs faster than conventional software logic simulators. It is also connected to a hardware environment, known as an *in-circuit* facility, to provide it with a high throughput of test vectors at appropriate speeds. Hardware emulation executes from three to six orders of magnitude faster than simulation and subsequently requires considerably less verification time. However, hardware emulators have limitations on the sizes of the circuits they can handle.

Table 61.1 presents the results of a survey conducted by 0-In Design Automation on verification techniques currently used in industry.[1] Columns 1 and 3 in the table list the different techniques, while columns 2 and 4 show the percentage of surveyed engineers currently using a particular approach. While formal methods are becoming popular as a means to more exhaustively cover the design, psuedo-random simulation is still a vital part of the verification engineer's repertoire. In Section 61.3 we review some conventional verification techniques that use psuedo-random and biased-random test programs for simulation.

TABLE 61.1 0-In Bug Survey Results: Percentages of Various Validation Techniques Used by Design Verification Engineers (May 1997–May 1998)

Stimulus Techniques	Percentage Use	Advanced Verification Techniques	Percentage Use
System stimulation	94%	Cycle-based simulation	25%
Directed tests	89%	Equivalence checking	19%
Regression tests	88%	Hardware/software co-design	15%
Pseudorandom	82%		
Prototype silicon	58%	Model checking	13%
Emulation	49%

61.3 Random and Biased-Random Instruction Generation

Random vector simulation is the primary verification methodology used for microprocessors today. New designs, as well as changes made to existing designs, are subjected to a battery of simulation and regression tests involving billions of pseudo-random vectors before focused testing is performed. Random test generation, also known as black-box testing, produces more complex combinations of instructions than can be manually written by the design verification engineer. A large number of test programs are generated randomly. Each test program consists of a set of register and memory initializations and a sequence of instructions. It may also contain the expected contents of the registers and memory after execution of the instructions, depending on the implementation. The expected contents of the registers and memory are obtained using an architectural model of the design. The test programs are translated to assembler or machine-language code that is supported by the HDL simulator, and are simulated on the RTL model. However, purely random test programs are not ideal because the instruction sequences developed may not exercise a sufficient number of corner cases; thus, millions of vectors and days of simulation are

required before reasonable levels of coverage can be achieved. In addition, random vectors may violate constraints on memory addressing, thus causing invalid instruction execution.

Biased-Random Testing

Biasing is the manipulation of the probability of selecting instructions and operands during instruction generation. Biased-random instruction generation is used to create test programs that have a higher probability of leading to execution hazards for the processor. For example, the biasing scheme in Ref. 24 utilizes knowledge of the Alpha 21264 architecture to favor the generation of instructions that test architecture-specific corner cases, specifically those affecting control-flow, out-of-order processing, superscalar structures, cache transactions, and illegal instructions.

Constraint solving, another biasing technique, identifies output conditions or intermediate values that are important to verify.[4] The instruction generator identifies input values that would lead to these conditions and generates instructions that utilize these "biased" input values. Constraint solving is useful because it improves the probability of exercising certain corner cases. Both of these schemes have biases hard-coded into the test generation algorithm based on the instruction type.

Static and Dynamic Biasing

Biasing can be classified as being either static or dynamic. *Static biasing* of test vectors involves randomly initializing the registers and memory, generating the biased-random test program and applying it to the architectural and RTL models (e.g., the RIS tool from Motorola[8]). A major complication of this method is that the test generator must construct a test that does not violate the acceptable ranges for data and memory addresses. The solution to this problem is to constrain biasing within a restricted set of choices that define a constrained model of the environment; for example, to reserve certain registers for indexed addressing.[22]

Dynamically-biased test generators use knowledge of the current processor states, memory state, and user bias preferences to generate more effective test programs. In dynamic instruction generation, the states of the programmer model in the test generator are updated to reflect the execution of the instruction after each instance of instruction generation.[2,4] The test generator interacts with a tightly coupled functional model of the design to update current state information.

Drawbacks of random and biased-random testing include the vast amount of simulation time required to achieve acceptable levels of coverage and the lack of effective biasing methodologies. Determining when an acceptable level of coverage has been achieved is a major concern. Semiformal verification techniques have therefore become popular as a means to monitor simulation coverage, as well as improve coverage by generating vectors to cover test cases that have not been exercised by random simulation.

In Section 61.4, we discuss several correctness checking techniques that are used to determine whether the simulation test was successful. Later, in Section 61.5, we review some of the common metrics used to evaluate the coverage of test programs.

61.4 Correctness Checking

Correctness checking is the process of isolating a design error by determining whether the simulation test was successful. In this section, we discuss three techniques for correctness checking: self-checking, reference model comparison, and assertion checking. The three methods are complementary and are often used in conjunction to achieve the highest coverage. Figure 61.4 illustrates the three correctness checkers in the verifiction flow of the Alpha 21164 microprocessor.[18]

Self-checking

Self-checking is the simplest way to determine success for focused, hand-coded tests. The test program sets up a combination of conditions and then checks to see if the RTL model reacted correctly to the

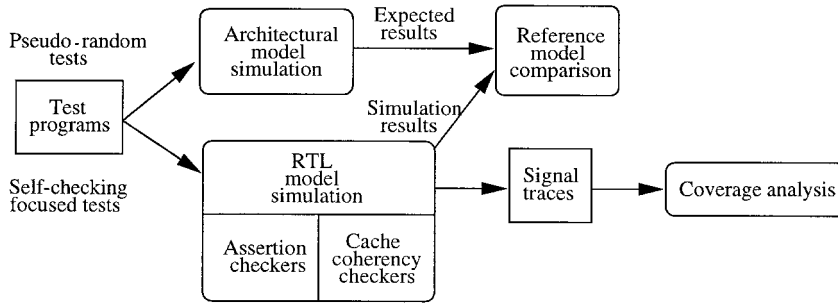

FIGURE 61.4 Verification flow and correctness checking for the Alpha 21164 microprocessor. (From Ref. 18.)

simulated situation.[15] However, this approach is time-consuming, prone to error, and intrusive at the register transfer level. The test generator may be required to maintain an extensive amount of state information. Furthermore, the technique is often not useful beyond a single focused test.

Reference Model Comparison

An alternative to self-checking is to compare the traces generated by the RTL model with the simulation traces of an architectural reference model, as illustrated in Fig. 61.2. This technique, known as reference model comparison, obviates the need for constantly checking the state of the processor being simulated. The reference model is an abstraction of the design architecture written in a high-level language such as C++. It represents all features visible to software, including the instruction set and support for memory and I/O space.[18]

Several correctness checks may be performed using the reference model, of which the simplest is *end-of-state* comparison. When simulation completes, the contents of memory locations are accessed, and the final states of the register files are compared. However, end-of-state comparison is not very useful for lengthy simulations because it may be difficult to identify incorrect intermediate results, which are overwritten during simulation. Comparing intermediate results during simulation is a solution; however, this requires the reference model to match the timing of the RTL model, and is not easily implemented. Additional comparisons that can be made include checking the PC flow and checking writes to integer and floating-point registers. Incorrect values here will signal problems with control-flow and data manipulation instructions.

Assertion Checking

Assertion checking, another popular means to check correctness, is the process of adding segments of code to the RTL model to verify that certain properties of design behavior always hold true under simulation. Examples of simple assertion checking include monitoring illegal states and invalid transitions. More complex checking involves monitoring queue overruns and violation of the bus protocol.[24] An example of a specialized assertion checker is the cache coherency checker used in the verification of the Alpha 21164 microprocessor.[18] The system supports three levels of caching, with the second and third-level caches being writeback. Cache coherency checking was activated at regular intervals during simulation to ensure that coherency rules were not violated. Table 61.2 presents the origins of bugs introduced into the design and the percentages of bugs detected by the various correctness checking mechanisms for the Alpha 21264 microprocessor.[24] Assertion checkers were the most successful; however, when viewed collectively, 44% of errors were found by reference model comparison.

With the correctness checking problem examined, the next major issue in simulation-based verification is determining whether acceptable levels of coverage have been achieved by the simulation vectors. In the next section, we look at several techniques for coverage analysis.

TABLE 61.2 Effectiveness of Correctness Checks Used in the Verification of the Alpha 21264 Microprocessor

Origin of Bug	Bugs Introduced[a]	Correctness Checker	Bugs Detected[a]
Implementation error	78%	Assertion checker	25%
Programming mistake	9%	Register miscompare	22%
Matching model to schematics	5%	Simulation "no progress"	15%
Architectural conception	3%	PC miscompare	14%
Other	5%	Memory state miscompare	8%
		Manual inspection	6%
		Self-checking test	5%
		Cache coherency check	3%
		SAVES check	2%

61.5 Coverage Metrics

Coverage analysis provides information on how thoroughly a design has been exercised during simulation. Coverage metrics are used to evaluate the effectiveness of random simulation vectors, as well as guide the generation of deterministic tests. A number of coverage metrics have been proposed, and verification engineers often use a variety of metrics simultaneously to determine test completeness. The simplest metrics used are based on the HDL description of the design. Examples are statement coverage, conditional branch coverage, toggle coverage, and path coverage.[6,18]

HDL Metrics

Statement coverage determines the number of statements in the HDL description that are executed. Conditional branch coverage metrics compute the number of conditional expressions that are toggled during simulation. Each of the important conditional expressions (e.g., **if** and **case** statements) is assigned to a monitored variable. If the variable is assigned to both 0 and 1 during simulation, both paths of the conditional branch are considered activated. Toggle coverage is the ratio of the number of signals that experienced 1-to-0 and 0-to-1 transitions during simulation, to the total number of effective signals. The number of effective signals is adjusted to include only those that can possibly be toggled in the fault-free model. Another recently proposed HDL metric is based on error observability at the primary outputs of the design.[7] Observability is computed by tagging variables during simulation and checking whether the tags are propagated to the outputs. A tag calculus, similar to that of the D-algorithm used for ATPG, is introduced. Coverage is measured as the percentage of tags visible at the design outputs. The method provides a stricter measure of coverage than does HDL-line coverage. However, while HDL-based metrics are useful, they are generally not effective measures of whether logic is being functionally exercised.

Manufacturing Fault Models

A second class of coverage metrics is based on manufacturing fault models.[25,26] These metrics characterize a class of design errors analogous to faults in hardware testing and measure coverage through fault simulation. Logic design errors, such as gate substitution, missing gates, and extra inverters, are injected randomly into the design. The design is then simulated using a stuck-at fault simulator. This approach has been used for measuring the coverage of ATPG tests for embedded arrays in microprocessors. ATPG is the process of automatically generating test patterns for manufacturing tests and is typically performed at the gate level. The problems with using manufacturing fault models to estimate coverage are that fault simulation is often computationally intensive, and faults introduced during the manufacturing process do not always model design errors.

Sequence and Case Analysis

Other metrics widely used in industry include sequence analysis, occurrence analysis, and case analysis.[18,24] *Sequence* analysis monitors sequences of events during simulation, for example, request-acknowledge sequences, interrupt assertions, and traps. *Occurrence* analysis determines the presence of one-time events, such as a carry-out being generated for every bit in an adder. The absence of such an event could signal a failure. Finally, *case* analysis consists of collecting and studying simulation statistics, such as exerciser type, cycles simulated, issue rate, and instruction types.[24]

State Machine Coverage

A more formal way to evaluate coverage is to look at an abstraction of the design in the form of a finite state machine (FSM).[5,12,14,20] The control logic of the design is extracted as an FSM, which has a smaller state space than the original design but which exhibits the design's control behavior. Coverage is typically estimated by the fraction of different states reached by the FSM or the fraction of state transitions exercised during simulation. FSM coverage metrics are also used to generate test programs with high coverage, as described in Section 61.6. Binary decision diagrams (BDDs), borrowed from formal verification, are used to describe and traverse the implementation state space. A BDD is a way of efficiently representing a set of binary-valued decisions (scalar Boolean functions) in the form of a tree or directed acyclic graph.

A method of transforming the high-level description of the circuit into a reduced FSM that has far fewer states than the original design, is proposed in Ref. 5. Simulation coverage is estimated by relating the fraction of transitions in the state graph traversed by this reduced FSM, to the number of HDL statements exercised in the high-level description.

More recently, Moundanos et al.[20] have described the extraction of the control logic of the design from its HDL description. The control logic is extracted in the form of an FSM, which represents the control space of the entire circuit. The vectors whose coverage is to be evaluated are simulated on the FSM. Simulation coverage is estimated by the following two ratios.

$$\text{State coverage metric}\left(\text{SCM}\right) = \frac{\text{Number of states visited}}{\text{Total number of reachable states}}$$

$$\text{Transition coverage metric}\left(\text{TCM}\right) = \frac{\text{Number of transitions visited}}{\text{Total number of reachable transitions}}$$

A similar approach to evaluating coverage is used in Ref. 14. Since only a subset of state variables directly controls the datapath, the non-controlling independent state variables are removed from the state graph of the FSM. This reduced state graph is called a *control event* graph, and each reachable state is a control event. Coverage is evaluated in terms of the number of control events visited and the number of transitions exercised in the control event graph.

Further along the spectrum toward formal verification lie techniques dubbed "smart simulation,"[6] which not only evaluate coverage of the given vectors, but also *generate* new functional tests using coverage metrics. In Section 61.6, we discuss several such techniques that use semiformal coverage metrics to derive simulation vectors. We begin with techniques based on identifying hazard patterns and later discuss more formal methods that use state machine coverage.

61.6 Smart Simulation

Deterministic or *smart* simulation uses vectors that cover a certain aspect of the design's behavior using details of its implementation. We first describe ad hoc techniques, such as hazard-pattern enumeration, which target specific blocks in the processor, and then describe more general techniques aimed at verifying the entire chip.

Hazard-Pattern Enumeration

Ad hoc techniques typically target a specific block in the design, such as a pipeline[16,19] or cache controller.[21] Errors in the pipeline mechanism represent only a small fraction of the total errors. In a study undertaken in Ref. 19, it was shown that only 2.79% of the total errors in a commercial 32-bit CPU design were related to the pipeline interlock controller. However, these errors are widely acknowledged as being the hardest to detect and are therefore targeted by ad hoc methods.

Pipeline hazards are situations that prevent the next instruction from executing in its designated clock cycle. These are classified as structural hazards, data hazards, and control hazards. *Structural* hazards occur when two instructions in different pipeline stages attempt to access the same physical resource simultaneously. *Data* hazards are of three types: read-after-write (RAW), write-after-write (WAW), and write-after-read (WAR) hazards. The most common are RAW hazards, in which the second instruction attempts to read the result of the first instruction before it is written. *Control* hazards are treated as RAW hazards in the program counter (PC). An algorithm that enumerates all the structural, data, and control hazard patterns for each common resource in the pipeline is presented in Ref. 16. Test programs that include all the patterns that can cause the pipeline to stall are then generated.

Lee and Siewiorek[19] define the set of state variables read by an instruction as its *read state* and the set written by the instruction as its *write state*. A conflict exists between two instructions if at least one of them is a write and the intersection of their read/write or write/write states is not empty. A dependency graph is constructed with nodes representing all the possible read/write instructions and edges (or dependency arcs) representing conflicts between instructions. Test programs are generated to cover all the dependency arcs in the graph, and the dependency arc coverage is calculated.

In Ref. 21, a cache controller is verified using a model of the memory hierarchy, a set of cache coherence protocols, and enumeration capabilities to generate test programs for the design.

The problem inherent in ad hoc techniques is that pipeline behavior after the detection of a hazard is usually not considered.[17] Test cases reachable only after a hazard has occurred are therefore not covered. We next discuss more general test generation techniques, which are applicable to a larger part of the design.

ATPG

An important class of verification techniques is based on the use of test programs generated by ATPG tools. Coverage is measured as the fraction of design errors detected. These methods have been used in industry to verify the equivalence between the gate-level and transistor-level models; for example, in the verification of PowerPC™ arrays.[25,26] In this approach, a gate-level model is created from the transistor-level implementation, and tests generated at the gate level are simulated at the transistor level to verify equivalence. However, these techniques, while effective at lower levels of abstraction, do not provide a good measure of the extent to which the design has been exercised.

State and Transition Traversal

Tests generated by traversing the design's state space work on the principle that verification will be close to complete if the processor either visits all the states or exercises all the transitions of its state graph during simulation.[5,13,20] Since memory limitations make it impossible to examine the state graph of the entire design, the design behavior is usually abstracted in the form of a reduced state graph. Test sequences are then generated which cause this reduced FSM to exercise all the transitions. Figure 61.5 illustrates the verification flow for this technique. The first step is to extract the control logic of the design in the form of an FSM. The datapath is usually not considered because most designs have datapaths of substantial size, which can lead to an unmanageable state space. Furthermore, errors in the datapath usually result from incorrect implementation — not incorrect design — and can be easily tested by conventional simulation.[20]

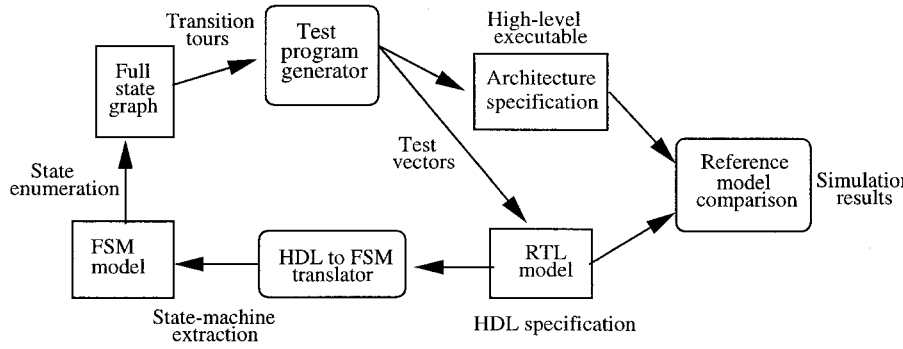

FIGURE 61.5 Verification flow for a representative state machine traversal technique. (From Ref. 13. With permission.)

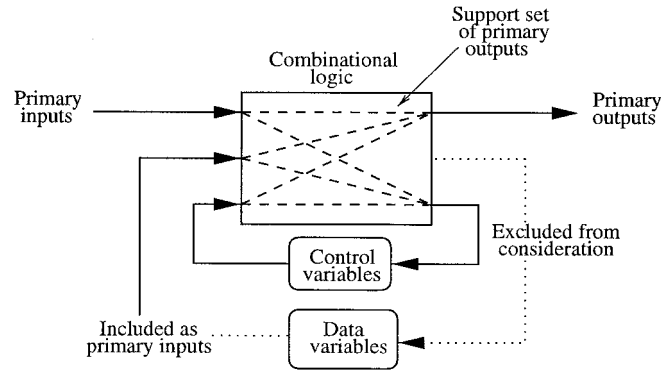

FIGURE 61.6 Extraction of the control flow machine. (From Ref. 20. With permission.)

A method to extract the control logic of the design in the form of an FSM can be found in Ref. 20. This is illustrated in Fig. 61.6. The data variables in the design are made nondeterministic by including them in the set of primary inputs to the FSM. Since the datapath is to be excluded from consideration, the inputs to the data variables are excluded. This is represented by the dotted lines in Fig. 61.6. The support set of the primary outputs and control state variables is now determined in terms of the primary inputs, control state variables, and data variables. This support set forms the new set of primary inputs to the FSM. Data variables that are not a part of the support set are excluded from the FSM. In this manner, the effect of the data variables on the control flow is taken into account, even though the data registers are abstracted.

After the FSM has been extracted, state enumeration is performed to determine the reachable states, and a state graph which details the behavior of the FSM is generated. Since coverage is typically evaluated by the number of states visited or the number of transitions exercised, a *state* or *transition tour* of the state graph is found. A state (transition) tour of a directed state graph is a sequence of transitions that traverses every state (transition) at least once. Several polynomial-time algorithms have been developed for finding transition tours in nonsymmetric, strongly connected graphs, since this problem (the Chinese Postman problem) is frequently encountered in protocal conformance testing.[13] The transition tour is translated into an instruction sequence which will cause the FSM to exercise all transtions.

Cheng and Krishnakumar[5] use exhaustive coverage of the reduced FSM to generate test programs guaranteeing that all statements in the original HDL representation are exercised. A test generation technique based on visiting all states in the state graph is presented in Ref. 17. Test cases are developed based on enumerating hazard patterns in the pipeline and are translated into sequences of states in the

state graph. Simulation vectors that satisfy all test cases are generated. A more general transition-traversal technique is given in Ref. 13. A translator is used to convert the HDL representation to a set of interacting FSMs. A full state enumeration of the FSMs is performed to find all reachable states from reset. This produces a complete state graph, which is used to generate vectors that cause the processor to take a transition tour.

Finally, several classes of processors for which transition coverage is effective are identified in Ref. 12. The authors demonstrate that under a given set of conditions, transition tours of the state graph can be used to completely validate a large class of processors.

State-space explosion is currently a key problem in computing state machine coverage. As designs get larger and considerably more complex, the maximum size of the state machine that can be handled is the major limiting factor in the use of formal methods. However, research is currently being undertaken to deal with state explosion, and we foresee an increasing use of formal coverage metrics in the future.

61.7 Wide Simulation

Near the formal end of the verification spectrum, *wide simulation* is performed by representing the FSM behavior as a set of transitions between valid control states and symbolically representing large sets of states in relatively few simulations. Assertions covering all the transitions in the state graph are written and are used to derive vectors for simulation.

Partitioning FSM Variables

The authors in Ref. 11 first focus on specific parts of the design by partitioning the FSM variables into three sets — *coverage Co, ignore Ig,* and *care CA* — based on their respective importance. Using these sets, the number of transitions in the graph that need to be exercised can be reduced.

For example, a state in the FSM is viewed as the 3-tuple $\{X, Y, Z\}$, where $X \in Co$, $Y \in Ig$, and $Z \in Ca$. Two transitions, $T_1((X_1Y_1Z_1), (X_2Y_2Z_2))$ and $T_2((X_3Y_3Z_3), (X_4Y_4Z_4))$, which differ in the value of a coverage variable, are distinct and require separate tests; for example, if $X_1 \neq X_3$ or $X_2 \neq X_4$, then T_1 and T_2 require different tests. However, two transitions that differ only in the value of an ignore variable are equivalent. Therefore, if $X_1 = X_3$, $X_2 = X_4$, $Z_1 = Z_3$, and $Z_2 = Z_4$, then T_1, T_2 are equivalent and a vector that tests T_1 will also test T_2. Finally, two transitions that differ in the value of a care variable do not necessarily require different tests.[11]

In this manner, the state graph is represented as the set of all valid transitions T, of which only a few must be exercised, based on the equivalence relations. Next, formal assertions are written for each transition. An assertion is a temporal logic expression of the form *antecedent* $\rightarrow$ *consequent*, where both antecedent and consequent can consist of complex logical expressions.[25] The first step in the test generation process is to choose a valid transition $T_1(v,v') \in T$ and write an assertion of the form $state(v) \rightarrow next(\neg state(v'))$, which means that if the FSM is in state v, then the next state cannot be v'.

Deriving Simulation Tests from Assertions

A model checker can be used to generate sequences of input vectors which satisfies the assertion.[11] A *model checker* is a formal verification tool that is used to either prove that a certain property is satisfied by the system or generate a counterexample to show that the property does not always hold true. The model checker reports that the assertion $state(v) \rightarrow next(\neg state(v'))$ is false and that the transition is indeed valid. The model checker also outputs a symbolic sequence of states and input patterns which lead to state v. This symbolic (high-level) sequence of patterns is then translated into a simulation vector sequence and is used to verify the design. The transition T_1 and all transitions equivalent to T_1 are removed from T, and the process is repeated.[11]

Wang and Abadir[25,26] use tools to automatically generate formal assertions for PowerPC™ arrays from the RTL model. *Symbolic trajectory evaluation*, a descendant of symbolic simulation, is used to formally

prove that all assertions are true. After the design has been formally verified, simulation vectors are derived from the assertions and are used for simulating the design. The methods used to derive these vectors are as follows. The symbolic values used in the antecedent of each assertion are replaced with a set of vectors based on each condition specified in the consequent. First, symbolic address comparison expressions are replaced with address marching sequences (e.g., to test large decoders). Next, symbolic data comparison expressions are replaced with data marching sequences (e.g., in testing comparators). Stand-alone symbolic values representing sets of states or input patterns are replaced with random vectors. Assertion decision trees are constructed and tests are generated to cover all branches (e.g., in testing control logic). Finally, control signal decision trees are constructed in order to generate tests that cover abnormal functional space.[25]

We have now reached the "formal" end of our discussion on verification techniques, which range from random simulation to semiformal verification. Formal verification, which uses mathematical formulae to prove correctness, is described by Levitan. In Section 61.8, we describe emulation, which is a means to implement a design using programmable hardware, with performance several orders of magnitude faster than conventional software simulators. Emulation has become popular as a means to test a processor against real-world application programs, which are impossibly slow to run using simulation.

61.8 Emulation

The fundamental difference between simulation and emulation is that simulation models the design in software on a general-purpose host computer, while emulation actually implements the design using dynamically configured hardware. Emulation, performed in addition to simulation has several advantages. It provides up to six orders of magnitude improvement in execution performance and enables several tests that are too complex to simulate to be performed prior to tapeout. These include power-on-self-tests, operating system boots, and running software applications (e.g., Open Windows).[10] Finally, emulation reduces the number of silicon iterations that are needed to arrive at the final design, because errors caught by emulation can be corrected before committing the design to silicon.

Pre-configuration

The emulation process consists of four major phases: pre-configuration, configuration, testbed preparation, and in-circuit emulation (ICE).[10] In the pre-configuration phase, the different components of the design are assembled and converted into a representation that is supported by the emulation vendor. For example, in the K5 emulation, each custom library cell was expressed in terms of primitives that could be mapped to a field-programmable gate array (FPGA).[9] An FPGA is a simple programmable logic device that allows users to implement multi-level logic. Several thousand FPGAs must be connected together to prototype a complex microprocessor. Once the cell libraries have been translated, the various gate-level netlists are converted to a format acceptable to the configuration software. This can be complicated because the netlists obtained from standard-cell and datapath designers are often in a variety of formats.[10]

There is often no FPGA equivalent for complex transistor-level megacells, which are commonly used in full custom processors. Gate-level emulation models for megacells must therefore be created. These gate-level blocks are implemented in the programmable hardware and are verified against simulation vectors to ensure that each module performs correctly according to the simulation model.

Full-Chip Configuration

In this phase, the design netlists and libraries are combined with control and specification files and downloaded to program the emulation hardware. In the first stage of configuration, the netlists are parsed for semantic analysis and logic optimization.[10] The design is then partitioned into a number of logic board modules (LBMs) in order to satisfy the logic and pin constraints of each LBM. The logic assigned to each LBM is flattened, checked for timing and connectivity and further partitioned into clusters to

allow the mapping of each cluster to an individual FPGA.[9] Finally, the interconnections between the LBMs are established, and the design is downloaded to the emulator.

Testbed and In-circuit Emulation

The testbed is the hardware environment in which the design to be emulated will finally operate. This consists of the target ICE board, logic analyzer, and supporting laboratory equipment.[10] The target ICE board contains PROM sockets, I/O ports, and headers for the logic analyzer probes.

Verification takes place in two modes: the simulation mode and ICE. In the simulation mode, the emulator is operated as a fast simulator. Software is used to simulate the bus master and other hardware devices, and the entire simulation test suite is run to validate the emulation model.[9] An external monitor and logic analyzer are used to study results at internal nodes and determine success. In the ICE mode, the emulator pins are connected to the actual hardware (application) environment. Initially, diagnostic tests are run to verify the hardware interface. Finally, application software provides the emulation model with billions of vectors for high-speed functional verification.

In Section 61.9, we conclude our discussion on design verification and review some of the areas of current research.

61.9 Conclusion

Microprocessor design teams use a combination of simulation and formal verification to verify pre-silicon designs. Simulation is the primary verification methodology in use, since formal methods are applicable mainly to well-defined parts of the RTL or gate-level implementation. The key problem in using formal verification for large designs is the unmanageable state space.

Simulation typically involves the application of a large number of psuedo-random or biased-random vectors in the expectation of exercising a large portion of the design's functionality. However, random instruction generation does not always lead to certain highly improbable (corner case) sequences, which are the most likely to cause hazards during execution. This has led to the use of a number of semiformal methods, which use knowledge-derived from formal verification techniques to more fully cover the design behavior. For example, techniques based on HDL statement coverage ensure that all statements in the HDL representation of the design are executed at least once. At a more formal level, a state graph of the design's functionality is extracted from the HDL description, and formal techniques are used to derive test sequences that exercise all transitions between control states. Finally, formal methods based on the use of temporal logic assertions and symbolic simulation can be used to automatically generate simulation vectors. We next describe some current directions of research in verification.

Performance Validation

With an increasing sophistication in the art of functional validation, ensuring the lack of performance bugs in microprocessors has become the next focus of verifiction. The fundamental hurdle to automating performance validation for microprocessors is the lack of formalism in the specification of error-free pipeline execution semantics.[3] Current validation techniques rely on focused, handwritten test cases with expert inspection of the output. In Ref. 3, analytical models are used to generate a controlled class of test sequences with *golden* signatures. These are used to test for defects in latency, bandwidth, and resource size coded into the processor model. However, increasing the coverage to include complex, context-sensitive parameter faults and generating more elaborate tests to cover the cache hierarchy and pipeline paths remain open problems.

Design for Verification

Design for verification (DFV) is the new buzzword in microprocessor verification today. With the costs of verification becoming prohibitive, verification engineers are increasingly looking to designers for

easy-to-verify designs. One way to accomplish DFV is to borrow ideas from design for testability (DFT), which is commonly used to make manufacturing testing easier. Partitioning the design into a number of modules and verifying each module separately is one such popular DFT technique. DFV can also be accomplished by adding extra modes to the design behavior, in order to suppress features such as out-of-order execution during simulation. Finally, a formal level of abstraction, which expresses the microarchitecture in a formal language that is amenable to assertion checking, would be an invaluable aid to formal verification.

Microprocessor Layout Method

Tanay Karnik
Intel Corporation

62.1 Introduction

This chapter presents various concepts and strategies employed to generate a layout of a high-performance, general-purpose microprocessor. The layout process involves generating a physical view of the microprocessor that is ready for manufacturing in a fabrication facility (fab) subject to a given target frequency. The layout of a microprocessor differs from ASIC layout because of the size of the problem, complexity of today's superscalar architectures, convergence of various design styles, the planning of large team activities, and the complex nature of various, sometimes conflicting, constraints.

In June 1979, Intel introduced the first 8-bit microprocessor with 29,000 transistors on the chip with 8-MHz operating frequency.[1] Since then, the complexity of microprocessors has been closely following Moore's law, which states that the number of transistors in a microprocessor will double every 18 months.[2] The number of execution units in the microprocessor is also increasing with generations. The increasing die size poses a layout challenge with every generation. The challenge is further augmented by the ever-increasing frequency targets for microprocessors. Today's microprocessors are marching toward the GHz frequency regime with more than 10 million transistors on a die. Table 62.1 includes some statistics of today's leading microprocessors[1]:

TABLE 62.1 Microprocessor Statistics

Manufacturer	Part Name	# Transistors (millions)	Frequency (MHz)	Die Size (mm^2)	Technology (μm)
Compaq	Alpha 21264	15.2	600	314	0.35
IBM	PowerPC	6.35	250	66.5	0.3
HP	PA-8000	3.8	250	338	0.5
Sun	Ultrasparc-I	5.2	167	315	0.5
Intel	Pentium II	7.5	450	118	0.25

[1]The reader may refer to Refs. 3 through 10 for further details about these processors.

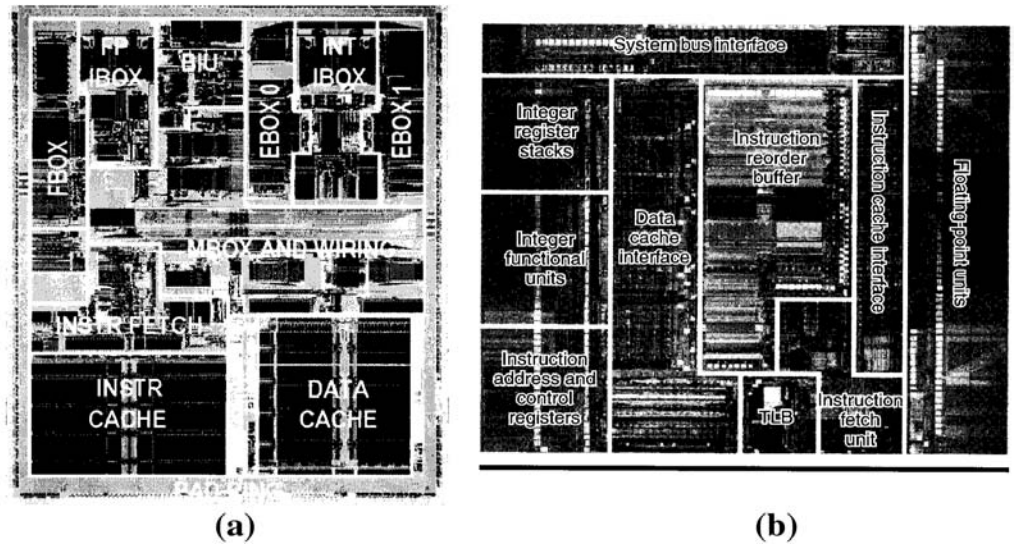

FIGURE 62.1 Chip micrographs. (a) Compaq Alpha 21264; (b) HP PA-8000. ((a) Courtesy of IEEE, Ref. 4; (b) Courtesy of IEEE, Ref. 6. With permission.)

In order to understand the magnitude of the problem of laying out a high-performance microprocessor, refer to the sample chip micrographs in Fig. 62.1. Various architectural modules, such as functional blocks, datapath blocks, memories, memory management units, etc. are physically separated on the die. There are many layout challenges apparent in this figure. The floorplanning of various blocks on the chip to minimize chip-level global routing is done before the layout of the individual blocks is available. The floorplanning has to fit the blocks together to minimize chip area and satisfy the global timing constraints. The floorplanning problem is explained in Section 62.4 (Floorplanning). As there are millions of devices on the die, routing power and ground signals to each gate involves careful planning. The power routing problem is described in Section 62.4 (Clock Planning). The microprocessor is designed for a particular frequency target. There are three key steps to high performance. The first step involves designing a high-performance circuit family, the second one involves design of fast storage elements, and the third is to construct a clock distribution scheme with minimum skew. Many elements need to be clocked to achieve synchronization at the target frequency. Routing the global clock signal exactly from an initial generator point to all of these elements within the given delay and skew budgets is a hard task. Section 62.4 (Power Planning) includes the description of clock planning and routing problems. There are various signal buses routed inside the chip running among chip I/Os and blocks. A 64-bit datapath bus is a common need in today's high-performance architectures, but routing that wide a bus in the presence of various other critical signals is very demanding, as explained in Section 62.4 (Bus Routing).

The problems identified by looking at the chip micrographs are just a glimpse of a laborious layout process. Before any task related to layout begins, the manufacturing techniques need to be stabilized and the requirements have to be modeled as simple design rules to be strictly obeyed during the entire design process. The manufacturing constraints are caused by the underlying process technology (Section 62.3, Technology Process) or packaging (Section 62.2, Packaging).

Another set of decisions to be taken before the layout process involve the circuit style(s) to be used during the microprocessor design. Examples of such styles include full custom, semi-custom, and automatic layout. They are described in Section 62.2. The circuit styles represent circuit layout styles, but there is an orthogonal issue to them, namely, circuit family style. The examples of circuit families include

static CMOS, domino, differential, cascode, etc. The circuit family styles are carefully studied for the underlying manufacturing process technology and ready-to-use cell libraries are developed to be used during the block layout. The library generation is illustrated in Section 62.5.

Major layout effort is required for the layout of functional blocks. The layout of individual blocks is usually done by parallel teams. The complex problem size prompts partitioning inside the block and reusability across blocks. Cell libraries as well as shared mega-cells help expedite the process. Well-established methodologies exist in various microprocessor design companies. Block-level layout is usually done hierarchically. The steps for block-level layout involve partitioning, placement, routing, and compaction. They are detailed in Section 62.6.

CAD Perspective

The complexity of microprocessor design is growing, but there is no proportional growth in design team sizes. Historically, many tasks during the microprocessor layout were carefully hand-crafted. The reasons were twofold. The size of the problem was much smaller than what we face today. The second reason was that computer-aided design (CAD) was not mature. Many CAD vendors today are offering fast and accurate tools to automatically perform various tasks such as floorplanning, noise analysis, timing analysis, placement, and routing. This computerization has enabled large circuit design and fast turnaround times. References to various CAD tools with their capabilities have been added throughout this chapter.

CAD tools do not solve all of the problems during the microprocessor layout process. The regular blocks, like datapath, still need to be laid out manually with careful management of timing budgets. Designers cannot just throw the netlist over the wall to CAD to somehow generate a physical design. Manual effort and tools have to work interactively. Budgeting, constraints, connectivity, and interconnect parasitics should be shared across all levels and styles. Tools from different vendors are not easily interoperable due to a lack of standardization. The layout process may have proprietary methodology or technology parameters that are not available to the vendors. Many microprocessor manufacturers have their own internal CAD teams to integrate the outside tools into the flow or develop specific point tools internally. This chapter attempts to explain the advantages as well as shortcomings of CAD for physical layout.

Invaluable information about Physical Design Automation and related algorithms is provided in Refs. 11 and 12. These two textbooks cover a wide range of problems and solutions from the CAD perspective. They also include detailed analyses of various CAD algorithms. The reader is encouraged to refer to Refs. 13 to 15 for a deep understanding of digital design and layout.

Internet Resources

The Internet is bringing the world together with information exchange. Physical design of microprocessors is a widely discussed topic on the internet. The following web sites are a good resource for advanced learning of this field.

The key conference for physical design is the International Symposium on Physical Design (ISPD), held annually in April. The most prominent conference in Electronic Design Automation (EDA) community is the ACM/IEEE Design Automation Conference (DAC), (www.dac.com). The conference features an exhibit program consisting of the latest design tools from leading companies in design automation. Other related conferences are International Conference on Computer Aided Design (ICCAD) (www.iccad.com), IEEE International Symposium on Circuits and Systems (ISCAS) (www.iscas.nps.navy.mil), International Conference on Computer Design (ICCD), IEEE Midwest Symposium on Circuits and Systems (MSCAS), IEEE Great Lakes Symposium on VLSI (GLSVLS) (www.eecs.umich.edu/glsvlsi), European Design Automation Conference (EDAC), International Conference on VLSI Design (vcapp.csee.usf.edu/vlsi99/), and Microprocessor Forum. There are several journals which are dedicated to the field of VLSI Design Automation and include broad coverage of all topics in

physical design. They are *IEEE Transactions on CAD of Circuits and Systems* (akebono.stanford.edu/users/nanni/tcad), *Integration*, *IEEE Transactions on Circuits and Systems*, *IEEE Transactions on VLSI Systems*, and the *Journal of Circuits, Systems and Computers*. Many other journals occasionally publish articles of interest to physical design. These journals include *Algorithmica, Networks, SIAM Journal of Discrete and Applied Mathematics*, and *IEEE Transactions on Computers*.

An important role of the Internet is through the forum of newsgroups. comp.lsi.cad is a newsgroup dedicated to CAD issues, while specialized groups such as comp.lsi.testing and comp.cad.synthesis discuss testing and synthesis topics. The reader is encouraged to search the Internet for the latest topics. *EE Times* (www.eet.com) and *Integrated System Design* (www.isdmag.com) magazines provide latest information about physical design and they are both online publications. Finally, the latest challenges in physical design are maintained at (www.cs.virginia.edu/pd_top10/). The current benchmark problems for comparison of PD algorithms are available at www.cbl.ncsu.edu/www/.

We describe various problems involved throughout the microprocessor layout process in the Section 62.2.

62.2 Layout Problem Description

The design flow of a microprocessor is shown in Fig. 62.2. The architectural designers produce a high-level specification of the design, which is translated into a behavioral specification using function design, structural specification using logic design, and a netlist representation using circuit design. In this chapter, we discuss the microprocessor layout method called *physical design*. It converts a netlist into a mask layout consisting of physical polygons, which is later fabricated on silicon. The boxes on the right side of Fig. 62.2 depict the need for verification during all stages of the design. Due to high frequencies and shrinking die sizes, estimation of eventual physical data is required at all stages before physical design during the microprocessor design process. The estimation may not be absolutely necessary for other types of designs.

Let us consider the physical design process. Given a netlist specification of a circuit to be designed, a layout system generates the physical design either manually or automatically and verifies that the design conforms to the original specification. Figure 62.3 illustrates the microprocessor physical design flow.

Various specifications and constraints have to be handled during microprocessor layout. Global specs involve the target frequency, density, die size, power, etc. Process specs will be discussed in Section 62.3. The chip planner is the main component of this process. It partitions the chip into blocks, assigns blocks

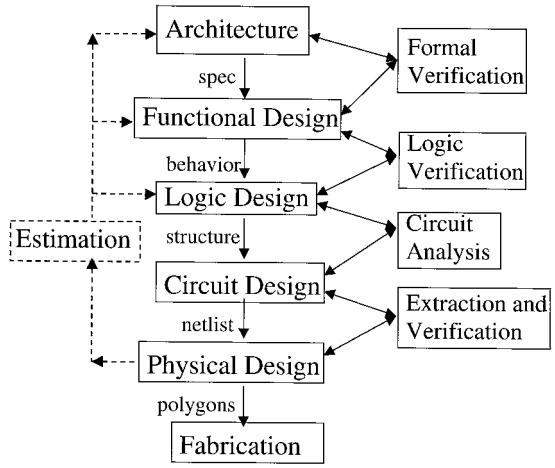

FIGURE 62.2 Microprocessor design flow.

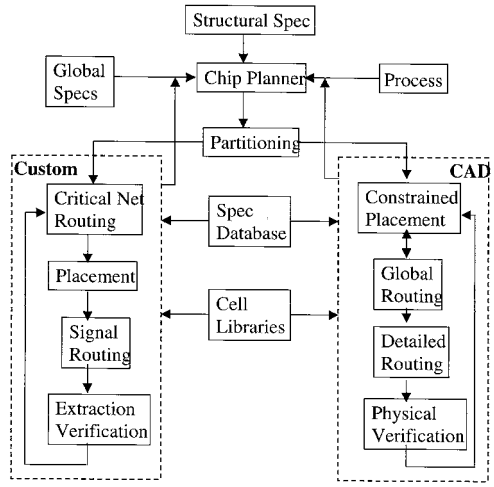

FIGURE 62.3 Microprocessor physical design flow.

for either full custom (manual) layout or CAD (automatic) layout and assembles the chip after block-level layout is finished. It may also iterate this process for better results. Full custom and CAD layout differ in the approach to handle critical nets. In the custom layout, critical nets are routed as a first step of block layout. In the CAD approach, the critical net requirements are translated into a set of constraints to be satisfied by placement and routing tools. The placement and global routing have to work in an iterative fashion to produce a dense layout. The double-sided arrow in CAD box represents this iteration. In both layout styles, iterations are required for block layout to completely satisfy all the specs. Some microprocessor teams employ a semi-custom approach which takes advantage of careful hand-crafting and power savings on the full custom side, and the efficiency and scalability of the CAD side.

Global Issues

The problems specific to individual stages of physical design are discussed in the following sections. This section attempts to explain the problems that affect the whole design process. Some of them may be applicable to the pre-layout design stages and post-layout verification.

Planning

There has to be a global flow to the layout process. The flow requires consistency across all levels and support for incremental re-design. A decision at one level affects almost all the other levels. The chip planning and assembly are the most crucial tasks in the microprocessor layout process. The chip is partitioned into blocks. Each block is allotted some area for layout. The allotment is based on estimation based on past experience. When the blocks are actually laid out, they may not fit in the allotted area. The full microprocessor layout process is long. One cannot wait until the last moment to assemble the blocks inside the chip. The planning and assembly team has to continuously update the flow, chip plans, and block interfaces to conform to the changing block data.

Estimation

New product generations rely on technology advances and providing the designer with a means of evaluating technology choices early in the product design.[16] Today's fine-line geometries jeopardize timing. Massive circuit density coupled with high clock rates, is making routed interconnects hardest to gauge early in the design process. A solid estimation tool or methodology is needed to handle today's complex microprocessor designs. Due to the uncertain effects of interconnect routing, the wall between logical and physical design is beginning to fall.[17] In the past, many microprocessor layout teams resorted

to post-layout updates to resolve interconnect problems. This may cause major re-design and another round of verification, and is therefore not acceptable. We cannot separate logical design and physical design engineers. Chip planners have to minimize the problems that interconnect effects may cause. Early estimation of placement, signal integrity, and power analysis information is required at the floorplanning stage even before the structural netlist is available.

Changing Specifications

Microprocessor design is a long process. It is driven by market conditions, which may change during the course of the design. So, architectural specs may be updated during the design. During physical design, the decisions taken during the early stages of the design may prove to be wrong. Some blocks may have added functionalities or new circuit families, which may need more area. The global abstract available to block-level designers may continuously change, depending on sibling blocks and global specs. Hence, the layout process has to be very flexible. Flexibility may be realized at the expense of performance, density, or area — but it is well worth it.

Die Shrinks and Compactions

The easiest way to achieve better performance is process shrinks. Optical shrinks are used to convert a die from one process to a finer process. Some more engineering is required to make the microprocessor work for the new process. A reduction in feature size from 0.50 μm to 0.35 μm results in an increase of approximately 60% more devices on a similarly sized die.[3] Layouts designed for a manufacturing process should be scalable to finer geometries. The decisions taken during layout should not prohibit further feature shrinks.

Scalability

CAD algorithms implemented in automatic layout tools must be applicable to large sizes. The same tools must be useful across generations of microprocessor. Training the designers on an entirely new set of CAD tools for every generation is impractical. The data representation inside the tools should be symbolic so that the process numbers can be updated without a major change in tools.

Explanation of Terms

There are many terms related to microprocessor layout used in the following sections. The definitions and explanation of those terms is provided in this section.

Capacitance: A time-varying voltage across two parallel metal segments exhibits capacitance. The voltage (v) and current (i) relation across a capacitor (C) is

$$i = C\frac{dv}{dt}$$

Closely spaced unconnected metal wires in layout can have significant cross-capacitance. Capacitance is very significant at 0.5-μm process and beyond.[18]

Inductance: A time-varying current in a wire loop exhibits inductance. If the current through a power grid or large signal buses changes rapidly, this can have inductive effects on adjacent metal wires. The voltage (v) and current (i) relation across an inductor (L) is

$$v = L\frac{di}{dt}$$

Inductance is not a local phenomenon like capacitance.

Parasitics: The shrinking technology and increasing frequencies are causing analog physical behavior in digital microprocessors.[19] The electrical parameters associated with final physical routes are called interconnect parasitics. The parasitic effects in the metal routes on the final silicon need to be estimated in the early phases of the design.

Design rules: The process specification is captured in an easy-to-use set of rules called design rules.

Spacing: If there is enough spacing between metal wires, they do not exhibit cross-capacitance. Minimum metal spacing is a part of the design rules.

Shielding: The power signal is routed on a wide metal line and does not have time-varying properties. In order to reduce external effects like cross-capacitance, on a critical metal wire, it is routed between or next to a power wire. This technique is called shielding.

Electromigration: Also known as metal migration, it results from a conductor carrying too much current. The result is a change in conductor dimensions, causing high resistive spots and eventual failure. Aluminum is the most commonly used metal in microprocessors. Its current density (current per width) threshold for electromigration is

$$2\frac{mA}{\mu m}$$

62.3 Manufacturing

Manufacturing involves taking the drawn physical layout and fabricating it on silicon. A detailed description of fabrication processes is beyond the scope of this book. Elaborate descriptions of the fabrication process can be found in Refs. 11 and 13. The reader may be curious as to why manufacturing has to be discussed before the layout process. The reality is that all of the stages in the layout flow need a clear specification of the manufacturing technology. So, the packaging specs and design rules must be ready before the physical design starts.

In this section, we present a brief overview of chip packaging and technology process. The reader is advised to understand the assessment of manufacturing decisions (see Ref. 16). There is a delicate balancing of the system requirements and the implementation technology. New product generation relies on technology advances and providing the designer with a means of evaluating technology choices early in the product design.

Packaging

ICs are packages into ceramic or plastic carriers usually in the form of a pin grid array (PGA) in which pins are organized in several concentric rectangular rows. These days, PGAs have been replaced by surface-mount assemblies such as ball grid arrays (BGAs) in which an array of solder balls connects the package to the board. There is definitely a performance loss due to the delays inside the package. In many microprocessors, naked dies are directly attached to the boards. There are two major methods of attaching naked dies. In wire bonding, I/O pads on the edge of the die are routed to the board. The active side of the die faces away from the board and the I/Os of the die lie on the periphery (peripheral I/Os). The other die attachment, control collapsed chip connection (C4) is a direct connection of die I/Os and the board. The I/O pins are distributed over the die and a solder ball is placed over each I/O pad (areal I/Os). The die is flipped and attached to the board. The technology is called C4 flip-chip. Figure 62.4 provides an abstract view of the two styles.

There is a discussion about practical issues related to packaging available in Ref. 20. According to the Semiconductor Industry Association's (SIA) roadmap, there should be 600 I/Os per package in 2507 rows, 7 μm package lines/space, 37.5 μm via size, and 37.5 μm landing pad size by the year 1999. The SIA roadmap lists the following parameters that affect routing density for the design of packaging parameters:

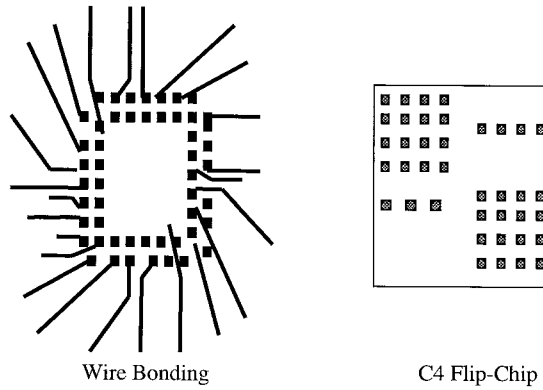

FIGURE 62.4 Die attachment styles.

- **Number of I/Os**: This is a function of die size and planned die shrinks. The off-chip connectivity requires more pins.
- **Number of rows**: The number of rows of terminals inside the package.
- **Array shape**: Pitch of the array, style of the array (i.e., full array, open at center, only peripheral).
- **Power delivery**: If the power and ground pins are located in the middle, the distribution can be made with fewer routing resources and more open area is available for signals. But then, the power cannot be used for shielding the critical signals.
- **Cost of package**: This includes the material, processing cost, and yield considerations. The current trend in packaging indicates a package with 1500 I/O on the horizon and there are plans for 2000 I/Os.

There is a gradual trend toward the increased use of areal I/Os. In the peripheral method, the I/Os on the perimeter are fanned out until the routing metal pitch is large enough for the chip package and board to handle it. There may be high inductance in the wire bonding. Inductance causes current time delay at switching, slow rise time, and ground bounce in which the ground plane moves away from 0 V, noise, and timing problems. These effects have to be handled during a careful layout of various critical signals. Silicon array attachments and plastic array packages are required for high I/O densities and power distribution. In microprocessors, the packaging technology has to be improvised because of the growth in bus widths, additional metal layers, less current capacity per wire, more power to be distributed over the die, and the growing number of data and control lines due to bus widths. The number of I/Os has exceeded the wire bonding capacity. Additionally, there is a limit to how much a die can be shrunk in the wire bonding method. High operating frequencies, low supply voltage, and high current requirements manifest themselves into a difficult power distribution across the whole die. There are assembly issues with fine pitches for wire bonds. Hence, the microprocessor manufacturers are employing C4 flip-chip technologies. Areal packages reduce the routing inside the die but need more routing on the board.

The effect of area packaging is evident in today's CAD tools.[21] The floorplanner has to plan for areal pads and placement of I/O buffers. Area interconnect facilitates high I/O counts, shorter interconnect rates, smaller power rails, and better thermal conductivity. There is a need for an automatic area pad planner to optimize thousands of tightly spaced pads. A separate area pad router is also desired. The possible locations for I/O buffers should be communicated top-down to the placement tool and the placement info should be fed back to the I/O pad router. After the block level layout is complete and the chip is assembled, the area pad router should connect the power pads to inner block-level power rails.

Let us discuss some industry microprocessor packaging specs. The packaging of DEC/Compaq's Alpha 21264 has 587 pins.[4] This microprocessor contains distributed on-chip decoupling capacitors (decap) as well as a 1-μm package decap. There are 144-bit (128-bit data, 16-bit ECC) secondary cache data interface and 72-bit system data interface. Cache and system data pins are interleaved for efficient multiplexing. The vias have to arrayed orthogonal to the current flow. HP's PA-8000 has a flip-chip package, which

enables low resistance, less inductance, and larger off-chip cache support. There are 704 I/O signals and 1200 power and ground bumps in the 1085-pin package. Each package pin fans out to multiple bumps.[6] PowerPC™ has a 255-pin CBGA with C4 technology.[7] 431 C4's are distributed around the periphery. There are 104 VDD and GND internal C4's. The C4 placement is done for optimal L2 cache interface.

There is a debate about moving from high-cost ceramic to low-cost plastic packaging. Ceramic ball grid arrays suffer from 50% propagation speed degradation due to high dielectric constant (10). There is a trend to move toward plastic. However, ceramic is advantageous in thermal conductivity and it supports high I/O flip-chip packaging.

Technology Process

The whole microprocessor layout is driven by the underlying technology process. The process engineers decide the materials for dielectric, doping, isolation, metal, via, etc. and design the physical properties of various lithographic layers. There has to be close cooperation between layout designers and process engineers. Early process information and timely updates of technology parameters are provided to the design teams, and a feedback about the effect of parameters on layout is provided to the process teams. Major process features are managed throughout the design process. This way, a design can be better optimized for process, and future scaling issues can be uncovered.

The main process features that affect a layout engineer are metal width, pitch and spacing specs, via specs, and I/O locations. Figure 62.5(a) shows a sample multi-layer routing inside a chip. Whenever two metal rails on adjacent layers have to be connected, a via needs to be dropped between them. Figure 62.5(b) illustrates how a via is placed. The via specs include the type of a via (stacked, staggered), coverage of via (landed, unlanded, point, bar, arrayed), bottom layer enclosure, top layer enclosure, and the via width. In today's microprocessors, there is a need for metal planarization. Some manufacturers are actually adding planarization metal layers between the usual metal layers for fabrication as well as shielding. Aluminum was the most common metal for fabrication. IBM has been successful in getting copper to work instead of aluminum. The results show a 30% decrease in interconnect delay.

The process designers perform what-if analyses and design sensitivity studies of all of the process parameters on the basis of early description of the chip with major datapath and bus modeling, net constraints, topology, routing, and coupled noise inside the package. The circuit speed is inversely proportional to the physical scale factor. Aggressive process scaling makes manufacturing difficult. On the other hand, slack in the parameters may cause the die size to increase. We have listed some of the process numbers in today's leading microprocessors in this section. The feature sizes are getting very small and many unknown physical effects have started showing up.[22] The processes are so complicated to correctly obey during the design, an abstraction called design rules is generated for the layout engineers. Design rules are constraints imposed on the geometry or topology of layouts and are derived from basic physics of circuit operation such as electromigration, current carrying capacity, junction breakdown, or

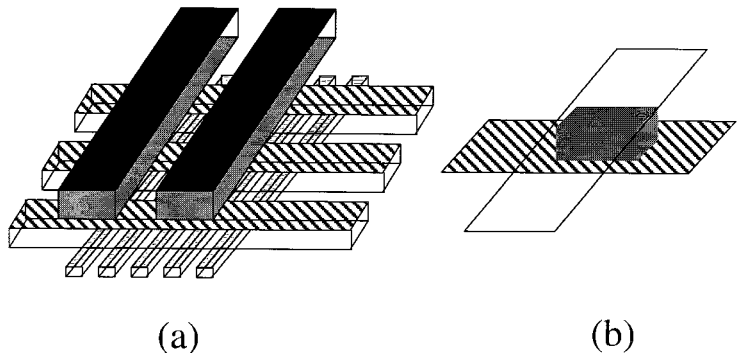

FIGURE 62.5 A view of multi-layer routing and a simple via.

punch-through, and limits on fabrication such as minimum widths, spacing requirements, misalignments during processing, and planarization. The rules reflect a compromise between fully exploiting the fabrication process and producing a robust design on target.[5]

As feature sizes are decreasing, optical lithography will need to be replaced with deep-UV, X-ray, or electron beam techniques for features sizes below 0.15 μm.[20] It was feared that quantum effects will start showing up below 0.1 μm. However, IBM has successfully fabricated a 0.08-μm chip in the laboratory without seeing quantum effects. Another physical limit may be the thickness of the gate oxide. The thickness has dropped to a few atoms. It is soon going to hit a fundamental quantum limit.

Alpha 21264 has 0.35-μm feature size, 0.25-μm effective channel length, and 6-nm gate oxide. It has four metal layers with two reference planes. All metal layers are AlCu. Their width/pitches are 0.62/1.225, 0.62/1.225, 1.53/2.8, and 1.53/2.8 μm, respectively.[4] Two thick aluminum planes are added to the process in order to avoid cycle-to-cycle current variations There is a ground reference plane between metal2 and metal3, and a VDD reference plane above metal4. Nearly the entire die is available for power distribution due to the reference planes. The planes also avoid inductive and capacitive coupling.[8]

PowerPC™ has 0.3-μm feature size, 0.18-μm effective channel length, 5-nm gate oxide thickness, and a five-layer process with tungsten local interconnect and tungsten vias.[7] The metal widths/pitches are 0.56/0.98, 0.63/1.26, 0.63/1.26, 0.63/1.26, and 1.89/3.78 μm, respectively.

HP-8000 has 0.5-μm feature size and 0.29-μm effective channel length.[6] There is a heavy investment in the process design for future scaling of interconnect and devices. There are five metal layers, the bottom two for local fine routing, metal3 and metal4 for global low resistive routing, and metal5 reserved for power and clock. The author could not find published detailed metal specs for this microprocessor.

Intel Pentium II is fabricated with a 0.25-μm CMOS four-layer process.[23] The metal width/pitches are 0.40/1.44, .64/1.36, .64/1.44, and 1.04/2.28 μm, respectively. The two lower metal layers are usually used in block-level layout, metal3 is primarily used for global routing, and metal4 is used for top-level chip power routing.

62.4 Chip Planning

As explained in Section 62.2, chip planning is the master step during the layout of a microprocessor. During the early stages of design, the planning team has to assign area, routing, and timing budgets to individual blocks on the basis of some estimation methods. Top-down constraints are imposed on the individual blocks. During the block layout, continuous bottom-up feedback to the planner is necessary in order to validate or update the imposed constraints and budgets. Once all the blocks have been laid out and their accurate physical information is available, the chip planning team has to assemble the full chip layout subject to the architectural and process specs.

Chip planning involves partitioning the microprocessor into blocks. The finite state machines are considered random control logic and partitioned into automatically synthesizable blocks. Regular structures like arrays, memories, and datapath require careful signal routing and pitch matching. They have to be partitioned into modular and regular blocks that can be laid out using full-custom or semi-custom techniques.

IBM adopted a two-level hierarchical approach for the G4 processor.[24] They identified groups of 10,000 to 20,000 non-array transistors as macros. Macros were individually laid out by parallel teams. The macro layouts were simplified and abstracted for floorplanning, place and route, and global extraction. The shapes of individual blocks varied during the design process. The chip planner performed the layouts for global interconnects and physical design of the entire chip. The global environment was abstracted down to the block level. A representation of global wires was added overlaying a block. That included global timing at block interfaces, arrival times with phase tags at primary inputs (PI), required times with phase tags at primary outputs (PO), PI resistances, and PO capacitances. Capacitive loading at the outputs was based on preliminary floorplan analysis. Each block was allowed sufficient wiring and cell area. The control logic was synthesized with high-performance standard cell library; datapaths were designed with semi-custom macros. Caches, Memrory Management Unit (MMU) arrays, branch unit

arrays, Phase-Locked Loop (PLL), and Delay-Locked Loop (DLL) were all full-custom layouts.[7] There were three distinct physical design styles optimizing for different goals, namely, full custom for high performance and density, structured custom for datapath, and fully automated for control logic. The floorplan was flexible throughout the methodology. There are 44% memory arrays, 21% datapath, 15% control, 11% I/O, 9% miscellaneous blocks on the die. Final layout was completely hierarchical with no limits on the levels of hierarchy involved inside a block. The block layouts had to conform to a top abstracted global shadow of interconnects and blockages. The layout engineers performed post-placement re-tuning and post-placement optimization for clock and scan chains.

For the 1-GHz integer PowerPC™ microprocessor, the planning team at IBM enforced strict partitioning on latch boundaries for global timing closure.[5] The planning team constructed a layout description view of the mega-cells containing physical shape data of the pads, power buses, clock spine, and global interconnects. At the block level, pin locations, capacitance, and blockages were available. The layouts were created by hand due to the very high-performance requirements of the chip.

We describe the major steps during the planing stages, namely, floorplanning, power planning, clock planning, and bus routing. These steps are absolutely essential during microprocessor design. Due to the complicated constraints, continuous intelligent updates, and top-down/bottom-up communication, manual intervention is required.

Floorplanning

Floorplannig is the task of placing different blocks in the chip so as to fit them in the minimum possible area with minimum empty space. It must fill the chip as close to the brim as possible. Figure 62.6 shows an example of floorplanning. The blocks on the left hand side are fitted inside the chip on the right. The reader can see that there is very little empty space on the chip. The blocks may be flexible and their orientation not fixed. Due to the dominance of interconnect in the overall delay on the chip, today's floorplanning techniques also try to minimize global connectivity and critical net lengths.

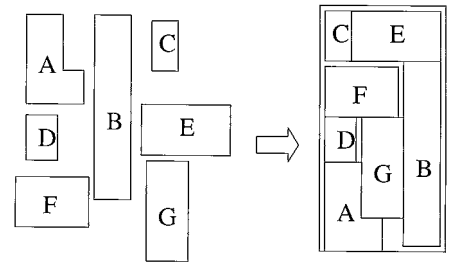

FIGURE 62.6 An example of floorplanning.

There are many CAD tools available for floorplanning from the EDA vendors. The survey of all such tools is available.[25] The tools are attempting to bridge the gap between synthesis and layout. All of the automatic tools are independent of IC design style. There are two types of floorplanners. Functional floorplanners operate at the RTL level for timing management and constraints generation. The goal of physical floorplanners is to minimize die size, maximize routability, and optimize pin locations. Some physical floorplanners perform placement inside floorplanning. As explained in the routing section, when channel routing is used, the die size is unpredictable. The floorplanners cannot estimate routing accurately. Hence, channel allocation on the die is very difficult. Table 62.2 summarizes the CAD tools available for floorplannning.

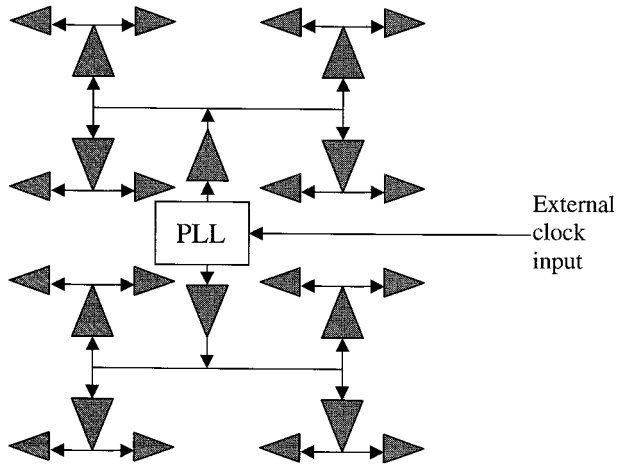

FIGURE 62.7 A sample global clock buffered H-tree.

Clock Planning

Clock is a global signal and clock lines have to be very long. Many elements in high-frequency microprocessors are continuously being clocked. Different blocks on the same die may operate at different frequencies. Multiple clocks are generated internally and there is a need for global synchronization. Clock methodology has to be carefully planned and the individual clocks have to be generated and routed from the chip's main phase-locked loop (PLL) to the individual sink elements. The delays and skews (defined later) have to exactly match at every sink point. There are two major types of clock networks, namely, trees and grids. Figure 62.7 illustrates a modified H-tree with clock buffers. Figure 62.8 shows a clock grid used in Alpha processors. Most of the power consumption inside today's high-frequency processors is in their clock networks. In order to reduce the chip power, there are architectural modifications to shut off some part of the chip. This is achieved by clock gating. The clock gator routing has become an integral part of clock routing.

Let us explain the some terms used in clock design. Clock skew is the temporal variation of the same clock edge arriving at various locations on the die. Clock jitter is the temporal variation of consecutive clock edges arriving at the same location. Clock delay is the delay from the source PLL to the sink element. Both skew and jitter have a direct relation to clock delay. Globally synchronous behavior dictates minimum skew, minimum jitter, and equal delay.

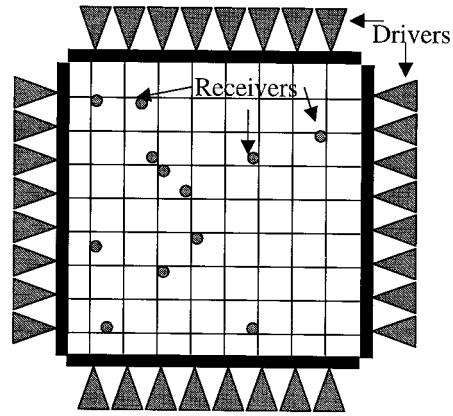

FIGURE 62.8 A sample clock grid.

Clock grids, being perfectly symmetric, achieve very low skews, but they need high routing resources and stacked vias, and cause signal reflections. The wire loading on driving buffers feeding to the grid is also high. This requires large buffer arrays that occupy significant device area. Electrical analysis of grids is more difficult than trees. Buffered trees are preferred in high-performance microprocessors because they achieve acceptable skews and delays with low routing resource usage.

Ideally, the skew should be 0. However, there are many unknowns due to processing and randomness in manufacturing. Instead of matching the clock receivers exactly, a skew budget is assigned. In high-performance microprocessor designs, there is usually a global clock routing scheme (GCLK) that spawns into multiple matched clock points in various regions on the chip. Inside the region, careful clock routing is performed to match the clock delay within assigned skew budgets.

Alpha 21264 has a modified H-tree. On-chip PLL dissipates power continuously, 40% of the chip power dissipation was measured to be in the clocking network. Reduction of clock power was a primary concern to reduce overall chip power.[26] There is a GCLK network that distributes clock to local clock buffers. GCLK is shielded with VCC or VSS throughout the die.[4] GCLK skew is 70 ps, with 50% duty cycle and uniform edge rate.[8] The clock routing is done on metal3 and metal4. In earlier Alpha designs, a clock grid was used for effective skew minimization. The grid consumed most of the metal3 and metal4 routing resources. In 21264, there is a savings of 10 W power over previous grid techniques. Also, significantly less metal3 and metal4 is used for clock routing. This proved that a less aggressive skew target can be achieved with a sparser grid and smaller drivers. The new technique also helped power and ground networks by spreading out the large clock drivers across the die.

HP-8000 also has a modified H-tree for clock routing.[6,18] External clock is delivered to the chip PLL through a C4 bump. The microprocessor has a three-level clock network. There is a modified H-tree that routes GCLK from PLL to 12 secondary buffers strategically placed at various critical locations in various regions on the chip. The output of the receiver is routed to matched wire lengths to a second level of clock buffers. The third level involves 7000 clock gators that gate the clock routing from the buffers to local clock receivers. There are many flavors of gated clocks on the chip. There is a 170-ps skew across the die. Due to a large die, PA8000 buffers were designed to minimize process variations.

In PowerPC™, a PLL is used for internal GCLK and a DLL is used for external SRAM L2 interface.[7] There is a semi-balanced H-tree network from PLL to local regenerators. Semi-balanced means the design was adjusted for variable skew up to 55 ps from main PLL to H-tree sinks. There are three variations of masking 486 local clock regenerators. The overall skew across the die was 300 ps.

Many CAD vendors have attempted to provide clock routing technologies. The microprocessor community is very paranoid about clock and clocking power. The designers prefer hand-crafting the whole clock network.

Power Planning

Every gate on the die needs the power and ground signals. Power arrives at many chip-level input pins or C4 bumps and is directly connected to the topmost metal layer. Routing power and ground from the topmost layer to each and every gate on the die without consuming too many routing resources, not causing voltage drops in the power network, and using effective shielding techniques constitutes the power planning problem. A high-performance power distribution scheme must allow for all circuits on the die to receive a constant power reference. Variation in the reference will cause noise problems, subthreshold conduction, latch-up, and variable voltage swings

The switching speed of CMOS circuits in the first order is inversely proportional to the drain-to-source current of the transistor (I_{ds}),in the linear region:

$$t = C\int \frac{dV}{I_{ds}}$$

where, C is the loading capacitance, V is the output voltage, and t is the switching delay. I_{ds}, in turn, depends on the IR drop (V_{drop}) as:

$$I_{ds} \propto \left(V_{gs} - V_t - V_{drop}\right)$$

where V_{gs} is the gate to source voltage and V_t is the threshold voltage of the MOS transistor. Therefore, achieving the highest switching speed requires distributing the power network from the pads at the periphery of the die or C4 bumps to the sources of the transistors with minimal IR drop due to routing. The problem of reducing V_{drop} is modeled in terms of minimum allowable voltage at the source and the difference between Vdd and Vss acceptable at the sinks. All physical stages from pads to pins have to be considered. Some losses, like tolerance of the power supply, the tester guardband, and power drop in the package, are out of the designer's control. The remaining IR drop budget is divided among global and local power meshes.

The designers at Motorola have provided a nice overview of power routing in Ref. 27. Their design of PowerPC™ power grid continued across all design stages. A robust grid design was required to handle the possible switching and large current flow into the power and ground networks. Voltage drops in power grid cause noise, degrading performance, high average current densities, and undesirable wearing of metal. The problem was to design a grid achieving perfect voltage regulation at all demand points on the chip, irrespective of switching activities and using minimum metal layers. The PowerPC™ processor family has a hierarchy of five or six metal layers for power distribution. Structure, size, and layout of the power grid had to be done early in the design phase in the presence of many unknowns and insufficient data. The variability continued until the end of design cycle. All commercial tools depend on post-layout power grid analysis after the physical data is available. One cannot change the power plan at that stage because too much is at stake toward the end. Hence, Motorola designers used power analysis tools at every stage. They generated applicable constant models for every stage. There are millions of demand points in a typical microprocessor. One cannot simulate all non-linear devices with a non-ideal power grid. Therefore, the approach was as follows. They simulated non-linear devices with fixed power, converted all devices to current sources, and then analyzed the power grid. There was still a large linear system to handle. So, a hierarchical approach was used. Before the floorplaning stage, the locations of clean VCC/GND pads and power grid widths/pitches were decided on the basis of design rules and via styles (point or bar vias). After the floorplan was fixed, all blocks were given block power service terminals. Wires that connect global power to block power were also modeled in the service terminals. Power was routed inside the blocks and PowerMill simulations were used for validation.

Alpha 21264 operates at a high frequency and has a large die as listed in Table 62.1. The large die and high frequency lead to high power supply currents. This has a serious effect on power, clock, and ground networks.[3,4] Power dissipation was the sole factor limiting chip complexity and size; 198 out of 587 chip-level pins are VDD and VSS pins. Supply current has doubled during every generation of Alpha microprocessor. Hence, a very complex power distribution was required. In order to meet very large cycle-to-cycle current variations, two thick low-resistance aluminum planes were added to the process.[8] One plane was placed between metal2 and metal3 connected to VSS, and the other above the topmost metal4 connected to VDD. Nearly the entire die area was available for power distribution. This helped in inductive and capacitive decoupling, reduced on-chip crosstalk, and presented excellent current returns paths for analysis and minimized inductive noise.

UltraSparce-I™ has 288 power and ground pins out of 520.[9] The methodology involved an early identification of excessive voltage drop points and seamless integration of power distribution and CAD tools. Correct-by-construction power grid design was done throughout the design cycle. The power networks were designed for cell libraries and functional blocks. They were reliability-driven designs before mask generation. This enabled efficient distribution of the Vdd and Vss networks on a large die. Minimization of area overhead, as well as IR drop for power distribution, was considered throughout the design cycle. Parts of power distribution network are incorporated into the standard cell library layouts.

CAD tools were used for the composition of standard cell and datapath with correct-by-construction power interconnections. The methodology was designed to be scalable to future generations. Estimation and budgeting of IR drops was done across the chip. Metal4 was the only over-the-block routing layer. It was used for routing power from peripheral I/O pads to individual functional units. It was the primary means of distributing power. The power distribution should not constrain the floorplan. Hence, two meshes were laid out: a top-down global mesh and an in-cell local mesh. This enabled block movement during placement because they have only local mesh. As long as the local power mesh crosses the global mesh, the power can be distributed inside the block. Metal3 local power routes have to be orthogonal to global metal4 power. The direction of metal1 and metal2 do not matter. The global chip is divided into two parts. In part 1, metal3 was vertical and metal4 was horizontal. The opposite directions were selected for the second part. A block could be moved half the die distance because of two types of regions for power on the chip. The power grid on three metal layers with interconnections, number of vias, and via types was simulated using HSPICE to determine the widths, spacings, and number of vias of the power grid. Vias had to be arrayed orthogonal to the current flow. There was a 90-mV IR drop from M3-M4 via to the source of a cell. Additional problems existed because the metal2 width is fixed in UltraSparc™. Up to a certain drive strength, the metal2 power rail was 2.5 μm. Beyond that, additional rail of 1 μm was added. The locations of clock receivers changed throughout the design process. They had to be shifted to align power.

Bus Routing

The author considers bus routing a critical problem and it needs the same attention as power or clock routing. The problem arises due to today's superscalar, large bit-width microprocessor architectures. The chip planners design the clock and power plans and floorplan the chip very efficiently to minimize empty space on the die, but leave limited routing resources on the top layers to route busses. There is a simple analogy to understand this problem. Whenever a city is being planned, the roads are constructed before the individual buildings. In microprocessor layout, busses must be planned before the blocks are laid out.

A bus, by nature, is bi-directional and must have matching characteristics at all data bits. There should be a matching RC delay viewed from both ends. It connects a wide datapath to another. If it is routed straight from one datapath block to another, then the characteristics match; but it is not always feasible on the die to achieve straight routes. Whenever there is a directional change, via delay comes into picture. The delays due to via and uneven lengths for all the bit-lines in the bus cause a mismatch across the bits of the bus. Figure 62.9 depicts a simple technique called bus interleaving, employed in today's microprocessors, to achieve matching lengths.

The problems do not end there. Bus interleaving may match the lengths across the bit-widths, but it does not guarantee matching environment for all the bit-lines. Crosstalk due to adjacent layers or busses may cause mismatch among the bit-lines. In differential circuits, very low voltage busses are routed with long routing lengths. Alpha designers had to carefully route low swing busses in 21264 to minimize all differential noise effects.[3] These types of busses need shielding to protect the low-voltage signals. If all bits in a bus switch simultaneously, large current variations inject inductive noise into the neighboring signal lines. Hence, other signals also need to be shielded from active busses.

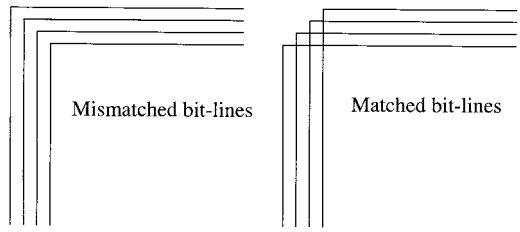

FIGURE 62.9 Bus interleaving.

Cell Libraries

A major step toward high performance is the availability of a fast ready-to-use circuit library. Due to large and complex circuit sizes, transistor-level layout is formidable. All microprocessor teams design a family of logic gates to perform certain logic operations. These gates become the bottom level units in the netlist hierarchy. They serve as a level of abstraction higher than a basic transistor. Predefined logic functions help in automatic synthesis. The gates may differ in their circuit family, logic functions, drive strength, power consumption, internal layout, placement of cell interface ports, power rails, etc. The number of different cells available in the design libraries can be as high as 2000. The libraries offer the most common predefined building blocks of logic and low-level analog and I/O functions. Complex designs require multiple libraries. The libraries enable fast time to market, aid synthesis in logic minimization, and provide an efficient representation of logic in hardware description languages.

Block-level layout tools support cell-based layout. They need the cells to be of a certain height and perform fast row-based layout. The block-level layout tools are very mature and fast. Many microprocessor design teams design their libraries to be directly usable by block-level layout tools. There are many CAD tools available for cell designs and cell-based block designs. The most common approach is to develop a different library for each process and migrate the design to match the library. Process-specific libraries lead to small die size with high performance. There are tools available on the market for automatic process porting, but the portability across processes causes performance and area degradation.

Microprocessor manufacturers have their in-house libraries designed and optimized for proprietary processes. The cell libraries have to be designed concurrently with the process design and they must be ready before the block-level design begins. The libraries for datapath and control can differ in styles, size, and routing resource utilization. As datapath is considered crucial to a microprocessor, datapath libraries may not support porosity, but the control logic library has to provide porosity for neighboring datapath cells to use some of its routing resources. Thus, datapath libraries are designed for higher performance than control. In UltraSparc-I™ processor, the design team at Sun Microsystems used separate standard cells for datapath and control.[9]

In this section, we present various layout aspects of cell library design. The reader is requested to refer to Refs. 13-15 for circuit aspects of libraries.

Circuit Family

The most common circuit family is CMOS. They are very popular because of the static nature. It is a fully restored logic in which output either sets at Vdd or Vss. The rise and fall times are of the same order. This family has almost zero static power dissipation. The main advantage in layout is its symmetric nature, nice separation of n and p transistors, and ability to produce regular layouts. Figure 62.10 shows a three-input CMOS NOR library cell.

The other popular circuit family in high-performance microprocessors is that of dynamic circuits. The inputs feed into the n-stack and not the p-stack. There is a precharge p-transistor and a smaller keeper p-transistor in the p-stack. So, the number of transistors in p-stack is exactly 2. The dynamic circuits need careful analysis and verification, but allow wide OR structures, less fan-in and fan-out capacitance. The switching point is determined by the nMos threshold and there is no crossover current during output transition. As there is less loading on the inputs, this circuit family is very fast. As one can see in Fig. 62.7, the area occupied by the p-stack is very large compared to the n-stack in static CMOS. Domino logic families have a significant area advantage over static if the same static netlist can be synthesized in monotonic domino gates. However, layout of domino gates is not trivial. Every gate needs a clock routed to it. As the family does not support fully restoring logic, the domino gate output needs to be shielded from external noise sources. Additional circuitry may be required to avoid charge-sharing and noise problems.

Other circuit families include BiCMOS, in which bipolar transistors are used for high speed and CMOS transistors are used for low power, high-density gates; differential cascode voltage switch logic (DVSL),

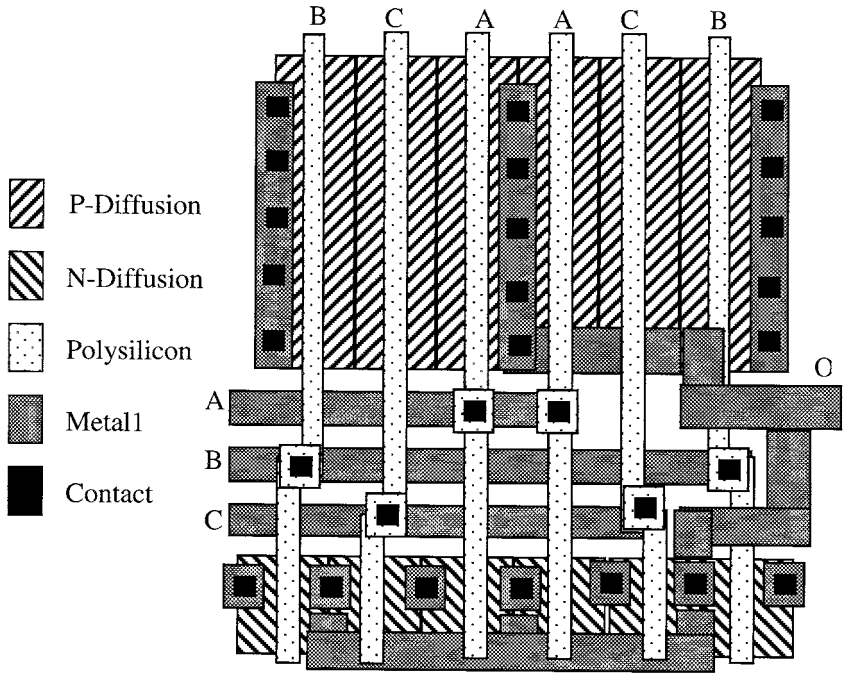

FIGURE 62.10 A three-input CMOS NOR layout.

in which differential output logic uses positive feedback for speed-up; differential split-level logic (DSL), in which load is used to reduce output voltage swing; and pass transistor logic (PTL), in which complex logic such as muxing is easily supported.

Cell Layout Architecture

There are various issues involved in deciding how a cell should be laid out. Let us look at some of the issues.

Cell height: If row-based block layout tools are going to be used, then the cells should be designed to have standard heights. This approach also helps in placement during full-custom layout. Basically, constraining one dimension (height) enables better optimization for the other one (width). However, snapping to a particular height may cause unnecessary waste of active transistor area for cells with small drive strengths.

Diffusion orientation: Manufacturing may cause some variation in cell geometries. In order to achieve consistent variations across all transistors inside a cell, process technology may dictate fixed orientation of transistors.

Metal usage: Cells are part of a larger block. They should allow block-level over-the-cell routing. Guidelines for strict metal usage must be followed while laying out cells. Some cell guidelines may force single-metal usage inside the cell.

Power: Cells must adhere to the block-level power grid. They should either instantiate power pins internally and include the power pins in the interface view, or should enable block-level power routing by abutment. In UltraSparc-I™, there was a clear separation of metal usage between datapath and control standard cells. The power in control was distributed on horizontal metal1 with adjacent cells abutting the rails. Metal2 was only used to connect metal1 to metal3 power. Metal2 power hook-up could have been longer for better power delivery, but it would consume routing resources. The datapath library had vertical metal2 abutting for power and it was directly connected to metal3 power grid.[9]

Cell abstraction: Internal layout details of a cell are not required at the block level. Cells should be abstracted to provide a simplified view of interface pins (ports), power pins, and metal obstructions. Design guidelines may have requirements for coherent cell abstract views. Multiple cell families may differ in their internal layout, but there may be a need for generating consistent abstract views for easy placement and routing.

Port placement: If channel routers are used, then interface ports must lie at the cell boundaries. For area routers, the ports can be either at the boundary or at internal locations where there is enough space to drop a via from a higher metal layer passing over the cell.

Gridding: All geometries inside the cell must lie on the manufacturing grid. Some automatic tools may enforce gridding for cell abstracts. In that case, the interface ports must be on a layout routing grid dictated by the tools.

Special requirements: These can include family-specific constraints. A domino cell may need specific clock placement; a different logic cell may need strict layout matching for differential signals, etc.

Stretchability: Consider two versions of the CMOS NOR3 gate as shown in Fig. 62.11. As we can see, the widths of the transistors changed, but the overall layout looks very similar. This is the idea behind stretchability and soft libraries. Generate new cells from a basic cell, depending on the drive strength required. In the G4 processor, IBM design team used a continuously tunable, parameterized standard cell library with logic functions chosen for performance.[24] The cells were available in discrete levels or sizes. The rules were continuously tunable. Parameterization was done for delay, not size. They also had a parameterized domino library. Beta and gain tuning enabled delay optimization during placement, even after initial placement. Changes due to actual routing were handled as engineering change orders (ECOs). The cell layouts were generated from soft libraries. The automatic generator concentrated on simple static cells. The most complex cell was a 2×2 AO/OA. The soft library also allowed customization of cell images. The cell generator generated a standard set of sizes, which were selected and used over the entire chip. This approach loses the cell library notion. So, the layout was completely flattened. Some cells were also non-parameterized. Schematics were generated on the basis of tuned library and flattened layout. This basically led to a block-level mega-cell just like a standard cell.

Characterization: As we mentioned before, circuit aspects of cell design are out of the scope of this section. However, we briefly explain characterization of the cell because it impacts layout. The detailed electrical parasitics of cell layout are extracted and the behavior of each library cell is

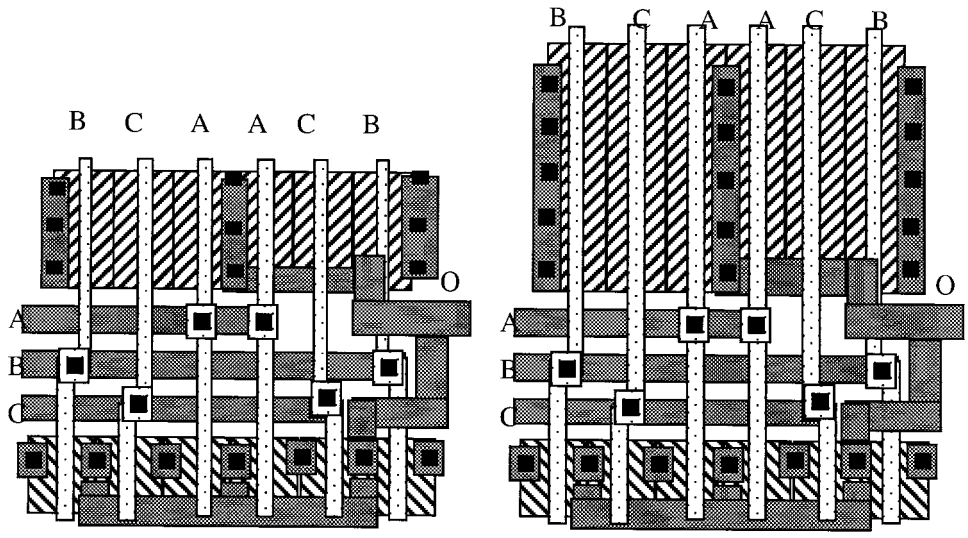

FIGURE 62.11 Cell stretching.

individually characterized over a range of output loads and input rise/fall times. The parameters tracked during this process are propagation delay, output rise/fall times, and peak/average current. The characterization can be represented as a closed-form equation of input rise/fall times, output loading, and device characteristics inside the cell. Another popular method involves generating look-up table models for the equations. The tables need interpolation methods. Using the process data and electromigration limits, the width of signal/supply rails and minimum number of contacts were determined in UltraSparc-I™. These values are formulated as a set of layout verification rules for post-layout checks.[9] In the PowerPC microprocessor, all custom circuits and library elements were simulated over various process corners and operating conditions to guarantee reliable operation, sufficient design margin, and sufficient scalability.[7]

Mega-cells: Today's superscalar microprocessors have regular and modular architectures. Not only standard cells, but large layout blocks such as clock drivers, ROMs, and ALUs can also be repeated at several locations on the die. Mega-cells is a concept that generalizes standard cells to a larger size. This automatically converts logic function to a datapath function. Automatic layout is not recommended for mega-cells because of the internal irregularity. Layout optimization of a mega-cell is done by full-custom technique, which is time-consuming; but if it is used multiple times on the die, the effort pays off.

Cell Synthesis

As mentioned earlier in this section, there are CAD vendors supporting library generation tools. Cadabra (www.cadabratech.com) is a leading vendor in this area with its CLASSIC tool suite. Another notable vendor tool is Tempest-Cell from Sycon Design Inc. (www.sycon-design.com). A very good overview of such tools and external library vendors is available in Ref. 28. The idea of external libraries originated from IC databooks. In the past, ready-to-use ICs were available from various vendors with fully detailed electrical characteristics. Now, the same concept is applied to cell libraries, which are not ICs, but ready-to-use layouts that can be included in bigger circuits. The libraries are designed specific to a particular process and gate family, but they can be ported to other architectures. Automatic process migration tools are available on the market. Complex combinational and sequential functions are available in the libraries with varying electrical characteristics comprising of strengths, fan-out, load matching, timing, power, area attributes, and different views. The library vendors also provide synthesis tools that work with logic design teams and enable usage of new cells.

Block-Level Layout

A block is a physically and logically separated circuit inside a microprocessor that performs a specific arithmetic, logic, storage, or control function. Roughly speaking, a full-custom technique is used for layout of regular structures, like arrays and datapath; whereas, automatic tools are used for random control logic consisting of finite state machines. Block-level layout is a very thoroughly researched and mature area. The author has biased the presentation in this section toward automation and CAD tools. Full-custom techniques accept more constraints, but approximately follow the same methodology.

Block-level layout needs careful tracking of all pieces.[29] Due to its hierarchical nature, strict signal and net naming conventions must be followed. The blocks' interface view may be a little fuzzy. Where does a block design end? At the output pin of the current block or at the input pin of the block it is feeding to? There may be some logic that cannot be classified into any of the types and it is not large enough to be considered a separate block of its own. Such logic is called glue logic. Glue logic at the chip level may actually be tightly coupled to lower-level gates. It needs physical proximity to the lower level. Every block may be required to include some part of such glue logic during layout.

In IBM's G4 microprocessor, custom layout was used for dataflow stacks and arrays. A semi-custom cell-based technique was used for control logic.[24] Capacitive loading at the block outputs was based on preliminary floorplan analysis. During the early phase of the design, layout-dependent device models were used for block-level optimization. For UltraSparc™, layout of mega-cells and memory cells was

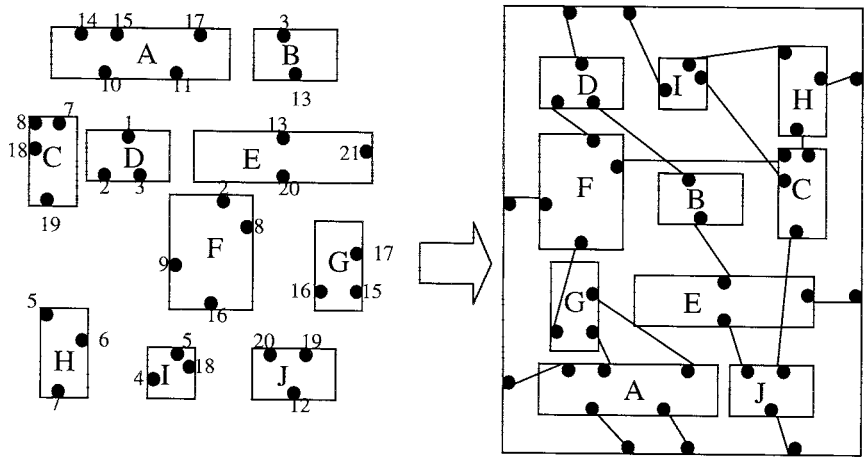

FIGURE 62.12 Example of placement.

done in parallel with RTL design.[30] Initial layout iterations were performed with estimated area and boundaries. There were concurrent chip and block-level designs as well as concurrent datapath and standard cell designs. The concurrency yielded faster turn-around time for logical-physical design iterations. Critical net routing and detailed routing was done after the block-level layout iterations converged.

A survey of CAD tools available on the market for block-level layout is included in Table 62.3. The author presents various steps in the block-level layout process in the following sections. Constraints associated with different block types are also included in the individual sections, wherever applicable.

Placement

The chip planner partitions the circuit into different blocks. Each block consists of a netlist of standard cells or subblocks, whose physical and electrical characteristics are known. For the sake of simplicity, let us only consider a netlist of cells inside the block. The area occupied by each block can be estimated and the number of block-level I/Os (pins) required by each block is known. During the placement step, all of the movable pins of the block and internal cells are positioned on the layout surface, in such fashion that no two cells are overlapping and enough space is left for interconnection among the cells.

Figure 62.12 illustrates an example placement of a netlist. The numbers next to the pins of the cells on the left side specify the nets they are connected to. The placement problem is stated as follows: given an electrical circuit consisting of cells, and a netlist interconnecting terminals on these cells and on the periphery of the block itself, construct a layout indicating positions of these blocks such that all the nets can be routed and the total layout area of the block is minimized. For high-performance microprocessors, an alternative objective is chosen where the placement is optimized to minimize the total delay of the circuit by minimizing lengths of all critical paths subject to a fixed block area constraint. In full-custom style, the placement problem is a packing problem where cells of different sizes and shapes are packed inside the block area.

Various factors affect the decisions taken during placement. We discuss some of the factors. All microprocessor designers may face many additional constraints due to the circuit families, types of libraries, layout methodology, and schedule.

Shape of the cells: In automatic placement tools, the cell are assumed to be rectangular. If the real cell is not rectangular, it may be snapped to an overlapping rectangle. The snapping tends to increase block area. Cells may be flexible and different aspect ratios may be available for each cell. Row-based placement approaches also need standardized height for all the cells.

Routing considerations: All of the tools and algorithms for placement are routing driven. Their objective is to estimate routing lengths and congestions at the placement stage and avoid

unroutability. The cells have to be spaced to allow routing completion. If over-the-cell (OTC) routes are used, then the spacing may be avoided.

Performance: For high-performance circuits, critical nets must be routed within their timing budgets. The placement tool has to operate with a fast and accurate timing analyzer to evaluate various decisions taken during placement. This approach is called performance-driven placement. It forces cells connected to critical nets to be placed very close to each other, which may leave less space for routing that critical net.

Packaging: When the circuit is operational, all cells generate heat. The heat dissipated should be uniform over the entire layout surface of the block. The high power-consuming cells will have to be spaced apart. This approach may directly conflict with performance-driven placement. C4 bumps and power grids may cause some restrictions on allowable locations for some of the cells.

Pre-placed cells: In some cases, the locations of some cells may be fixed or a region may be specified for their placement. For instance, a block-level clock buffer must be at the exact location specified by the clock planner to achieve minimum skew. The placement approach must follow these restrictions.

Special considerations: In microprocessor designs, the placement methodology may be expected to place and sometimes reorder the scan chain. Parts of blocks may be allowed to overlap. Block-level pins may be ordered but not fixed. If the routing plan separates chip and block-level routing layers, there may be areal block-level I/Os in the middle of the layout area.

The CAD algorithms for placement have been thoroughly studied over many decades. The algorithms are classified into simulated annealing-based, partitioning-based, genetic algorithm-based, and mathematical programming-based approaches. All of these algorithms have been extended to performance-driven techniques for microprocessor layouts. For an in-depth analysis of these algorithms, please refer to Refs. 11 and 12.

Global Routing

The placement step determines the exact locations of cells and pins. The nets connecting to those pins have to be routed. The input at a general routing stage consists of a netlist, timing budgets for critical nets, full placement information, and the routing resource specs. Routing resources include available metal layers with obstructions/porosity and their specs include RC delay per unit length on each metal layer and RC delay for each type of via. The objective of routing a block in a microprocessor is to achieve routing completion and timing convergence. In other words, the net loads presented by the final routes must be within the timing budgets. In microprocessor layout, routing also involves special treatment for clock nets, power, and ground lines.

The layout area of the block can be divided into smaller regions. They may be the open spaces not occupied by the cells. These open spaces are called channels. If the routing is only allowed in the open spaces, it is called a channel routing problem. Due to multiple layers available for routing and areal I/Os, over-the-cell routing has become popular. The approach where the whole region is considered for routing with pins lying anywhere in the layout area is called area routing.

Traditionally, the routing problem is divided into two phases. The first phase is called global routing and generates an approximate route for each net. It assigns a list of routing regions to each net without specifying the actual geometric layout of wires. The second phase, called detailed routing, will be discussed in the next subsection.

Global routing consists of three phases: region definition, region assignment, and pin assignment. During definition, the regions are decided by partitioning the routing space into different regions. Each region has a capacity, which means the maximum number of nets that can pass through that region on a layer in a direction. The routing capacity of a region is a function of design rules and wire geometries. During the second phase, nets or parts if the nets, are assigned to various regions, depending on the current occupancy and the net criticality. This phase identifies a sequence of regions through which a net will be routed. Once the region assignment is done, pins are assigned at the boundary of the regions

so that the detailed routing can proceed on each region independently. As long as the pins are fixed at the region boundaries, the whole layout area will be fully connected by abutment.

There is a slight difference between full-custom and automatic layout styles for global routing. In full custom, since regions can be expanded, some violations of region capacities is allowed. However, too many violations may enforce a re-placement.

Some of the factors affecting the decisions taken at global routing are:

Block I/O: Location of block I/Os and their distribution along the periphery may affect region definitions. Areal I/Os need special considerations because they may not lie at a region boundary.

Nets: Multi-terminal nets need special consideration during global routing. There is a different class of algorithms to handle such nets.

Pre-routes: There may be pre-routed nets, like clock, already occupying region capacities. A completely unconnected bus may be passing through the block. Such pre-routes have to be correctly modeled in the region definition.

Performance: Critical nets may have a length and via bound. The number of vias must be minimized for such nets. Critical nets may also need shielding, so they have to be routed next to a power route. Some nets may have spacing requirements with respect to other nets. Some nets may be wider than others, and the region occupancy must include the extra resources required for wide routes.

Detailed router: The type and style of detailed routing affects the decisions taken during the global routing. The detailed router may be a channel router, for which pins must be placed on the opposite sides of the region. In some cases, the detailed router may need information about via bounds from the global router.

Global routing is typically studied as a graph problem. There are three types of graph models to represent regions and their capacities, namely, the grid graph model, the checker board model, and the channel intersection graph model. For two terminal nets, there are three types of global routing algorithms: maze routing, line-probe, and shortest path based. For multi-terminal routing, Steiner tree-based approaches are very popular. There are some mathematical formulations for global routing; however, they provide solutions on small blocks only.

Detailed Routing

Global routing uses the original net information and separates the routing problem into a set of restricted region routing problems. A routing region can be a channel (pins on opposite sides), a 2-D switchbox (pins on all sides in 2-D), or a 3-D switchbox (pins on all faces in 3-D). The detailed router places the actual wire segments within the regions, thus completing the required connection between the cells. There is a limited scope for the regions to expand into other regions. A detailed router has to intelligently order the regions to be routed, depending on the occupancy and criticality. Factors affecting detailed routing are:

Metal layers: Traditionally, two or three routing layers were available at the block-level detailed routing. There are numerous techniques published for two- or three-layer detailed routing. Today's microprocessors consist of four or five metal layers. The number of layers is likely to increase to ten in the near future. A detailed router should fully utilize the available layers. Their widths, spacing, pitch, and electrical requirements must be obeyed. Obstructions must be handled on all metal layers.

Via: The via count is of major concern in detailed routing and must be minimized to improve performance and area. Vias impact manufacturability, cause RC delays, signal reflections, and transmission line effects. They also make post-layout compaction difficult.

Nets: Traditionally, a multi-terminal net is decomposed into a set of two terminal nets for ease of routing. Current approaches handle multi-terminal nets directly. Variable-width nets need special attention during detailed routing. In high-performance designs, nets may also be tapered, that is,

the same routing segment of a net may have variable widths. The detailed router should support tapering. Due to the criticality, some nets may be required to be routed across all the regions before the rest of the nets. This breaks the paradigm for sequential region routing, unless such nets are modeled as pre-routes.

Region specs: Depending on the type of the region, pins may be located at various boundaries or faces. Regions may be flexible to some extent. However, the detailed router must try not to exceed the region bounds.

Gridding: A detailed router may assume wire gridding, implying that the pitch of wires on any metal layer is considered fixed. All pins in the regions and on the cell are on the routing grid specified by the detailed router. The layout area can be modeled as an array of grid points. Hence, the routing is very fast. Gridding hinders routing with variable-width variable spacing of metal layers. It can be accomplished at the cost of area. Hence, non-gridded routers are used in microprocessors for critical net routing.

Until the process technology advanced to the point when over-the-cell (OTC) routing became feasible, channel routing was the most popular area of research for CAD. The channel routing approaches are classified into algorithms for a single layer, a single row, two layers, and three layers. Multi-layer channel routing algorithms have also been published. Channel routing approaches can also be extended to switchboxes. The switchbox routing is not guaranteed to complete. A rip-up and re-route utility is added to the detailed routers for switchboxes.

Let us understand some of the routing tools and methodologies followed internal to various microprocessor companies. IBM developed a grid-based router to connect blocks together.[5] For the G4 processor, they employed two strategies. In the first method, chip-level routing was performed without any blockages from the block level.[24] Then, the block level routes tap the chip-level shadows appropriately. This approach was used only where wiring resources were limited. In the alternative method, the wiring tracks were divided between chip and block level. The negative image of each level was available at the other level. Pre-routes were also supported. The second method enables parallel routing effort while the first enables efficient use of wiring resources. Long routes were split at appropriate places and buffers (repeaters) were placed to minimize delays.

In HP's PA-8000, the block router is really pushing the limits of technology. It achieves high routing completion, supports multi-width wires, optimizes the ratio of wire area/block area, has a fast turnaround time, and strictly follows a rigid placement model.[31] The router was originally a channel router with blocks and channels, but it was modified for multiple layers. The placement of C4 I/O bumps is fixed. Changes in locations of bumps may cause alpha-particle emission. Hence, metal5 was not included with other layers during automatic routing. Routing channels were not expandable, but they could be moved. An electrical model of the block I/Os was supplied to the router. The area routing problem was converted to channels with blockages so that an in-house channel router could be used. L-shaped blocks were cut into two rectangular blocks, but intelligent port placement and constraints bound them together so that the same block router was used. In earlier HP processors, the ports were at the block boundary. In PA-8000, over-the-block (OTB) routing was supported. Blocks were considered black-boxes at the chip level and no internals were supplied to the router; however, an abstract virtual grid model of each block was available. The grid model enabled the lowest cost path of a global net to traverse through any region over a block. The router minimized jogging and distributed unavoidable jogs to reduce congestion. A sophisticated net flow optimizer was developed for obstacles, ports inside the block, jog allocation, and optimal exit points to avoid jogging. A density estimator was used for close estimation of detailed routing. It had port models and net characteristics for multi-terminal net routing. The topology of ports and obstacles was negotiated between the chip and block layouts. The OTB router supported variable widths and spacing. A graph theoretic approach was used to allocate trunks in channels with obstacles. The routers did not support crosstalk or delay modeling. When these violations occurred, jog insertion and wrong-side segmenting was employed. The router always finished routing under constrained placement and reported spacing problems.

Compaction

The original idea behind compaction was to improve layout productivity. The designers were free to explore alternative layout strategies and generate a topological design without geometrical details. The compaction tool was expected to produce a correct geometrical design from the topological design that completely satisfied all of the design rules of the manufacturing process.[32] The approaches employing hierarchical compaction helped in chip planning and assembly because the compactors had flexibility to choose interconnections, abutment, routing area, etc.

Today, compactors are used to minimize layout area after detailed routing. They are used as automatic tools or layout aids. Due to excessive area allotment by the chip planner, sub-optimal layout algorithms, or local optimization of internal layout, some vacant space is present in the block layout area. The goal of compaction is to minimize layout without violating design rules, without significant changes to the existing layout topology, and without violating the designer specified constraints.[11] The main idea is to reduce the space between features as much as possible without violating spacing design rules. Compaction can also be used when scaling down a design to a new set of process rules. The features can be regenerated to the new process spec and the empty area around the features can be recovered using compaction.[12]

A compactor needs three things: the initial layout representation, technology information, and a compaction strategy. The same approach can be applied to full-custom and automatic layout styles because there is no apparent difference between the three inputs generated by both styles.

The initial layout is represented as a constraint graph or a virtual grid. The former represents connection and separation rules as linear inequalities, which can be modeled as a weighted directed graph. A separation constraint leads to one inequality, while a connection constraint leads to two. Shadow propagation and scanlines are two examples of techniques to generate constraint graphs. The latter representation requires that each component be attached to a grid line on the layout grid. The minimum distance between grid lines is the maximum separation required between any two features occupying the grid lines. This representation leads to very fast and simple algorithms, but does not produce as good results as the constraint graph representation. All compactors allow the designers to specify additional constraints specific to a circuit.

The most popular strategy is 1-D compaction. The layout is compacted along the *x*-direction, followed by a compaction in the *y*-direction. Longest path or network flow methods are commonly used for 1-D compaction. As the full 2-D view is not available, the results may be inferior to 2-D strategy. The reader should note that the 2-D compaction problem is proven to be NP-complete. The 2-D problem is solved by an integer linear programming technique, whose complexity is exponential. So the 2-D approach is impractical even for moderate-sized circuits. There are 1½-D approaches employing zone refinement techniques, but they change the original topology of the layout.

Hierarchical compaction strategies are used to compact a full chip or large blocks. In this approach, hierarchical input representation is generated at each level of the hierarchy from the bottom up. Initially, leaf-level individual blocks or subblocks are compacted and then layout of group of blocks is compacted. Finally, a flat level compactor can also be used for generating a compact cell library.

CAD Tools

Surveys of the latest CAD tools for block-level layout are available in Refs. 25 and 33. The routers are classified into three stages. Stage 1 routing means point-to-point single-width routing without any electrical info; stage 2 means routing with geometric data and design rules, and stage 3 means interconnect RC aware routing. All tools interact with the floorplan. They consider length, timing, routability, and use automatic cell padding to minimize congestion. Some tools also perform scan chain reordering. Placement with estimated global routing is a very common feature. The tools are very mature and widely used. However, some physical design problems stem less from the technical challenge than from the lack of industry standards. Except for GDSII, there are no standard data formats. One cannot easily represent block boundaries, dimensions, ports, channel locations, connection points, open spaces for OTC across all the tools. Microprocessor layout teams go through strenuous processes to integrate point tools from various vendors to work as a common tool suite.

TABLE 62.3 Currently Available Block-Level Tools

Company	Internet	Tool	Block Type	Description
Arcadia Design Systems	www.arcadiadesign.com	Mustang	Datapath	Regularity extraction and placement
Avant! Corp.	www.avanticorp.com	Apollo	Control, mega-blocks	All path timing-driven place and route
Cadence	www.cadence.com	Silicon Ensemble	Control, mega-blocks	Timing-driven place and route
Cadence	www.cadence.com	IC Craftsman	All	Detailed routing
Duet Technologies	www.duettech.com	Epoch	Control	Placement and timing-driven routing
Everest Design Automation	www.everest-da.com	(Under development)	Control	Interconnect design, physical floorplannig, gridless routing
Gambit Automated Design	www.gambit.com	Grandmaster	Control	Parallel processing-based place and route
Mentor Graphics Corp.	www.mentorg.com	IC Station	Control, mega-blocks	Cell-based place and route
Snaketech, Inc.	www.snaketech.com	Cellsnake	Control	For cell-based ICs
Stanza Systems, Inc.	www.stanzas.com	PolarSLE	All	Custom layout editor with router
Sycon Design, Inc.	www.sycon-design.com	Tempest-Cell	All	Layout synthesis, structured custom style or block-level place and route
Tanner EDA	www.tanner.com	Tanner Tools Pro	Control	Editing, placement, routing, simulation
Timberwolf Systems, Inc.	www.twolf.com	TimberWolf	Control	Placement, global routing, detailed routing

There are three types of constraint driven routing tools: channel routing, area routing, and hybrid routing. In channel routing, the die size is unknown. Hence, they force an additional floorplanning iteration. Area routers try to finish routing even if they violate design rules

The major vendor for block-level placement and routing tools is Cadence (www.cadence.com). It is supplying fundamentally new engines. There is a new timing-driven flow with no need to re-synthesize. Buffer optimization is done during placement. It will soon include an extraction capability and analysis of crosstalk, electromigration, and hot electron effects. The new Warp router eliminates clock skew. Cadence also supplies a detailed router, IC craftsman, capable of shape-based routing. It is a stage 3 router. The warp router will have the same capability soon. Currently available block-level layout tools are presented in Table 62.3. The reader should note that all of the automatic tools also support manual editing. So they can be used as layout editors for full custom techniques.

Physical Verification

Let us re-visit the physical design flow described earlier. The chip planner partitions the chip into blocks, the blocks are floorplanned, critical signals are routed, the blocks are laid out, and finally the chip is assembled. A large database of polygons representing the physical features inside the chip is generated. The chip layout represented in the database must be verified against the high-level architectural goals of the microprocessor, such as frequency, power, manufactuarability, etc. Post-silicon debug is an expensive process. In some cases, editing the manufactured die may be impossible. Physical verification is the last, but very important step during microprocessor layout method. If a serious design rule or timing violation is observed, the entire layout process may have to be re-visited, followed by re-verification.

The reader may be aware of commonly used terms during physical verification: post-layout performance verification (PLPV), design rule checking (DRC), electrical rule checking (ERC), and layout verification system (LVS). ERC and PLPV involve extracting the layout in the form of electrical elements and analyzing the electrical representation of the circuit by simulation methods. Some CAD vendors and

microprocessor design teams are investing in new tools to reveal the full effects of a circuit's parasitic coupling, delays, degradation, signal integrity, crosstalk, IR drops, hot spots from thermal build-up, charge accumulation, electromigration, etc. Simulation and electrical analysis is beyond the scope of this chapter.

There are two types of design rules checked during DRC. The first type are composition rules, which describe how to construct components and wires from the layers that can be fabricated. The other type are spacing rules, which describe how far apart objects in the layout must be for them to be reliably built.[32] Adherence to both types is required during DRC. The rules are checked by expanding the components and wires into rectangles as specified by their design rule views.

Due to the confidential nature of manufacturing process, the exact details of the verification methods are proprietary to the microprocessor manufacturers. There is a significant gap between silicon capabilities and CAD tools on the market.[29] The high-performance requirements need verification to be done at greater levels of detail and accuracy. Due to the large number of transistors in a microprocessor, there is an explosion of layout data. To solve this problem, verification should provide a close interaction between front-end design and back-end layout. It should be able to operate on approximate data available at various stages of the layout to identify potential problems related to power, signal integrity, electromigration, electromagnetic interference, reliability, and thermal effects.

The challenges involved in physical verification and available vendor tools for automatic verification are presented in Ref. 33. These tools are modified inside the microprocessor design teams to conform to the confidential manufacturing and architectural specification. The basic problem suffered by all tools is too much data from accurate physical analysis. In a typical microprocessor, there may be 500,000 nets, which lead to 21 million coupling capacitors and 2.5 million resistances. Hence, fast and accurate verification is a problem. The number of parasitic effects and circuit data is growing with every microprocessor generation. Unless efficient physical verification tools are available, over-engineering will continue to compensate for the uncertainty in final parasitics. Process shrinks are causing more layers, more interconnect, 3-D capacitive effects, and even inductive effects. The lack of efficient verification tools prohibits further feature shrinks. Verification has to be a complex set of algorithms handling large data. There is a need for incremental and hierarchical systems that have new parasitic extractors, circuits analyzers, and optimizers. Some microprocessor layout designers have employed automatic updates of routed edges, non-uniform etching, and remedies for the antenna effect.

Let us discuss some verification approaches followed by leading microprocessor manufacturers. Alpha 21264 includes very high-speed circuits and the layout was full-custom.[8] It needed careful and detailed post-layout electrical verification. No CAD tools capable of handling this were available. Therefore, an internally developed simulator was used. It is non-logic; that is, it checks timing behavior, electrical hazards, reliability, charge sharing, IR noise, interconnect capacitance, noise-induced minority carrier injection, circuit topology violations, dynamic nodes, latches, stack height minimization, leaker usage, fan-in-fan-out restrictions, wireability, beta ratios, races, edge rates, and delays.

The verification for the G4 microprocessor at IBM was divided between chip level and block level.[24] The modeling had three levels of accuracy: namely, statistical, Steiner, and detailed RC. Pathmill[2] was used for timing analysis. The verification tool extracted and analyzed the layout and inserted decoupling capacitors, wide wires, and repeaters automatically. If a full-chip long net was found not to meet its timing, a repeater had to be inserted on the net. IBM observed a problem with the repeater insertion methodology. What if the die does not have a space at the location of the repeater to be inserted? Some space had to be deliberately created for this problem.

In UltraSparc-I™, the power network was extensively verified using an internal tool called PGRID.[9] The block-level layout was translated into a schematic model for the chip-level verification. The voltages at four corners of a block were extracted from HSPICE runs. Finally, a graphical error map for electromigration and IR drop violations was generated at all levels of the layout.

63.1 Introduction

The microprocessor industry is divided into the computer and embedded sectors. Both computer and embedded microprocessors share aspects of computer design, instruction set architecture, organization, and hardware. The term "computer architecture" is used to describe these fundamental aspects and, more directly, refers to the hardware components in a computer system and the flow of data and control information among them. In this chapter, various types of microprocessors will be described, fundamental architecture mechanisms relevant in the operation of all microprocessors will be presented, and microprocessor industry trends discussed.

63.2 Types of Microprocessors

Computer microprocessors are designed for use as the Central Processing Units (CPU) of computer systems such as personal computers, workstations, servers, and supercomputers. Although microprocessors started as humble programmable controllers in the early 1970s, virtually all computer systems built in the 1990s use microprocessors as their central processing units. The dominating architecture in the computer microprocessor domain today is the Intel 32-bit architecture, also known as IA-32 or X86. Other high-profile architectures in the computer microprocessor domain include Compaq-Digital Alpha, HP PA-RISC, Sun Microsystems SPARC, IBM/Motorola PowerPC, and MIPS.

Embedded microprocessors are increasingly used in consumer and telecommunications products to satisfy the demands for quality and functionality. Major product areas that require embedded microprocessors include digital TV, digital cameras, network switches, high-speed modems, digital cellular phones, video games, laser printers, and automobiles. Future improvements in energy consumption, fabrication cost, and performance will further enable new applications such as the hearing aid. Many experts expect that embedded microprocessors will form the fastest growing sector of the semiconductor business in the next decade.[1]

Embedded microprocessors have been categorized into DSP processors and embedded CPUs due to historic reasons. DSP processors have been designed and marketed as special-purpose devices that are mostly programmed by hand to perform digital signal processing computations. A recent trend in the DSP market is to use compilers to alleviate the need for tedious hand-coding in DSP development. Another recent trend in the DSP market is toward integrating a DSP processor core with application-specific logic to form a single-chip solution. This approach is enabled by the fast increasing chip density technology. The major benefit is reduced system cost and energy consumption. Two general types of DSP cores are available to application developers today. Foundry-captive DSP cores and related application-specific logic design services are provided by major semiconductor vendors such as Texas Instruments, Lucent Technologies, and SGS-Thompson to application developers who commit to their fabrication lines. A very large volume commitment is usually required to use the design service. Licensable DSP cores are provided by small to medium design houses to application developers who want to be able to choose fabrication lines.

There are several ways that the needs of embedded computing differ from those of more traditional general-purpose systems. Constraints on the code size, weight, and power consumption place stringent requirements on embedded processors and the software they execute. Also, constraints rooted in real-time requirements are often a significant consideration in many embedded systems. Furthermore, cost is a severe constraint on embedded processors.

Embedded CPUs are used in products where the computation involved resembles that of general-purpose applications and operating systems. Embedded CPUs have been traditionally derived from out-of-date computer microprocessors. They often reuse the compiler and related software support developed for their computer cousins. Recycling the microprocessor design and compiler software minimizes engineering cost. A trend in the embedded CPU domain is similar to that in the DSP domain: to provide embedded CPU cores and application specific logic design services to form single-chip solutions. For example, MIPs customized its embedded CPU core for use in Nintendo64, in return for engineering fees and royalty streams. ARM, NEC, and Hitachi offer similar products and services. Due to an increasing need to perform DSP computation in consumer and telecommunication products, an increasing number of embedded CPUs have extensions to enable more effective DSP computation.

Contrary to the different constraints and product markets, both computer and embedded microprocessors share traditional elements of computer architecture. These main elements will be described. Additionally, over the past decade, substantial research has gone into the design of microprocessors embodying parallelism at the instruction level, as well as aggressive compiler optimization and analysis techniques for harnessing this opportunity. Much of this effort has since been validated through the proliferation of mainstream general-purpose computers based on these technologies. Nevertheless, growing demand for high performance in embedded computing systems is creating new opportunities to leverage these techniques in application-specific domains. The research of Instruction-Level Parallelism (ILP) has developed a distinct architecture methodology referred to as Explicitly Parallel Instruction Computing (EPIC) technology. Overall, these techniques represent fundamental substantial changes in computer architecture.

63.3 Major Components of a Microprocessor

The main hardware of a microprocessor system can be divided into sections according to their functionalities. A popular approach is to divide a system into four subsystems: the central processor, the memory subsystem, the input/output (I/O) subsystem, and the system interconnection. Figure 63.1 shows the connection between these subsystems. The main components and characteristics of these subsystems will be described.

Central Processor

A modern microprocessor's central processor system can typically be further divided into control, data path, pipelining, and branch prediction hardware.

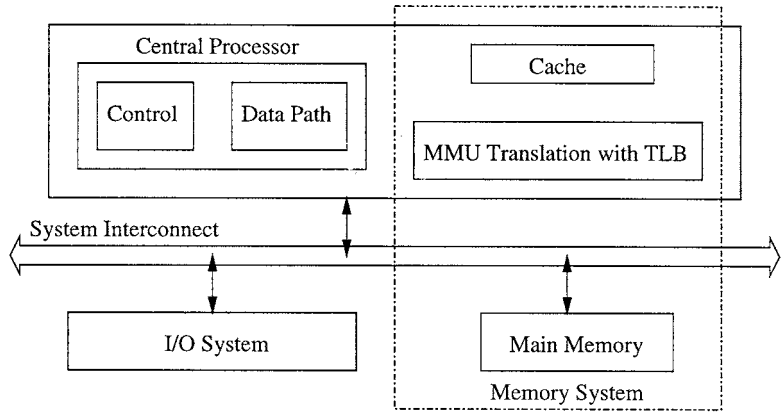

FIGURE 63.1 Architecture subsystems of a computer system.

Control Unit

The *control unit* of a microprocessor generates the control signals to orchestrate the activities in the data path. There are two major types of communication lines between the control unit and the data path: the control lines and the condition lines. The *control lines* deliver the control signals from the control unit to the data path. Different signal values on these lines trigger different actions in the data path. The *condition lines* carry the status of the execution from data path to the control unit. These lines are needed to test conditions involving th registers in the data path in order to make future control decisions. Note that the decision is made in the control unit but the registers are in the data path. Therefore, the conditions regarding the register contents are formed in the data path and then shipped to the control unit for decision-making. A control unit can be implemented with hardwiring, microprogramming, or a combination of both.

In a hardwired design, each control unit is viewed as an ordinary sequential circuit. The design goals are to minimize the component count and to maximize the operation speed. The finite state machine is realized with registers, logic, and wires. Once constructed, the design can be changed only through physically rewiring the unit. Therefore, the resulting circuits are called *hardwired control units.* Due to design optimizations, the resulting circuits often exhibit little structure. The lack of structure makes it very difficult to design and debug complicated control units with this technique. Therefore, hardwiring is normally used when the control unit is relatively simple.

Most of the design difficulties in the hardwired control units are due to the effort of optimizing the combinational circuit. If there is a method that does not attempt to optimize the combinational circuit, the design complexity could be significantly reduced. One obvious option is to use either Read-Only Memory (ROM) or Random Access Memory (RAM) to implement the combinational circuit. A control unit whose combinational circuit is simplified by the use of ROM or RAM is called a *microprogrammed control unit.* The memory used is called *Control Memory* (CM). The practice of realizing the combinational circuit in a control unit with ROM/RAM is called *microprogramming.* The concept of microprogramming was first introduced by Wilkes.

The idea of using a memory to implement a combinational circuit can be illustrated with a simple example. Assume that we are to implement a logic function with three input variables, as described in the truth table illustrated in Fig. 63.2(a). A common way to realize this function is to use Karnaugh maps to derive highly optimized logic and wiring. The result is shown in Fig. 63.2(b). The same function can also be realized in memory. In this method, a memory with eight 1-bit locations can be used to retain the eight possible combinations of the three-input variable. Location *i* contains an F value corresponding to the *i*-th input combination. For example, location 3 contains the F value (0) for the input combination 011. The three input variables are then connected to the address input of the memory to complete the design (Fig. 63.2(c)). In essence, the memory implicitly contains the entire truth table. Considering the

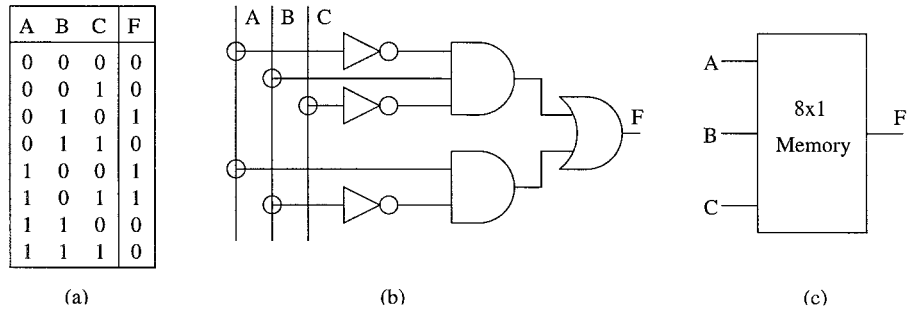

FIGURE 63.2 Using memory to simplify logic design: (a) Karnaugh map, (b) logic, (c) memory.

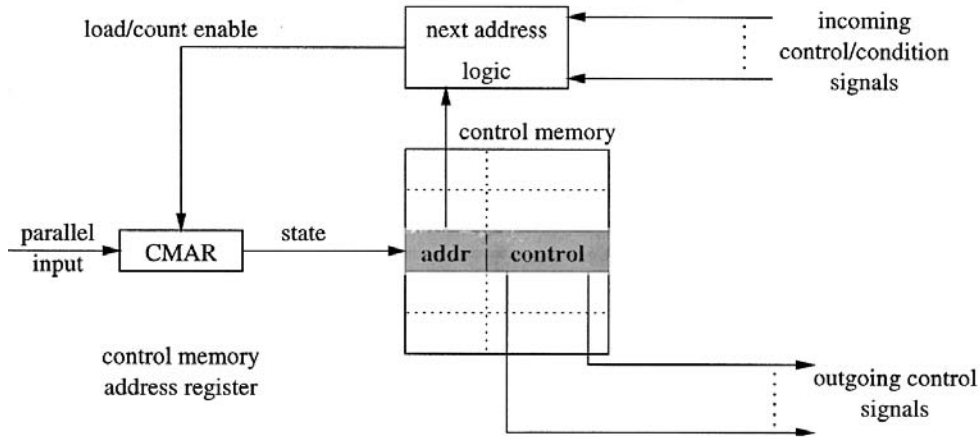

FIGURE 63.3 Basic model of microprogrammed control units.

decoding logic and storage cells involved in a 8×1 memory, it is obvious that the memory approach uses a lot more hardware components than the Karnaugh map approach. However, the design is much simpler in the memory approach.

Figure 63.3 illustrates the general model of a microprogrammed control unit. Each control memory location consists of an address field and some control fields. The address field plus the next address logic implements the combinational circuit for generating the next state value. The control fields implement the combinational circuit for generating the control signal. Both the control memory and the next addrss logic will be studied in detail in this section. The state register/counter has been renamed the *Control Memory Address Register* (CMAR) for an obvious reason: the contents of the register are used as the address input to the control memory. An important insight is that the CMAR stores the state of the control unit.

Data Path

The data path of a microprocessor contains the main arithmetic and logic execution units required to execute instructions. Designing the data path involves analyzing the function(s) to be performed, then specifying a set of hardware registers to hold the computation state, and designing computation steps to transform the contents of these registers into the final result. In general, the functions to be performed will be divided into steps, each of which can be done with a reasonable amount of logic in one clock cycle. Each step brings the contents of the registers closer to the final result. The data path must be equipped with a sufficient amount of hardware to allow these computation steps in one clock cycle. The data path of a typical microprocessor contains integer and floating-point register files, ten or more

functional units for computation and memory access, and pipeline registers. One must understand the concept of pipelining in order to understand the data paths of today's microprocessors.

Pipelining

In the 1970s, only supercomputers and mainframe computers were pipelined. Today, most commercial microprocessors are pipelined. In fact, pipelining has been a major reason why microprocessors today outperform supercomputers built less than 10 years ago. Pipelining is a technique to coordinate parallel processing of operations.[2] This technique has been used in assembly lines of major industries for more than a century. The idea is to have a line of workers specializing in different pieces of work required to finish a product. A conveying belt carries each product through the line of workers. Each worker will do a small piece of work on each product. Each product is finished after it is processed by all the workers in the assembly line.

The obvious advantage of pipelining is to allow one worker to immediately start working on a new product after finishing the work on a current product. The same methodology is applied to instruction processing in microprocessors. Figure 63.4(a) shows an example five-stage pipeline dividing instruction execution into Fetch (F), Decode (D), Execute (E), Memory (M), and Write-back (W) operations, each requiring various stage-specific logic. Between each stage is a stage register (SR) used to hold the instruction information necessary to control the instruction. A very basic principle of pipelining is that the work performed by each stage must take about the same amount of time. Otherwise, the efficiency will be significantly reduced because one stage becomes a bottleneck of the entire pipeline. Similarly, the time duration of the slowest pipeline stage determines the overall clock frequency of the processor. Due to this constraint and the characteristics of memory speeds, the five-stage pipeline model often requires some of the principle five stages to be divided into smaller stages. For instance, the memory stage may be divided into three stages, allowing memory accesses to be pipelined and the overall processor clock speed to be a function of a fraction of the memory access latency.

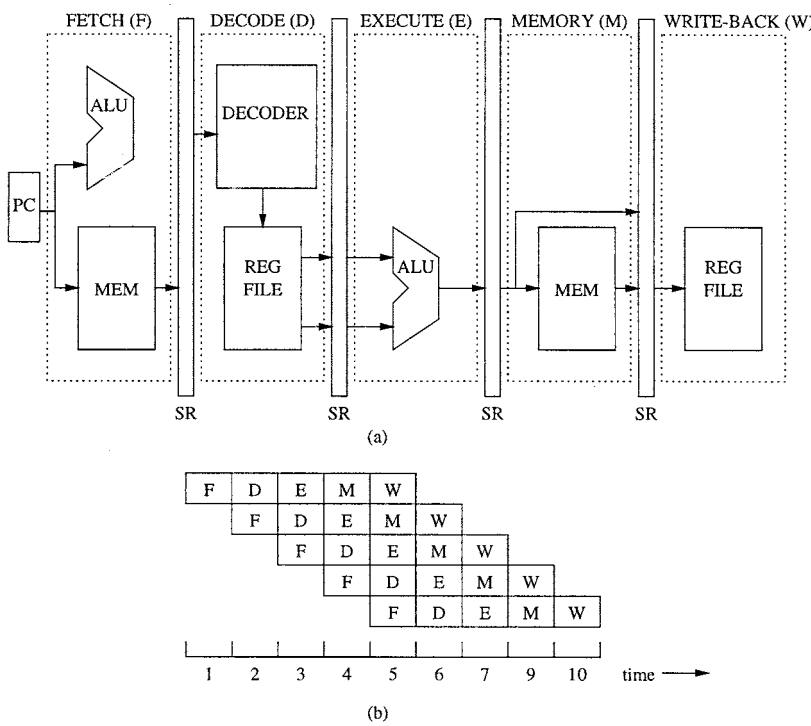

FIGURE 63.4 Pipeline architecture: (a) machine, (b) overlapping instructions.

The time required to finish N instructions in a pipeline with K stages can be calculated. Assume a cycle time of T for the overall instruction completion, and an equal T/K processing delay at each stage. With a pipeline scheme, the first instruction completes the pipeline after T, and there will be a new instruction out of the pipeline per stage delay T/K. Therefore, the delays of executing N instructions with and without pipelining, respectively, are:

$$T*\left(N\right) \tag{63.1}$$

$$T+\left(T/k\right)*\left(N-1\right) \tag{63.2}$$

There is an initial delay in the pipeline execution model before each stage has operations to execute. The initial delay is usually called *pipeline start-up delay* (P), and is equal to total execution time of one instruction. The speed-up of a pipelined machine relative to a non-pipelined machine is calculated as:

$$\frac{P*N}{P+\left(N-1\right)} \tag{63.3}$$

When N is much larger than the number of pipestages P, the ideal speed-up approaches P. This is an intuitive result since there are P parts of the machine working in parallel, allowing the execution to go about P times faster in ideal conditions.

The overlap of sequential instructions in a processor pipeline is shown in Fig. 63.4(b). The instruction pipeline becomes full after the pipeline delay of $P = 5$ cycles. Although the pipeline configuration executes operations in each stage of the processor, two important mechanisms are constructed to ensure correct functional operation between dependent instructions in the presence of data hazards. Data hazards occur when instructions in the pipeline generate results that are necessary for later instructions that are already started in the pipeline. In the pipeline configuration of Fig. 63.4(a), register operands are initially retrieved during the decode stage. However, the execute and memory stage can define register operands and contain the correct current value but are not able to update the register file until the later write-back execution stage. Forwarding (or bypassing) is the action of retrieving the correct operand value for an executing instruction between the initial register file access and any pending instruction's register file updates. Interlocking is the action of stalling an operation in the pipeline when conditions cause necessary register operand results to be delayed. It is necessary to stall early stages of the machine so that the correct results are used, and the machine does not proceed with incorrect values for source operands. The primary causes of delay in pipeline execution are initiated due to instruction fetch delay and memory latency.

Branch Prediction

Branch instructions pose serious problems for pipelined processors by causing hardware to fetch and execute instructions until the branch instructions are completed. Executing incorrect instructions can result in severe performance degradation through the introduction of wasted cycles into the instruction stream.

There are several methods for dealing with pipeline stalls caused by branch instructions. The simplest performance scheme handles branches by treating every branch as either *taken* or *not-taken*. This treatment can be set for every branch or determined by the branch opcode. The designation allows the pipeline to continue to fetch instructions as if the branch was a normal instruction. However, the fetched instruction may need to be discarded and the instruction fetch restarted when the branch outcome is incorrect. *Delayed branching* is another scheme which treats the set of sequential instructions following a branch as delay slots. The delay-slot instructions are executed whether or not the branch instruction is taken. Limitations on delayed branches are caused by the compiler and program characteristics being unable to support numerous instructions that execute independent of the branch direction. Improvements have

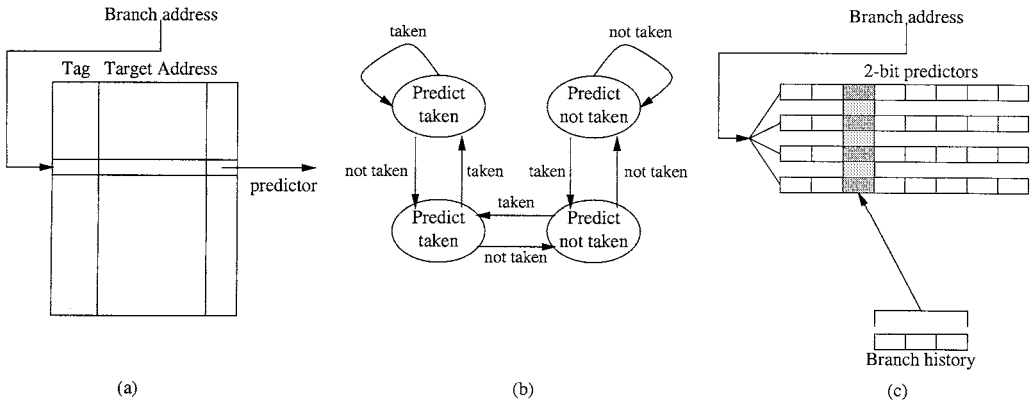

FIGURE 63.5 Branch prediction.

been introduced to provide *nullifying* branches, which include a predicted direction for the branch. When the prediction is incorrect, the delay-slot instructions are nullified.

A more modern approach to reducing branch penalties uses hardware to dynamically predict the outcome of a branch. Branch prediction strategies reduce overall branch penalties by allowing the hardware to continue processing instructions along the predicted control path, thus eliminating wasted cycles. Efficient execution can be maintained while branch targets are correctly predicted. However, a large performance penalty is incurred when a branch is mispredicted. Branch target buffer is a cache structure that is accessed in parallel with the instruction fetch. It records the past history of branch instructions so that a prediction can be made while the branch is fetched again. This prediction method adapts the branch prediction to the run-time program behavior, generating a high prediction accuracy. The target addresses of the branch is also saved in the buffer so that the target instruction can be fetched immediately if a branch is predicted taken.

Several methodologies of branch target prediction have been constructed.[3] Figure 63.5 illustrates several general branch prediction schemes. The most common implementation retains history information for each branch as shown in Fig. 63.5(a). The history includes the previous branch directions for making predictions on future branch directions. The simplest history is last-taken, which uses 1-bit to recall whether the branch condition was taken or not-taken. A more effective branch predictor uses a 2-bit saturating state history counter to determine the future branch outcome similar to Fig. 63.5(b). Two bits rather than one bit allows each branch to be tagged as strongly or weakly taken or not-taken. Every correct prediction reinforces the prediction, while an incorrect prediction weakens it. It takes two consecutive mispredictions to reverse the direction (whether taken or not taken) of the prediction.

Recently, more complex two-level adaptive branch prediction schemes have been built which use two levels of branch history to make predictions, as shown in Fig. 63.5(c). The first level is the branch outcome history of the last branches encountered. The second level is the branch behavior for the last occurrences of a specific pattern of branch histories. There are alternative ways of constructing both levels of adaptive branch prediction schemes, the mechanisms can contain information that is either based on individual branches, groups (set-based), and all (global). Individual formation contains the branch history for each branch instruction. Set-based information groups branches according to their instruction address, thereby forming sets of branch history. Global information uses a global history containing all branch outcomes. The second level containing branch behaviors can also be constructed using any of the three types. In general, the first-level branch history pattern is used as an index into the second-level branch history.

Memory Subsystem

The *memory system* serves as a repository of information in a microprocessor system. The processing unit retrieves information stored in memory, operates on the information, and returns new information

back to memory. The memory system is constructed of basic semiconductor DRAM units called modules or banks.

There are several properties of memory, including speed, capacity, and cost that play an important role in the overall system performance. The speed of a memory system is the key performance parameter in the design of the microprocessor system. The *latency* (L) of the memory is defined as the time delay from when the processor first requests data from memory until the processor receives the data. *Bandwidth* is defined as the rate which information can be transferred from the memory system. Memory bandwidth and latency are related to the number of outstanding requests (R) that the memory system can service:

$$BW = \frac{L}{R} \tag{63.4}$$

Bandwidth plays an important role in keeping the processor busy with work. However, technology tradeoffs to optimize latency and improve bandwidth often conflict with the need to increase the capacity and reduce the cost of the memory system.

Cache Memory

Cache memory, or simply cache, is a small, fast memory constructed using semiconductor SRAM. In modern computer systems, there is usually a hierarchy of cache memories. The top-level cache is closest to the processor and the bottom level is closest to the main memory. Each higher level cache is about 5 to 10 times faster than the next level. The purpose of a cache hierarchy is to satisfy most of the processor memory accesses in one or a small number of clock cycles. The top-level cache is often split into an instruction cache and a data cache to allow the processor to perform simultaneous accesses for instructions and data. Cache memories were first used in the IBM mainframe computers in the 1960s. Since 1985, cache memories have become a standard feature for virtually all microprocessors.

Cache memories exploit the principle of locality of reference. This principle dictates that some memory locations are referenced more frequently than others, based on two program properties. *Spatial locality* is the property that an access to a memory location increases the probability that the nearby memory location will also be accessed. Spatial locality is predominantly based on sequential access to program code and structured data. *Temporal locality* is the property that access to a memory location greatly increases the probability that the same location will be accessed in the near future. Together, the two properties ensure that most memory references will be satisfied by the cache memory.

There are several different cache memory designs: direct-mapped, fully associative, and set-associative. Figure 63.6 illustrates the two basic schemes of cache memory, direct-mapped and set-associative. Direct-mapped cache, shown in Fig. 63.6(a) allows each memory block to have one place to reside within a cache. Fully associative cache, shown in Fig. 63.6(b), allows a block to be placed anywhere in the cache. Set associative cache restricts a block to a limited set of places in the cache.

Cache misses are said to occur when the data requested does not reside in any of the possible cache locations. Misses in caches can be classified into three categories: conflict, compulsory, and capacity. Conflict misses are misses that would not occur for fully associative caches with LRU (Least Recently Used) replacement. Compulsory misses are misses required in cache memories for initially referencing a memory location. Capacity misses occur when the cache size is not sufficient to contain data between references. Complete cache miss definitions are provided in Ref. 4.

Unlike memory system properties, the latency in cache memories is not fixed and depends on the delay and frequency of cache misses. A performance metric that accounts for the penalty of cache misses is *effective latency*. Effective latency depends on the two possible latencies, hit latency (L_{HIT}), the latency experienced for accessing data residing in the cache, and miss latency (L_{MISS}), the latency experienced when accessing data not residing in the cache. Effective latency also depends on the *hit rate* (H), the percentage of memory accesses that are hits in the cache, and the *miss rate* (M or $1 - H$), the percentage of memory accesses that miss in the cache. Effective latency in a cache system is calculated as:

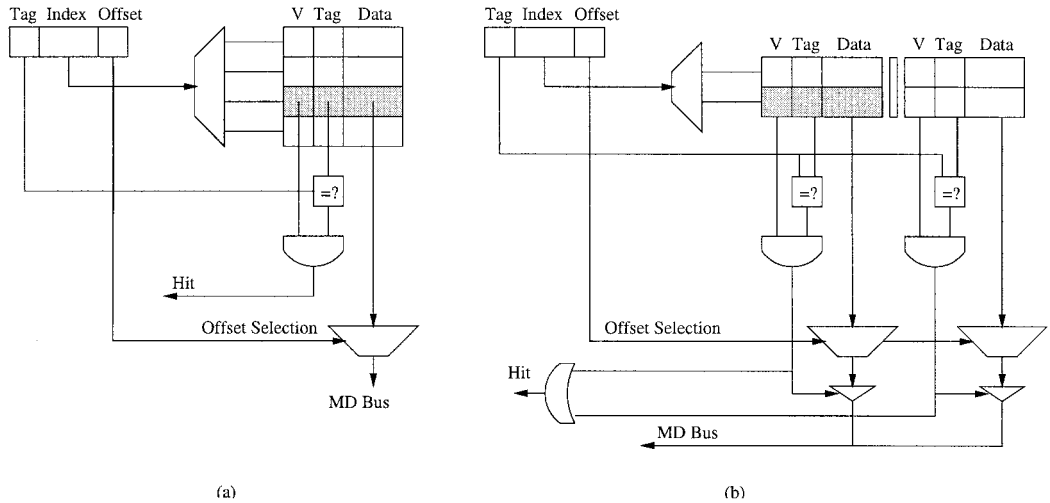

FIGURE 63.6 Cache memory: (a) direct-mapped design, (b) two-way set-associative design.

$$L_{effective} = L_{HIT} * H + L_{MISS} * \left(1 - H\right) \tag{63.5}$$

In addition to the base cache design and size issues, there are several other cache parameters that affect the overall cache performance and miss rate in a system. The main memory update method indicates when the main memory will be updated by store operations. In *write-through* cache, each write is immediately reflected to the main memory. In *write-back* cache, the writes are reflected to the main memory only when the respective cache block is replaced. Cache block allocation is another parameters and designates whether the cache block is allocated on writes or reads. Last, block replacement algorithms for associative structures can be designed in various ways to extract additional cache performance. These include LRU (least recently used), LFU (least frequently used), random, and FIFO (first-in, first-out). These cache management strategies attempt to exploit the properties of locality. Spatial locality is exploited by deciding which memory block is placed in cache, and temporal locality is exploited by deciding which cache block is replaced. Traditionally, when cache service misses, they would *block* all new requests. However, *non-blocking* cache can be designed to service multiple miss requests simultaneously, thus alleviating delay in accessing memory data.

In addition to the multiple levels of cache hierarchy, additional memory buffers can be used to improve cache performance. Two such buffers are a streaming/prefetch buffer and a victim cache.[2] Figure 63.7 illustrates the relation of the streaming buffer and victim cache to the primary cache of a memory system. A streaming buffer is used as a prefetching mechanism for cache misses. When a cache miss occurs, the streaming buffer begins prefetching successive lines starting at the miss target. A victim cache is typically a small, fully associative cache loaded only with cache lines that are removed from the primary cache. In the case of a miss in the primary cache, the victim cache may hold additional data. The use of a victim cache can improve performance by reducing the number of conflict misses. Figure 63.7 illustrates how cache accesses are processed through the streaming buffer into the primary cache on cache requests, and from the primary cache through the victim cache to the secondary level of memory on cache misses.

Overall, cache memory is constructed to hold the most important portions of memory. Techniques using either hardware or software can be used to select which portions of main memory to store in cache. However, cache performance is strongly influenced by program behavior and numerous hardware design alternatives.

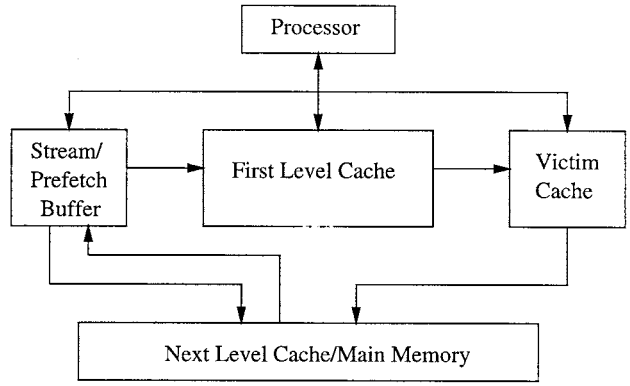

FIGURE 63.7 Advanced cache memory system.

Virtual Memory

Cache memory illustrated the principle that the memory address of data can be separate from a particular storage location. Similar address abstractions exist in the two-level memory hierarchy of main memory and disk storage. An address generated by a program is called a *virtual address*, which needs to be translated into a *physical address* or location in main memory. Virtual memory management is a mechanism which provides the programmers with a simple, uniform method to access both main and secondary memories. With virtual memory management, the programmers are given a virtual space to hold all the instructions and data. The virtual space is organized as a linear array of locations. Each location has an address for convenient access. Instructions and data have to be stored somewhere in the real system; these virtual space locations must correspond to some physical locations in the main and secondary memory. Virtual memory management assigns (or maps) the virtual space locations into the main and secondary memory locations. The mapping of virtual space locations to the main and secondary memory is managed by the virtual memory management. The programmers are not concerned with the mapping.

The most popular memory management scheme today is demand paging virtual memory management, where each virtual space is divided into pages indexed by the page number (PN). Each page consists of several consecutive locations in the virtual space indexed by the page index (PI). The number of locations in each page is an important system design parameter called page size. Page size is usually defined as a power of two so that the virtual space can be divided into an integer number of pages. Pages are the basic unit of virtual memory management. If any location in a page is assigned to the main memory, the other locations in that page are also assigned to the main memory. This reduces the size of the mapping information.

The part of the secondary memory to accommodate pages of the virtual space is called the swap space. Both the main memory and the swap space are divided into page frames. Each page frame can host a page of the virtual space. If a page is mapped into the main memory, it is also hosted by a page frame in the main memory. The mapping record in the virtual memory management keeps track of the association between pages and page frames.

When a virtual space location is requested, the virtual memory management looks up the mapping record. If the mapping record shows that the page containing requested virtual space location is in main memory, the management performs the access without any further complication. Otherwise, a secondary memory access has to be performed. Accessing the secondary memory is usually a complicated task and is usually performed as an operating system service. In order to access a piece of information stored in the secondary memory, an operating system service usually has to be requested to transfer the information into the main memory. This also applies to virtual memory management. When a page is mapped into the secondary memory, the virtual memory management has to request a service in the operating system

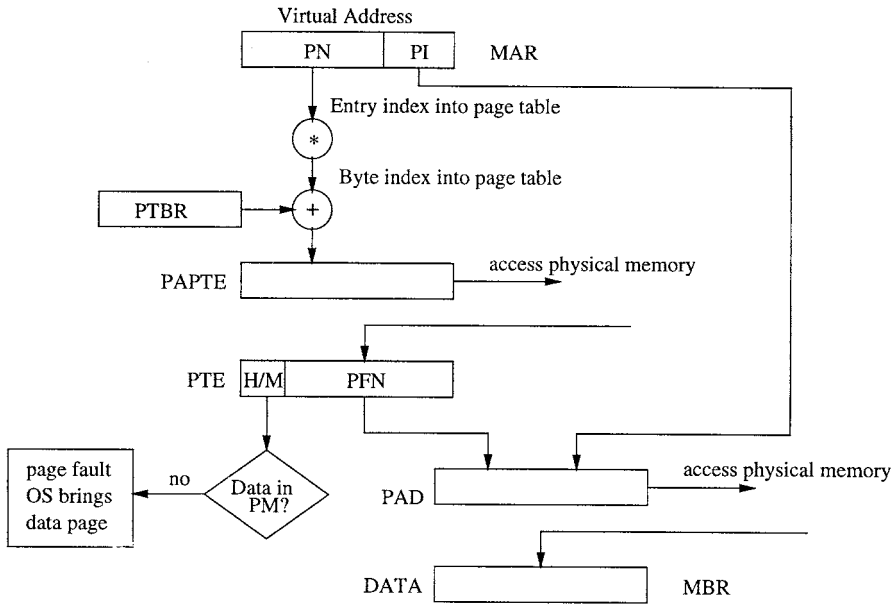

FIGURE 63.8 Virtual memory translation.

to transfer the requested virtual space location into the main memory, update its mapping record, and then perform the access. The operating system service thus performed is called the page fault handler.

The core process of virtual memory management is a memory access algorithm. A one-level virtual address translation algorithm is illustrated in Fig. 63.8. At the start of the translation, the memory access algorithm receives a virtual address in a Memory Address Register (MAR), looks up the mapping record, requests an operating system service to transfer the required page if necessary, and performs the main memory access. The mapping is recorded in a data structure called the Page Table located in main memory at a designated location marked by the Page Table Base Register (PTBR).

The page table index and the PTBR form the physical address (PAPTE) of the respective Page Table Entry. Each PTE keeps track of the mapping of a page in the virtual space. It includes two fields: a hit/miss bit and a page frame number. If the hit/miss (H/M) bit is set (hit), the corresponding page is in main memory. In this case, the page frame hosting the requested page is pointed to by the page frame number (PFN). The final physical address (PAD) of the requested data is then formed using the PFN and PI. The data is returned and placed in the Memory Buffer Register (MBR) and the processor is informed of the completed memory access. Otherwise (miss), a secondary memory access has to be performed. In this case, the page frame number should be ignored. The fault handler has to be invoked to access the secondary memory. The hardware component that performs the address translation algorithm is called the Memory Management Unit (MMU).

The complexity of the algorithm depends on the mapping structure. A very simple mapping structure is used in this section to focus on the basic principles of the memory access algorithms. However, more complex two-level schemes are often used due to the size of the virtual address space. The size of the page table designated may be quite large for a range of main memory sizes. As such, it becomes necessary to map portions of page table into a second page table. In such designs, only the second-level page table is stored in a reserved region of main memory, while the first page table is mapped just like the data in the virtual spaces. There are also requirements for such designs in a multiprogramming system, where there are multiple processes active at the same time. Each processor has its own virtual space and therefore its own page table. As a result, these systems need to keep multiple page tables at the same time. It usually take too much main memory to accommodate all the active page tables. Again, the natural solution to this problem is to provide other levels of mapping.

Translation Lookaside Buffer

Hardware support for a virtual memory system generally includes a mechanism to translate virtual addresses into the real physical addresses used to access main memory. A Translation Lookaside Buffer (TLB) is a cache structure which contains the frequently used page table entries for address translation. With a TLB, address translation can be performed in a single clock cycle when TLB contains the required page table entries (TLB hit). The full address translation algorithm is performed only when the required page table entries are missing from the TLB (TLB miss).

Complexities arise when a system includes both virtual memory management and cache memory. The major issue is whether address translation is done before accessing the cache memory. In *virtual* cache systems, the virtual address directly accesses cache. In a *physical* cache system, the virtual address is translated into a physical address before cache access. Figure 63.9 illustrates both the *virtual* and *physical* cache translation approaches.

A virtual cache system typically overlaps the cache memory access and the access to the TLB. The overlap is possible when the virtual memory page size is larger than the cache capacity divided by the degree of cache associativity. Essentially, since the virtual page index is the same as the physical address index, no translation for the lower indexes of the virtual address is necessary. Thus, the cache can be accessed in parallel with the TLB, or the TLB can be accessed after the cache access for cache misses. Typically, with no TLB logic between the processor and the cache, access to cache can be achieved at lower cost in virtual cache systems and multi-access per cycle cache systems can avoid requiring a multiported TLB. However, the virtual cache translation alternative introduces virtual memory consistency problems. The same virtual address from two different processes mean different physical memory locations. Solutions to this form of aliasing are to attach a process identifier to the virtual address or to flush cache contents on context switches. Another potential alias problem is that different virtual addresses of the same process may be mapped into the same physical address. In general, there is no easy solution; and it involves a reverse translation problem.

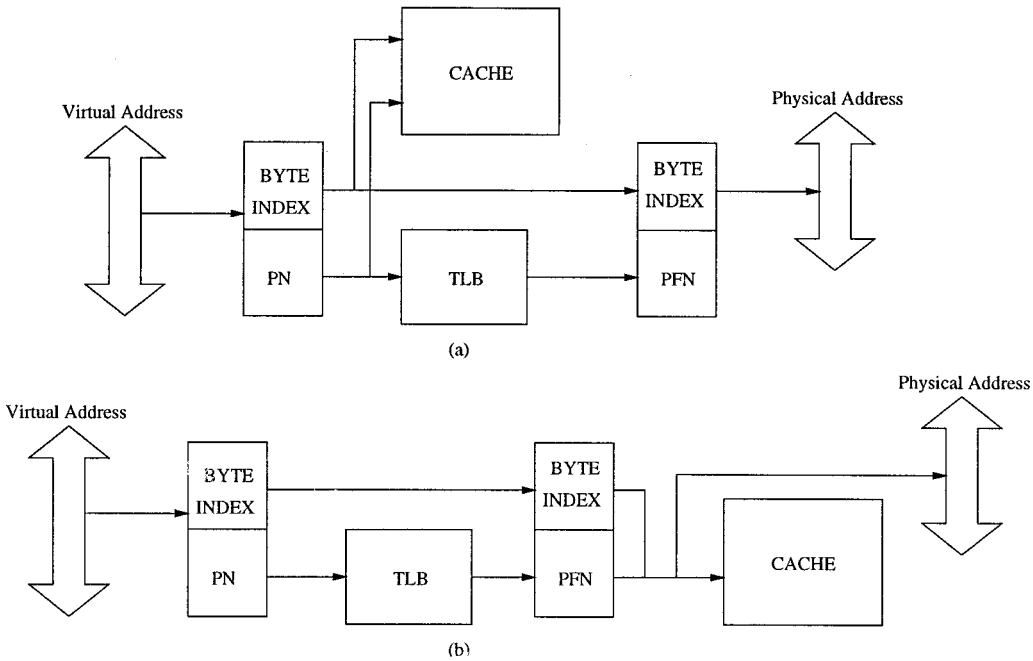

FIGURE 63.9 Translation Lookaside Buffer (TLB) architectures: (a) virtual cache, (b) physical cache.

Physical cache designs are not always limited by the delay of the TLB and cache access. In general, there are two solutions to allow large physical cache design. The first solution, employed by companies with past commitments to page size, is to increase the set associativity of cache. This allows the cache index portion of the address to be used immediately by the cache in parallel with virtual address translation. However, large set associativity is very difficult to implement in a cost-effective manner. The second solution, employed by companies without past commitment, is to use a larger page size. The cache can be accessed in parallel with the TLB access similar to the other solution. In this solution, there are fewer address indexes that are translated through the TLB, potentially reducing the overall delay. With larger page sizes, virtual caches do not have advantage over physical caches in terms of access time.

Input/Output Subsystem

The Input/Output (I/O) subsystem transfers data between the internal components (CPU and main memory) and the external devices (disks, terminals, printers, keyboards, scanners).

Peripheral Controllers

The CPU usually controls the I/O subsystem by reading from and writing into the I/O (control) registers. There are two popular approaches for allowing the CPU to access these I/O registers; I/O instructions and memory-mapped I/O. In an I/O instruction approach, special instructions are added to the instruction set to access I/O status flags, control registers, and data buffer registers. In a memory-mapped I/O approach, the control registers, the status flags, and the data buffer registers are mapped as physical memory locations. Due to the increasing availability of chip area and pins, microprocessors are increasingly including peripheral controllers on-chip. This trend is especially clear for embedded microprocessors.

Direct Memory Access Controller

A DMA controller is a peripheral controller that can directly drive the address lines of the system bus. The data is directly moved from the data buffer to the main memory, rather than from data buffer to a CPU register, then from CPU register to main memory.

System Interconnection

System interconnection is the facilities that allow the components within a computer system to communicate with each other. There are numerous logical organizations of these system interconnect facilities.

Dedicated links or point-to-point connections enable dedicated communication between components. There are different system interconnection configurations based on the connectivity of the system components. A complete connection configuration, requiring $N \cdot (N-1)/2$ links, is created when there is one link between every possible pair of components. A *hypercube* configuration assigns a unique n-tuple {1,0} as the coordinate of each component and constructs a linke between components whose coordinates differ only in one dimension, requiring $N \cdot \log N$ links. A *mesh* connection arranges the system components into an N-dimensional array and has connections between immediate neighbors, requiring $2 \cdot N$ links.

Switching networks are a group of switches that determine the existence of communication links among components. A cross-bar network is considered the most general form of switching network and uses a $N \times M$ two dimensional array of switches to provide an arbitrary connection between N components on one side to M components on another side using $N \cdot M$ switches and $N + M$ links. Another switching network is the multistage network, which employs multiple stages of shuffle networks to provide a permutation connection pattern between N components on each side by using $N \cdot \log N$ switches and $N \cdot \log N$ links.

Shared buses are single links which connect all components to all other components and are the most popular connection structure. The sharing of buses among the components of a system requires several

aspects of bus control. First, there is a distinction between bus masters, the units controlling bus transfers (CPU, DMA, IOP) and bus slaves, the other units (memory, programmed I/O interface).

Bus interfacing and bus addressing are the means to connect and disconnect units on the bus. Bus arbitration is the process of granting the bus resource to one of the requesters. Arbitration typically uses a selection scheme similar to interrupts; however, there are more fixed methods of establishing selection. Fixed-priority arbitration gives every requester a fixed priority, and round-robin ensures every requester the most favorable at one point in time. Bus timing refers to the method of communication among the system units and can be classified as either synchronous or asynchronous. Synchronous bus timing uses a shared clock that defines the time other bus signals change and stabilize. Clock sharing by all units allows the bus to be monitored at agreed time intervals and action taken accordingly. However, the synchronous system bus must operate at the speed of the slowest component. Asynchronous bus timing allows units to use different clocks, but the lack of a shared clock makes it necessary to use extra signals to determine the validity of bus signals.

63.4 Instruction Set Architecture

There are several elements that characterize an instruction set architecture, including word size, instruction encoding, and architecture model.

Word Size

Programs often differ in the size of data they prefer to manipulate. Word processing programs operate on 8-bit or 16-bit data that correspond to characters in text documents. Many applications require 32-bit integer data to avoid frequent overflow in arithmetic calculation. Scientific computation often requires 64-bit floating-point data to achieve desired accuracy. Operating systems and databases may require 64-bit integer data to represent a very large name space with integers. As a result, the processors are usually designed to access multiple-byte data from memory systems. This is a well-known source of complexity in microprocessor design.

The endian convention specifies the numbering of bytes with a memory word. In the little endian convention, the least significant byte in a word is numbered byte 0. The number increases as the positions increase in significance. The DEC VAX and X86 architectures follow the little endian convention. In the big endian convention, the most significant byte in a word is numbered 0. The number decreases as the positions decrease in significance. The IBM 360/370, HP PA-RISC, Sun SPARC, and Motorola 680X0 architectures follow the big endian convention. The difference usually manifests itself when users try to transfer binary files between machines using different endian conventions.

Instruction Encoding

Instruction encoding plays an important role in the code density and performance of microprocessors. Traditionally, the cost of memory capacity was the determining factor in designing either a fixed-length or variable-length instruction set. Fixed-length instruction encoding assigns the same encoding size to all instructions. Fixed-length encoding is generally a characteristic of modern microprocessors and the product of the increasing advancements in memory capacity.

Variable-length instruction set is the term used to describe the style of instruction encoding that uses different instructions lengths according to addressing modes of operands. Common addressing modes included either register or methods of indexing memory. Figure 63.10 illustrates two potential designs found in modern use of decoding variable length instructions. The first alternative, in Fig. 63.10(a) involves an additional instruction decode stage in the original pipeline design. In this model, the first stage is used to determine instruction lengths and steer the instructions to the second stage, where the actual instruction decoding is performed. The second alternative, in Fig. 63.10(b) involves pre-decoding and marking instruction lengths in the instruction cache. This design methodology has been effectively used in decoding X86 variable instructions.[5] The primary advantage of this scheme is the simplification of the number of decode stages in the pipeline design. However, the method requires a larger instruction cache structure for holding the resolved instruction information.

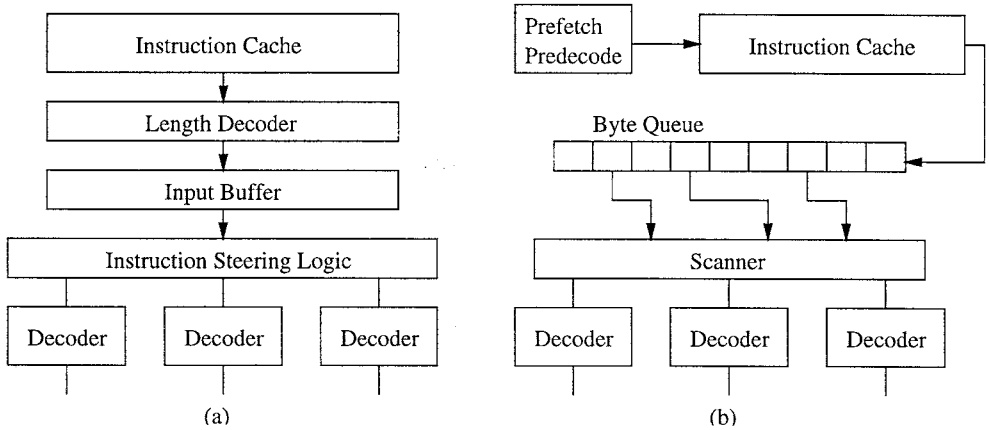

FIGURE 63.10 Variable-sized instruction decoding: (a) staging, (b) predecoding.

Architecture Model

Several instruction set architecture models have existed over the last three decades of computing. First, CISC (Complex Instruction Set Computers) characterized designs with variable instruction formats, numerous memory addressing modes, and large numbers of instruction types. The original CISC philosophy was to create instructions sets that resembled high-level programming languages in an effort to simplify compiler technology. In addition, the design constraint of small memory capacity also led to the development of CISC. The two primary architecture examples of the CISC model are the Digital VAX and Intel X86 architecture families.

RISC (Reduced Instruction Set Computers) gained favor with the philosophy of uniform instruction lengths, load-store instruction sets, limited addressing modes, and reduced number of operation types. RISC concepts allow the microarchitecture design of machines to be more easily pipelined, reducing the processor clock cycle frequency and the overall speed of a machine. The RISC concept resulted from improvements in programming languages, compiler technology, and memory size. The HP PA-RISC, Sun SPARC, IBM Power PC, MIPS, and DEC Alpha machines are examples of RISC architectures.

Architecture models allowing multiple instructions to issue in a clock cycle are VLIW (Very Long Instruction Word). VLIWs issue a fixed number of operations conveyed as a single long instruction and place the responsibility of creating the parallel instruction packet on the compiler. Early VLIW processors suffered from code expansion due to instructions. Examples of VLIW technology are the Multiflow Trace and Cydrome Cydra machines. EPIC (Explicitly Parallel Instruction Computing) is similar in concept to VLIW in that both use the compiler to explicitly group instructions for parallel execution. In fact, many of the ideas for EPIC architectures come from previous RISC and VLIW machines. In general, the EPIC concept solves the excessive code expansion and scalability problems associated with VLIW models by not completely eliminating its functionality. Also, the trend of compiler controlled architecture mechanisms are generally considered part of the EPIC-style architecture domain. The Intel IA-64, Philips Trimedia, and Texas Instruments ‘C6X are examples of EPIC machines.

63.5 Instruction Level Parallelism

Modern processors are being designed with the ability to execute many parallel operations at the instruction level. Such processors are said to exploit ILP (Instruction-Level Parallelism). Exploiting ILP is recognized as a new fundamental architecture concept in improving microprocessor performance, and there are a wide range of architecture techniques that define how an architecture can exploit ILP.

Dynamic Instruction Execution

A major limitation of pipelining techniques is the use of in-order instruction execution. When an instruction in the pipeline stalls, no further instructions are allowed to proceed to insure proper execution of in-flight instruction. This problem is especially serious for multiple issue machines, where each stall cycle potentially costs work of multiple instructions. However, in many cases, an instruction could execute properly if no data dependence exists between the stalled instruction and the instruction waiting to execute. Static scheduling is a compiler-oriented approach for scheduling instructions to separate dependent instructions and minimize the number of hazards and pipeline stalls. Dynamic scheduling is another approach that uses hardware to rearrange the instruction execution to reduce the stalls. The concept of dynamic execution uses hardware to detect dependences in the in-order instruction stream sequence and rearrange the instruction sequence in the presence of detected dependences and stalls.

Today, most modern superscalar microprocessors use dynamic out-of-order scheduling techniques to increase the number of instructions executed per cycle. Such microprocessors use basically the same dynamically scheduled pipeline concept, all instructions pass through an issue stage in-order, are executed out-of-order, and are retired in-order. There are several functional elements of this common sequence which have developed into computer architecture concepts. The first functional concept is *scoreboarding*. Scoreboarding is a technique for allowing instructions to execute out-of-order when there are available resources and no data dependences. Scoreboarding originates from the CDC 6600 machine's issue logic, named the scoreboard. The overall goal of scoreboarding is to execute every instruction as early as possible.

A more advanced approach to dynamic execution is *Tomasulo's approach*. This scheme was employed in the IBM 360/91 processor. Although there are many variations on this scheme, the key concept of avoiding Write-After-Read (WAR) and Write-After-Write (WAW) dependences during dynamic execution is attributed to Tomasulo. In Tomasulo's scheme, the functionality of the scoreboarding is provided by the *reservation stations*. Reservation stations buffer the operands of instructions waiting to issue as soon as they become available. The concept is to issue new instructions immediately when all source operands become available instead of accessing such operands through the register file. As such, waiting instructions designate the reservation station entry that will provide their input operands. This action removes WAW dependences caused by successive writes to the same register by forcing instructions to be related by dependences instead of by register specifiers. In general, renaming of register specifiers for pending operands to the reservation station entries is called *register renaming*. Overall, Tomasulo's scheme combines scoreboarding and register renaming. *An Efficient Algorithm for Exploring Multiple Arithmetic Units*[6] provides the complete details of Tomasulo's scheme.

Predicated Execution

Branch instructions are recognized as a major impediment to exploiting (ILP). Branches force the compiler and hardware to make frequent predictions of branch directions in an attempt to find sufficient parallelism. Misprediction of these branches can result in severe performance degradation through the introduction of wasted cycles into the instruction stream. Branch prediction strategies reduce this problem by allowing the compiler and hardware to continue processing instructions along the predicted control path, thus eliminating these wasted cycles.

Predicated execution support provides an effective means to eliminate branches from an instruction stream. Predicated execution refers to the conditional execution of an instruction based on the value of a Boolean source operand, referred to as the predicate of the instruction. This architectural support allows the compiler to use an *if-conversion* algorithm to convert conditional branches into predicate defining instructions, and instructions along alternative paths of each branch into predicated instructions.[7] Predicated instructions are fetched regardless of their predicate value. Instructions whose predicate value is true are executed normally. Conversely, instructions whose predicate is false are nullified, and thus are prevented from modifying the processor state. Predicated execution allows the compiler to trade instruction fetch efficiency for the capability to expose ILP to the hardware along multiple execution paths.

Predicated execution offers the opportunity to improve branch handling in microprocessors. Eliminating frequently mispredicted branches may lead to a substantial reduction in branch prediction misses. As a result, the performance penalties associated with the eliminated branches are removed. Eliminating branches also reduces the need to handle multiple branches per cycle for wide issue processors. Finally, predicated execution provides an efficient interface for the compiler to expose multiple execution paths to the hardware. Without compiler support, the cost of maintaining multiple execution paths in hardware grows rapidly.

The essence of predicated execution is the ability to suppress the modification of the processor state based upon some execution condition. Full predication cleanly supports this through a combination of instruction set and microarchitecture extensions. These extensions can be classified as a support for suppression of execution and expression of condition. The result of the condition which determines if an instruction should modify state is stored in a set of 1-bit registers. These registers are collectively referred to as the predicate register file. The values in the predicate register file are associated with each instruction in the extended instruction set through the use of an additional source operand. This operand specifies which predicate register will determine whether the operation should modify processor state. If the value in the specified register is 1, or true, the instruction is executed normally; if the value is 0, or false, the instruction is suppressed.

Predicate register values may be set using predicate define instructions. The predicate define semantics used are those of the HPL Playdoh architecture.[8] There is a predicate define instruction for each comparison opcode in the original instruction set. The major difference with conventional comparison instructions is that these predicate defines have up to two destination registers and that their destination registers are predicate registers. The instruction format of a predicate define is shown below.

$$\text{pred\_<}cmp\text{>}\ \text{Pout1}_{<type>},\ \text{Pout2}_{<type>},\ \text{src1},\ \text{src2}\ (\text{P}_{in})$$

This instruction assigns values to *Pout1* and *Pout2* according to a comparison of *src1* and *src2* specified by <*cmp*>. The comparison <*cmp*> can be: equal (eq), not equal (ne), greater than (gt), etc. A predicate <*type*> is specified for each destination predicate. Predicate defining instructions are also predicated, as specified by P_{in}.

The predicate <*type*> determines the value written to the destination predicate register based upon the result of the comparison and of the input predicate, P_{in}. For each combination of comparison result and P_{in}, one of three actions may be performed on the destination predicate: it can write 1, write 0, or leave it unchanged. There are six predicate types which are particularly useful, the unconditional (*U*), *OR*, and *AND* type predicates and their complements. Table 63.1 contains the truth table for these predicate definition types.

TABLE 63.1 Predicate Definition Truth Table

		P_{out}					
P_{in}	Comparison	U	$\overline{U}$	OR	$\overline{OR}$	AND	$\overline{AND}$
0	0	0	0	—	—	—	—
0	1	0	0	—	—	—	—
1	0	0	1	—	1	0	—
1	1	1	0	1	—	—	0

Unconditional destination predicate registers are always defined, regardless of the value of P_{in} and the result of the comparison. If the value of P_{in} is 1, the result of the comparison is placed in the predicate register (or its compliment for $\overline{U}$). Otherwise, a 0 is written to the predicate register. Unconditional predicates are utilized for blocks which are executed based on a single condition.

The *OR*-type predicates are useful when execution of a block can be enabled by multiple conditions, such as logical AND (&&) and OR (||) constructs in C. *OR*-type destination predicate registers are set if P_{in} is 1 and the result of the comparison is 1 (0 for $\overline{OR}$); otherwise, the destination predicate register is

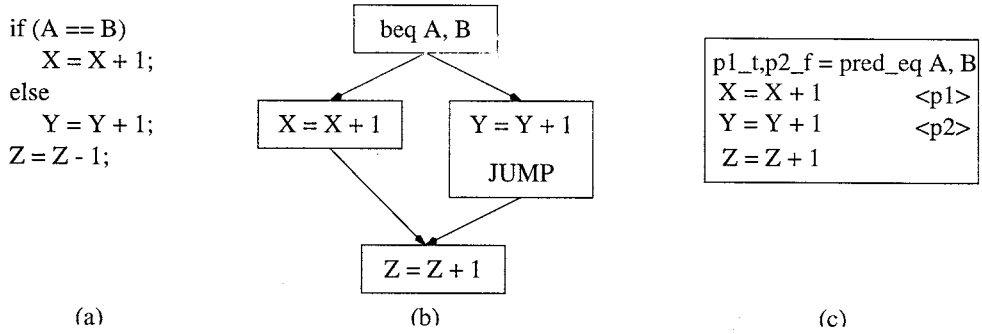

FIGURE 63.11 Instruction sequence: (a) program code, (b) traditional execution, (c) predicated execution.

unchanged. Note that *OR*-type predicates must be explicitly initialized to 0 before they are defined and used. However, after they are initialized, multiple *OR*-type predicate defines may be issued simultaneously and in any order on the same predicate register. This is true since the *OR*-type predicate either writes a 1 or leaves the register unchanged, which allows implementation as a wired logical *OR* condition. *AND*-type predicates are analogous to the *OR* type predicate. *AND*-type destination predicate registers are cleared if P_{in} is 1 and the result of the comparison is 0 (1 for *AND*); otherwise, the destination predicate register is unchanged.

Figure 63.11 contains a simple example illustrating the concept of predicated execution. Figure 63.11(a) shows a common programming if-then-else construction. The related control flow representation of that programming code is illustrated in Fig. 63.11(b). Using if-conversion, the code in Fig. 63.11(b) is then transformed into the code shown in Fig. 63.11(c). The original conditional branch is translated into a *pred_eq* instructions. Predicate register *p1* is set to indicate if the condition ($A = B$) is true, and *p2* is set if the condition is false. The "then" part of the if-statement is predicated on *p1* and the "else" part is predicated on p_2 The *pred_eq* simply decides whether the addition or subtraction instruction is performed and ensures that one of the two parts is not executed. There are several performance benefits for the predicated code. First, the microprocessor does not need to make any branch predictions since all the branches in the code are eliminated. This removes related penalties due to misprediction branches. More importantly, the predicated instructions can utilize multiple instruction execution capabilities of modern microprocessors and avoid the penalties for mispredicting branches.

Speculative Execution

The amount of ILP available within basic blocks is extremely limited in non-numeric programs. As such, processors must optimize and schedule instructions across basic block code boundaries to achieve higher performance. In addition, future processors must content with both long latency load operations and long latency cache misses. When load data is needed by subsequent dependent instructions, the processor execution must wait until the cache access is complete.

In these situations, out-of-order machines dynamically reorder the instruction stream to execute non-dependent instructions. Additionally, out-of-order machines have the advantage of executing instructions that follow correctly predicted branch instructions. However, this approach requires complex circuitry at the cost of chip die space. Similar performance gains can be achieved using static compile-time speculation methods without complex out-of-order logic. Speculative execution, a technique for executing an instruction before knowing its execution is required, is an important technique for exploiting ILP in programs. Speculative execution is best known for hiding memory latency. These methods utilize instruction set architecture support of special speculative instructions.

A compiler utilizes speculative code motion to achieve higher performance in several ways. First, in regions of code where insufficient ILP exists to fully utilize the processor resources, useful instructions

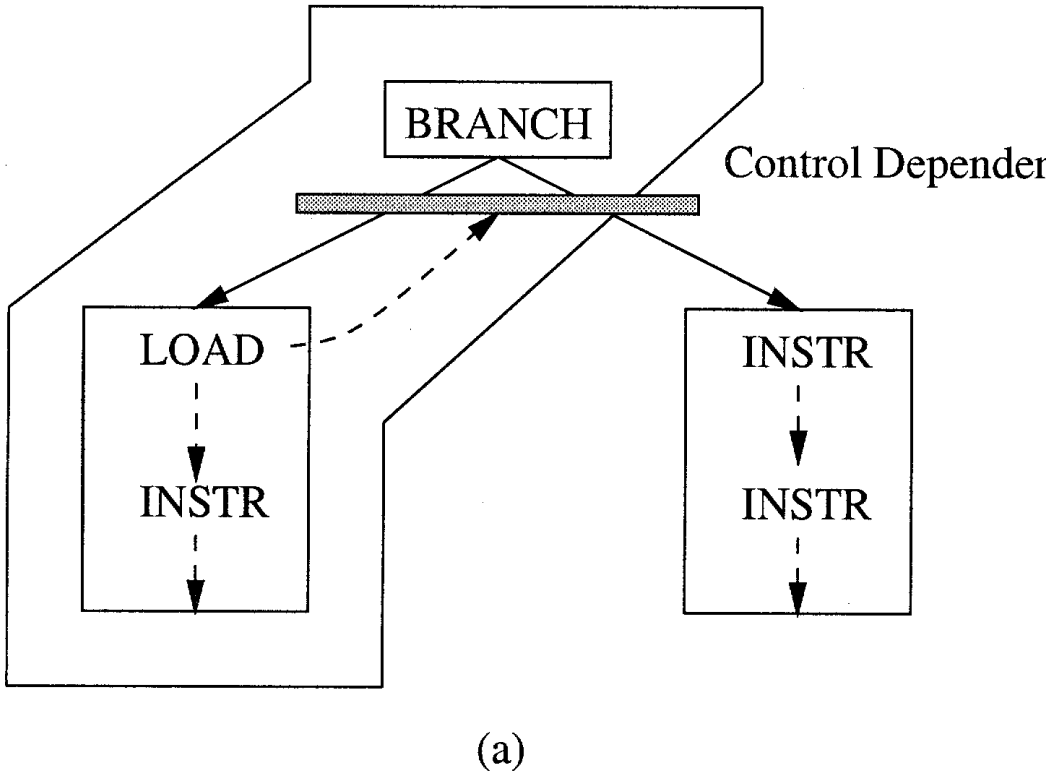

FIGURE 63.12 Instruction sequence: (a) traditional execution, (b) speculative execution.

may be executed. Second, instructions at the beginning of long dependence chains may be executed early to reduce the computation's critical path. Finally, long latency instructions may be initiated early to overlap their execution with other useful operations. Figure 63.12 illustrates a simple example of code before and after a speculative compile-time transformation is performed to execute a load instruction above a conditional branch.

Figure 63.12(a) shows how the branch instruction and its implied control flow define a control dependence that restricts the load operation from being scheduled earlier in the code. Cache miss latencies would halt the processor unless out-of-order execution mechanisms were used. However, with speculation support, Fig. 63.12(b) can be used to hide the latency of the load operation.

The solution requires the load to be speculative or nonfaulting. A speculative load will not signal an exception for faults such as address alignment or address space access errors. Essentially, the load is considered silent for these occurrences. The additional check instruction in Fig. 63.12(b) enables these signals to be detected when the original execution does reach the original location of the load. When the other path of branch's execution is taken, such silent signals are meaningless and can be ignored. Using this mechanism, the load can be placed above all existing control dependences, providing the compiler with the ability to hide load latency. Details of compiler speculation can be found in Ref. 9.

63.6 Industry Trends

The microprocessor industry is one of the fastest moving industries today. Healthy demands from the market-place have stimulated strong competition, which in turn resulted in great technical innovations.

Computer Microprocessor Trends

The current trends of computer microprocessors include deep pipelining, high clock frequency, wide instruction issue, speculative and out-of-order execution, predicated execution, natural data types, large on-chip caches, floating point capabilities, and multiprocessor support. In the area of pipelining, the Intel Pentium II processor is pipelined approximated twice as deeply as its predecessor Pentium. The deep pipeline has allowed the clock Pentium II processor to run at a much higher clock frequency than Pentium.

In the area of wide instruction issue, the Pentium II processor can decode and issue up to three X86 instructions per clock cycle, compared to the two-instruction issue bandwidth of Pentium. Pentium II has dedicated a very significant amount of chip area to Branch Target Buffer, Reservation Station, and Reorder Buffer to support speculative and out-of-order execution. These structures together allow the Pentium II processor to perform much more aggressive speculative and out-of-order execution than Pentium. In particular, Pentium II can coordinate the execution of up to 40 X86 instructions, which is several times larger than Pentium.

In the area of predicated execution, Pentium II supports a conditional move instruction that was not available in Pentium. This trend is furthered by the next generation IA-64 architecture where all instructions can be conditionally executed under the control of predicate registers. This ability will allow future microprocessors to execute control intensive programs much faster than their predecessors.

In the area of data types, the MMX instructions from Intel have become a standard feature of all X86 microprocessors today. These instructions take advantage of the fact that multimedia data items are typically represented with a smaller number of bits (8 to 16 bits) than the width of an integer data path today (32 to 64 bits). Based on an observation, the same operation is often repeated on all data items in multimedia applications, the architects of MMX specify that each MMX instruction performs the same operation on several multimedia data items packed into one integer word. This allows each MMX instruction to process several data items simultaneously to achieve significant speed-up in targeted applications. In 1998, AMD proposed the 3DNow! instructions to address the performance needs of 3-D graphics applications. The 3DNow! instructions are designed based on the concept that 3-D graphics data items are often represented in single precision floating-point format and they do not required the sophisticated rounding and exception handling capabilities specified in the IEEE Standard format. Thus, one can pack two graphics floating-point data into one double-precision floating-point register for more efficient floating-point processing of graphics applications. Note that MMX and 3DNow! are similar in concepts applied to integer and floating-point domains.

In the area of large on-chip caches, the popular strategies used in computer microprocessors are either to enlarge the first-level caches or to incorporate second-level and sometimes third-level caches on-chip. For example, the AMD K7 microprocessor has a 64KB first-level instruction cache and a 64-KB first-level data cache. These first-level caches are significantly larger than those found in the previous generations. For another example, the Intel Celeron microprocessor has a 128-KB second level combined instruction and data cache. These large caches are enabled by the increased chip density that allows many more transistors on the chip. The Compaq Alpha 21364 microprocessor has both: a 64-KB first-level instruction cache, a 64-KB first-level data cache, and a 1.5-MB second-level combined cache.

In the area of floating-point capabilities, computer microprocessors in general have much stronger floating-point performance than their predecessors. For example, the Intel Pentium II processor achieves several times the floating-point performance improvements of the Pentium processor. For another example, most RISC microprocessors now have floating-point performances that rival supercomputer CPUs built just a few years ago.

Due to the increasing demand of multiprocessor enterprise computing servers, many computer microprocessors now seamlessly support cache coherence protocols. For example, the AMD K7 microprocessor provides direct support for seamless multiprocessor operation when multiple K7 microprocessors are connected to a system bus. This capability was not available in its predecessor, the AMD K6.

Embedded Microprocessor Trends

There are three clear trends in embedded microprocessors. The first trend is to integrate a DSP core with an embedded CPU/controller core. Embedded applications increasingly require DSP functionalities such as data encoding in disk drives and signal equalization for wireless communications. These functionalities enhance the quality of services of their end computer products. At the *1998 Embedded Microprocessor Forum*, ARM, Hitachi, and Siemens all announced products with both DSP and embedded microprocessors.[10]

Three approaches exist in the integration of DSP and embedded CPUs. One approach is to simply have two separate units placed on a single chip. The advantage of this approach is that it simplifies the development of the microprocessor. The two units are usually taken from existing designs. The software development tools can be directly taken from each unit's respective software support environments. The disadvantage is that the application developer needs to deal with two independent hardware units and two software development environments. This usually complicates software development and verification.

An alternative approach to integrating DSP and embedded CPUs is to add the DSP as a co-processor of the CPU. This CPU fetches all instructions and forwards the DSP instructions to the co-processor. The hardware design is more complicated than the first approach due to the need to more closely interface the two units, especially in the area of memory accesses. The software development environment also needs to be modified to support the co-processor interaction model. The advantage is that the software developers now deal with a much more coherent environment.

The third approach to integrating DSP and embedded CPUs is to add DSP instructions to a CPU instruction set architecture. This usually requires brand-new designs to implement the fully integrated instruction set architecture.

The second trend in embedded microprocessors is to support the development of single-chip solutions for large-volume markets. Many embedded microprocessor vendors offer designs that can be licensed and incorporated into a larger chip design that includes the desired input/output peripheral devices and Application-Specific Integrated Circuit (ASIC) design. This paradigm is referred to as system-on-a-chip design. A microprocessor that is designed to function in such a system is often referred to as a licensable core.

The third major trend in embedded microprocessors is aggressive adoption of high-performance techniques. Traditionally, embedded microprocessors are slow to adopt high-performance architecture and implementation techniques. They also tend to reuse software development tools, such as compilers from the computer microprocessor domain. However, due to the rapid increase of required performance in embedded markets, the embedded microprocessor vendors are now making fast moves in adopting high-performance techniques. This trend is especially clear in the DSP microprocessors. Texas Instruments, Motorola/Lucent, and Analog Devices have all announced aggressive EPIC DSP microprocessors to be shipped before the Intel/HP IA-64 EPIC microprocessors.

Microprocessor Market Trends

Readers who are interested in market trends for microprocessors are referred to *Microprocessor Report*, a periodical publication by MicroDesign Resources (www.MDRonline.com). In every issue, there is a summary of microarchitecture features, physical characteristics, availability, and pricing of microprocessors.

64.1 Introduction

Microelectronic technology has matured considerably in the past few decades. Systems which until the start of the decade required a printed circuit board for implementation are now being developed on a single chip. These systems-on-a-chip (SOCs) are becoming a reality due to vast improvements in chip fabrication and process technology. A key component in SOC and other semiconductor chips are *Application-Specific Integrated Circuits* (ASICs). These are specialized circuit blocks or entire chips which are designed specifically for a given application or an application domain. For instance, a video decoder circuit may be implemented as an ASIC chip to be used inside a personal computer product or in a range of multimedia appliances. Due to the custom nature of these designs, it is often possible to squeeze in more functionality under performance requirements — while reducing system size, power, heat, and cost — than possible with standard IC parts. Due to cost and performance advantages, ASICs and semiconductor chips with ASIC blocks are used in a wide range of products, from consumer electronics to space applications.

Traditionally, the design of ASICs has been a long and tedious process because of the different steps in the design process. It has also been an expensive process due to the costs associated with ASIC manufacturing for all but applications requiring more than tens of thousands of IC parts. Lately, the

situation has been changing in favor of increased use of ASIC parts, in part helped by robust design methodologies and increased use of automated circuit synthesis tools. These tools allow designers to go from high-level design descriptions, all the way to final chip layouts and mask generation for the fabrication process. These developments, coupled with an increasing market for semiconductor chips in nearly all every-day devices, have led to a spur in the demand for ASICs and chips which have ASICs in them.

ASIC design and manufacturing span a broad range of activities, which includes product conceptualization, design and synthesis, verification, and testing. Once the product requirements have been finalized, a high-level design is done from which the circuit is synthesized or successively refined to the lowest level of detail. The design has to be verified for functionality and correctness at each stage of the process to ensure that no errors are introduced and the product requirements are met. Testing here refers to manufacturing test, which involves determining if the chip has no manufacturing defects. This is a challenging problem since it is difficult to control and observe internal wires in a manufactured chip and it is virtually impossible to repair the manufactured chips. At the same time, volume manufacturing of semiconductors requires that the product be tested in a very short time (usually less than a second). Hence, we need to develop a test methodology which allows us to check if a given chip is functional in the shortest possible amount of time. In this chapter, we focus on ASIC design issues and their relationship to other ASIC aspects, such as testability, power optimization, etc. We concentrate on the design flow, methodology, synthesis, and physical issues, and relate these to the computer-aided design (CAD) tools available.

The rest of this chapter is organized in the following manner. Section 64.2 introduces the notion of a design style and the ASIC design methodologies. Section 64.3 outlines the steps in the design process followed by a discussion of the role of hierarchy and design abstractions in the ASIC design process. Following sections on architectural design, logic synthesis, and physical design give examples to demonstrate the key ideas. We elucidate the availability and the use of appropriate CAD tools at various steps of the ASIC design.

64.2 Design Styles

ASIC design starts with an initial concept of the required IC part. Early in this product conceptualization phase, it is important to decide the *design style* that will be most suitable for the design and validation of the eventual ASIC chip. A design style refers to a broad method of designing circuits which uses specific techniques and technologies for the design implementation and validation. In particular, a design style determines the specific design steps and the use of library parts for the ASIC part. Design styles are determined, in part, by the economic viability of the design, as determined by tradeoffs between performance, pricing, and production volume. For some applications, such as defense systems and space applications, although the volume is low, the cost is of little concern due to the time-criticality of the application and the requirements of high performance and reliability. For applications such as consumer electronics, the high volume can offset high production costs.

Design styles are broadly classified into *custom* and *semi-custom* designs.[1] Custom designs, as the name suggests, involve the complete design to be hand-crafted so as to optimize the circuit for performance and/or area for a given application. Although this is an expensive design style in terms of effort and cost, it leads to high-quality circuits for which the cost can be amortized over a large volume production.

The semi-custom design style limits the circuit primitives and uses predesigned blocks which cannot be further fine-tuned. These predesigned primitive blocks are usually optimized, well-designed, and well-characterized, and ultimately help raise the level of abstraction in the design. This design style leads to reduced design times and facilitates easier development of CAD tools for design and optimization. These CAD tools allow the designer to choose among the various available primitive blocks and interconnect them to achieve the design functionality and performance. Semi-custom design styles are becoming the norm due to increasing design complexity. At the current level of circuit complexity, the loss in quality by using a semi-custom design style is often very small compared to a custom design style.

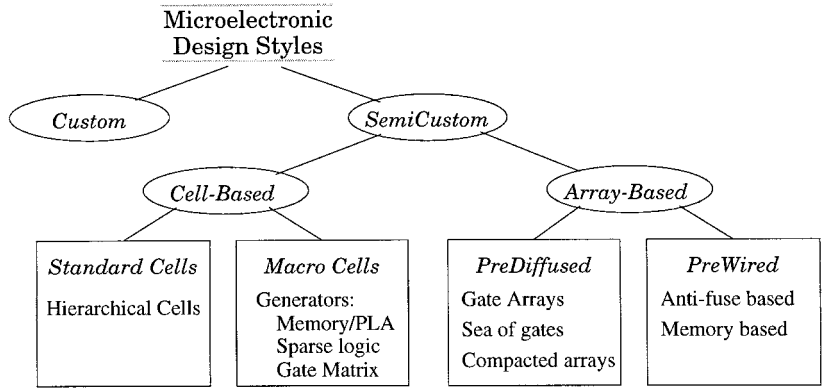

FIGURE 64.1 Classification of custom and semi-custom design styles.

Semi-custom designs can be classified into two major classes: *cell-based design* and *array-based design*, which can further be further subdivided into subclasses as shown in Fig. 64.1.[1] Cell-based designs use *libraries* of predesigned cells or *cell generators*, which can synthesize cell layouts given their functional description. The predesigned cells can be characterized and optimized for the various process technologies that the library targets.

Cell-based designs can be based on *standard-cell* design, in which basic primitive cells are designed once and, thereafter, are available in a library for each process technology or foundry used. Each cell in the library is parameterized in terms of area, delay, and power. These libraries have to be updated whenever the foundry technology changes. CAD tools can then be used to map the design to the cells available in the library in a step known as *technology mapping* or *library binding*. Once the cells are selected, they are placed and wired together.

Another cell-based design style uses *cell generators* to synthesize primitive building blocks which can be used for *macro-cell*-based design (see Fig. 64.1). These generators have traditionally been used for the automatic synthesis of memories and programmable logic arrays (PLAs), although recently module generators have been used to generated complex datapath components such as multipliers.[2] Module generators for macro-cell generation are *parameterizable*, that is, they can be used to generate different instances of a module such as a 8×8 and a 16×8 multiplier.

In contrast to cell-based designs, *array-based* designs use a prefabricated matrix of non-connected components known as *sites*. These sites are wired together to create the circuit required. Array-based circuits can either be *pre-diffused* or *pre-wired*, also known as *mask programmable* and *field programmable gate arrays*, respectively (MPGAs and FPGAs). In MPGAs, wafers consisting of arrays of unwired sites are manufactured and then the sites are programmed by connecting them with wires, via different routing layers during the chip fabrication process. There are several types of these pre-diffused arrays, such as gate arrays, sea-of-gates, and compacted arrays (see Fig. 64.1).

Unlike MPGAs, pre-wired gate arrays or FPGAs are programmed outside the semiconductor foundry. FPGAs consist of programmable arrays of modules implementing generic logic. In the *anti-fuse* type of FPGAs, wires can be connected by programming the anti-fuses in the array. Anti-fuses are open-circuit devices that become a short-circuit when an appropriate current is applied to them. In this way, the circuit design required can be achieved by connecting the logic module inputs appropriately by programming the anti-fuses. On the other hand, *memory-based* FPGAs store the information about the interconnection and configuration of the various generic logic modules in memory elements inside the array.

The use of FPGAs is becoming more and more popular as the capacity of the arrays and their performance are improving. At present, they are used extensively for circuit prototyping and verification. Their relative ease of design and customization leads to low cost and time overheads. However, FPGA is still an expensive technology since the number of gate arrays required to implement a moderately complex

design is large. The cost per gate of prototype design is decreasing due to continuous density and capacity improvement in FPGA technology.

Hence, there are several design styles available to a designer, and choosing among them depends upon tradeoffs using factors such as cost, time-to-market, performance, and reliability. In real-life applications, nearly all designs are a mix of custom and semi-custom design styles, particularly cell-based styles. Depending on the application, designers adopt an approach of embedding some custom designed blocks inside a semi-custom design. This leads to lower overheads since only the critical parts of the design have to be hand-crafted. For example, a microprocessor typically has a custom designed data path and the control logic is synthesized using a standard cell-based technique. Given the complexity of microprocessors, recent efforts in CAD are attempting to automate the design process of data path blocks as well.[3] Prototyping and circuit verification using FPGA-based technologies has become popular due to high costs and time overruns in case of a faulty design once the chip is manufactured.

64.3 Steps in the Design Flow

An important decision for any design team is the design flow that they will adopt. The design flow defines the approach used to take a design from an abstract concept through the specification, design, test, and manufacturing steps.[28] The *waterfall model* has been the traditional model for ASIC development. In this model, the design goes through various steps or phases while it is constantly refined to the highest level of detail. This model involves minimal interaction between design teams working on different phases of the design.

The design process starts with the development of a *specification* and high-level design of the ASIC, which may include requirements analysis, architecture design, executable specification or C model development, and functional verification of the specification. The design is then coded at the register transfer level (RTL) in hardware description languages such as VHDL[12] or Verilog.[13] The functionality of the RTL code is verified against the initial specification (e.g., C model), which is used as the *golden model* for verifying the design at every level of abstraction (see Section 64.5). The RTL is then synthesized into a *gate-level netlist* which is run through a *timing verification* tool which verifies that the ASIC meets the timing constraints specified. The physical design team subsequently develops a floorplan for the chip, places the cells, and routes the interconnects, after which the chip is manufactured and tested (see Fig. 64.2).

The disadvantage with this design methodology is that as the complexity of the system being designed increases, the design becomes more error prone. The requirements are not properly tested until a working system model is available, which only becomes available late in the design cycle. Errors are hence discovered late in the design process and error correction often involves a major redesign and rerun through the steps of the design again. This leads to several design reworks and may even involve multiple chip fabrication runs.

The steps and different levels of detail that the design of an integrated circuit goes through as it progresses from concept to chip fabrication, are shown in Fig. 64.2. The requirements of a design are represented by a behavioral model which represents

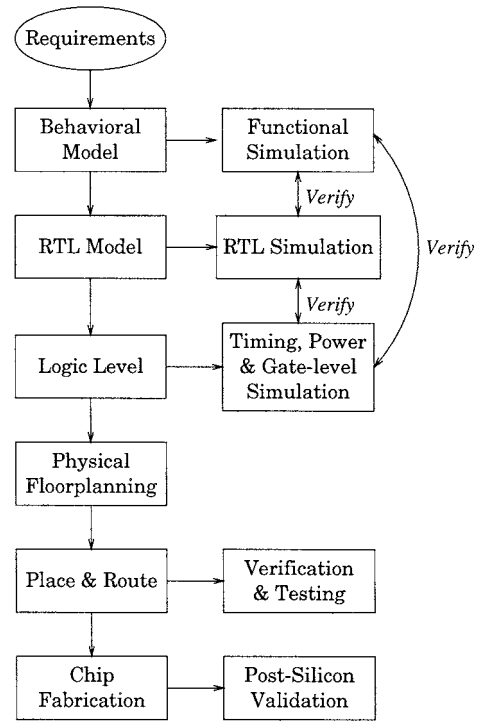

FIGURE 64.2 A typical ASIC design flow.

the functions the design must implement with the timing, area, power, testing, etc. constraints. This behavioral model is usually captured in the form of an executable functional specification in a language such as C (or C++). This functional specification is simulated for a wide set of inputs to verify that all the requirements and functionalities are met.

For instance, when developing a new microprocessor, after the initial architectural design, the design team develops an instruction set architecture. This involves making decisions on issues such as the number of pipeline stages, width of the data path, size of the register file, number and type of components in the data path, etc. An instruction set simulator is then developed so that the range of applications being targeted (or a representative set) can be simulated on the processor simulator. This verifies that the processor can run the application or a benchmark suite within the required timing performance. The simulator also verifies that the high-level design is correct and attempts to identify data and pipeline hazards in the data path architecture. The feedback from the simulator may be used to refine the instruction set of the processor.

The functional specification (or behavioral model) is converted into a register transfer level (RTL) model, either manually or by using a behavioral or high-level synthesis tool.[27] This RTL model uses register-level components like adders, multipliers, registers, multiplexors, etc. to represent the structural model of the design with the components and their interconnections. This RTL model is simulated, typically using event-driven simulation (see Section 64.7) to verify the functionality and coarse-level timing performance of the model. The tested and verified software functional model is used as the *golden model* to compare the results against. The RTL model is then refined to the logic gate level using logic synthesis tools which implement the components with gates or combination of gates, usually using a cell-library-based methodology. The gate-level netlist undergoes the most extensive simulation. Besides functionality, other constraints such as timing and power are also analyzed. Static timing analysis tools are used to analyze the timing performance of the circuit and identify critical paths in the design. The gate-level netlist is then converted into a physical layout, by floorplanning the chip area, placement of the cells, and routing of the interconnects. The layout is used to generate the set of masks[1] required for chip fabrication.

Logic synthesis is a design methodology for the synthesis and optimization of gate-level logic circuits. Before the advent of logic synthesis, ASIC designers used a *capture-and-simulate* design methodology.[4] In this methodology, a team of design architects starts with the requirements for the product and produces a rough block diagram of the chip architecture. This architecture is then refined to ensure completeness and functionality and then given to a team of logic and layout designers who use logic and circuit schematic design tools to capture the design and each of its functional blocks and their interconnections. Layout, placement, and routing tools are then used to map this schematic into the technology library or to another custom or semi-custom design style.

However, the development of logic synthesis in the last decade has raised the ante to a *describe-and-synthesize* methodology. Designs are specified in hardware description languages (HDL) such as *VHDL*[12] and *Verilog*,[13] using Boolean equations and finite-state machine descriptions or diagrams, in a technology-independent form. *Logic synthesis* tools are then used to synthesize these Boolean equations and finite-state machine descriptions into functional units and control units, respectively.[5,6,23]

Behavioral or *high-level synthesis* tools work at a higher level of abstraction and use programs, algorithms, and dataflow graphs as inputs to describe the behavior of the system and synthesize the processors, memories, and ASICs from them.[24,27] They assist in making decisions that have been the domain of chip architects and have been based mostly on experience and engineering intuition.

The relationship of the ASIC design flow, synthesis methodologies, and CAD tools is shown in Fig. 64.3. This figure shows how the design can go from behavior to register to gate to mask level via several paths which may be manual or automated or may involve sourcing out to another vendor. Hence, at any stage of the design, the design refinement step can either be performed manually or with the help of a synthesis

[1]Masks are the geometric patterns used to etch the cells and interconnects onto the silicon wafer to fabricate the chip.

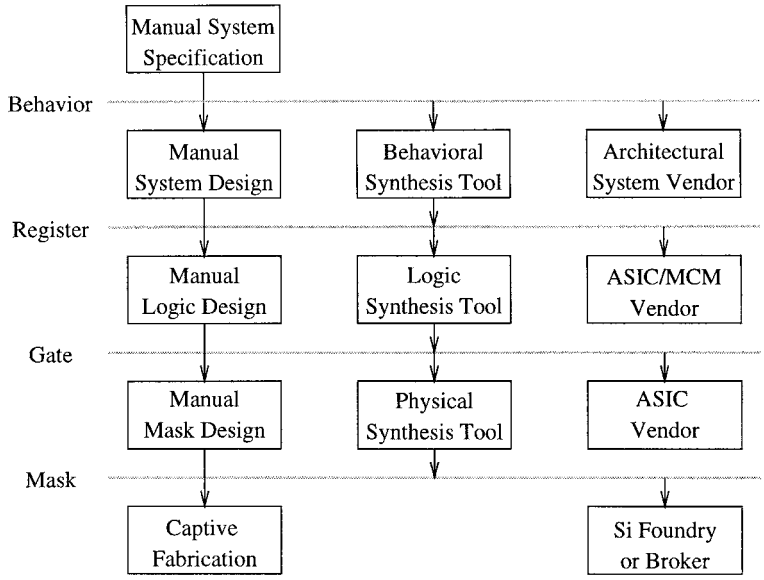

FIGURE 64.3 Manual design, automated synthesis, and outsourcing.

CAD tool or the design at that stage can be sent to a vendor who refines the current design to the final fabrication stage. This concept has been popular among *fab-less* design companies that use technology libraries from foundries for logic synthesis and send out the logic gate netlist design for final mask generation and manufacturing to the foundries. However, in more recent years, vendors are specializing in design of reusable blocks which are sold as *intellectual property* (IP) to other design houses, who then assemble these blocks together to create systems-on-a-chip.[28]

Frequently, large semiconductor design houses are structured around groups which specialize in each one of these stages of the design. Hence, they can be thought of as independent vendors: the architectural design team defines the blocks in the design and their functionality, the logic design team refines the system design into a logic level design for which the masks are then generated by the physical design team. These masks are used for chip fabrication by the foundry. In this way, the design style becomes modular and easier to manage.

64.4 Hierarchical Design

Hierarchical decomposition of a complex system into simpler subsystems and further decomposition into subsystems of ever-more simplicity is a long established design technique. This *divide-and-conquer* approach attempts to handle the problem's complexity by recursively breaking it down into manageable pieces which can be easily implemented.

Chip designers extend the same hierarchical design technique by structuring the chip into a hierarchy of components and subcomponents. An example of hierarchical digital design is shown in Fig. 64.4.[25] This figure shows how a 4-bit adder can be created using four single-bit *full adders* (FAs) which are designed using logic gates such as AND, OR, and XOR gates. The FAs are composed into the 4-bit adder by interconnecting their pins appropriately; in this case, the carry out of the previous FA is connected to the carry-in of the next FA in a ripple-carry manner.

In the same manner, a system design can be recursively broken down into components, each of which is composed of smaller components until the smallest components can be described in terms of gates and/or transistors. At any level of the hierarchy, each component is treated as a black-box with a known input-output behavior, but how that behavior is implemented is unknown. Each black-box is designed

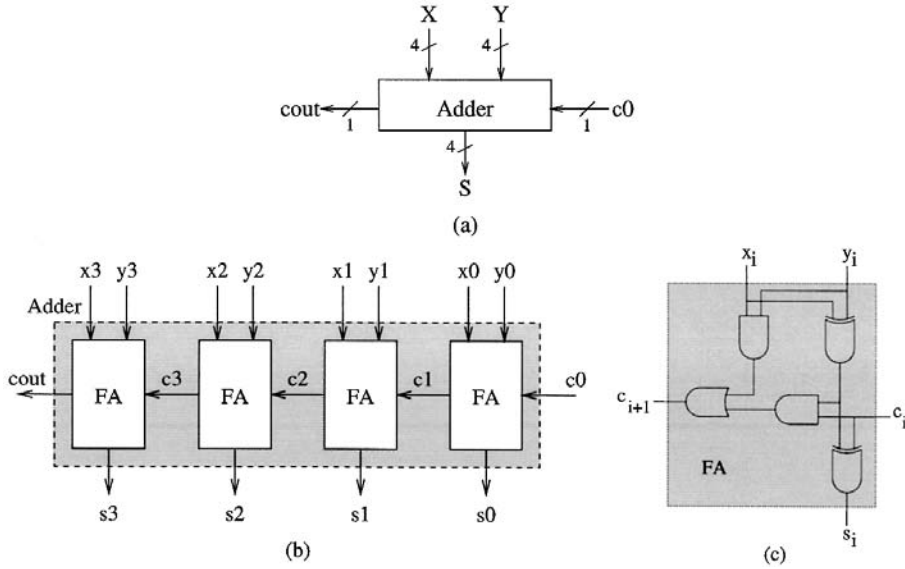

FIGURE 64.4 An example of hierarchical design: (a) a 4-bit ripple-carry adder; (b) internal view of the adder composed of full adders (FAs); (c) full-adder logic schematic.

by building simpler and simpler black-boxes based on the behavior of the component. The smallest primitive components (such as gates and transistors) are used at the lowest level of hierarchy.

Besides assisting in breaking down the complexity of a large system, hierarchy also allows easier conceptualization of the design and its functionality. At higher levels of the hierarchy, it is easier to understand the functionality at a behavioral level without having to worry about lower-level details. Hierarchical design also enables the reuse of components with little or no modification to the original design.

The design approach described above is a *top-down design approach* to hierarchy. The top-down design approach is a recursive process that takes a high-level specification and successively decomposes and refines it to the lowest level of detail and ends with integration and verification. This is in contrast to a *bottom-up approach*, which starts by designing and building the lowest-level components and successively using these components to build components of ever-increasing complexity until the final design requirements are met.

Since a top-down approach assumes that the lowest-level blocks specified can, in fact, be designed and built, the whole process has to be repeated if a low-level block turns out to be infeasible. Current design teams use a mixture of top-down and bottom-up methodologies, wherein critical low-level blocks are built concurrently as the system and block specifications are refined. The bottom-up approach attempts to abstract parameters of the low-level components so that they can be used in a generic manner to build several components of higher complexity.

64.5 Design Representation and Abstraction Levels

Another hierarchical approach is based on the concept of *design abstraction*. This approach views the design with different degrees of resolution at different levels of abstraction. In the design process, the design goes through several levels of abstraction as it progresses from concept to fabrication — namely, *system*, *register-transfer*, *logic*, and *geometrical*.[1] The *system-level* description of the design consists of a behavioral description in terms of functions, algorithms, etc. At the *register transfer level*, the circuit is represented by arithmetic and storage units and corresponds to the register transfer level (RTL) discussed earlier. The register-level components are selected and interconnected so as to achieve the functionality

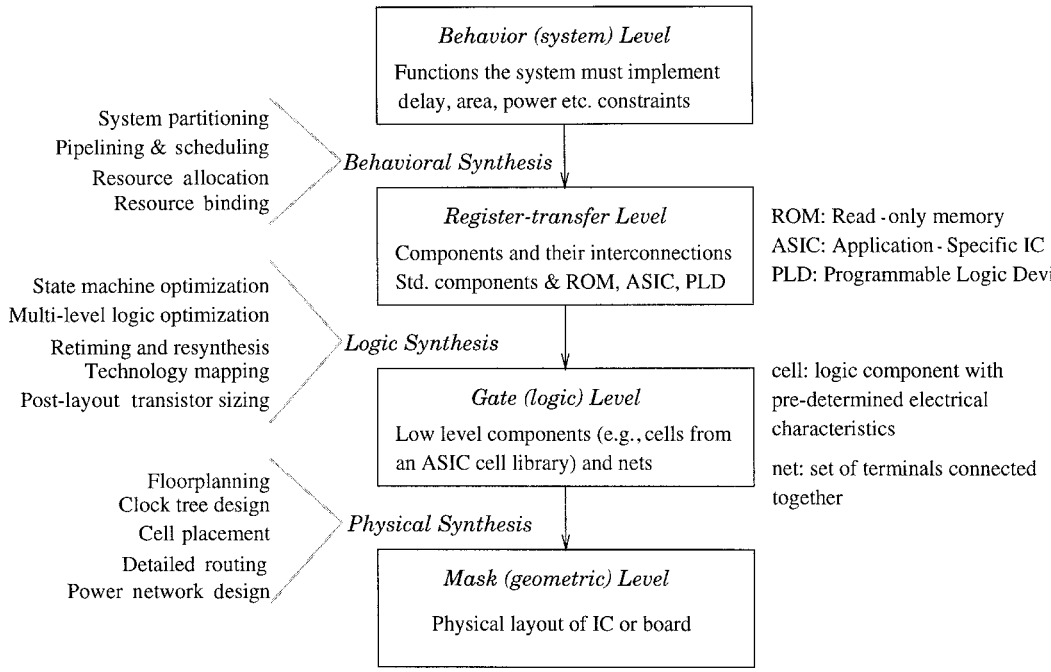

FIGURE 64.5 Simplified ASIC design flow: the progress of the design from the behavior to mask level and the synthesis processes and steps involved.

of the design. The *logic* level describes the circuit in terms of logic gates and flip-flops and the behavior of the system can be described in terms of a set of logic functions. These logic components are represented at the *geometric* level by a layout of the cells and transistors using geometric masks.

These levels of abstraction can be further understood with the help of the simplified ASIC design flow shown in Fig. 64.5.[26] This figure shows *behavior* as the initial abstraction level which represents the system level functionality of the design. The *register-transfer level* comprises components and their interconnections and, for more complex systems, may also comprise standard components such as ROMs (read-only memory), ASICs, etc. The logic level corresponds to the *gate* level representation and the set of *masks* of the physical layout of the chip correspond to the geometric level.

This figure also shows the synthesis processes and the steps involved in each process. These synthesis processes help refine the design from one level of detail to the next finer level of detail. These synthesis processes are known as behavioral synthesis, logic synthesis, and physical synthesis, and each of these synthesis processes are discussed in detail in later sections. It is possible to go from one level of detail to the next by following the steps within the synthesis process, either manually or with the help of CAD tools.

The circuit can also be viewed at different levels of design detail as the design progresses from concept to fabrication. These different design representations or views are differentiated by the type of information that they capture. These representations can be classified as *behavioral*, *structural*, and *physical*.[4] In a *behavioral representation*, only the functional behavior of the system is described and the design is treated as a black-box. A *structural representation* refines the design by adding information about the components in the system and their interconnection. The detailed physical characteristics of the components are specified in the *physical representation*, including the placement and routing information.

The relationships between the different abstraction levels and design representations or views is captured by the Y-chart shown in Fig. 64.6.[10] This chart shows how the same design at the system level can have a behavioral view and a structural view. Whereas the behavioral view would conceptualize the design in terms of flowcharts and algorithms, the structural view would represent the design in terms of processors, memories, and other logic blocks. Similarly, the behavioral view at the register-transfer level

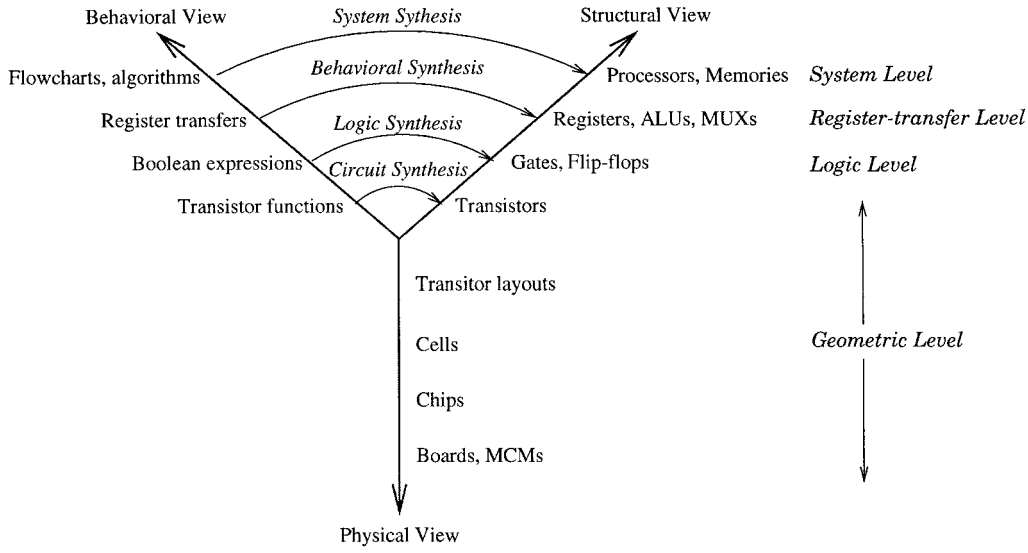

FIGURE 64.6 Y-chart: relationship of different abstraction levels and design representations.

would represent the register transfer flow by a set of behavioral statements, whereas the structural view would represent the same flow by a set of components and their interconnections. At the logic level, a circuit can be represented with Boolean equations or finite-state machines in the behavioral view, or it can be represented as a network of interconnected gates and flip-flops in the structural view. The geometric level is represented as transistor functions in the behavioral level, as transistors in the structural view, and as layouts, cells, chips, etc. in the physical view. In this way, the Y-chart model helps to understand the various phases, levels of detail, and views of a design. There have been many extensions to this model, including adding aspects such as testing and design processes.[11]

64.6 System Specification

In the following sections, we will discuss each of the steps in the design process of an ASIC. Any design or product starts with determining and capturing the requirements of the system. This is typically done in the form of a *system requirements specification* document. This specification describes the end-product requirements, functionality, and other system-level issues that impose requirements such as environment, power consumption, user acceptance requirements, and system testing. This leads to more specific requirements on the device itself, in terms of functionality, interfaces, operating modes, operating conditions, performance, etc.

At this stage, an initial analysis is done on the system requirements to determine the feasibility of the specification. It is determined which design style will be used (see Section 64.2) and the foundry, process, and library are also selected. Some other parameters such as packaging, operating frequency, number of pins on the chip, area, and memory size are also estimated.

Traditionally, for simple designs, design entry is done after the high-level architecture design has been completed. This design entry can be in the form of *schematics* of the blocks that implement the architecture. However, with increasing complexity of designs, concerns about system modeling and verification tools are becoming predominant. System designers want to ensure hardware design quality and quickly produce a working hardware model, simulate it with the rest of the system, and synthesize and formally verify it for specific properties. Hence, designers are adopting high-level hardware description languages (HDLs) for the initial specification of the system. These HDLs are simulatable and, hence, the functionality and architectural design can be simulated to verify the correctness and fulfillment of end-product

requirements. In present ASIC design methodologies used in the industry, HDLs are typically used to capture designs at a register-transfer level and logic synthesis tools are then used to synthesize the design.

However, recently the use of executable specifications for capturing system requirements is becoming popular, as proposed in the *Specify-Explore-Refine* (SER) methodology for system design.[4] After this *specify* phase, the *explore* phase consists of evaluating various different system components to implement the system functionality within the design constraints specified. The specification is updated with the design decisions made during the exploration phase in the *refine* phase. This methodology leads to a better understanding of the system functionality at a very early stage in the process. An *executable specification* is particularly useful to validate the product functionality and correctness and for the automatic verification of various design properties. Executable specifications can be easily simulated and the same model can be used for synthesis. Current design methodologies produce functional verification models in C or C++ and these are then thrown away and the design is manually entered again for the design tools.

The selection of a language to capture the system specification is an area of active research. The language must be easy to understand and program, and must be able to capture all the system's characteristics besides having the support of CAD tools which can synthesize the design from the specification. Many languages have been used to capture system descriptions, including VHDL,[12] Verilog,[13] HardwareC,[14] Statecharts,[15] Silage,[16] Esterel,[17] and SpecSyn.[18] More recently, there has been a move toward the use of programming languages for digital design due to their ability to easily express executable behaviors and allow quick hardware modeling and simulation and also due to system designers' familiarity with general-purpose, high-level programming languages such as C and C++.[53]

These languages have raised the level of abstraction at which the designer specifies the design to being closer to the conceptual model. The conceptual behavioral design can then be partitioned and structured and components can be allocated. In this manner, the design progresses from a purely functional specification to a structural implementation in a series of steps known as *refinement*. This methodology leads to lower design times, more efficient exploration of a larger design space, and lower re-design time.

64.7 Specification Simulation and Verification

Once a design has been captured in a hardware description language or a schematic capture tool, the functionality of the specification needs to be verified. The most popular technique for design verification is *simulation*, in which a set of input values are applied to the design and the output values are compared to the expected output values. Simulation is used at every stage of the design process and at various levels of design description: behavioral, functional, logic, circuit, and switch level.

Formal verification tools attempt to do equivalence checks between different stages of a design. Currently, in the industry, once the requirements of a design have been finalized, a functional specification is captured by a software model of the design in C or C++, which also models other design properties and architectural decisions. This software model is extensively simulated to verify that the design meets the system requirements and to verify the correctness of the architectural design. Often, a C or C++ model is used as the *golden model* against which the hardware model is verified at every stage of the design. The functional specification is translated (usually manually) into a structural RTL description, and their outputs are compared by simulation to verify that their functionality is equivalent. This is typically done by applying a set of input patterns to both the models and comparing their outputs on a cycle-by-cycle basis. As the design is further refined from RTL to logic level to physical layout, at each stage, the circuit is simulated to verify functional correctness and some other design properties, such as timing and area constraints.

The simulations of the RTL, logic, and physical level descriptions are done by different kind of simulators.[19] *Logic-level* simulators simulate the circuit at the logic gate level and are used extensively to verify the functional correctness of the design. *Circuit-level* simulation, which is the most accurate simulation technique, operates at a circuit level. The SPICE program is the foremost circuit simulation and analysis tool.[20] SPICE simulates the circuit by solving the matrix differential equations for circuit

currents, voltages, resistances, and conductances. Switch-level simulators, on the other hand, model transistors as switches and, unlike logic simulators, wires are not assumed to be ideal but instead are assumed to have some capacitance. Another simulator, *RSIM*, is a switch-level simulator with timing, which models CMOS gates as pull-down or pull-up structures and calculates their resistance to power or ground, so that it can be used with output capacitance to determine rise and fall times.[21]

Logic-level simulators are typically *event-driven*. These model the system in a discrete event system by defining appropriate events of interest and how the events are propagated throughout the model.[6,22] Hardware description languages (HDLs) such as VHDL and Verilog[12,13] have been designed based on event-driven simulation semantics. They have constructs to represent hardware features such as concurrency, hierarchy, and timing. Extensive simulation and functional verification techniques are used by designers at every stage of the design to ensure that no *bugs* are introduced in the process of refining the design from the behavioral level to the final layout.

64.8 Architectural Design

After the design specification has been captured, the system is partitioned into blocks with clearly defined functionality and the interfaces and interaction between the blocks are defined. This structuring of the design is known as *architectural* design. Besides partitioning, architectural decisions include deciding number and type of components and their interconnects such as adders, multipliers, ALUs, buses, etc., whether the design will be pipelined[2], number of pipeline stages, and the operations in each pipeline stage. These high-level architectural decisions have traditionally been done by a few experienced system architects in the design team. However, in the last decade, CAD tools such as high-level synthesis have been introduced which automatically or interactively make many of these architectural decisions and schedule the design, allocate components for it and interconnect them to create a register transfer level design optimized for different parameters.[24,27]

Behavioral Synthesis

Behavioral or *high-level synthesis*, which is the automated synthesis of systems from behavioral descriptions, has received a lot of attention recently due to its ability to provide the low turn-around time required for an ASIC design. High-level synthesis accepts a behavioral description of a system and generates a data path for this description at a register-transfer level.[29-31] High-level synthesis tools allow designers to work at a system level closer to the original conceptual model of the system. High-level synthesis tools can be targeted to optimize the area, performance, power, and testability of the final design. The tasks in high-level synthesis can be broadly classified into allocation, scheduling, and binding. *Allocation* consists of determining the number and type of components and other resources that are required for the implementation of the design. These components and resources are at the register-transfer level (RTL) and are taken from a library of available modules, which includes components such as ALUs, adders, multipliers, register files, registers, and multiplexers. Allocation also determines the number, width, and type of each bus in the system.

Scheduling assigns each of the operations in the behavioral description to time intervals, also known as control steps. The data flows from one stage of registers to the next during each control step and may be operated upon by a functional unit. The control steps are usually the length of a clock-cycle. The operations in each control step are then assigned to particular register-level components by the *binding* task. Hence, operations are assigned to functional units, variables to storage units, and the interconnect between the various units are also established.

Consider the sample data flow graph shown in Fig. 64.7(a) and its corresponding data path shown in Fig. 64.7(b). This data path was synthesized using a high-level synthesis system.[30] The data flow graph

[2]Pipelining is a technique where a series of operations are done in a pipeline or assembly-line fashion so as to increase concurrency among different types of operations.

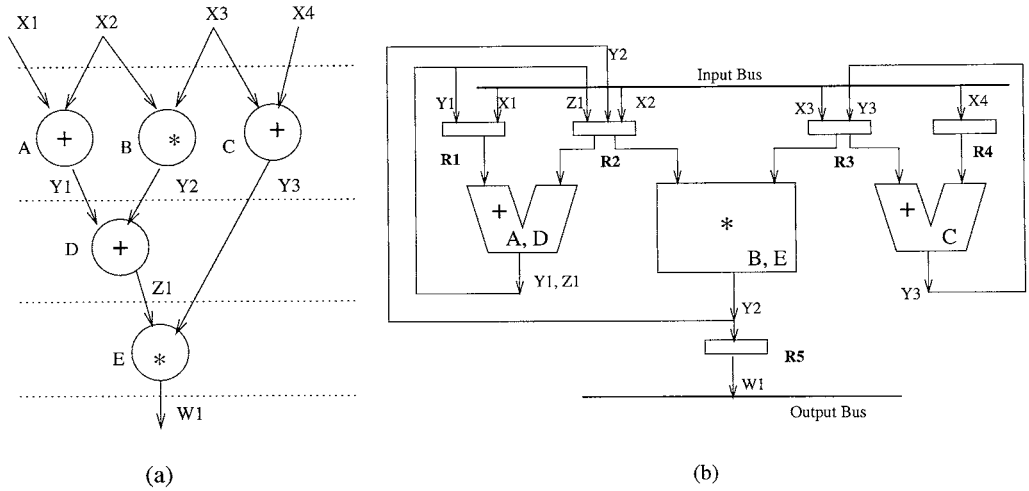

FIGURE 64.7 High-level synthesis: (a) a sample data flow graph, (b) corresponding data path.

shows the variables *X*1, *X*2, *X*3, *Y*1, *Y*2, *Y*3, *Z*1, and *W*1, and the operations *A* to *E*. The data path in Fig. 64.7(b) shows the mapping of the variables to the registers and the operations to the functional units. Multiplexers are not shown in this figure. This example demonstrates the ability of CAD tools to synthesize behavioral descriptions into data paths. These CAD tools can also synthesize the control logic and make high-level decisions, such as number of pipeline stages, etc.[27]

Testable Design

Testability of digital circuits has become a major concern with the increasing complexity of designs. Testability refers to the ability to detect manufacturing faults in a fabricated chip. Designers are increasingly using a *design for testability* (DFT) methodology to ensure that the circuit is testable. DFT attempts to modify the circuit during the design phase without affecting its functionality so as to make it testable. There are several approaches and techniques that are used to make chips and the individual components in them testable. Additional test hardware and pins are added to the chip, such as *boundary scan* test hardware[37] which enable testing the chip, introduce test modes to the chip functionality, and provide pins dedicated to shifting in and out of the test vectors and their responses. The testability of the internal components of the chip is enhanced primarily by two techniques: serial scan and built-in self-test (BIST). In the first approach, the components within a chip are tested by applying test vectors to the input pins of the chip and shifting out the output patterns and checking for correctness. In the second approach, known as the *built-in self-test* (BIST) technique, the chip is tested by specialized hardware built-in within the chip that self-tests the components in the chip. The former approach is known as the *full-scan* or *partial-scan* test technique since all or some of the registers in the chip are connected in a test scan chain.

Full-Scan Testing

In practice, the *full-scan* technique for testing the data path in a chip is more popular among designers. This technique improves the observability and controllability of the circuit by using *scan registers*.[37] A scan register has both serial shift and parallel-load capability and has additional serial-in and serial-out pins over a standard register. All the scan registers in the circuit are tied together in a chain by connecting the serial-out of a register to the serial-in of the next register.

During normal circuit operation mode, the scan registers behave as parallel load registers. However, in the test mode, a test pattern is serially scanned into all the registers of the circuit and then the circuit is clocked and the values in the registers are serially shifted out. The output bit vector values are compared with the expected results to verify that the circuit is functioning correctly. In this way, only one serial-in

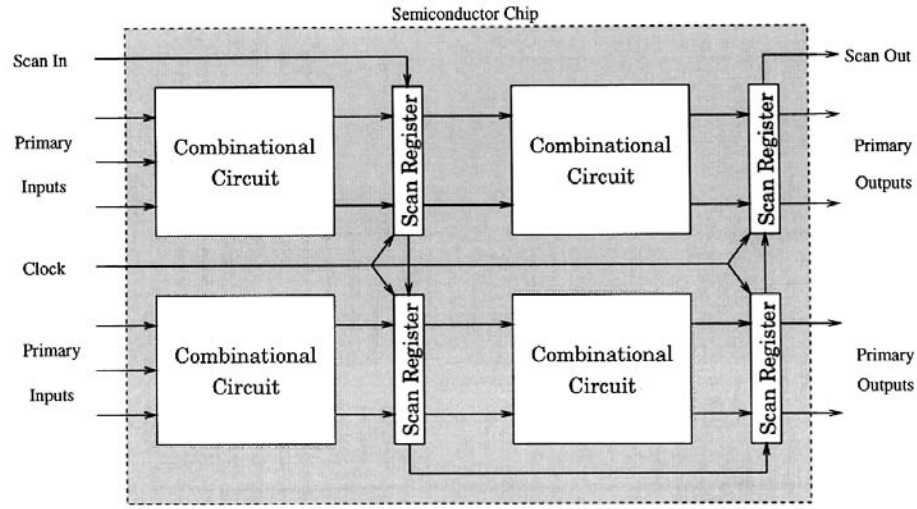

FIGURE 64.8 Full-scan register-based design.

pin and one serial-out pin has to be assigned at the chip level. However, since for each test vector that is applied to the chip, it has to be scanned in serially and then the output has to be serially scanned out, this approach is very slow. The slow speed of testing using full-scan is its main disadvantage. The overhead of scan-based test techniques comprises area overhead and performance slow-down. However, the overhead is relatively low compared to other schemes such as BIST.

The full-scan technique is demonstrated in Fig. 64.8. In this figure, there are four combinational blocks each of which feeds into registers which have been modified to be scan registers. There is a scan-in pin and a scan-out pin at the chip level and all the scan registers are tied together to form a scan chain.

Built-In Self-testing

The built-in self-test (BIST) methodology has gained popularity over the past decade and techniques have been demonstrated to incorporate it into behavioral synthesis tools.[30,40] Memory blocks such as RAMs (random access memories) are usually tested by inserting built-in self-test (BIST) logic in the memory design. These BIST circuits apply pseudo-random patterns to the memory and test it by several techniques such as writing data into an address location and then reading it back out and comparing the two.

Datapath units can also be tested by BIST techniques by applying a set of test vectors to the inputs of the units and doing a *signature analysis* of the output bit stream.[37,39] This signature analysis is enough to ensure that the unit is not faulty. The input test vectors are generated in a pseudo-random manner using registers which are configured as *pseudo-random pattern generators* (PRPGs). Similarly, signature analysis is done by configuring registers as *signature analyzers* (SAs). Registers which can be configured in this manner are known as *built-in logic block observers* (BILBOs). One way, then, of ensuring testability of a functional unit is by creating a *n:m* embedding for the functional unit, where *n* is the number of inputs to the functional unit and *m* is the number of outputs. In such an embedding, it is ensured that each functional unit is fed by at least *n* registers and the functional unit feeds at least *m* registers which are different from the input registers. The input registers are configured as PRPGs and the output registers as SAs. In the *test mode* of the chip, the input PRPGs generate a test vector, a clock cycle is applied to the functional unit's embedding, at the end of which the outputs of the unit are analyzed by the output registers configured as SAs.

In this way, each functional unit can be tested by running the chip in test mode. However, to reduce the test time of the chip, multiple functional units can be tested simultaneously provided that any input PRPG register of one unit is not the output SA register of another. A test schedule or plan can be generated for testing the various units in as few test sessions as possible.[38]

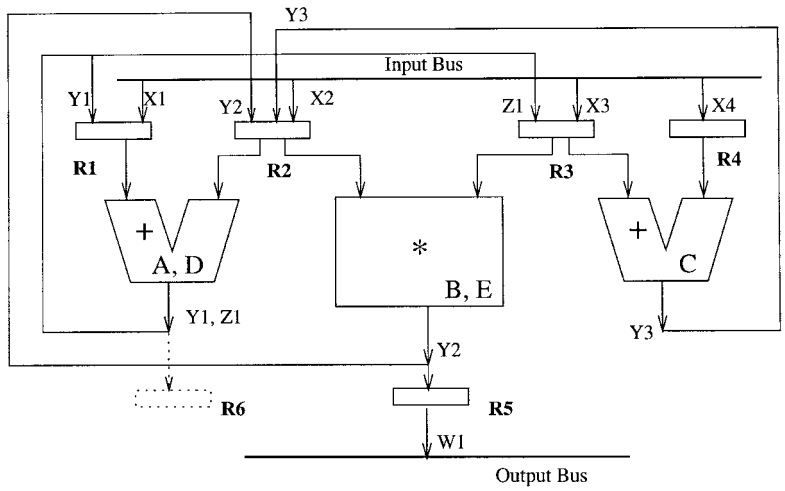

FIGURE 64.9 Built-in self-test (BIST)-based testable data path for sample data flow graph.

Consider the example of the data path of the sample data flow graph shown earlier in Fig. 64.7(b). In this figure, the multiplier module is part of a 2-1 embedding consisting of registers *R*2, *R*3, and *R*5. In the test mode, *R*2 and *R*3 are configured as pseudo-random test pattern generators, whereas *R*5 is configured as a signature register. However, both the adders cannot be part of a 2-1 embedding since their outputs are stored in the same registers as their inputs. By adding a register *R*6 (shown dotted in Fig. 64.9) at the output of the left adder, we can make this adder testable since it becomes part of a 2-1 embedding consisting of input registers *R*1 and *R*2 and output register *R*6. The other adder can be made testable by changing the binding of variables to registers such that *Z*1 is mapped to *R*3 and *Y*3 is mapped to *R*2, along with the necessary changes in the interconnect. If the modified embedding is used, the second adder will be the part of a 2-1 embedding which consists of input registers *R*3 and *R*4 and output register *R*2. The modified testable data path is shown in Fig. 64.9. There are several other ways that this circuit can be modified to make it testable.

Some of the main challenges in this BIST-based methodology for testing data path units are ensuring that each functional unit is part of a *n*:*m* embedding while at the same time converting as few registers into BILBOs (since these are more expensive in terms of area) and generating an efficient test schedule such that the total test time is minimum.

Although in this section we have attempted to introduce the issues in testability and design for testability, it is by no means a complete picture of the field of testing. Several test issues such as delay faults, mixed-signal test, partial scan have not been discussed. There are several techniques and test styles which can be adopted, depending on the characteristics of the system under design. Other chapters in this book offer a more detailed discussion on the subject.

64.9 Logic Synthesis

Logic synthesis deals with the synthesis and optimization of circuits at the logic gate level.[5,7-9] Digital circuits typically have sequential and combinational components. These can be specified by finite-state machines, state transition diagrams or tables, Boolean equations, schematic diagrams, or HDL descriptions. Finite-state machine representations are optimized by state minimization and encoding and Boolean functions are optimized either by two-level optimization techniques which are exact or by heuristic multi-level optimization techniques.

Logic synthesis includes a range of optimizations and techniques like state machine optimization, multi-level logic optimization, retiming, re-synthesis, technology mapping, or post-layout transistor sizing. The optimization steps are selected and ordered according to the chosen optimization metric,

whether it may be area, speed, power, or a tradeoff between these. These steps are divided into two phases: the *technology-independent* phase, where the logic circuit is optimized by Boolean or algebraic manipulation or state minimization, and the *technology-mapping* phase, in which the logic network is mapped into a technology library of cells and then, transistor-level optimizations are performed.

Since circuits are usually a combination of combinational and sequential parts and the techniques to optimize the two differ a lot, we discuss each one separately.

Combinational Logic Optimization

Combinational circuits can be modeled by two-level sum-of-products expressions. These expressions can be optimized by two-level minimization tools such as Espresso, Mini, or Presto.[1,41] Two-level logic networks can be easily mapped onto macrocell-based design styles such as PLAs (programmable logic arrays). However, in practice, logic networks are usually multi-level and, hence, multi-level logic optimization tools such as MIS[42] are becoming popular. Unlike two-level logic networks, multi-level network graphs can be mapped onto cell libraries with complex n-level gates, thereby allowing more complex cell and array-based design styles.

To demonstrate the steps in technology-independent steps in combinatorial logic optimization, we show the optimization of Boolean functions representing two-level logic networks in a sum-of-products format of the logic variables. Boolean functions can be optimized by minimizing the number of operators using either *map-based* or *table-based* methods. The map-based method uses *Karnaugh maps* to minimize a Boolean function as shown in the example below. Consider the Boolean function:

$$F = a'b'c'd' + a'b'c'd + a'b'cd' + a'b'cd + a'bc'd + a'bcd' + ab'cd' + a'bcd + ab'cd + abcd$$

where a, b, c, and d are single-bit Boolean variables. The Karnaugh map corresponding to this example is shown in Fig. 64.10(a).[25] This map represents the terms in the Boolean expression by assigning a 1 in the squares that correspond to a term in the expression. Each term in a Boolean function is called a *minterm*. For any Boolean function with n-variables or literals, it has 2^n possible minterms and a *n-cube* is defined as a minterm with all n-variables. A *subcube* is a minterm with fewer variables than n in it. From the Karnaugh map shown, we determine that the *prime implicants* (PIs), which are the subcubes not contained in any other subcube, are $a'b'$, $a'c$, $a'd$, cd, $b'c$. These are marked in the figure by dashed boxes. The dashed boxes were created by grouping together the maximal set of minterms in groups of multiples of 2 (i.e., 2, 4, 8, etc.). *Essential primary implicants* are the prime implicants which include a minterm that is not included in any other subcube. For this example, all the prime implicants are also essential prime implicants. A *cover* is a set of prime implicants such that each minterm in the Boolean

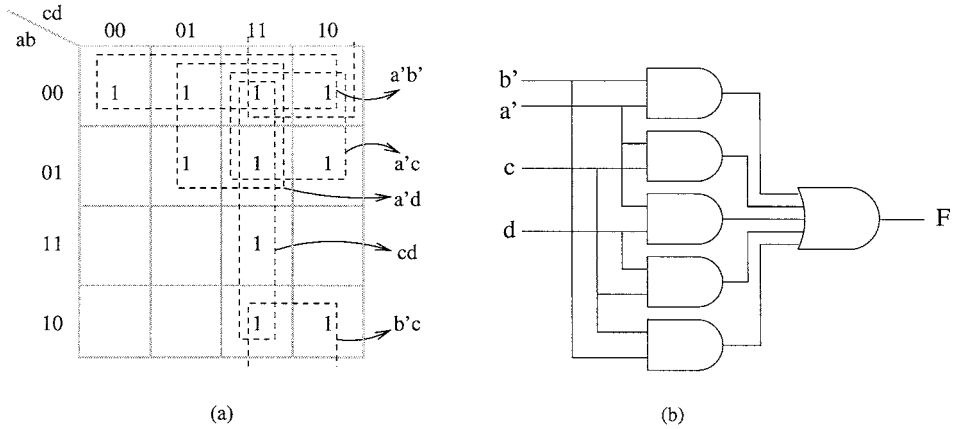

FIGURE 64.10 An example function: (a) Karnaugh map, (b) circuit implementation.

function is contained in at least one prime implicant. A *minimal* cover is a selection of the minimum number of prime implicants that form a cover over all the minterms in the function. For this example, a minimal cover is $a'b'$, $a'c$, $a'd$, cd, $b'c$. Hence, the reduced Boolean function is:

$$F = a'b' + a'c + a'd + cd + b'c$$

The circuit corresponding to this function is shown in Fig. 64.10(b). The 5-input OR gate at the end of the circuit can be implemented by splitting it into several 2-input OR gates.

The same minimization can be done using tabular methods such as the Quine-McCluskey method.[25] This method represents the same information in tables which then reduce the minterms by iteratively finding subcubes with fewer variables. The reader is referred to standard texts on digital design for further discussion on this method.

The Karnaugh map shown in Fig. 64.10(a) conceptually demonstrates the combinational logic optimization process. However, in practice, two-level optimizers such as *Espresso* are used for logic optimization. Espresso uses an expand-irredundant-reduce iterative algorithm to reduce the size of the given Boolean function.[41] A n-variable function can be represented by a set of points in n-dimensional space. The function then has an *on-set*, which is the set of points for which the function's value is 1, an off-set, which is the set of points for which the function's value is 0 and a *don't-care* or *dc-set*, which is the set of points for which the function's value is don't care. The basic Espresso algorithm first *expands* each cube in the on-set to make it as large as possible, without covering a point in the off-set (points in the dc-set may be covered). Then, for points covered by several cubes, the smaller cubes are removed in favor of the larger covering cubes in the *irredundant* step. Finally, the cubes are *reduced* so as to minimize the variables in the cubes.

The example and strategies discussed above demonstrate the two-level optimization methodology. The final circuit implementation for the example, (see Fig. 64.10(b)) has two stages of logic. However, cell libraries used to map the gates in the logic circuit to the gates available from the foundry, usually have more complex gates which are a combination of several gates such as AND-OR, OR-AND, or NOR-AND gates. To fully utilize these cell libraries, multi-level logic optimization techniques are used. These techniques are not restricted to two-level logic networks but instead deal with multiple-level logic circuits. This provides the necessary flexibility required to map the logic network to complex cells in the technology library, hence optimizing area and delay. However, multi-level optimization techniques are not exact, i.e., only heuristics exist for modeling and optimizing multiple-level networks. For further discussion on this subject, the reader is referred to Ref. 1.

Sequential Logic Optimization

Sequential circuits are usually represented by a finite-state machine (FSM) model. This consists of a combinational circuit and a set of registers as shown in Fig. 64.11. The model has a set of inputs, I, a set of outputs O, the state S, and a clock signal. The clock signal defines the *clock cycle*, which is a time

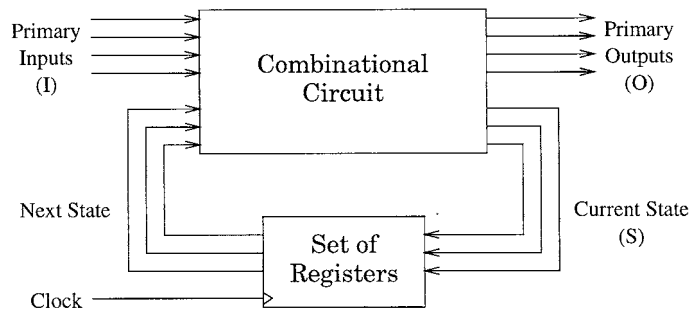

FIGURE 64.11 Finite state machine model.

interval in which the combinational circuit analyzes the inputs and the state to calculate the outputs and the next state. At every clock cycle, the data computed by the combinational circuit is stored in the registers along with other state and control information.

A finite-state machine (FSM) is defined by the quintuple $<S,I,O,f,h>$ where S, I, and O are the set of states, inputs, and outputs, respectively, and f and h represent the next state and output calculation functions. The next state function f can be represented as $f: S \times I \rightarrow S$ and the output function h can be either represented as $h: S \times I \rightarrow O$ or as $h: S \rightarrow O$, depending on whether the finite-state machine is implemented as a *Mealy* machine or a *Moore* machine. In the Mealy machine, the output function is dependent on the inputs and the state, whereas in the Moore machine the output is state based only.

In a sequential circuit represented by an FSM, the set of states, inputs and outputs, S, I, and O correspond to k flip-flops, $Q_0, \ldots, Q_{k-1}$, n input signals, $I_0, \ldots, I_{n-1}$ and m output signals, $O_0, \ldots, O_{m-1}$. Each of these correspond to a single bit in the implementation. The finite-state machine model is usually represented using state transition diagrams or state tables.[1,25] State transition diagrams are mainly optimized by *state minimization* and *state encoding* (explained in the next subsection).

Let us first discuss an example to demonstrate the design of sequential circuits. Consider the example of a modulo-4 counter shown in Fig. 64.12. Figure 64.12(a) shows the finite-state machine transition graph for the counter. The counter counts from 0 to 3 back to 0 whenever the count signal C is 1. When the count signal C is 0, the counter stays in the same state. The counter outputs the count Z at each clock cycle. Hence, the state transition graph has four states S_0 to S_3 corresponding to the count states 0 to 3. There is a transition from one state to the next if $C = 1$ and the output Z is the count at that time. If $C = 0$, the state does not change and the output Z is the same as when entering the state. The states S_0 to S_3 have been encoded as 00, 01, 11, 10, respectively. This is an example of an input-based or Mealy-type FSM.

(e)

FIGURE 64.12 Sequential circuit example: modulo-4 counter (a) FSM for counter, (b) circuit for the counter, (c) state transition table, (d) next state Karnaugh map, (e) output Karnaugh map.

The information from the FSM can be captured in a state transition table as shown in Fig. 64.12(c). In this figure, the present and the next states are shown using their encoding and are marked by bit variables Q_1 Q_0 and D_1 D_0, respectively. The output Z is a two-bit variable Z_1 Z_0 which goes from 0 to 3 (or 00 to 11). The Karnaugh maps corresponding to the next state and the output bit vectors are shown in Figs. 64.12(d) and 64.12(e) respectively. The maximal coverings for all the bits in the next state variables and the output variable are shown in these Karnaugh maps by dotted boxes. Note that although the Karnaugh Maps for D_1 D_0 and Z_1 Z_0 have been grouped together, their coverings and optimizations are independent. From these coverings, we get the following reduced Boolean equations for the bit variables:

$$D_1 = Q_1\overline{C} + Q_0C \qquad Z_1 = Q_1\overline{C} + Q_0C$$
$$D_0 = Q_0\overline{C} + \overline{Q}_1C \qquad Z_0 = \overline{Q}_1Q_0\overline{C} + Q_1\overline{Q}_0\overline{C} + \overline{Q}_1\overline{Q}_0C + Q_1Q_0C$$

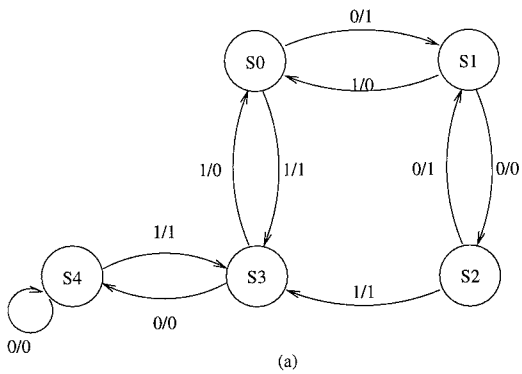
The circuit diagram corresponding to these equations is shown in Fig. 64.12(b). The circuit has two D-flip-flops which correspond to the two-bit variables in the state, and the combinational part has been implemented using simple AND, OR, and NOT gates. Note that in this example, the state minimization and encoding steps are assumed to have already been done.

State Minimization and Encoding

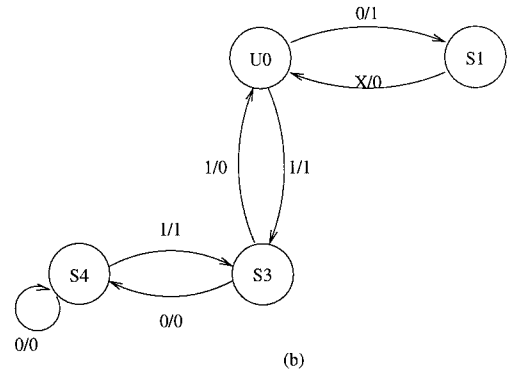
State minimization aims at reducing the number of machine states used to represent an FSM. Since the minimum number of bits required to encode n states is $[\log_2 n]$, reducing the number of states can lead to a reduced number of bits and, hence, flip-flops required to encode the states. It also leads to fewer transitions, fewer logic gates, and fewer inputs per gate. These reductions not only lead to lower area cost but also speed up the design and reduce the power consumption.

State minimization can be done by finding *equivalent* states and by using *don't-care* information to remove states. Two states are equivalent if and only if, for every input, both the states produce the same output and the corresponding next states are equivalent.

Consider the example state transition graph shown in Fig. 64.13(a). The state transition table corresponding to this graph is shown in Fig. 64.13(c). State minimization can be done in two steps. The first



(a)



(b)

Pres. State	Next State/Out	
	Inp I=0	Inp I=1
s_0	$s_1/1$	$s_3/1$
s_1	$s_2/0$	$s_0/0$
s_2	$s_1/1$	$s_3/1$
s_3	$s_4/0$	$s_0/0$
s_4	$s_4/0$	$s_3/1$

(c)

Pres. State	Next State/Out	
	Inp I=0	Inp I=1
$u_0 = \{s_0, s_2\}$	$u_1, u_1/1$	$u_1, u_1/1$
$u_1 = \{s_1, s_3\}$	$u_0, u_2/0$	$u_0, u_0/0$
$u_2 = \{s_4\}$	$u_2/0$	$u_1/1$

(d)

Pres. State	Next State/Out	
	Inp I=0	Inp I=1
u_0	$s_1/1$	$s_3/1$
s_1	$u_0/0$	$u_0/0$
s_3	$s_4/0$	$u_0/0$
s_4	$s_4/0$	$s_3/1$

(e)

FIGURE 64.13 An example of state minimization: (a) original state transition graph, (b) minimized state transition graph, (c) original state transition table, (d) states grouped based on their outputs, (e) minimized state transition table.

step is finding the states with the same outputs for the same inputs. We group these states such that states in the same group have the same output for each input. This is shown in Fig. 64.13(d). There are three groups u_0, u_1, and u_2 which, respectively, give output 1, 0, and 0 when the input 0 is applied and give output 1, 0, and 1 when the input 1 is applied. In the next step, we compare the next states for each state in a group for all inputs. If the next state for two states within a group is in the same group, then the two states are considered equivalent. In this example, we find the states s_0 and s_2 in the group u_0 are equivalent since all the next states of these two states are in the same group. Hence, these two states can be combined into one state and the minimized state transition table is shown in Fig. 64.13(e). The corresponding minimized state transition graph for the example is shown in Fig. 64.13(b). Note, that the transition from $s1$ to $u0$ is denoted as X/0 since for all inputs, when in state s_1, the next state is u_0 and the output is 0.

After the states have been minimized, *state encoding* is performed to assign a binary representation to the states of the finite-state machine. In the example shown earlier in Fig. 64.13(b), the minimized state transition graph has four states, whereas the original state transition graph had five states (see Fig. 64.13(a)). Hence, whereas it would have taken 3 bits to encode the five states in the original FSM, the reduced FSM requires only 2 bits for the encoding. Fewer encoding bits implies fewer flip-flops in the circuit and, hence, reduced area and increased speed of the final design. There are several other encoding methodologies such as gray encoding, NRZ encoding, etc., which are used to reduce circuit switching, bus switching, etc.[1]

Technology Mapping

Technology mapping forms the link between logic synthesis and physical design. After logic synthesis, a circuit-level schematic or netlist of the design is created using a vendor-independent logic library. This library has elements such as low-level gates, flip-flops, latches, and at times, multiplexers, counters, and adders. The schematic entry tool then generates a netlist of the elements with their interconnections. Typically, a *netlist translator* along with a vendor-specific library is used to replace the vendor-independent generic elements and generate the netlist in a particular vendor's netlist format. This allows the schematic entry or netlist generation to be independent of the vendor-specific library.

The process of transforming the generic cell based logic network into a vendor library-specific network is known as *library binding* or *technology mapping*. This step allows us to retarget the same design to different technologies and implementation styles. The library contains a set of parameterized logic cells. These cells may be primitive or a combination of a set of cells to produce a commonly used functionality such as adders, shifters, etc. Typically, the cell library vendor provides different libraries optimized for area, performance, power, and/or testability.

Each cell in the vendor library contains a physical layout of the cell, its timing model (delay characteristics and capacitances on each input), a wire load model, a behavioral model (VHDL/Verilog model), circuit schematic, cell icon (for schematic tools), and for bigger cells, its routing and testing strategy. CAD tools use the timing characteristics to analyze the circuit and determine the capacitances at each node in the netlist, and use the delay formulas along with the timing characteristics of each element to compute the delays for each node. Wiring capacitances are included by estimating a wire-load model initially and then later using the back-annotation information from the floorplanning and place-and-route tools (see Section 64.10).

Cell-Library Binding

Cell-library binding is the process of transforming the set of Boolean equations or the Boolean network into a logic gate network with the gates in the cell library. Cell-library binding approaches are classified into two types: *rule-based* and *tree-based* approaches. Rule-based approaches iteratively replace parts of the logic network with equivalent cells from the cell library. This is done using local transformations which do not affect the behavior of the circuit. The tree-based approach does either *structural covering* and *matching* or *Boolean covering* and *matching*. In the structural approach, the logic network is expressed

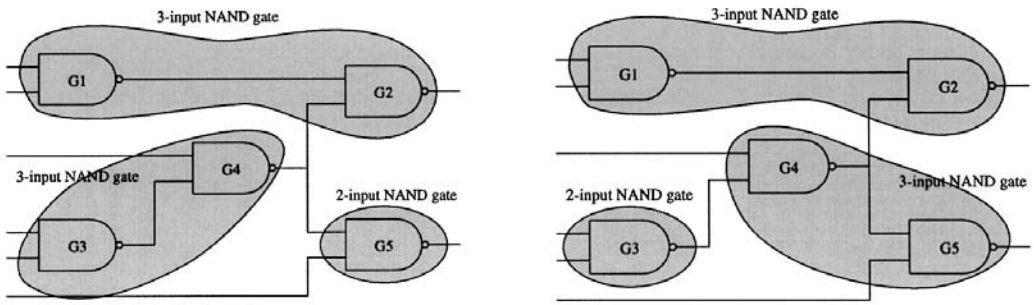


FIGURE 64.14 Two different network coverings for the same 2-input NAND logic subnetwork.

as an algebraic expression which is represented as a graph. Similarly, the cells in the library are also represented by graphs and the problem is reduced to one of subgraph matching and graph covering. The Boolean approach is similar but uses the matching of Boolean functions instead of graphs.

Tree-based matching is similar to pattern matching.[33] The cells in the library are represented as *pattern graphs* and then the aim is to find an optimal covering of the nodes in the logic network so as to optimize for the cost function (which may be area, power, etc.). This problem then reduces to a tree matching and covering problem which can be solved in linear time. One approach is to transform the logic network into a canonical form using only 2-input NAND gates and represent it as a logic graph. The cells in the library are also represented as pattern graphs in the canonical 2-input NAND gate format along with their area and delay costs. The pattern matching algorithm then attempts to find a cover of all the gates in the given logic graph using the cell-library pattern graphs so as to minimize the area and/or delay costs. An illustrative example is shown in Fig. 64.14. In this figure, two different network coverings are shown for the same logic subnetwork. Both these coverings use 3-input NAND gates from the cell library; however, a simple covering could have bound each node with a 2-input NAND gate.

Rule-based library binding techniques apply simple rules to identify circuit patterns and replace them with an equivalent pattern from the library. The cells from the library are characterized and rules derived from them. For example, a simple rule might replace two 2-input AND gates in series with a 3-input AND gate. More complex rules can even restructure a subnetwork of the given logic network so as to replace it with a more optimal subnetwork in terms of area and/or delay. Rule-based approaches are heuristic since the quality of results are affected to a great extent by the sequence in which the rules are applied. However, rule-based approaches allow complex transformations such as replacing nodes with high loads by high-drive cells or by inserting buffers. Also, rule-based approaches allow stepwise refinement and rebinding of cells to search for globally optimal results.

Static Timing Analysis

Timing analysis is required to verify the correctness and the timing performance of a circuit by ensuring that the timing constraints such as set-up and hold times of the flip-flops are met and the *critical paths*[3] in the circuit meet the timing budgets set for them. *Static timing analysis* exhaustively analyzes all the paths in the circuit netlist to check if they meet the timing requirements of the design. It computes the delay along the various paths and times all of them and determines the critical paths in the circuit.

The timing analysis is done using the gate delay, rise time, fall time, capacitance, and load values in the cell library to determine the delay of each gate and the interconnect delay. Delay across a gate (or any other node) depends on the delay through the gate, the loading on the gate, the number of fan-outs, and load due to the interconnect. The delay through a path (i.e., a chain of nodes) is also affected by the

[3]A critical path is a path in the circuit which has the maximum delay among all the paths in the circuit from its input to the output of the circuit.

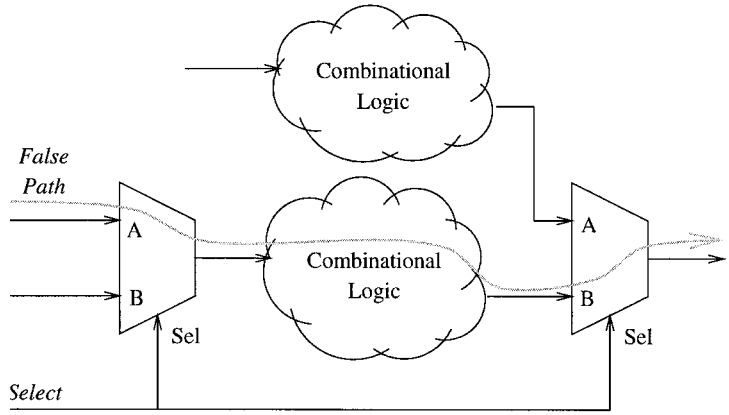

FIGURE 64.15 An example of a *false path* (i.e., a path which can never be activated).

skew or path delays due to the interconnect capacitances. In deep submicron designs, interconnect delays dominate over gate delays. For computing the path delays during static timing analysis, it is very important to have accurate estimates of the interconnect capacitances and wire-load model of the chip. Early floorplanning techniques are adopted to obtain these accurate estimates (see Section 64.10).

In this way, by timing all the paths in the circuit, the timing analyzer can determine all the critical paths in the circuit. However, the circuit may have *false paths*, which are paths in the circuit which are never exercised during normal circuit operation for any set of inputs. An example of a false path is shown in Fig. 64.15. The path going from the *A* input of the first multiplexor through the combinational logic out through the *B* input of the second multiplexor to the output is a false path. This path can never be activated since if the *A* input of the first multiplexor is activated, then the *Sel* line will also select the *A* input of the second multiplexor. Static timing analysis tools are able to identify simple false paths; however, they are not able to identify all the false paths and sometimes report false paths as the critical paths. For hard-to-detect false paths, the designer has to explicitly mark the known false paths as such before running the static timing analysis tool.

Circuit Emulation and Verification

Since testing and correcting a chip once it has been manufactured is a difficult and expensive task, it is essential to verify functional and timing characteristics of the design. As mentioned earlier in Section 64.2, FPGAs (field-programmable gate arrays) are increasingly being used for circuit prototyping and verification due to their ease of reconfigurability and programming. Once the netlist of the circuit design has been generated, it is used to program an FPGA-based circuit consisting of several FPGAs (depending on the size of the design).[32] Test patterns are then applied to this design to check its functionality in such a way, so as to exercise all the functions possible and all the inputs possible. The outputs of the emulation circuit are compared with the responses expected as per the functionality as described in the system specification. If design errors are found, the FPGA boards can easily be reprogrammed after the design has been fixed, and it is this ease of reconfigurability that makes FPGAs an attractive — albiet expensive — prototyping system.

64.10 Physical Design

The physical design process consists of specification of area and power of each block, floorplanning, placement, routing, and clock tree design.[34,35] The flow of the entire process is shown in Fig. 64.16, starting from logic synthesis to layout, parasitic extraction, and delay calculation. The physical design process starts during the logic synthesis process with the block circuit design, optimization and characterization steps, along with transistor resizing for taking care of loading and timing anamolies.

Floorplanning is a chip-level layout process where the layout cells, blocks, and inputs/outputs (I/Os) are placed on the chip to create a map of the location of the various blocks and devices. The layout program places the blocks on the chip by defining both their position and orientation, while leaving enough space between blocks for wires and interconnects. An initial floorplan is developed, sometimes as early as the initial architectural design of the system, to assess if the chip can meet its timing, performance, and cost goals. This is done by estimating the sizes of the blocks and the interconnect area. A preliminary floorplan is critical in accurately estimating the area budgets of each of the components, clock distribution requirements of the chip, the wire-load model of the design, and the interconnect resistances and capacitances. These estimates can be used to guide logic synthesis and the layout process. When there is no early floorplanning, an area-based wire-load model is adopted, based on the estimate of the die size of the final chip. However, in this method, the estimates of capacitances for global interconnects can be highly inaccurate.

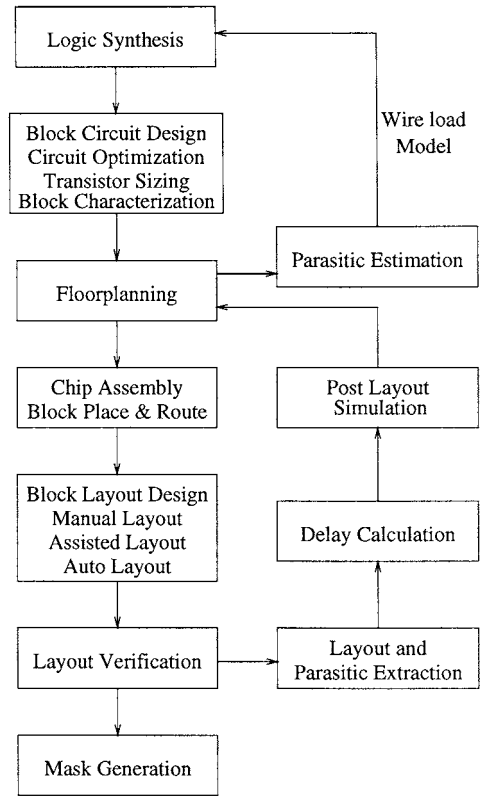

FIGURE 64.16 Physical design methodology.

Placement tools are used to optimally place the components or modules on the chip area. These tools take into account the size, aspect ratios, and pin positions of each component, so that the placement minimizes the area occupied by all the components. *Routing tools* then lay out or position the wires that connect the components so as to minimize the maximum, total, and average wire length. Routing on wafer can be done on multiple layers of metal, depending on the process technology being used. Usually, placement and routing tools make a lot of decisions that affect each other and are done iteratively or combined together in a single environment. Place-and-route tools are usually packaged with *layout tools*. These tools convert the logic-level design into the mask geometry of the targeted foundry using the techonology files of the foundry.

The *clock distribution* architecture of the chip is determined to a great extent by the area of the chip, placement of the blocks, target clock frequency, and the target library. As the size of chips increases, *clock skew* and other clock distribution delays become significant. A single clock can be distributed throughout the chip using a *balanced clock tree* with a low enough skew to prevent hold-time violations for flip-flops that directly drive other flip-flops. However, as the clock frequency and size of the chip increases, this approach leads to extremely large, high-power clock buffers, which are unacceptable. An alternative approach being used now, is to use a lower-speed bus to distribute the clock as a bused signal. Each major block in the chip synchronizes its local clock to the bus block, either by buffering the bus block or by using a phase-locked loop (PLL). The local bus can be at higher frequency which is a multiple of the bus clock.

Once the blocks have been placed and routed, the layout for each block is done either manually or with help of design automation tools. The layout is verified to check if the design works with the actual values of the parasitics of the interconnect on the chip and the clock distribution network. The parasitics are extracted, the delays along the interconnects are calculated, and the circuit is simulated. The results of the simulation are used to iterate over the entire physical design process as shown in Fig. 64.16.

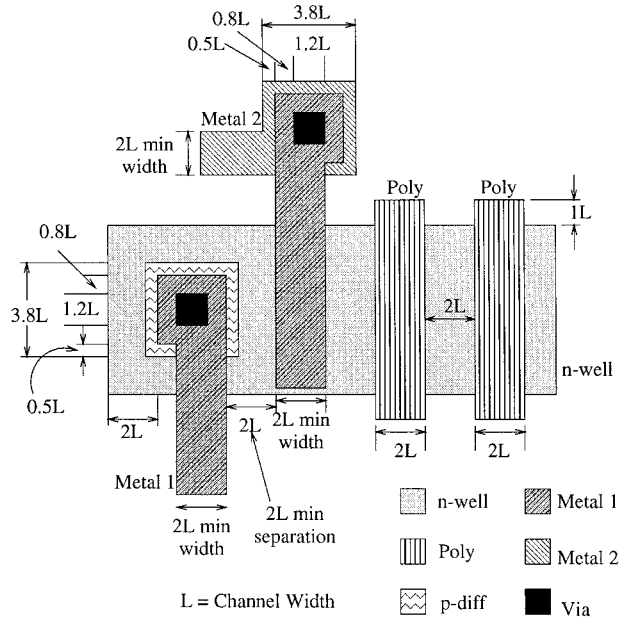

FIGURE 64.17 Illustrative example of layout design rules.

The final step in the physical design process is the *mask generation* phase. The masks are the geometric patterns that are used to etch the silicon by lithography. The output of design process is usually written out in *Caltech Intermediate Format* (CIF) or GDSII Stream. This is sent to the foundry, which manufactures the chip using the masks and runs its own design rule checks.

Layout Verification

The layout is verified using verification tools such as *design rule checkers* (DRC) and *extractors*. The DRC verifies that the geometric layout of the design does not violate the spacing and dimension rules of the foundry. In ensures that the mask layout has the minimum spacing and size required, and also verifies the spacings among the mask features. The extractor produces a netlist file, usually in SPICE format, after analyzing the connectivity of the design. The extracted SPICE file, which includes transistor sizes and parasitic capacitances, is used to run SPICE simulations on the circuit.[20]

Figure 64.17 demonstrates layout design rules. The numbers used in this figure are illustrative. The figure shows rules such as the minimum separation between two lines of metal-1 or polysilicon, the minimum overlap of polysilicon over the n-type (or p-type) subtrate, etc. These design rules are specified by the technology library provider (i.e., the foundry) and have to be obeyed while performing the layout. The DRC tools verify that the rules have been obeyed and flag errors if they have not. The design rules are necessary since violations can potentially lead to manufacturing faults in the chip. Layout and layout verification is discussed in detail in other chapters in this book.

64.11 I/O Architecture and Pad Design

Another important decision while developing the architecture of the chip is the *package* and *pin count* of the chip. The package type is determined by the area and heat generation of the chip. Packages are of various types such as plastic or ceramic, and each one has a different number of pins and different layout of pins in the chips.[36] Hence, the pin count is also determined at the same time as the package and is estimated during the initial architecture design.

Pads are the interface between the pins on the outside of the chip and the inputs and outputs in the digital circuits within the chip. Pads are usually distributed around the edge of the chip or, in recent packaging schemes, across the entire chip face. Each pad has an associated input or output circuitry which provides the necessary drive current required. Hence, each pad has V_{dd} and V_{ss} (i.e., positive and negative voltage) wires running through it. The number of pads and corresponding pins dedicated to V_{dd} and V_{ss} depends on how much current the chip draws and the power it consumes.

64.12 Tests after Manufacturing

There are several types of defects that can be introduced by the manufacturing process, such as stuck-at faults, delay faults, etc.[37] Hence, after the chip has been fabricated, it is tested extensively to find the faulty ones from the batch. By far one of the most expensive phases in the production of an integrated circuit, testing is done by applying test patterns to the unit being tested and comparing the unit's responses with the expected outputs for a working unit. *Automatic test pattern generation* (ATPG) tools use the description of the circuit to derive the sequence of the test vectors which exercise as many paths in the design as possible and test for the faults that may occur.[37]

Manufacturing tests aim at finding several different types of faults based on which they can be broadly classified into functional tests, diagnostic tests, and parametric tests.[43] *Functional tests* are simple tests which determine if a chip is functional or not and, hence, are also known as *go/no go* tests. *Diagnostic tests* are more involved since they aim at debugging the manufactured chip to determine which component in the chip has failed and possibly locate the fault within the component. This test is important to locate a manufacturing fault which is causing a large percentage of manufactured chips to fail. *Parameteric tests* check for clock skew, delay faults, noise margins, clock frequencies, etc. in the range of working conditions, such as supply voltage and temperature, for which the chip is supposed to function.

However, it is very difficult to create a set of test patterns that test for all the potential faults in the circuit. Recent developments have led to design methodologies which aim to improve the testability of the circuit while it is being designed. In this way, it is possible to design a circuit so that a set of test patterns can be generated which tests for all possible faults in the circuit. A detailed discussion on testing and testing methodologies is beyond the scope of this chapter.

64.13 High-Performance ASIC Design

The main optimization goal of ASIC chips is usually area. However, in a lot of mission-critical designs, speed is of foremost concern. Such high-performance designs require special design methodologies. A lot of design teams adopt a completely hand-crafted design methodology for these chips. However, it is recommended to use standard logic synthesis tools to make one pass over the design and the components in the chip, so as to at least get an estimate of the speed and area of the components. Since CAD tools are able to explore a much larger design space, they often can generate fairly optimal designs which come close to meeting the speed constraints of the design team. The design team can then take these components and hand-tune them to improve their speed. Common methods used are transistor resizing and transistor reodering.

Although most of the datapath blocks can be synthesized using standard cell libraries, there are always situations where a component is on the critical path. These critical blocks are typically completely hand-crafted. Alternatively, although most of the chip may be in CMOS technology, designers may choose faster technologies for the custom-crafted components and, hence, adopt a mixed technology methodology for the chip. *Dynamic* and dual-rail logic are popular as high-speed design styles, although their power consumption is much higher. In dynamic logic, all the nodes are precharged and typically require less number of transistors than static circuits and, hence, switch faster than CMOS circuits. However, these circuits are more power hungry since there is more switching activity and each node has to be precharged. Dual-rail logic has, as the name implies, two rails of signals, one being the complement of the other. The main disadvantage with this type of design is that it leads to reduced current drives,

especially at reduced voltages. However, recent technologies such as the *differential current switch logic* (DCSL) family have high-speed and low-power operations.[44]

Another factor often overlooked by designers is the fact that in most companies, technology libraries are designed so as to be optimum in terms of area (i.e., all the cells in the library have been hand-crafted so as to have the least area). However, there is always an area-speed tradeoff, and if a design is more speed critical and system architects are willing to throw some more area at the chip in order to improve speed, then the designers should request speed optimized technology libraries from the physical design team or foundry, as the case may be. This does not necessarily mean that all the cells in the library have to be redesigned to make them faster, but instead, only critical cells such as registers, full adders, or other components which are being used in components which are on the critical path, can be optimized.

64.14 Low Power Issues

The demand for portable semiconductor devices has fueled the need for more power-efficient semiconductor designs since the battery life on these portable devices is limited. This has led to the development of several power estimation and minimization design techniques. A considerable amount of this work is is focused on circuit-level power savings by modifying circuits and circuit design techniques to introduce low-power modes.[45-47] Several synthesis tools[23] also incorporate power estimation as part of their cost functions. In general, power management and savings have become a very important issue in IC design.

Power dissipation in CMOS circuits arises from switching or dynamic power due to the switching current, short-circuit current when both n-channel and p-channel transistors are momentarily on during switching, and leakage current during static operation. Of these, the main source of power consumption in CMOS gates is the switching current or dynamic power. The average power consumption of a CMOS gate due to the switching current is given by

$$P = \alpha C_L V_{dd}^2 f \tag{64.1}$$

where f is the system clock frequency, V_{dd} is the supply voltage, C_L is the load capacitance, and α is the switching activity (i.e., the probability of a $0 \rightarrow 1$ transition during a clock cycle). Some of the high-level strategies for reducing power consumption that can be deduced from this expression include:

- *Activity-based component shutdown:* Shut the component down during periods of inactivity by either shutting the clock ($f = 0$) or shutting the power supply ($V_{dd} = 0$). This can be done when it is known that a component will not be used in a clock cycle, by either gating the clock or gating the power supply or asserting a disable on the component's *enable* input (if any).
- *Supply voltage reduction:* Operate at the lowest possible supply voltage (since $P = \alpha V_{dd}^2$). Many chips which are embedded in portable devices adopt this methodology since the battery life of a portable device is limited. However, tradeoffs are made with other factors such as speed, noise margins, etc.
- *Switching activity reduction:* Architectural changes to restructure the computation, communication, or memory for example to reduce the switching activity, α. By far, this has been the area of most research which has led to methods for achieving fewer transitions, especially on interconnect and memory.

Recent work on system-level power shutdown and use of low-power modes, has shown that significant savings can be achieved by considering high-level system inactivity and usage information.[48-50]

64.15 Reuse of Semiconductor Blocks

In the past few years, the reuse of semiconductor functional blocks has become popular. High-level functional blocks such as signal-processing functions, input/output interface devices, audio/video compression and decompression functions etc., are being designed once and reused in several designs. These blocks are

also known *cores* and several companies specializing in developing these cores are selling them as intellectual property (IP).[51] These cores are designed with clear well-defined and well-documented interfaces so that they can be integrated into system designs easily. The resulting *system-on-a-chip* (SOC) uses several of these cores and sometimes a microprocessor core to implement a complex system targeted at, say, multimedia processing. This is akin to the use of software component libraries in software design.

This core reuse methodology has created a new set of challenges for ASIC design.[28,52] Frequently, while integrating the cores, a significant amount of "glue logic" is required to tie in the varied integration requirements of the cores. This glue logic effects system verification detrimentally, since the cores have to be tested and verified with the glue logic. Testing a chip with several cores is an open research problem. A methodology has to be developed that allows core access and isolation during scan-based testing.

The industry is moving towards defining modular design styles and standard interface templates for cores, so that they can easily be plugged-in to a system and parameterizable features can be included or deleted depending on the design requirements. Bus and interconnect standards are also being developed, which will allow minimal glue logic to incorporate cores. New core test strategies are being developed to facilitate test and verification of cores and their interaction with other cores in the system.

This system-on-a-chip technology is driving the next step in the evolution of semiconductor design and development of CAD tools. Design teams are re-learning the way designs are conceived and created, so as to allow reuse. The bus interface standardization efforts will eliminate glue logic and hence, the performance overheads due to glue logic. These standardizations will allow the development of CAD tools which will make the use of cores as easy as a standard cell library and core integration tools as interactive as circuit schematic tools of today.

64.16 Conclusion

As advances in semiconductor technology continue to provide the ability to put more on silicon with increasing circuit densities and performance, the ASIC design methodology is evolving to higher levels of system specification and an increasing use of CAD tools to automate the design process. Increasing complexity has also led to the proliferation of language-based approaches for digital design. More recently, programming languages are being used for system design due to their ability to quickly model and simulate digital system designs and the familiarity they enjoy with designers.[53] The use of high-level programming languages for hardware modeling also helps in the semiconductor block reuse methodology. At a lower level of abstraction, logic synthesis tools have matured to the extent that they are indispensible for large, complex designs. The linking of the physical design and logic synthesis is becoming important and popular since the effectiveness and accuracy of logic synthesis is impacted to a great extent by the feedback and parasitic information provided by floorplanning tools.

Behavioral synthesis methodologies are fast becoming available which allow the synthesis of high-level functional descriptions of systems in C-based languages. These tools attempt to raise the abstraction level and design entry level close to the conceptualization level. These high-level synthesis tools allow a more complete and efficient exploration of the design space which cannot be done effectively manually. They remove the onus from "experienced" system designers to tried and proven methodologies.

Additionally, the ever-increasing demands for semiconductor devices in all aspects of everyday life is fueling the development of better and faster design turn-around tools and methodologies. Logic design productivity is increasing due to the availability of new tools and methodologies such as emulators and prototyping environments, cycle simulators, hardware accelerators, formal verification tools, system-on-a-chip methodologies etc. The need for devices which are portable is prompting more power efficient design and power estimation methodologies. Increasingly complex interactions between physical aspects and higher levels of the design are causing a tighter integration of the various levels of design from high-level synthesis to logic design to physical design. Finally, better development styles are being adopted which allow fast prototyping of a system and involve more interaction between the various design teams working on different levels of the design.

Logic Synthesis for Field Programmable Gate Array (FPGA) Technology

John W. Lockwood
Washington University

65.1 Introduction

Field Programmable Gate Arrays (FPGAs) enable rapid development and implementation of complex digital circuits. FPGA devices can be reprogrammed and reused, allowing the same hardware to be employed for entirely new designs or for new iterations of the same design. While much of traditional IC logic synthesis methods apply, FPGA circuits have special requirements that affect synthesis.

The FPGA device consists of a number of configurable logic blocks (CLBs), interconnected by a routing matrix. Pass transistors are used in the routing matrix to connect segments of metal lines. There are three major types of CLBs: those based on PLAs, those based on multiplexers, and those based on table look-up (TLU) functions.

Automated logic synthesis tools are used to optimize the mapping of the Boolean network to the FPGA device. FPGA synthesis is an extension to the general problem of multi-level logic synthesis. FPGA logic synthesis is usually solved in two phases. The *technology-independent* phase uses a general multi-level logic optimization tool (such as Berkeley's MIS) to reduce the complexity of the Boolean network. Next, a *technology-dependent* optimization phase is used to optimize the logic for the particular type of device. In the case of the TLU-based FPGA, each CLB can implement an arbitrary logic function of a limited

number of variables. FPGA optimization algorithms aim to minimize: the number of CLBs used, the logic depth, and the routing density.

The *Chortle* algorithm is a direct method that uses dynamic programming to map the logic into TLU-based CLBs. It converts the Boolean network into a forest of directed acyclic graphs (DAGs); then it evaluates and records the optimal subsolutions to the logic mapping problem as it traverses the DAG. The *two-step* algorithms operate by first *decomposing* the nodes, and then performing a *node elimination*. Later sections of this chapter discuss and detail the *Xmap, Hydra*, and *MIS-pga* algorithms.

FPGA devices are fabricated using the same sub-micron geometries as other silicon devices. As such, the devices benefit from the rapid advances in device-technology. The overhead of the programming bits, general function generators, and general routing structures, however, reduce the total amount of logic available to the end user.

65.2 FPGA Structures

An FPGA consists of reconfigurable logic elements, flip-flops, and a reprogrammable interconnect structure. The logic elements are typically arranged in a matrix. The interconnect is arranged as a mesh of variable-length metal wires and pass transistors to interconnect the logic elements. The logic elements are programmed by downloading binary control information from an external ROM, a build-in EPROM, or a host processor. After download, the control information is stored on the device and used to determine the function of the logic elements and the state of the pass transistors. Unlike a PLA, the FPGA can be used for multi-level logic functions.

The *granularity* of an FPGA refers to the complexity of the individual logic elements. A *fine-grain* logic block appear to the user to be much like a standard mask-programmable gate array. Each logic block consists of only a few transistors, and is limited to implementing only simple functions of a few variables. A *course-grain* logic block (such as those from Xilinx, Actel, Quicklogic, and Altera) provides more general functions of a larger number of variables. Each Xilinx 4000-series logic block, for example, can implement any Boolean function of five variables, or two Boolean functions of four variables.

It has been found that the course-grain logic blocks generally provide better performance than the fine-grain logic blocks, as the course-grained devices require less space for interconnect and routing by combining multiple logic functions into one logic block. In particular, it has been shown that a four-input logic block uses the minimal chip area for a large variety of benchmark circuits.[1] The expense of a few extra underutilized logic blocks outweighs the area required for the larger number of fine-grained logic blocks and their associated larger interconnect matrix and pass transistors. This paper will focus on the logic synthesis for course-grained logic elements.

A course-grained configurable logic block (CLB) can be implemented using: a PLA-based AND/OR elements, multiplexors, or SRAM-based table look-up (LUT) elements. These configurations are described below in detail.

Look-up Table (LUT)-Based CLB

The basic unit of look-up table (LUT)-based FPGAs is the *configurable logic block* (CLB), implemented as an SRAM of size $2^n \times 1$. Each CLB can implement any arbitrary logic function of n variables, for a total of 2^n functions.

An example of an LUT-based FPGA is the Xilinx 4000-series FPGA, as illustrated in Fig. 65.1. Each CLB has three LUT generators, and two flip-flops.[2] The first two LUTs implement any function of four variables, while the third LUT implements any function of three variables. Separately, each CLB can implement two functions of four variables. Combined, each CLB can implement any one function of five variables, or some restricted functions of nine variables (such as AND, OR, XOR).

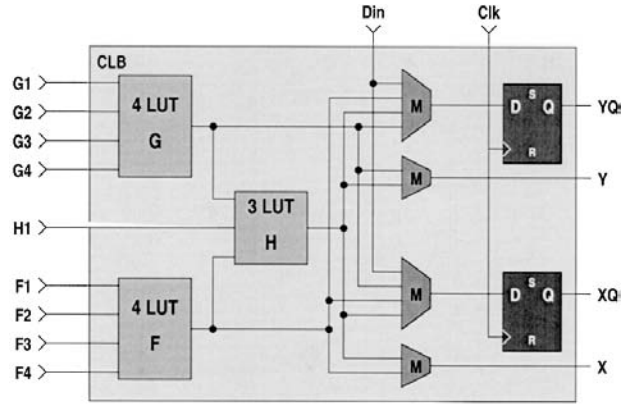

FIGURE 65.1 Xilinx 4000-series CLB.

PLA-Based CLB

PLA-based FPGA devices evolved from the traditional PLDs. Each basic logic block is an AND-OR block consisting of wide fan-in AND gates feeding a few-input OR gate. The advantage of this structure is that many logic functions can be implemented using only a few levels of logic, due of the large number of literals that can be used at each block. It is, however, difficult to make efficient use of all inputs to all gates. Even so, the amount of wasted area is minimized by the high packing density of the wired-AND gates.

To further improve the density, another type of logic block, called the *logic expander*, has been introduced. It is a wide-input NAND gate whose output could be connected to the input of the AND-OR block. While its delay is similar, the NAND block uses less area than the AND-OR block, and thus increases the effective number of product terms available to a logic block.

Multiplexer-Based CLB

Multiplexer-based FPGAs utilize a multiplexer to implement different logic function by connecting each input to a constant or a signal.[3] The ACT-1 logic block, for example, has three multiplexers and one logic gate. Each block has eight inputs and one output, implementing:

$$f = \left(\overline{s_3 + s_4}\right)\left(\overline{s}_1 w + s_1 x\right) + \left(s_3 + s_4\right)\left(\overline{s}_2 y + s_2 x\right)$$

Multiplexer-based FPGAs can provide a large degree of functionality for a relatively small number of transistors. Multiplexer-based CLBs, however, place high demands on routing resources due to the large number of inputs.

Interconnect

In all structures, a reprogrammable routing matrix interconnects the configurable logic blocks. A portion of the routing matrix for the Xilinx 4000-series FPGA, for example, is illustrated in Fig. 65.2. Local interconnects are used to join adjacent CLBs. Global routing modules are used to route signals across the chip.

The routing and placement issues for the FPGAs are somewhat different from those of custom logic. For a large fan-out node, for example, an optimal placement for the elements for the fan-out

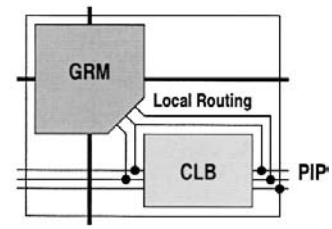

FIGURE 65.2 Xilinx routing matrix.

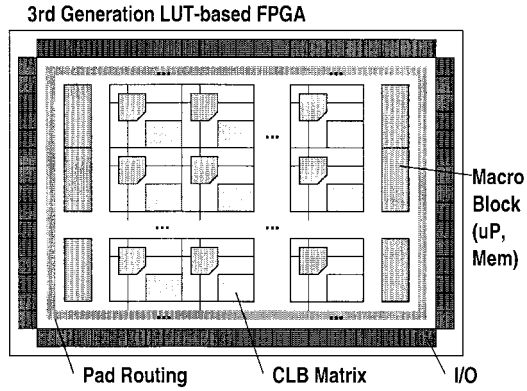

FIGURE 65.3 FPGA chip layout.

would be along a single row or column, where the routing could be done using a long line. For custom logic, the optimal placement would be as a cluster, where the optimization attempted to minimize the distance between nodes. For the FPGA, the routing delay is more influenced by the number of pass transistors for which the signal must cross rather than by the length of the signal line.

The power of the FPGA comes from the flexibility of the interconnect. A block diagram of a typical third-generation FPGA device is shown in Fig. 65.3. The CLB matrix and the mesh of the interconnect occupy most of the chip real area. Macro blocks, when present, implement functions such as high-density memory or microprocessing cores. The I/O blocks surround the chip and provide connectivity to external devices.

65.3 Logic Synthesis

Logic synthesis is typically implemented as a two-phase process: a technology-independent phase, followed by a technology mapping phase.[4] The first phase attempts to generate an optimized *abstract representation* of the target circuit, and the second phase determines the optimal mapping of the optimized abstract representation onto a particular type of device, such as an FPGA. The second phase optimization may drastically alter the circuit to optimize the logic for a particular technology. In most approaches published, the technology-dependent FPGA optimization is based on the area occupied by the logic as measured by the number of LUTs.

The abstract representation of a combination logic function f is not unique. For example, f may be expressed by a truth table, a *sum-of-products* (SOP) (such as $f = ab + cd + e'$), a *factored form* (such as $f = (a + b)(c + (e'(f + g')))$), a *binary decision diagram* (BDD) *directed acyclic graph* DAG), an *if-then-else DAG*, or any combination of the above forms.

The BDD is a DAG where the logic function is associated with each node, as shown in Fig. 65.4. It is canonical because, for a given function and a given order of the variables along all the paths, the BDD DAG is unique. A BDD may contain a great deal of redundant information, however, as the sub-functions may be replicated in the lower portions of the tree.

The *if-then-else DAG* consists of a set of nodes, each with three children. Each node is a two-to-one selector, where the first child is connected to the control input of the selector and the other two are connected to the signal inputs of the node.

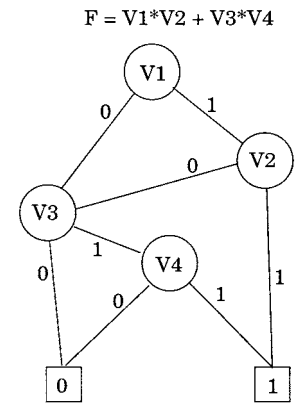

FIGURE 65.4 Binary decision diagram.

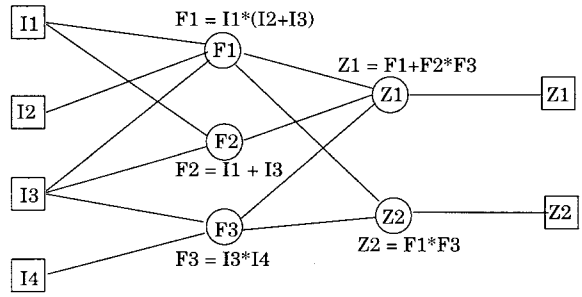

FIGURE 65.5 An example of Boolean network.

Technology-Independent Optimization

In the technology-independent synthesis phase, the combinational logic function is represented by the Boolean network, as illustrated in Fig. 65.5. The nodes of the network are initially *general nodes*, which can represent any arbitrary logic function. During optimization, these nodes are usually mapped from the *general form* to a *generic form*, which only consists of AND, OR, and NOT logic nodes.[4] At the end of first synthesis phase, the complexity and number of nodes of the Boolean network has been reduced.

Two classes of operations — *network restructuring* and *node minimization* — are used to optimize the network. Network restructuring operations modify the structure of the Boolean network by introducing new nodes, eliminating others, and adding and removing arcs. Node minimization simplifies the logic equations associated with nodes.[5]

Restructuring Operations

Decomposition reduces the *support* of the function, F, (denoted as $sup(F)$). The support of the function refers to the set of variables that F explicitly depends on. The *cardinality* of a function (denoted by $|sup(F)|$), represents the number of variables that F explicitly depends on.

Factoring is used to transform the SOP form of a logic function into a factored form. *Substitution* expresses one given logic function in terms of another. *Elimination* merges a subfunction, G, into the function, F, so that F is expressed only in terms of its fan-in nodes of F and G (not in terms of G itself).

The efficiency of the restructuring operations depends on finding a suitable *divisor*, P, to factor the function, that is, given functions F, choose a divisor P, and find the functions Q and R such that $F = PQ+R$. The number of possible divisors is hopelessly large; thus, an effective procedure is required to restrict the searching subspace for good divisors. The Brayton and McMullen kernel matching technique is used.

The *kernels* of a function F are the set of expressions: $K(F) = \{g \mid g \subset D(F)$, where g is cube-free, and $D(F)$ are the primary divisors.

A *cube* is a logic function given by the product of literals. A *cube of a function F* is a cube whose *on-set* does not have vertices in the *off-set* of F (e.g., if $F = ab(c + d)$, ab is a cube of F). An expression F is *cube-free* if no cube divides the expression evenly.[6] For example, $F = ab + c$ is cube-free, while $F = ab + ac$ is not cube-free. Finally, the *primary divisors* of F are the set of expression: $D(F) = F/C \mid C$ is a cube.[7]

Kernel functions can be computed effectively by several fast algorithms. Based on the kernel functions extracted, the restructuring operations can generate acceptable results usually within a reasonable amount of time.[4] Speed/quality tradeoffs are still needed, however, as is the case with MIS, which is a multi-level logic synthesis system.[8]

Node Minimization

Node minimization attempts to reduce the complexity of a given network by using Boolean minimization techniques on its nodes.

A two-level logic minimization with consideration of the *don't-care* inputs and outputs can be used to minimize the nodes in the circuit. Two types of *don't-care* sets — satisfiability don't care (SDC) and observability don't care (ODC) — are used in the two-level minimizer. The SCD set represents combinations of input variables that can never occur because of the structure of the network itself, while the ODC set represents combinations of variables that will never be observed at outputs. If the ODCs and SDCs are too large, a practical running time can only be achieved by using a limited subset of ODCs and SDCs.[8]

Another technique is to use a tautology checker to determine if two Boolean networks are equivalent, by taking XNOR of their corresponding primary outputs.[9] A node is first tentatively simplified by deleting either variables or cubes. If the result of tautology check is 1 (equivalent), then this deletion is performed. As with the first method, an exhaustive search is usually not possible because of the computational cost of the tautology check.

Technology Mapping

Taking the special characteristics of a particular FPGA device into account, the technology mapping phase attempts to realize the Boolean network using a minimal number of CLBs. Synthesis algorithms fall into two main categories: *algorithmic approaches* and *rule-based techniques.*

By expressing the optimized AND/OR/NOT network as a *subject graph* (a network of two-input NAND gates), and a library of potential mappings as a *pattern graphs,* the first approach converts the mapping problem to a covering problem with the goal of finding the minimum-cost cover of the subject graph by the pattern graphs. The problem is NP-hard; thus, heuristics must be used. If the network to be mapped is a tree, an optimal heuristic method has been found. It is inspired by Aho et al.'s work on optimizing compilers. If the Boolean network is not a tree, a step of decomposition into forest of trees is performed; then the mapping problem is solved as a tree-covering-by-tree problem, using the proven optimal heuristic.

The rule-based technique traverses the Boolean network and replaces subnetworks with patterns in the library when a match is found. It is slow compared to the first method, but can generate better results. Mixed approaches, which a perform tree-covering step followed by a rule-based clean-up step, are the current trend in industry.

65.4 Look-up Table (LUT) Synthesis

The existing approaches to synthesize FPGAs based on look-up tables (LUTs) are summarized in Fig. 65.6. Beginning with an optimized AND/OR/NOT Boolean network generated by a general-purpose multi-level logic minimizer, such as MIS-II, these algorithms attempt to minimize the number of LUTs needed to realize the logic network.

Library-Based Mapping

Library-based algorithms were originally developed for use in the synthesis of standard cell designs. It was assumed that there was a small number of pre-designed logic elements. The goal of the mapping function was to optimize the use of these blocks.

MIS is one such library-based approach that performs multi-level logic minimization. It existed long before the conception of FPGAs and has been used for TLU logic synthesis. Non-equivalent functions in MIS are explicitly described in terms of two-input NAND gates. Therefore, an optimal library needs to cover all functions that can be implemented by the TLU. Library-based algorithms are generally not appropriate for TLU-based FPGAs due to their large number of functions which each CLB can implement.

Direct Approaches

Direct approaches generate the optimized Boolean network directly, without the explicit construction of library components. Two classes of method are used currently: *modified tree covering algorithms* (i.e., *Chortle* and its improved versions) and *two-step methods.*

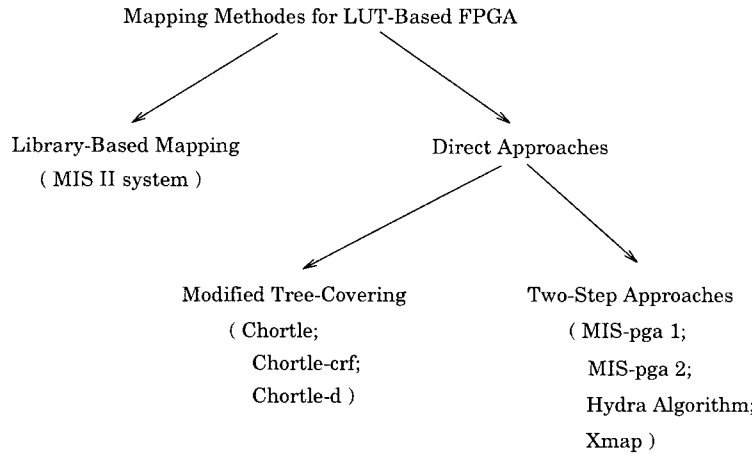

FIGURE 65.6 Approaches to synthesize FPGAs based on LUTs.

Modified Tree-Covering Approaches

The modified tree-covering approach begins with an AND/OR representation of the optimized Boolean network. *Chortle*, and its extensions (*Chortle-crf* and *Chortle-d*), first decompose the network into a forest of trees by clipping the multiple-fan-out nodes. An optimal mapping of each tree into LUTs is then performed using dynamic programming, and the results are assembled together according to the interconnection patterns of the forest. The details of the Chortle algorithms are given in the Section 65.5.

Two-step Approaches

Instead of processing the mapping in one direct step, the *two-step methods* handle the mapping by *node decompostion* followed by *node elimination*. The decomposition operation yields a network that is *feasible*. The node elimination step reduces the number of nodes by combining nodes based on the particular structure of a CLB.

A Boolean network is feasible if every intermediate node is realized by a feasible function. A *feasible function* is a function that satisfies $|sup(f)| \leq K$, or informally, can be realized by one CLB.

Different two-step approaches have been proposed and implemented, including MIS-pga1 and MIS-pga2 from U.C. Berkeley, Xmap from U.C. Santa Cruz, and Hydra from Stanford. Each algorithm has its own advantages and drawbacks. Details of these methods are given in Section 65.6. Comparisons among the direct and two-step methods are given in Section 65.7.

65.5 Chortle

The Chortle algorithm is specifically designed for TLU-based FPGAs. The input to the Chortle algorithm is an optimized AND/OR/NOT Boolean network. Internally, the circuit is represented as a forest of directed acyclic graphs (DAGs), with the leaves representing the inputs and the root representing the output, as shown in Fig. 65.7. The internal nodes represent the logic functions AND/OR. Edges represent inverting or non-inverting signal paths.

The goal of the algorithm is to implement the circuit using the fewest number of K-input CLBs in minimal running time. Efficient running time is a key advantage of Chortle, as FPGA mapping is a computationally intensive operation in the FPGA synthesis procedure.

The terminology of the Chortle algorithm defines the *mapping* of a node, n, in a tree as the circuit of look-up tables rooted at that node that extends to the leaf nodes. The *root look-up table* of node n is the mapping of the Boolean function that has the node n as its single output. The *utilization* of a look-up table refers to the number of inputs, U, out of the K inputs actually used in the mapping. Finally, the

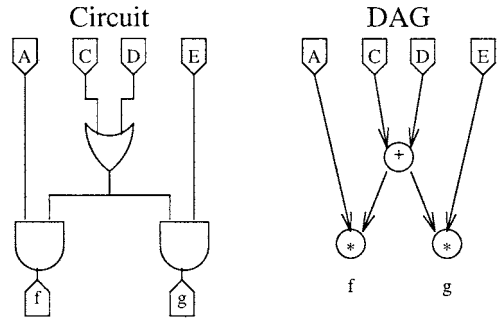

FIGURE 65.7 Boolean network and DAG representation.

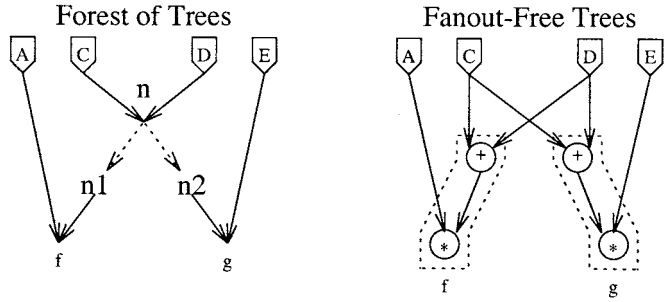

FIGURE 65.8 Forest of fan-out-free trees.

utilization division, μ, is a vector that denotes the distribution of the inputs to the root look-up table among subtrees. For example, a utilization vector of $\mu = \{2,1\}$ would refer to a table look-up function that has two of the K inputs from the left logic subtree, and one input from the right subtree.

Tree Mapping Algorithm

The first step of the Chortle algorithm is to convert the input graph to forest of fan-out-free trees, where each logic function has exactly one output. As illustrated in Fig. 65.8, node n has a fan-out degree of two; thus, two new nodes, n_1 and n_2, are created that implement the same Boolean equation of node n. Each subtree is then evaluated independently.

Chortle uses a *postorder traversal* of each DAG to determine the mapping of each node. The logic functions connecting the inputs (leaves) are processed first; the logic functions connecting those functions are processed next, and so on until reaching the output node (root).

Chortle's tree mapping algorithm is based on dynamic programming. Chortle *computes* and *records* the solution to all subproblems, proceeding from the smallest to the largest subproblem, avoiding recomputation of the smaller subproblems. The subproblem refers to computation of the minimum-cost mapping function of the node n in the tree. For each node n_i, the subproblem, $minMap(n_i,U)$, is solved for each value of U, ranging from 2 … K ($U = K$ refers to a look-up function that is fully utilized, while $U = 2$ refers to a TLU with only two inputs).

In general, for the same value of U, multiple utilization vectors, $\mu(u_1, u_2, \ldots, u_f)$, are possible, such that $\sum_{i=1}^{f} u_i = U$. The utilization vector determines how many inputs are to be used from each of the previous optimal subsolutions. Chortle examines each possible mapping function to determine this node's minimum-cost mapping function, $cost(minMap(n,U))$. For each value of $U \in \{2 \ldots K\}$, the utilization division of the minimum-cost mapping function is recorded.[10]

Example

The Chortle mapping function is best illustrated by an example, as illustrated in Fig. 65.9. For this example, we will assume that each CLB may have as many as four inputs (i.e., $K = 4$). The inputs, {A,B,C,D,E,F}, perform the logic function: A * B + (C * D) E + F.

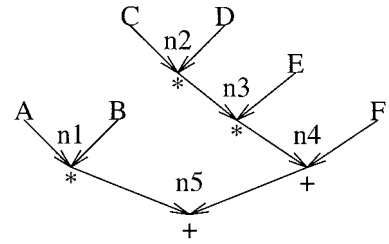

FIGURE 65.9 Chortle mapping example.

In the postorder traversal n_1 is visited first, followed by n_2 … n_5. For n_1, there is only one possible mapping function, namely, $U = 2$, $\mu = \{1,1\}$. The same is true for n_2.

When n_3 is evaluated, there are two possibilities, as illustrated in Fig. 65.10. First, the function could be implemented as a new CLB with two inputs ($U = 2$), driven from the outputs of n_2 and E. This sub-graph would use two TLBs; thus, it would have a cost function of 2. For $U = 3$, only one utilization vector is possible, namely, $\mu = \{2,1\}$. All three primary inputs C, D, and E are grouped into one CLB, thus producing a cost function of 1. We store only the utilization vectors and cost functions for $minMax(n_3, 2)$ and $minMax(n_3,3)$.

When n_4 is evaluated, there are many possibilities, as illustrated in Fig. 65.11. With $U = 2$ ($\mu = \{1,1\}$), a two-input CLB would combine the optimal result for n_3 with the primary input F, producing a function with a cost of 2. For $U = 3$ ($\mu = \{2,1\}$), a three-input CLB would combine the optimal result for n_3: $U = 2$ with both inputs E and F, also at a cost of two CLBs. Finally, for $U = 4$, a single CLB would implement the function (C * D) * E + F), at a cost of 1. We store the utilization vectors and cost functions for $minMax(n_4,2)$, $minMax(n_4,3)$, and $minMax(n_4,4)$.

Finally, we evaluate the output node, n_5, as illustrated in Fig. 65.12. We see that there are four possible mappings and, of those, two minimal mappings are possible. Chortle may return either of the mappings where two CLBs implement: $n_5 = (A * B) + n_3 + F$ and $n_3 = (C * D) * E$.

Chortle-crf

The Chortle-crf algorithm is an improvement of the original Chortle algorithm. The major innovation with Chortle-crf involves the method for choosing gate-level node decomposition. The other improvements involve the algorithm's response to reconvergent and replicated logic. The name, Chortle-crf, is based on the new command line options (`-crf`) that may be given when running the program (`-c` for constructive bin-packing for decomposition, `-r` for reconvergent optimization, and `-f` for replication optimization).[11] Each of the optimizations are detailed below.

Decomposition

Decomposition involves splitting a node and introducing intermediate nodes. Decomposition is *required* if the original circuit has a fan-in greater than K. In this case, no one CLB could implement the entire

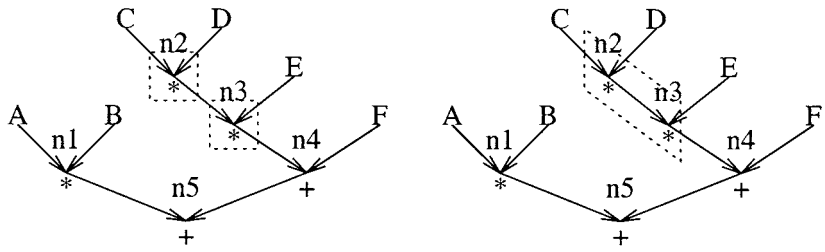

FIGURE 65.10 Mapping of node 3.

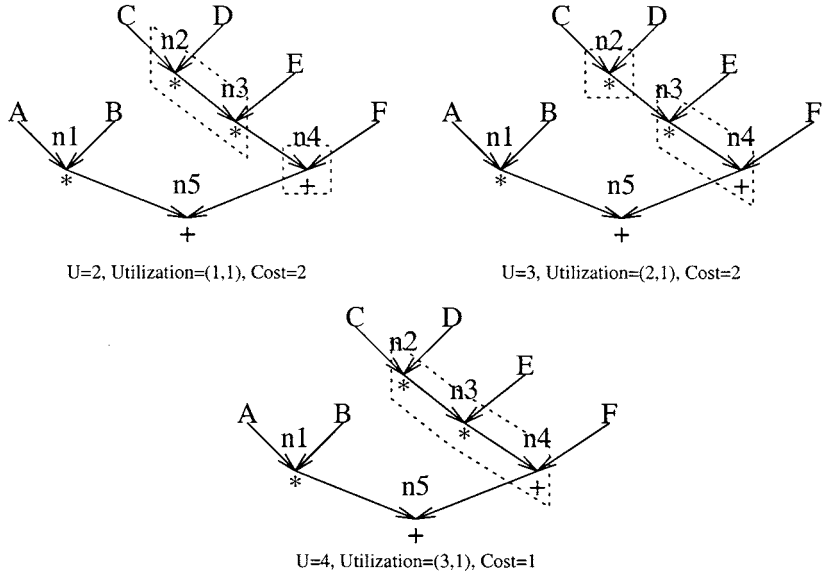

FIGURE 65.11 Mapping of node 4.

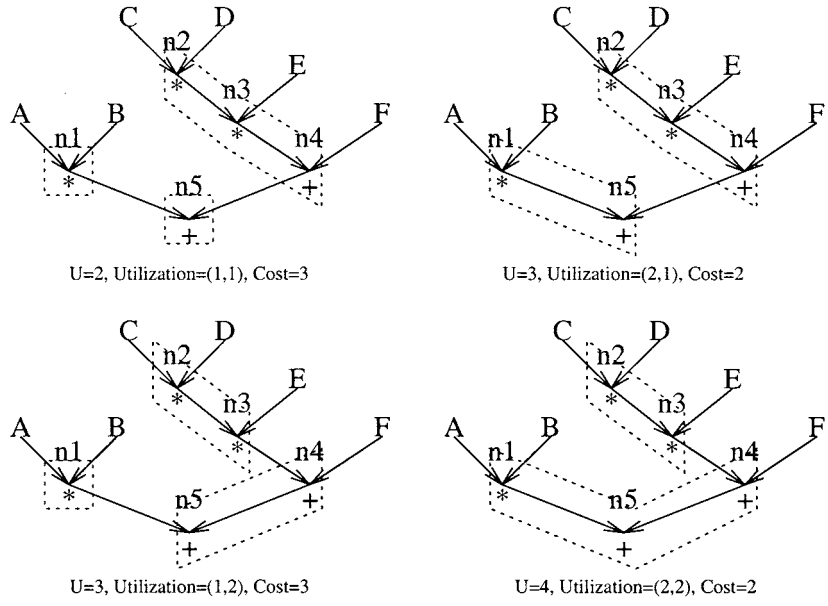

FIGURE 65.12 Mapping of node 5.

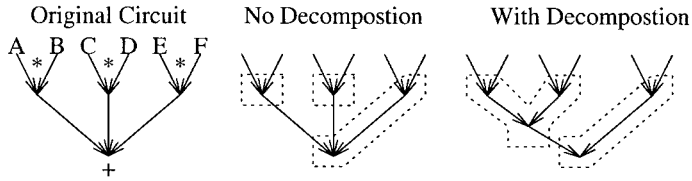

FIGURE 65.13 Decomposition example.

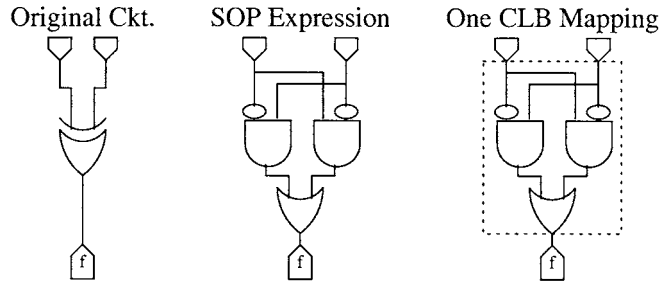

FIGURE 65.14 Reconvergent logic example.

function. In general, the decomposition of a node may yield a circuit that uses fewer CLBs. Consider, for example, implementations with four-input CLBs ($K = 4$) of the circuit shown in Fig. 65.13. Without decomposition, the output node forces the sub-optimal use of the first two function generators (i.e., A * B and C * D are implemented as individual CLBs). With decomposition, however, the output node OR gate is decomposed to form a new node, which implements the function: (A * B) + (C * D), which can be implemented in one CLB.

The original Chortle algorithm used an *exhaustive search* of all possible decompositions to find the optimal decomposition for the subcircuit, causing the running time at a node to increase exponentially as the fan-in increased. As a heuristic within the original Chortle algorithm, nodes would be arbitrarily *split* if the fan-in to a node exceeded 10, allowing each subfunction to be computed in a reasonable amount of time. If a node was split, however, the solution was no longer guaranteed to be optimal.

The improved Chortle-crf algorithm uses *first-fit-decreasing bin packing* algorithm to solve the decomposition problem. Large fan-in nodes are decomposed into smaller subnodes with smaller fan-in. Next, the look-up tables for the input functions are bin-packed into CLBs. A look-up table with k inputs is merged into the first CLB that has at least $K - k$ unused inputs remaining. A new CLB is generated, if needed, to accommodate the k inputs.

Reconvergent Logic

Reconvergent logic occurs when a signal is split into multiple function generators, and then those output signals merge at another generator. An example of reconvergent logic is shown in Fig. 65.14. When the XOR gate was converted to a SOP format by the technology-independent minimization phase, two AND gates and an OR gate were generated. Both AND gates share the same inputs. If the total number of *distinct* inputs is less than the size of the CLB, it is possible to map these functions into one CLB. The Chortle-crf algorithm finds all local reconvergent paths, and then examines the effect of merging those signals into one CLB.

Replicated Logic

For multi-output logic circuits, there are cases when logic duplication uses fewer CLBs than logic that uses subterms generated by a shared CLB. Figure 65.15 shows an example of a six-input circuit with two outputs. One product term is shared for both functions f and g. Without replication, the subfunction implemented by the middle AND gate would be implemented as one CLB, as well as the subfunctions for f and g. In this case, however, the middle AND gate can be replicated, and mapped into *both* function generators, thus allowing the entire circuit to be implemented using two CLBs, rather than three.

When a circuit has a fan-out greater than one, Chortle may implement the node *explicitly* or *implicitly*. For an explicit node, the subfunction is generated by a dedicated CLB, and this output signal is treated as an input to the rest of the logic. For an implicit node, the logic is replicated for each fan-out subcircuit. The algorithm computes the cost of the circuit, both with replication and without. Logic replication is chosen if this reduces the number of CLBs used to implement the circuit.

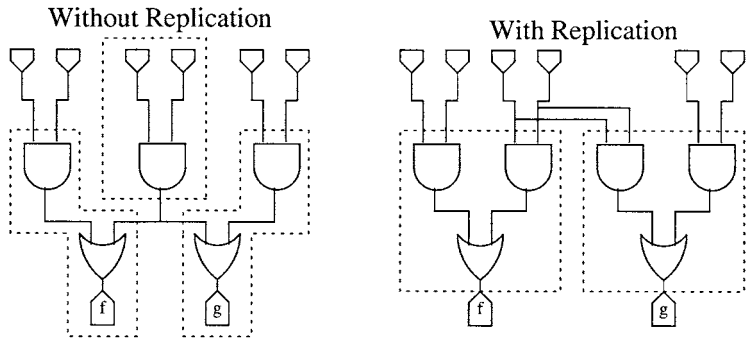

FIGURE 65.15 Replicated logic example.

Chortle-d

The primary goal of Chortle-d is to reduce the *depth* of the logic (i.e., the largest number of CLBs for any signal path through combinational logic).[12] By minimizing the longest paths, it is possible to increase the frequency at which the circuit can operate. Chortle-d is an enhancement of the Chortle-crf algorithm. Chortle-d, however, may use more look-up tables than Chortle-crf to implement a circuit with a shorter depth.

The Chortle-d algorithm separates logic into *strata*. Each *stratum* contains logic at the same depth. When nodes are decomposed, the outputs of the tables with the deepest stratum are connected to those at the next level. Chortle-d also employs logic replication, where possible. Replication often reduces the depth of the logic, as illustrated in Fig. 65.15.

The depth optimization is only applied to the critical paths in the circuit. The algorithm first minimizes depth for the entire circuit to determine the maximum *target depth*. Next, the Chortle-crf algorithm is employed to find a circuit that has minimum area. For paths in the area-optimized circuit that exceed the target depth, depth-minimization decomposition is performed. This has the effect of equalizing the delay throuth the circuit.

It was found that for the 20 circuits in the MCNC logic synthesis benchmark, the chortle-d algorithm constructed circuits with 35% fewer logic levels, but at the expense of 59% more look-up tables.

65.6 Two-Step Approaches

As with Chortle, the *two-step methods* start with an optimized network in which the number of literals is minimized. The network is decomposed to be feasible in the first step; then the number of nodes is reduced in the second step. If the given network is already feasible, the first step is skipped.

First Step: Decomposition

For a given FPGA device, with a k-input TLU, all nodes of the network with more than k inputs must be decomposed. Different methods decompose the network in different ways.

MIS-pga 1

MIS-pga 1 was developed at Berkeley for FPGA synthesis, as an extension of MIS-II. It uses two algorithms, *kernel decomposition* and *Roth-Karp decomposition*, to decompose the infeasible nodes separately; then it selects the better result.

Kernel decomposition decomposes an infeasible node n_i by extracting a kernel function, k_i, and splitting n_i based on k_i and its *residue*, r_i. The residue r_i, of a kernel k_i, of a function F, is the expression for F with a new variable substituted for all occurrences of k_i in F; for example, if $F = x_1x_2 + x_1x_3$, then

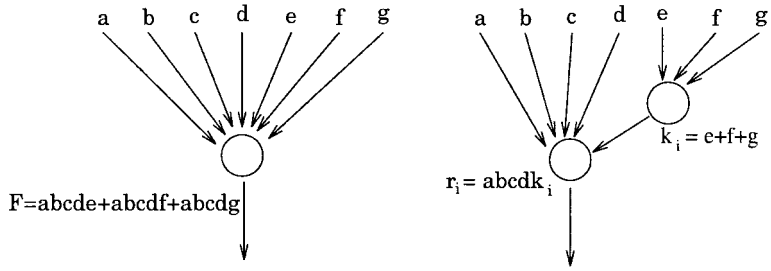

FIGURE 65.16 Example of kernel decomposition.

$k_i = x_2 + x_3$, and $r_i = x_1 k_i$. As there may be more than one kernel function that exists for a node, a cost function is associated with each kernel: $cost(k_i) = |sup(k_i) \bigcap sup(r_i)|$. The kernel with minimum cost is chosen. A kernel decomposition is illustrated in Fig. 65.16.

Splitting infeasible nodes by kernel functions minimizes the number of new edges generated. Therefore, the considerations of wiring resources and logic area are integrated together. This procedure is applied recursively until all nodes are feasible. If no kernels can be extracted for a node, an AND-OR decomposition is applied.

Roth-Karp decomposition is based on the classical decomposition of Ashenhurst and Curtis.[13] Instead of building a decomposition chart whose size grows exponentially, as it does with the original method, a compact cover representation of the on-set and the off-set of the function is used. The Roth-Karp algorithm avoids the expensive computation of the best solution by accepting the first bound set. As with kernel decomposition, the AND/OR decomposition is used as a last resort.

Hydra Decomposition

The Hydra algorithm, developed at Stanford University, is designed specifically for two-output TLU FPGAs.[14] Decomposition in Hydra is performed in three stages. The first and third stages are AND-OR decompositions, while the second stage is a *simple-disjoint decomposition*, which is defined as the following:

> Given a function, F, and its support, S, with $F = G(H(S^a), S^b)$, where S^a, $S^b \subseteq S$ and $S^a \bigcup S^b = S$; If $S^a \bigcap S^b = 0$, then G is a *disjoint decomposition* of F.

The first stage is executed only if the number of inputs to the nodes in the given network is larger than a given threshold. Without performing the first stage, the efficiency of the second stage would be reduced. The last stage is applied only if the resulting network is still infeasible.

In the second stage, the algorithm searches for all the function pairs that have common variables and then applies the simple-disjoint decomposition on them. As a result, two CLBs with the same fan-ins can be merged into one two-output CLB. The rationale is illustrated in Fig. 65.17.

A weighted graph $G(V,E,W)$ that represents the shared-variable relationship is constructed based on the given Boolean network. In the $G(V,E,W)$, V is the node set corresponding to that of the Boolean network; edge, $e_{ij} \subset E$, exists for any pair of nodes, $\{v_i, v_j\} \subset V$, if they share variables; and weight, $w_{ij} \subset W$, is the number of variables shared correspondingly. Edges are first sorted by weight and then traversed in decreasing order to check for simple-disjoint decomposition. A cost function, which is the linear combination of the number of the shared inputs and the total number of variables in the extracted functions, is computed to decide whether or not to accept a certain simple decomposition.

Xmap Decomposition

The Xmap decomposes the infeasible network by converting the SOP form from MIS--II to an if-then-else DAG representation.[15] The terms of the SOP network are collected in a set, T; then, variables are sorted in decreasing order of the frequency of their appearance in T; finally, the if-then-else DAG is formed by the following recursive function:

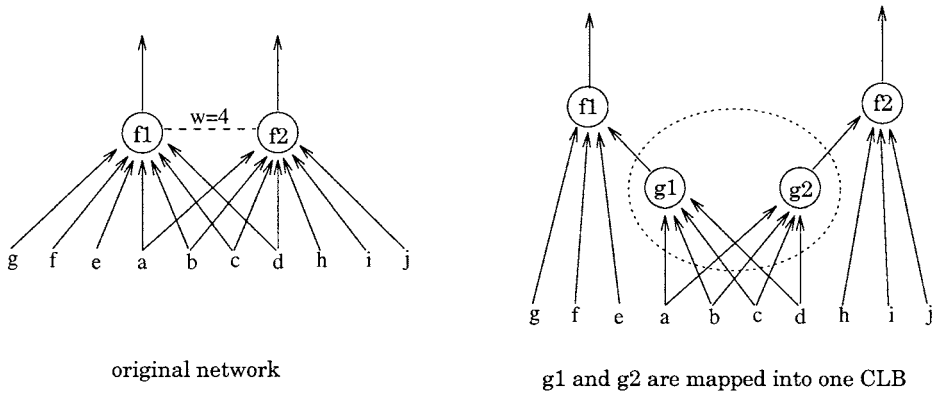

FIGURE 65.17 CLB mapping example.

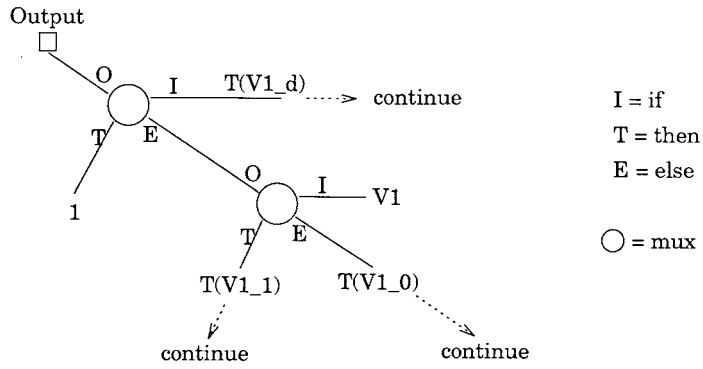

FIGURE 65.18 Result of first iteration.

- Let V be the most frequently used variable in the current set, T.
- Sort the terms in T into subsets $T(V_d)$, $T(V_1)$, according to V. $T(V_d)$ is the subset in which V does not appear, $T(V_1)$ is the onset of V, and $T(V_0)$ is the offset of V.
- Delete V from all terms in T; then apply the same procedure recursively to the three subsets until all variables are tested.

The resulting if-then-else DAG after first iteration is given in Fig. 65.18. A circuit that has been mapped to an if-then-else DAG is immediately suited for use with multiplexer-based CLBs.[16] Additional steps are used to optimize the DAG for use with TLU functions.

Second Step: Node Elimination

Three approaches have been proposed for node elimination: *local elimination*, *covering*, and *merging*.

Local Elimination

The operation used for *local elimination* is *collapsing*, which merges node n_i into node n_j whenever n_i is a fan-in node to n_j and the new node obtained is feasible. The **Hydra algorithm** accepts local eliminations as soon as they are found. **MIS-pga 1,** however, first orders all possible local eliminations as a function of the increase in the number of interconnections resulting from each elimination, and then greedily selects the best local eliminations.

The number of nodes can be reduced by local elimination, but its myopic view of the network causes local elimination to miss better solutions. Additionally, the new node created by merging multi-fan-out nodes may substantially increase the number of connections among TLUs and hence make the wiring problem more difficult. This problem is more severe in Hydra than in MIS-pga 1.

Covering

The *covering* operation takes a global view of the network by identifying clusters of nodes that could be combined into a single TLU. The operation is a procedure of finding and selecting supernodes. A *supernode*, S_i, of a node n_i, is a cluster of nodes consisting of n_i and some other nodes in the transitive fan-in of n_i such that the maximum number of inputs to S_i is k. Obviously, more than one supernode may exist for a node.

In **MIS-pga 1,** the covering operation is performed in two stages. In the first stage, the supernodes are found by repeatedly applying the *maxflow algorithm* at each node. In the second stage, an optimal subset of the supernodes that can cover the whole network using a minimum number of supernodes is selected by solving a *binate covering* problem whose constrains are: first, all intermediate nodes should be included in at least one supernode; second, if a supernode S_i is selected, some supernodes that supply the inputs of S_i must be selected [the ordinary (*unate*), covering problem just has the first constraint].

Hydra examines the nodes of the network in order of decreasing number of inputs. An unassigned node with the maximal number of inputs is chosen first. A second node is then chosen such that the two nodes can be merged into the same TLU and the cost function (same cost function as was used in decomposition step) is maximized. This greedy procedure stops when all unexamined nodes have been considered.

For **Xmap**, the logic blocks to be found are sub-DAGs of the if-then-else DAG for the entire circuit. The algorithm traverses the if-then-else DAG from inputs to outputs and keeps a log of inputs in the paths (called *signals set*) that can be used to compute the function of the node under consideration. Nodes in the signals set could be a *marked* node or a *clean* node. A marked node isolates its inputs to the current node, while a clean node exposes all its fan-ins. For an *overflow* node, whose signals set is larger than k (the number of inputs of the TLU), a *marking* procedure is executed to reduce the fan-ins of the overflow node. Xmap first marks the high-fan-out descendants of the node, and then marks the children of the node in decreasing order of the size of their signals set. The more inputs Xmap can isolate from the node under consideration, the better. The marking process cuts the if-then-else into pieces, each of which can be mapped into one CLB.

Merging

The purpose of the merging step is to combine nodes that share some inputs to exploit some of the particular features of FPGA architecture. For example, each CLB in the Xilinx XC4000 device has two four-input TLUs and a third TLU combining them with the ninth input (Section 65.3). In the three approaches discussed above, a post-processing step is performed to merge pairs of nodes after the covering operation. The problem is formulated as a maximum cardinality matching problem.

MIS-pga 2: A Framework for TLU-Logic Optimization

MIS-pga 2 is an improved version of MIS-pga 1. It combines the advantageous features of Chortle-crf, MIS-pga 1, Xmap, and Hydra. In each step, Mis-pga 2 tries different algorithms and chooses the best.[17]

Four decomposition algorithms are executed in the decomposition step:

1. *Bin-packing*: the algorithm is similar to that of Chortle-crf, except the heuristic of MIS-pga 2 is the *Best-Fit Decreasing.*
2. *Co-factoring decomposition*: it decomposes a node based on computing its *Shannon cofactor* ($f = f_1 f_2 + f_1' f_3$). The nodes in the resulting network have, at most, three inputs. This approach is particularly effective for functions in which cubes share many variables.

3. *AND/OR decomposition*: it can always find a feasible network, but is usually not a good network for the node elimination step. Therefore, it is used as the last resort.
4. *Disjoint decomposition*: unlike Hydra, this method is used on a node-by-node basis. When it is used as a preprocessing stage for the bin-packing approach, a locally optimal decomposition can be found.

MIS-pga 2 interweaves some operations of the two-step methods. For example, the local elimination operation is applied to the original infeasible network as well as to the decomposed, feasible network. This same operation is referred to as *partial collapse* when applied before decomposition. Unlike MIS-pga 1, which separates the covering and the merging operations, these two operations are combined together to solve a single, binate covering problem.

Because MIS-pga 2 does a more exhaustive decomposition phase, and because the combined covering/merging phase has a more global view of the circuit, MIS-pga 2 results are almost always superior to those of Chortle-crf, MIS-pga 2's results are almost always superior to those of Chortle-crf, MIS-pga 1, Hydra, and Xmap. For the same reason, MIS-pga 2 is relatively slow, as compared to the other algorithms.

65.7 Conclusion

By understanding how FPGA logic is synthesized, hardware designers can make the best use of their software development tools to implement complex, high-performance circuits. Synthesis of FPGA logic devices combines the algorithms of Chortle and its extensions, Xmap, Hydra, MIS-pga 1, and MIS-pga 2. Each of these methods starts with an optimized Boolean network and then maps the logic into the configurable logic blocks of a field-programmable gate array circuit. Because the optimal covering problem is NP-hard, heuristic approaches must balance between the optimality of the solution and the running time of the optimizer. Understanding this tradeoff is the key to rapidly prototyping logic using FPGA technology.

66.1 Introduction: Basic Concepts

Physical faults or *design errors* may alter the behavior of a digital circuit. Design errors are tackled by redesigning the circuit, whereas physical errors can be reduced by determining appropriate operating conditions.[1,2]

There are many sources of physical faults: improper interconnections between parts, improper assembly, missing parts, and erroneous parts may occur while the circuit is being manufactured. After manufacturing, the circuit may fail due to excessive heat dissipation or for mechanical reasons associated with corrosions and, in general, bad maintenance. *Short-circuit faults* are those due to connections of signal lines that must be disconnected. In addition, disconnecting lines that must be connected may cause open-circuit faults.[1,3]

Failures in the operation of digital circuits are addressed in the testing process, which is abstracted in Fig. 66.1. Typically, the testing process determines the presence of faults. The circuit being tested is often called the *circuit under test* (CUT). Errors are detected by applying *test patterns* on the inputs of the CUT and analyzing the responses on its outputs. A test pattern is typically a vector of 0 and 1, and every bit corresponds to an input of the CUT. A test pattern is generated by a *test pattern generator* (TPG) tool. The responses are analyzed using an *output response verification* (ORV) tool. The ORV tool is a comparator circuit.

The testing process is done periodically during the circuit's life span. It is initially done after fabrication and while the CUT is still at the wafer. Testing is also done when it is removed from the wafer, and later it is tested as part of a *printed circuit board* (PCB).

Testing is done either at the *transistor level* or at the *logical level*. We are considering here logical-level testing for which TPG and ORV are concerned with binary values, that is, the signals are binary values. The components are gates and flip-flops (or latches). We do not consider *parametric testing*, which analyzes waveforms at the transistor level. A circuit $C = (V,E)$ is considered as a collection V of components and E lines. Figure 66.2 depicts a combinational circuit at the logic level. The components represent gates. The integer value on each circuit line indicates its label. the circuit inputs are lines 1, 2, 3, 6, 7, 23, and 24.

The test patterns may be precomputed by a pattern generator program, often referred to as an *automatic test pattern generator* (ATPG). The goal in an ATPG program is to quickly compute a small set of test patterns that detect all faults. The design of ATPG tools is a difficult task. Once the patterns are generated, they are stored in the memory of an *automatic test equipment* (ATE) mechanism that applies the test patterns and analyzes the responses using the ORV tool. In order for the ATE tools to test PCBs or complex digital systems, they must be controlled by computer programs.

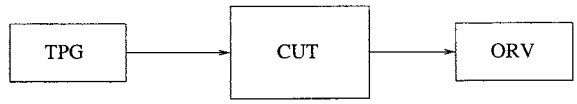

FIGURE 66.1 The testing process.

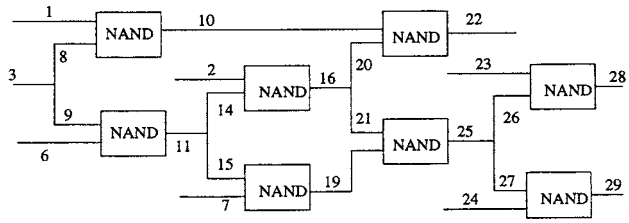

FIGURE 66.2 A circuit at the logic level.

ATE equipment is often very expensive. Thus, some circuits are designed so that they can test themselves. This concept is called *built-in self-testing* (BIST). In BIST, the TPG and ORV tools are on-chip and the concern is twofold: accuracy and hardware cost. Chapter 67 reviews popular ATPG tools and BIST mechanisms. Furthermore, the complexity of current *application-specific integrated circuits* (ASICs) has led to the development of sophisticated CAD tools that automate the design of BIST mechanisms. Such tools are presented in Chapter 68.

The testing process requires fault models that precisely define the behavior of the (logic-level) circuit. The standard model for logical-level testing is the *stuck-at fault model*. This model associates two types of faults for each line l of the circuit: the stuck-at 0 fault and the stuck-at 1 fault. The stuck-at 0 fault assumes that line l is permanently stuck at the logic value 0. Similarly, the stuck-at 1 assumes it is stuck at 1. The single stuck-at fault model assumes that only one such fault is present at a time. Under the single stuck-at fault model, a circuit with $|E|$ lines can have at most $2 \cdot |E|$ faults. Although the stuck-at fault model appears to be simplistic, it has been shown to be very effective, and a set of patterns that detect all single stuck-at faults covers most (physical) faults as well.

However, the stuck-at fault model is of limited use to faults associated with delays in the operation of the CUT. Such faults are called *delay faults*. Although it has been shown that testing for delay faults can be theoretically reduced to testing for stuck-at faults in an auxiliary circuit, the size of the latter circuit is prohibitively large. Instead, an alternative fault model, the path delay fault model, is applied successfully. The path delay fault model is postponed until Chapter 68.

In order for a test pattern to detect a stuck-at fault on line l, it must guarantee that the complementary logic value is applied on l. In addition, it must apply an appropriate logic value to each of the other lines in the circuit so that the erroneous behavior of the circuit at line l is propagated all the way to an output line. This way, the fault is observed and detected. The problem of generating a test pattern that detects a given stuck-at fault is an intractable problem, that is, it requires algorithms whose worst-case complexity it exponential to $O(|V| + |E|)$, the size of the input circuit. ATPG algorithms for the stuck-at fault model are described in Chapter 67. They are very efficient, and require seconds per stuck-at fault, even for very large circuits.

The stuck-at fault model is easy to use, involves only $2 \cdot |E|$ faults, and requires at most $2 \cdot |E|$ test patterns. Once a pattern is applied by the ATE equipment, a process called *fault simulation* is performed in order to determine how many faults are detected by the applied test pattern. A key measure of the effectiveness of a set of test patterns is its *fault coverage*. This is defined as the percentage of faults detected by the set of patterns.

Fault simulation is needed in order to determine the fault coverage of a set of test patterns. Fault simulation is important in testing with ATE as well as in the design of the on-chip test mechanisms. Fault

simulation is an inherently polynomial process for the stuck-at fault model. However, an overview of sophisticated fault simulation techniques is presented in Chapter 68.

Exhaustive TPG applies all possible test patterns at the circuit inputs, that is, $2^{|I|}$ test patterns for a circuit with $|I|$ inputs. Instead, *pseudo-exhaustive TPG* guarantees that all stuck-at faults are covered with less than $2^{|I|}$ patterns. BIST schemes are often designed so that pseudo-exhaustive TPG is guaranteed. (See also Chapter 67.)

However, sometimes we need to generate patterns only for a given set of stuck-at faults. This type of TPG is called a *deterministic TPG*, and the generated test patterns must detect the predefined set of test patterns. A good pseudo-exhaustive or deterministic TPG tool must guarantee that a compact test set is generated.

Consider a three-input NAND gate where lines *a*, *b*, and *c* are the three inputs and line *d* is the output. There exist three directly *controllable lines* and one *observable line*. Let us describe a test pattern as a binary vector of three values applied to lines *a*, *b*, and *c*, respectively. There are $2 \cdot 4$ stuck at faults. By applying 2^3 patterns, all the faults are covered. However, a compact test set contains at least four test patterns. Consider the following order of pattern application. Pattern (111) is applied first and covers four stuck-at faults. Pattern (110) covers two additional stuck-at faults. Finally, patterns (101) and (011) are needed to cover the last two faults. The number of applied patterns is also called the *test length*. The problem of minimizing the test length, which guarantees 100% fault coverage, is intractable.

Heuristic methods can be applied to reduce the test length. Two faults are called *indistinguishable* if they are detected by the same set of test patterns. Identification of indistinguishable faults is an important concept in test set compaction.

A stuck-at fault is called *undetectable* if it cannot be detected by any pattern. Any circuit that has at least one undetectable fault is called *redundant*. Any redundant circuit can be simplified by removing the line that contains the undetectable fault, and possibly other lines, without changing its functionality.

In the above, the CUT was assumed to be a combinational circuit. The TPG process is significantly more difficult in sequential logic. In order for a stuck-at fault to be detected, a sequence of test patterns rather than a single pattern must be applied. The process of generating sequences of pattern with ATPG or on-chip TPGs is a tedious job. These concepts are discussed in more details in Chapter 67.

66.2 Design for Testability

Design for testability (DFT) is applied to reduce difficulties associated with the TPG process on sequential circuits. DFT suggests that the digital circuit is designed with *built-in* features that assist the testing process. The goal in DFT is to maximize fault coverage, the test pattern generation process, the time required to apply the generated patterns, and the *built-in hardware overhead*. By definition, DFT is needed for BIST where TPG and ORV are on-chip. However, the majority of the proposed DFT methods are targeting the simplification of the ATPG process for sequential circuits, and assume that ATE is used.

There are some guidelines that have been developed by experienced engineers and lead the insertion of the built-in mechanisms so that the input sequential CUT becomes testable with ATPG tools.

1. Set the circuit at a known state before and during testing. This is achieved by a RESET control line that is connected to the asynchronous CLEAR of each flip-flop in the CUT.
2. Partition the CUT into subcircuits which are tested easier.
3. Simplify the circuit to avoid redundancies.
4. Control and observe lines on feedback paths, lines that are far from inputs and outputs, and lines with high fan-in and fan-out.

One way to implement the first guideline (1) is by inserting *test points* to control and observe at lines *x* that break all feedbacks. A test point on line $x = (x_{in}, x_{out})$ is a simple circuit that simulates the function $f(x, s, c) = s' \cdot (x + c)$. The output of this circuit feeds x_{out}. Input signals *s* and *c* are controlling. When $s = 0$ and $c = 0$, we have that $f = x$; that is, this combination can be used in operation mode. When $s = 0$ and $c = 1$, function *f* evaluates to 1. When $s = 1$ and $c = 0$, *f* evaluates to 0. The last two combinations

can be used in the testing mode, and they guarantee that the line is fully controllable. It can be made observable by simply allowing for a new primary output at signal *x*.

Another mechanism is to use *bypass latches*, also referred to as *bypass storage elements* (bses). These latches are bypassed during the *operation mode* and are fully controllable and observable points in the *testing mode*. This dual functionality is easily obtained with a simple multiplexing circuitry. (See also Fig. 66.3 below.)

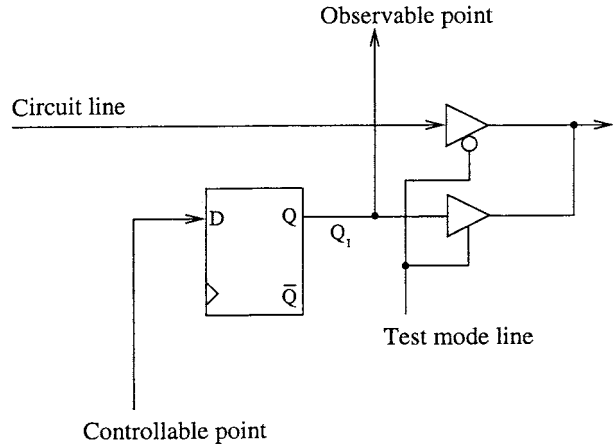

FIGURE 66.3 The structure of a bypass storage element.

In both cases, the total hardware must be minimized, subject to a lower bound on the enhancement of the circuit's testability. This optimization criterion requires sophisticated CAD tools, some of which are described in Chapter 68.

The most popular DFT approach is the *scan design*. The approach is a variation of the bypass latch approach discussed earlier. Instead of adding new latches, as the bypass latch approach suggests, the scan design approach enhances every flip-flop in the circuit with a multiplexing mechanism that allows for the following. In the operation mode, the flip-flop behaves as usual. In the *testing mode*, all the flip-flops are connected to a single shift chain. The input of this chain is a single controllable point and its output is a single observable point.

In the testing mode, each scanned flip-flop is a fully controllable and observable point. Observe that the testing phase amounts to testing combinational logic. Therefore, the ATPG (or the on-chip TPG) needs to generate single patterns instead of sequences of patterns. Each generated pattern is serially shifted in the scan chain. Typically, this process requires as many clock cycles as the number of flip-flops. Once every flip-flop obtains its controlling value, the circuit is turned to operation mode for a single cycle. Now the flip-flops are disconnected from the scan chain, and at the end of the clock cycle, the flip-flops are loaded with values that are to be observed and analyzed. Now the circuit is switched back into the testing mode (i.e., all flip-flops form again a scan chain). At this point, the states of the flip-flops are shifted out and are analyzed. This requires no more clock cycles than the number of flip-flops.

The described scan approach is also called *full scan* because all flip-flops in the circuit are scanned. The advantage of the full scan approach is that it requires only two additional I/O pins: the input and output of the scan chain, respectively. The disadvantage is that it is time-consuming due to the shift-in and shift-out processes for each applied pattern, especially for circuits with many flip-flops. For such circuits, it is also hardware intensive because every flip-flop must have dual operation mode capability. The hardware and the application time can be reduced by employing CAD tools. See also Chapter 68.

Another way to reduce application time and hardware cost is through *partial scan*. In partial scan, only a subset of flip-flops is scanned. The flip-flops and their ordering in the scan also require sophisticated CAD tools. The tradeoff in partial scan is that the ATPG tool may have to generate test sequences

rather than single patterns. A CAD tool is needed in order to select and scan a small number of flip-flops. This guarantees low hardware overhead and low application time. The flip-flop selection must also guarantee an upper bound on the length of any generated test sequence. This simplifies the task of the ATPG tool and has an impact on the test application time.

67.1 Automatic Test Pattern Generation

Automatic test pattern generation (ATPG) refers in general to the set of algorithmic techniques for obtaining a set of test patters that detect possible faulty behavior of a circuit after its fabrication. Faults during fabrication can affect the functional correctness of the circuit (*functional faults*) and its timing performance (*delay faults*). In this chapter, we deal only with functional faults. The physical faults in a circuit (such as breaks, opens, technology-specific faults) have to be modeled as *logical faults* (like "stuck-at" and "bridging" faults) in order to reduce the required complexity of ATPG. The most common fault model used in practice is the *stuck-at model*, where lines in a gate-level or register-transfer-level description of a circuit are assumed to be set permanently to a "1" or "0" value in the presence of a fault. An additional restriction is that the modeled faults cause only one line in the circuit to have a stuck-at value (*single stuck-at fault model*). Patterns generated under this model have been shown in practice to cover many of the unmodeled faults as well.

Given a list of stuck-at faults of interest, the primary goal of ATPG is to generate a test pattern for each of these faults, and additionally to keep the overall number of test patterns generated as small as possible. The latter is required for reducing the time/cost of applying the test patterns to the circuit. In this section, we describe basic test pattern generation (TPG) algorithms for finding a test pattern given a stuck-at fault, and other aspects of the ATPG process for facilitating the task of TPG algorithms and reducing the number of generated test patterns.

TPG Algorithms

Given a target fault of line l being stuck at value v, denoted by l s–a–v, a TPG algorithm attempts to generate a pattern such that (1) the pattern brings l to have a value $\bar{v}$ (*fault activation*) and (2) the same pattern carries over the effect of the fault to a primary output (*fault propagation*). A path from line l to a primary output along each line of which the effect of the fault is carried over is called a sensitized path.

The case of a line having a value of "1" in the correct circuit and a value of "0" in the circuit under the fault l s–a–v is denoted by the symbol D and, similarly, the opposite case is denoted by $\overline{D}$. Given the symbols D and $\overline{D}$, the basic Boolean operations AND, OR, NOT can be extended in a straightforward manner. For example, AND $(1, D) = D$, AND$(1, \overline{D}) = \overline{D}$, AND$(0, D) = 0$, AND$(0, \overline{D}) = 0$, AND$(x, D) = x$, AND$(x, \overline{D}) = x$ (where x denotes the don't-care case), etc.

TPG Algorithms for Combinational Circuits

A basic TPG algorithm for combinational circuits is the *D*-algorithm.[1] This algorithm works as follows. All values are initially assigned a value of *x*, except line *l* which is assigned a value of *D* if the fault is *l* s–a–0, and a value of $\overline{D}$ if the fault is *l* s–a–1. Let *G* be the gate whose output line is *l*. The algorithm goes through the following steps:

1. Select an assignment for the inputs of *G* out of all possible assignments that produce the appropriate *D*-value (i.e., a *D* or $\overline{D}$) at the output of *G*. This step is known as *fault activation*. All possible assignments are fixed for each gate type and are referred to as the *primitive d-cubes for the faul* (*pdcf*s) of the gate. For example, the *pdcf*s of a two-input AND gate are $0x\overline{D}$, $x0\overline{D}$, and $11D$, and the *pdcf*s of a two-input OR gate are $1xD$, $x1D$, and $00\overline{D}$ (using the notation *abc* for a gate with input values *a* and *b* and output value *c*).
2. Repeatedly select a gate from the set of gates whose output is currently *x* but has at least one input with a *D*-value. This set of gates is known as the *D*-frontier. Then select an assignment for the inputs of that gate out of all possible assignments that set the output to a *D*-value. All possible assignments are fixed for each gate type and are referred to as the *propagation d-cubes* (*pdc*s) of the gate. For example, the *pdc*s of a two-input AND gate are $1DD$, $D1D$, $1\overline{D}\overline{D}$, $\overline{D}1\overline{D}$, DDD, and $\overline{D}\overline{D}\overline{D}$. By repeated application of this step, a *D*-value is eventually propagated to a primary output. This step is known as *fault propagation*.
3. Find an assignment of values for the primary inputs that establishes the candidate values required in steps (1) and (2). This step is known as *line justification*. For each value that is not currently accounted for, the line justification process tries to establish ("justify") the value by (a) assigning binary values (and no *D*-values) on the inputs of the corresponding gate, working its way back to the primary inputs (this process is referred to as *backtracing*; and (b) determining all values that are imposed by all candidate assignments thus far (*implication*) and checking for any inconsistencies (*consistency check*).
4. If during step (3), an inconsistency is found, then the computation is restored to its state at the last decision point. This process is known as *backtracking*. A decision point can be (a) the decision in step (1) of which *pdcf* to select; (b) the decisions in step (2) of which gate to select from the *D*-frontier and which *pdc* to select for that gate; (c) the decision in step (3) of which binary combination to select for each value that has to be justified.
5. If line justification is eventually successful after zero or more backtrackings, then the existing values on the primary inputs (some of which may well be *x*) constitute a test pattern for the fault. Otherwise, no pattern can be found to test the given fault and that fault is thus shown to be redundant.

The order of steps (2) and (3) may be interchanged, or even the two steps may be interspersed, in an attempt to reduce the running time, but the discovery or not of a pattern is not affected by such changes.

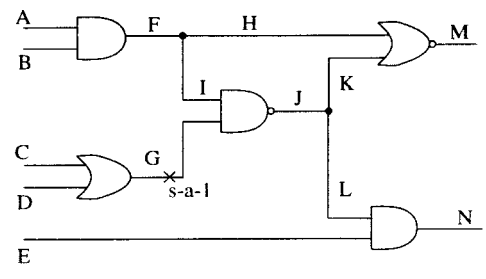

FIGURE 67.1 Example circuit.

As an example of the application of the *D*-algorithm, consider the circuit in Fig. 67.1 and the fault G s–a–1. In order to establish G ← $\overline{D}$, the *pdcf* CD ← 00 is chosen and the *D*-frontier becomes {J} (gates are named by their output line). Then, gate J is considered and the *pdc* setting I ← 1 is selected with result J ← *D* and new *D*-frontier {M, N}. Assume gate M is selected. Then, the *pdc* setting H ← 0 is selected with result M ← $\overline{D}$. However, the justification of current values H ← 0 and I ← 1 results in conflict, so the algorithm backtracks and tries the next *pdc* for gate M which sets H ← *D*. But again, this cannot be justified. Then the algorithm backtracks once

more and selects gate N from the *D*-frontier. Then the assignment E ← 1 is made, which results in N ← *D*. Since the values E ← 1 and I ← 1 can now be justified without conflict, the algorithm terminates successfully, returning test pattern ABCDE = 11001.

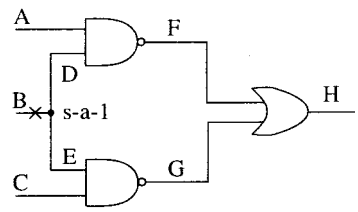

FIGURE 67.2 Multipath sensitization.

As another example, consider the circuit in Fig. 67.2 and the fault B s–a–1. In order to establish B ← $\overline{D}$, the assignment B ← 0 is made and the *D*-frontier becomes {F, G}. Assume that gate F is selected. In order to propagate the fault to line H, the *pdc* setting A ← 1 is selected and the *pdc* of gate H setting G ← 0 is tried. But this results in conflict, as B (and E) are required to be 0. Then the algorithm backtracks and tries the next available *pdc* of H which sets G ← *D*. This value can now be justified by setting C ← 1, with resulting test pattern ABC = 101. A similar thing happens if gate G is selected from the original *D*-frontier. That is, in this example, the algorithm had to sensitize two paths simultaneously from the fault site to a PO in order to detect the fault. This is referred to as *multipath sensitization*, but its need rarely arises in practice. To reduce computational time, examination of *pdc*s involving more than one input being set to *D* (or $\overline{D}$) is often omitted.

Another basic TPG algorithm is the PODEM.[2] The PODEM algorithm uses also the five-valued logic (0, 1, *x*, *D*, $\overline{D}$), and works as follows. Initially, all lines are assigned a value of *x* except line *l*, which is assigned a value of $\overline{D}$ if the fault is *l* s–a–0, and a value of *D* if the fault is *l* s–a–1. The algorithm at each step tries to satisfy an *objective* (*v*, *l*), defined as a desired value *v* at a line *l* by making assignments only to primary inputs (PIs), one PI at a time. The mapping of an objective to a single PI value is done heuristically, as explained below. The initial objective is ($\bar{v}$, *l*), assuming that the examined fault is *l* s–a–*v*. Then the algorithm computes all implications of the current pattern of values assigned to PIs. If the effect of the fault is propagated to a primary output (PO), the algorithm terminates with success. If a conflict occurs and the fault cannot be activated or cannot be propagated to a PO, then the algorithm backtracks to the previous decision point, which is the last assignment to a PI. If no conflict occurs but the fault has not been activated or not been propagated to a PO because the currently implied values on the lines involved are *x*, then the algorithm continues with the same objective (*v*, *l*) if the fault is still not activated, or with an objective ($\bar{c}$, *l*′) if the fault has been activated but not propagated, where *l*′ is an input line of a gate from the *D*-frontier that has currently assigned a value of *x* on it, and *c* is the controlling value of that gate.

The determination of which single PI to selected and which value to assign to it given an objective (*v*, *l*) is done heuristically (in the worst case, at random). A simple heuristic is to select a path from line *l* to a PI such that every line of the path except *l* has an *x* value on it, and assign to that PI the value *v* ($\bar{v}$) if the total number of inverting gates (i.e., NOT, NAND, NOR) along that path is even (odd). In addition, concerning the selection of a gate from the *D*-frontier, a simple heuristic is to select the gate that is closest to a PO. As an example of the application of PODEM, consider the circuit of Fig. 67.1 and the fault G s–a–1. The initial objective is (0, G). The chosen PI assignment is C ← 1, and this has no implications. The objective remains the same, with chosen PI assignment D ← 0 and implications G ← $\overline{D}$. The *D*-frontier becomes {J} and the next objective is (1, I). This results in PI assignments A ← 1 and B ← 1 with implications F ←1, H ← 1, I ← 1, M ← 0, J ← *D*, K ← *D*, L ← *D*, and new *D*-frontier {N}. The next objective is (1, E), which is immediately satisfied and has implication N ← *D*. So, the algorithm returns successfully with test pattern ABCDE = 11001.

In the example of Fig. 67.2, PODEM works as follows. The original objective is (0, B). With PI assignment B ← 0, the *D*-frontier becomes {F, G}. Assuming gate F is selected, the next objective is (1, A), which is immediately satisfied with resulting implication F ← *D* and new *D*-frontier {G, H}. Given that gate H is selected as closer to the output, the next objective is (0, G) which leads to the PI assignment C ← 1 with implications G ← *D* and H ← *D*. That is, the resulting test pattern is ABC = 101. Notice that although the implied value for G was *D* while the objective generated was (1, G), this is not considered a conflict, since the goal of any objective is only to lead to a PI assignment that activates and propagates the fault to a PO.

As an example involving backtracking in PODEM, consider the circuit of Fig. 67.3 and the fault J s–a–1. Starting with objective (0, J), the PI assignment A ← 0 is made (using path HFEA) with no implication, and then the PI assignment B ← 0 is made (using path HFEB) with implications E ← 0, F ← 0, G ← 0, H ← 0, I ← 1, J ← 1. But the latter constitutes a conflict, and so the algorithm backtracks trying PI assignment A ← 1. The implications of this assignment are E ← 1, F ← 1, G ← 1. Since the fault at J is still not activated, the objective (1, B) is generated next (using path HFEB), which is satisfied immediately but has no new implications, then the objective (0, C) is generated (using path HC), which is satisfied immediately and has implication H ← 0. Finally, the objective (1, D) is generated (using path ID), which is satisfied immediately and has implications I ← 0 and J ← 0. Since the fault is now activated and (trivially) propagated, the algorithm terminates successfully with test pattern ABCD = 1101.

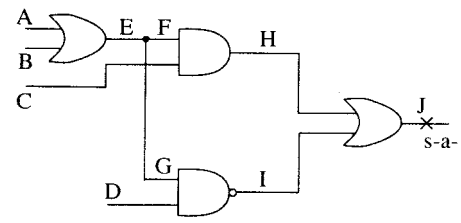

FIGURE 67.3 Backtracking in PODEM.

Both of these basic algorithms are complete in that given enough time, they will find a pattern for a fault if and only if the fault is not redundant. The *D*-algorithm performs an implicit state-space search by assigning values to the lines of the circuit, whereas PODEM performs an implicit state-space search by assigning values to the PIs only. For circuits with no fan-out or without reconvergent fan-out, the algorithms take linear time to the size of the circuit; but for general circuits (with reconvergent fan-out), the algorithms may take exponential time. In fact, the test pattern generation problem has been shown to be NP-complete.[3] The implicit state search in conjunction with a variety of heuristic measures can cut down the running time requirements. For instance, performing as many implications at each point as possible and checking for the existence of at least one path from a gate in the *D*-frontier to a PO such that every line on that path has an *x* value (otherwise, fault propagation is impossible) are very useful measures.

In general, PODEM is faster than the *D*-algorithm. Several extensions to PODEM have been proposed, such as working with more than one objective each time, and stopping backtracking before reaching PIs. For instance, the FAN algorithm[4] maintains a list of multiple objectives and stops backtracking at headlines rather than just PI lines. A *headline* is a line that is driven by a subcircuit containing no line that is reachable from some fan-out stem, and, therefore, can be justified at the end with no conflicts. As a short illustration, consider the example in Fig. 67.3. In order to activate the fault (i.e., J ← 0), both lines H and I must be driven to 0. The objectives (H, 0) and (I, 0) are now both taken into consideration. In order to achieve objective (H, 0), the assignment E ← 0 can be selected, as line E is a headline. But in order to achieve objective (I, 0), the assignment E ← 1 is required. Therefore, the algorithm selects the alternative assignment C ← 0 (as C is a PI) for objective (0, H), and then selects the assignment E ← 1 (as E is a headline) and D ← 1 (as D is a PI) for objective (0, I), which results in success. The justification of the value on E is left for a final pass with resulting test pattern ABCD = 1*x*00 or ABCD = *x*100.

There are a plethora of TPG algorithms based on various strategies (see, e.g., Ref. 5 for more information). There are also parallel TPG algorithms designed for particular devices such as ROMs and PLAs.

TPG Algorithms for Sequential Circuits

Detecting faults in sequential circuits is much more difficult than for combinational circuits. This is due to the fact that because of the memory elements present in the logic, a sequence of patterns is generally required for each fault, along with an appropriate initial state. In general, TPG techniques for combinational circuits can be applied to sequential circuits by considering the iterative logic array model of the sequential circuits. This model applies to both synchronous and asynchronous sequential circuits, although it is more complex for the latter.

Given a current state vector Q and a current input vector X, the function of a sequential circuit is specified as a mapping from (X, Q) to (Q^+, Z), where Q^+ is the next state vector and Z is the resulting

output. In the *iterative logic array* representation, the sequential circuit is modeled as a series of combinational circuits C_0, C_1, …, C_N, where N is the length of the current input pattern sequence applied to the sequential circuit. Each circuit C_i, referred to as a *time frame*, is an identical copy of the sequential circuit but with all feedback removed, and has inputs X_i and Q_i, and outputs Q_i^+ and Z_i. Inputs X_i are driven by the ith pattern applied to the sequential circuit and inputs Q_i are driven by the outputs Q_{i-1}^+ of the previous time frame for $i > 0$, with Q_0 being set to the original initial state of the sequential circuit. All outputs Z_i are ignored except for the outputs Z_N of the last time frame, which constitute the output of the sequential circuit resulting from the specific input sequence and initial state.

Given a stuck-at fault, the fundamental idea in sequential TPG is to create an iterative logic array of appropriate length N and justify all the values necessary for the fault to be activated and propagated to the outputs Z_N of the last time frame. If this can be achieved with the values of the Q_0 inputs of the first time frame being set to 'x's, then a *self-initializing* test sequence is produced. Otherwise, the specific values required for the Q_0 inputs (preferably, all "0"s) are assumed to be easily established through a reset capability. In principle, one can start from one time frame C_t (with the index t to be appropriately adjusted later) and try to propagate the effect of the fault to either some of the Z_t lines or some of the Q_t^+ lines. In case of propagation to the Z_t lines, C_t becomes tentatively the last frame in the iterative logic array and line justification by assignments to the X_t and Q_t lines is repeatedly done in additional time frames C_{t-1}, C_{t-2}, …, C_{t-N_b} (up to some number N_b), until all lines are justified with either Q_{t-N_b} being set to all 'x's or to a resetable initial state. In case of propagation to the Q_t lines, additional time frames C_{t+1}, C_{t+2}, …, C_{t+N_f} are considered (up to some number N_f), until the effect of the fault is propagated to the Z_{Nf} lines. Notice that because each time frame contains the same fault, the propagation can be done from any of the C_{t-1}, C_{t-2}, …, C_{t-N_b} time frames to the Z_{N_f} lines. Then, line justification is again attempted as above. In case of conflict during the justification process, backtracking is attempted to the last decision point, and this backtracking can reach as far as the C_{t-N_f} frame.

In order to reduce the storage required for the computation status as well as the time requirements of this process, algorithms that consider only backward justification and no forward fault propagation have been proposed. For example, the *Extended Backtrace* (EBT) algorithm[6] selects a path from the fault site to a primary output which may involve several time frames C_{t-1}, C_{t-i+1}, …, C_t, and then tries to justify all values for the sensitization of this path (along with the requirements for the initial state) by working with time frames C_t, C_{t-1}, …, C_{t-i}, …, C_{t-N_b}.

As an illustration of the application of the EBT algorithm, consider the sequential circuit in Fig. 67.4(a). The structure of each time frame in the iterative logic array representation of it is given in Fig. 67.4(b).

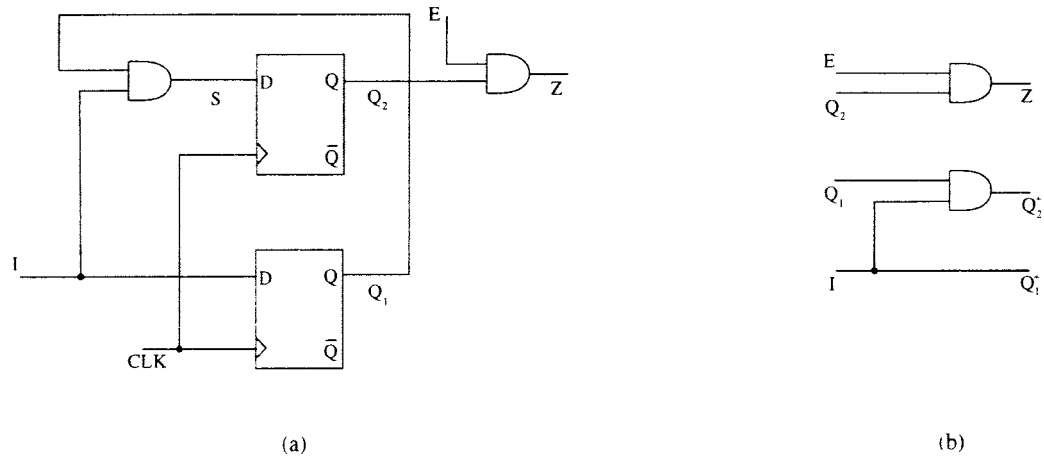

FIGURE 67.4 A sequential circuit and a time frame in the iterative logic array representation.

Consider the fault S s–a–0. The EBT algorithm selects the path SQ_2Z to propagate the fault. This path involves two time frames, as the value of line S is the value of line Q_2 before one clock cycle (by definition of the D-type flip-flop). Considering the index of the last frame to be t and following the structure of each time frame (Fig. 67.4(b)), the path actually comprises the lines $Z_{[t]}$, $Q_{2[t]}$, $Q^+_{2[t-1]}$. In order to sensitize this path, line $E_{[t]}$ must be set to 1. Now, in order to activate the fault at line S, which is identified with $Q^+_{2[t-1]}$, lines $I_{[t-1]}$ and $Q_{1[t-1]}$ must be set to 1. Assuming a self-initializing sequence is sought, further justification needs to be made for the value $Q_{1[t-1]}$, which is equal tot he value of line $Q^+_{1[t-2]}$ in an additional time frame indexed by $t-2$. Since $Q^+_{1[t-2]}$ is set directly by $I_{[t-2]}$, the search is over and the self-initializing sequence (first pattern first) is IE = ($1x$, $1x$, $x1$).

Other ATPG Aspects

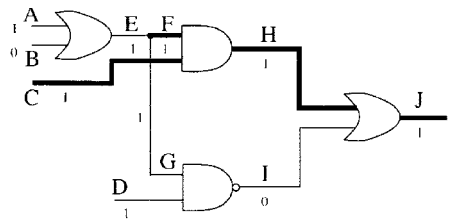
There are several components in the ATPG process that are centered around the TPG algorithm and can be viewed as preprocessing or postprocessing steps to it.

Given a list of target faults on which the TPG algorithm is to work on, some very useful preprocessing steps include the following:

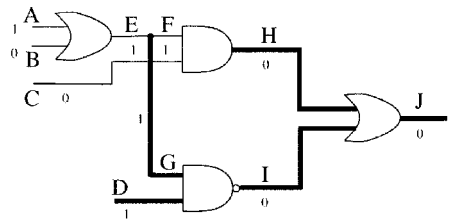
1. *Fault collapsing:* For a circuit with n lines in total, there are $2n$ possible stuck-at faults to consider. Fault collapsing reduces this initial number by taking advantage of equivalence and dominance relations among faults. Two faults are said to be *functionally equivalent* if all patterns that detect the one detect also the other. Given a set of functionally equivalent faults, only one fault from that set has to be considered for test generation. A fault f_1 is said to *dominate* a fault f_2 if all patterns that detect f_2 detect also f_1 and there is at least one pattern that detects f_1 but not f_2. Then only f_2 needs to be considered for test generation. It can be shown that the fault s–a–$(c \oplus i)$ on the output of a gate is functionally equivalent with the fault s–a–c on any of the gate inputs and that the fault s–a–$(\bar{c} \oplus i)$ on the output of a gate dominates the fault s–a–$\bar{c}$ on any of the gate inputs, where c is the controlling value of the gate and i is 1 (0) if the gate is inverting (non-inverting). As an example, using these relations on the circuit of Fig. 67.1, we obtain that (F–s–0, A–s–0, B–s–0), (G–s–1, C–s–1, D–s–1), (J–s–1, G–s–0, I–s–0), (M–s–0, H–s–1, K–s–1), (N–s–0, E–s–0, L–s–0) are functionally equivalent sets of faults, and that F–s–1 dominates A–s–1 and B–s–1, G–s–0 dominates C–s–0 and D–s–0, J–s–0 dominates G–s–1 and I–s–1, M–s–1 dominates H–s–0 and K–s–0, and N–s–1 dominates E–s–1 and L–s–1. Given tese relations, only the set of faults {A–s–1, B–s–1, C–s–0, D–s–0, G–s–1, I–s–1 H–s–0, K–s–0, E–s–1, L–s–1, F–s–0, M–s–0, N–s–0} need be considered; the number of target stuck-at faults is reduced from 28 to 13.
2. *Removal of randomly testable faults:* A very simple way of eliminating faults from a target fault list is to generate test patterns at random and verify, by *fault simulation*, which target faults (if any) each generated pattern detects. The generation of such patterns is done by a *pseudorandom* method, that is, an algorithmic method whose behavior under specific statistical criteria seems close to random. Eliminating all faults by pseudorandom test pattern generation generally requires a very large number of patterns. For instance, under the assumption of uniform input distribution and independent test pattern generation, the smallest number of patterns to detect with probability P_s a fault whose detection probability is d is $N = \left\lceil \frac{\ln(P_s)}{\ln(1-d)} \right\rceil$. In general, faults with small detection probability are referred to as *randomly untestable* or *hard-to-detect* faults, whereas faults with high detection probability are referred to as *randomly testable* or *easy-to-detect* faults. For example, in a circuit consisting of a single k-input AND gate with output line l, the fault l s–a–0 is a hard-to-detect fault as only one out of 2^k patterns can detect it, whereas the fault l s–a–1 is an easy-to-detect fault as $2^k - 1$ out of 2^k patterns can detect it; whereas the fault l s–a–1 is an easy-to-detect fault as $2^h - 1$ out of 2^k patterns can detect it. In practice, an acceptable number of pseudorandom test patterns are generated and simulated in order to drop many easy-to-detect faults from the target fault list, with all remaining faults given over to a *deterministic* (as opposed to pseudorandom) TPG tool, in case a complete test is desired.

3. *Removal of faults identified by critical path tracing:* A *critical path* under an input pattern t is a path from a primary input or internal line to a primary output such that if there is a change in the value under t of any line in the path, the PO also changes (in other words, input pattern t can serve as a test pattern for each fault l s–a–$\bar{v}$, where l is any line of the path and v is the value of that line under t). *Critical path tracing* is a technique for systematically identifying critical paths in a circuit. Starting from an assigned value to a PO (a PO line always constitutes a critical subpath), it works its way back to the PIs trying to extend current critical subpaths. The extension however cannot be done safely through stems of reconvergent fan-out. Given a gate whose output is the beginning of a current critical subpath, the method assigns only one input of the gate to a value c or all inputs of the gate to value $\bar{c}$ in order to justify the output value, where c is the critical value of the gate. In both cases, longer critical subpaths are created that can be developed further recursively. Once the PIs are reached and all non-critical values are justified, all corresponding faults on lines in critical paths are covered by the resulting input pattern, and so these faults can be dropped from the initial fault list. Some critical paths for the circuit of Fig. 67.3 are shown in Fig. 67.5. Notice that stem E in Fig. 67.5(a) is not critical (as found by separate fault simulation), whereas stem E in Fig. 67.5(b) turns out to be actually critical. Critical path tracing can also be viewed as a *fault-independent* (in contrast to *fault-driven*) deterministic TPG algorithm that is generally faster but may not cover all possible detectable faults or prove that a fault is undetectable.

A basic postprocessing step after test patterns have been generated by an ATPG technique is *compaction*. Compaction attempts to reduce the number of patterns by taking advantage of any x values in the patterns generated. The basic step is to merge two patterns which do not have conflicting values in any bit position. For example, in Fig. 67.6(a), we can compact patterns t_1, t_2 and t_3, t_4 to obtain the test set in Fig. 67.6(b), which cannot be compacted further. However, we can also compact patterns t_2, t_3, t_4 and t_1, t_5 to obtain the test set in Fig. 67.6(c), which is smaller than that of Fig. 67.6(b). In general, finding a compacted test set of minimum size is an NP-hard problem, but efficient heuristics exist to solve the problem satisfactorily. Compaction can also be done simultaneously with test pattern generation in order to better exploit



(a)



(b)

FIGURE 67.5 Some critical paths (shown in bold) found by critical path tracing.

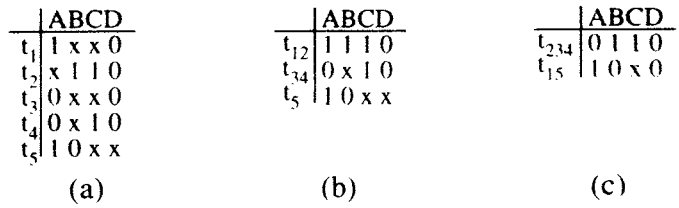


FIGURE 67.6 Compaction of test patterns.

the *x* values as soon as they are generated. This is referred to as *dynamic compaction* (in contrast to *static compaction*), and its basic idea is to assign appropriately any *x* values in the last generated pattern in order to obtain test patterns for additional faults.

67.2 Built-In Self-Test

In order to make the testing of a VLSI circuit easier, several design-for-testability criteria can be taken into account along with the other "traditional" design criteria of cost, delay, area, power, etc. For example, transforming a sequential circuit into combinational parts by linking in a "test mode" all its flip-flops into a shift register so that patterns to initialize the flip-flops can be easily loaded and responses can be observed is a common design-for-testability technique known as *full-scan. Built-in Self-Test* (BIST) is an ultimate design-for-testability technique in which extra circuitry is introduced on-chip in order to provide test patterns to the original circuit and verify its output responses. The aim is to provide a faster and more economic alternative to external testing. The difficulty in the BIST approach is the discovery of schemes which have very low hardware overhead and provide the required test quality in order to justify their inclusion on-chip.

Online BIST

A special form of BIST is the design of *self-checking* circuits in which no explicit test patterns are provided, but the operation of the circuit is tested *online* by identifying any *invalid* output responses (i.e., responses that can never occur under fault-free operation). If, however, there is a fault that can cause a valid response to be changed into another valid response, then that fault cannot be detected. The identification of faulty behavior is done by a special built-in circuit called *checker*. For example, in a k: 2^k decoder, a checker can check if exactly one of the 2^k output lines has a value 1 each time. If the number of 1s in the output pattern is zero or more than one, then an error is detected. If, however, a fault in the decoder causes an input pattern to assert only one output line but not the correct one, then the fault cannot be detected by such a checker. In general, the design of self-checking circuits is based on coding theory. The checker has to encode all output responses of the circuit under fault-free operation in order to distinguish between valid and invalid responses. For example, using the single-bit parity code, a checker can compute the parity of the actual response of the circuit for the current input, compute also the parity of the (known) correct output response corresponding to that input, and compare the two parities.

Faults in the checker can beat the purpose of fault detection in the original circuit. However, the assumption is that the logic of the checker is much simpler than the circuit it checks and therefore can be tested far more easily. Research on the design of *self-checking checkers* seeks to minimize the logic that is not self-testable.

Offline BIST

In a general offline BIST scheme, test pattern generation and application, as well as output response verification, are done by built-in mechanisms while the circuit operates in a test mode.

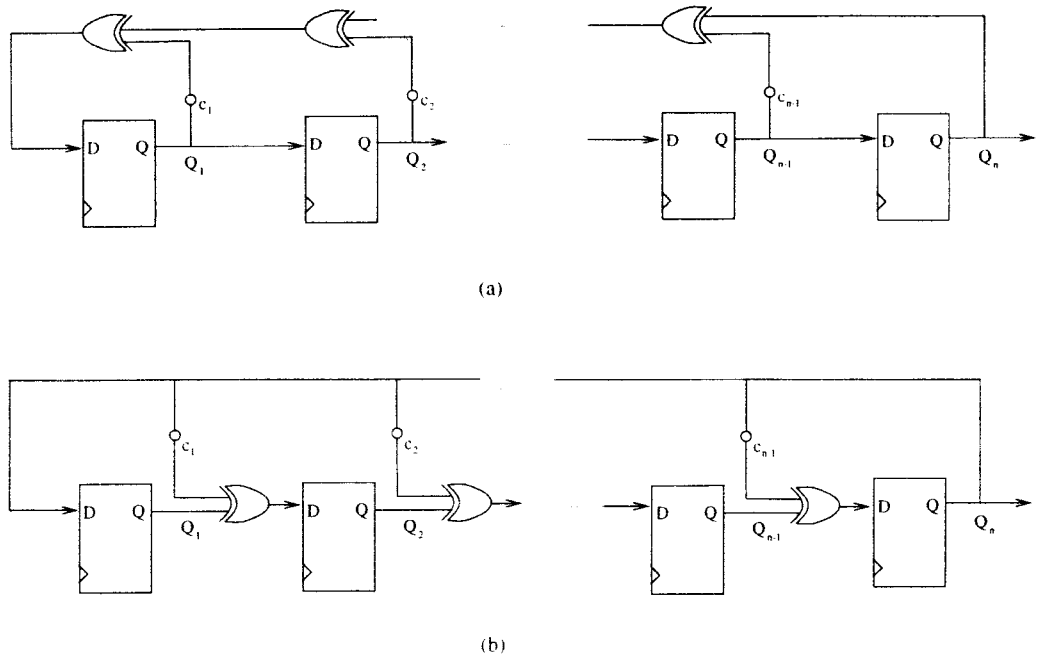

FIGURE 67.7 LFSR configurations.

Built-in TPG Mechanisms

Mechanisms that have been considered for built-in test pattern generation and application include read-only memories, counters, cellular automata, and linear feedback shift registers (LFSRs). Of these mechanisms, LFSRs offer the most flexibility and have received the most attention. A *linear feedback shift register* (LFSR) consists of a series of flip-flops connected in a circular structure by means of exclusive-OR (XOR) gates. The two basic types of an LFSR are shown in Fig. 67.7(a) and Fig. 67.7(b).

The structure in Fig. 67.7(a) uses the XOR gates externally, while the structure in Fig. 67.7(b) uses the XOR gates internally. The connections of the flip-flops to the XOR gates are fixed for a basic n-bit LFSR and are specified by the values c_i, $1 \le i \le n$, where $c_i = 1$ denotes a connection, and $c_i = 0$ denotes no connection. The specific pattern of c_i values is conveniently represented as a polynomial $P(x) = 1 + \Sigma_{i=1}^{n} c_i x^i$ over the field of elements mod 2 and is referred to as the *characteristic polynomial* of the LFSR. (The representation can also be done by the polynomial $P_r(x) = x^n + \Sigma_{i=1}^{n-1} c_{n-i} x^i$, which is referred to as the *reciprocal* polynomial of $P(x)$.) Given an initial state, an LFSR cycles through a sequence of states as determined by its characteristic polynomial. For particular characteristic polynomials known as *primitive polynomials*, the corresponding sequence of states has the maximum possible length (that is, $2^n - 1$, since the all-0 state will cause the LFSR to cycle through it continuously). A primitive polynomial of degree n has the property that the smallest value k such that $x^k \bmod P(x) = 1$ is $k = 2^n - 1$. Primitive polynomials exist for every degree and a list of them can be found in Ref. 7.

An example of a specific LFSR with characteristic polynomial $P(x) = x^4 + x + 1$, along with the sequence of the resulting states, is given in Fig. 67.8(a) for the external-XOR type and in Fig. 67.8(b) for the internal-XOR type. Although the properties of interest to most BIST applications are the same for the two LFSR types, an external-XOR type LFSR may be slower due to the multiple-level XOR logic. (Notice also that the stae of the external-XOR type LFSR at cycle i (starting from $i = 0$) is exactly the pattern $x^i \bmod P(x)$.)

There are three basic schemes for the design of a built-in test pattern generator: (1) deterministic, (2) pseudorandom, and (3) pseudo-exhaustive.

FIGURE 67.8 LFSRs with (a) characteristic polynomial $P(x) = x^4 + x + 1$ and (b) resulting sequences.

In *deterministic* TPG, a set of patterns for a list of target faults obtained by a TPG algorithm (after any postprocessing, like compaction) are "embedded" in a TPG mechanism. The obvious solution is to use a read-only memory (ROM) for this purpose, but this is applicable only for very small test sets. An alternative simple solution is to use a binary counter or an LFSR of length w (where w is the test pattern length) that starts from an initial state s_i and cycles through until it reaches another state s_j so that all the desired patterns appear somewhere between states s_i and s_j, with each intermediate state constituting a required or not required pattern. The problem here is to find (if at all) a pair of states s_i, s_j in the sequence produced by the underlying mechanism such that the absolute distance between s_i and s_j is acceptably smaller than 2^w, in order to keep the number of testing cycles acceptably low.

In *pseudorandom* built-in TPG, an LFSR is typically used as a pseudorandom generator, which cycles through a subsequence of l states, each state constituting a pseudorandom pattern, where l is again acceptably low. Such a sequence is analyzed by *fault simulation* in order to determine its *fault coverage* (defined as the ratio of the number of faults that the patterns in the sequence detected over the number of all detectable faults of interest). In general, very long subsequences are needed to achieve an acceptable level of fault coverage. An enhancement of this idea is to use *weighted random* LFSRs. These include extra logic in order to change the bit probabilities in the states that the LFSR generates. For example, by having bit i of each test pattern be the output of an AND gate driven by two LFSR bits, the probability of having a '1' in bit i is the product of the probabilities of having a '1' in those LFSR bits.

In *pseudo-exhaustive* built-in TPG, the goal is to reduce the testing of the circuit to the testing of appropriate subcircuits of it such that each subcircuit depends on a small number of primary inputs, then apply all possible patterns to each of these subcircuits. The benefits of an exhaustive test set is that no test pattern generation or fault simulation is needed and that the generated patterns guarantee that all detectable faults that do not induce sequential behavior are detected. In order for pseudo-exhaustive TPG to achieve the benefits of exhaustive testing without taking prohibitive time, particular relations must hold between the primary outputs (POs) and the primary inputs (PIs) on which they depend. If

such relations do not hold, they may be imposed upon the circuit through design-for-testability techniques.

In general, there are many pseudo-exhaustive test sets that can be obtained for a given circuit. The goal in pseudo-exhaustive built-in TPG is to find and embed a pseudo-exhaustive test set that offers the best tradeoff in hardware implementation cost and testing time.

As a simple example of how a pseudo-exhaustive test set can be obtained, consider a circuit with n inputs and one output fed by a two-input gate whose inputs are driven in turn by two disjoint subcircuits. Then, that output can be tested pseudo-exhaustively by $2^{n_1} + 2^{n_2} + 1$ patterns instead of 2^n, where n_1 and n_2 are the numbers of the (disjoint) primary inputs that drive the two subcircuits. The first 2^{n_1} of these patterns contain a constant subpattern (consisting of n_2 bits) required to sensitize the paths from the first subcircuit to the output; the next 2^{n_2} of these patterns contain a constant subpattern (consisting of n_1 bits) required to sensitize the paths from the second subcircuit to the output; and the last pattern is required to provide both inputs of the gate with the controlling value of the gate. This pseudo-exhaustive test set could be generated on-chip by using, for instance, a counter and some extra storage for the constant subpatterns, but such pseudo-exhaustive test sets can be impractical to implement in large circuits.

Obtaining suitable pseudo-exhaustive test sets for built-in implementation is based on the consideration of the subsets of PIs on which each PO depends. Let us call such a set a D-set. All D-sets must be smaller than the number n of PIs; otherwise, pseudo-exhaustive testing is not applicable. A general preprocessing step for pseudo-exhaustive TPG is to identify groups of PIs that never appear together in a D-set. All PIs in such a group can share the same test signal for the pseudo-exhaustive testing. In this way, the number of test signals is reduced from n to n', with an immediate reduction of the test time from 2^n to $2^{n'}$. Minimizing the value of n' is an NP-hard problem, but efficient heuristics exist to reduce it in practice.

Pseudo-exhaustive test sets can be obtained by considering only the size $k < n$ of the maximum D-set in a circuit and ignoring the structure of the D-sets as well as their number (i.e., such pseudo-exhaustive test sets are good for any n-input circuit with no output being dependent on more than k inputs). For example, it has been shown[8] that a test set that comprises all binary patterns containing w_1 '1's, all binary patterns containing w_2 '1's, etc., up to w_i '1's, where w_1, w_2, …, w_i are all the solutions of the equation $w = c \bmod (n - k + 1)$, for some constant $c \le n - k$, constitute a pseudo-exhaustive test set. For instance, if $n = 6$ and $k = 3$, the set of all patterns with 0 or 4 '1's (corresponding to $c = 0$), the set of all patterns with 1 or 5 '1's (corresponding to $c = 2$), the set of all patterns with 2 or 6 '1's (corresponding to $c = 2$), the set of all patterns with 3 '1's (corresponding to $c = 3$) constitute pseudo-exhaustive test sets that can be applied to any circuit with n inputs and maximum D-set size k. The structure of one of these sets (corresponding to $c = 2$) is given in Fig. 67.9. The generation of such a set of patterns can be done by using *constant-weight counters*, which produce a sequence of states with the same constant number of '1's in each. The disadvantages of this approach are the size of the test set which, although not 2^n, is still large $\left(\approx \frac{2^n}{n-k+1}\right)$, and the hardware overhead required for the implementation of a constant-weight counter.

Better solutions may be obtained by considering the particular structure of each D-set. A very important mechanism in this regard is the Extended LFSR. An Extended LFSR (also known as LFSR/SR) is a shift register (SR) of n cells whose initial k cells are configured into an LFSR with a characteristic polynomial of degree k. Let $P(x)$ be that characteristic polynomial. It has been shown (see, e.g., Ref. 9) that the successive states of such an LFSR/SR test exhaustively a D-set $D = \{d\_1, d\_2, \ldots, d\_s\}$, $s = |D|$ (the d_i elements denote the indices of the cells that drive the circuit inputs), if an only if the set of vectors $x^{d1} mod P(x)$, $x^{d2} mod P(x)$, …, $x^{ds} mod P(x)$ are linearly independent. If this relation holds for every D-set, then the corresponding test sequence tests the circuit pseudo-exhaustively in time 2^k (after the initialization of the LFSR and SR parts of the LFSR/SR). As an example, consider the D-sets $D_1 = \{1, 2, 3, 4\}$, $D_2 = \{2, 3, 5\}$, $D_3 = \{3, 5, 6\}$. All these D-sets satisfy the above relation under primitive polynomial $P(x) = x^4 + x + 1$ (see Fig. 67.10(a)). However, if a D-set $D_4 = \{1, 2, 5\}$ were also present, that D-set could no more be tested pseudo-exhaustively, as its corresponding vectors are linearly dependent (see Fig. 67.10(b)).

Obtaining an LFSR/SR under which the independency relation holds for every D-set of the circuit involves basically a search for an applicable polynomial of degree d, $k \le d \le n$, among all primitive polynomials of degree d, $k \le d \le n$. Primitive polynomials of any degree can be algorithmically generated. An applicable polynomial of degree n is, of course, bound to exist (this corresponds to exhaustive testing), but in order to keep the number of test cycles low, the degree should be minimized.

Built-in Output Response Verification Mechanisms

Verification of the output responses of a circuit under a set of test patterns consists, in principle, of comparing each resulting output value against the correct one, which has been precomputed and prestored for each test pattern. However, for built-in output response verification, such an approach cannot be used (at least for large test sets) because of the associated storage overhead. Rather, practical built-in output response verification mechanisms rely on some form of *compression* of the output responses so that only the final compressed form needs to be compared against the (precomputed and prestored) compressed form of the correct output response. Some representative built-in output response verification mechanisms based on compression are given below.

1. Ones count: In this scheme, the number of times that each output of the circuit is set to '1' by the applied test patterns is counted by a binary counter, and the final count is compared against the corresponding count in the fault-free circuit.
2. Transition count: In this scheme, the number of transitions (i.e., changes from both $0 \rightarrow 1$ and $1 \rightarrow 0$) that each output of the circuit goes through when the test set is applied is counted by a binary counter and the final count is compared against the corresponding count in the fault-free circuit. (These counts must be computed under the same ordering of the test patterns.)
3. Signature analysis: In this scheme, the specific bit sequence of responses of each output is represented as a polynomial $R(x) = r_0 + r_1x + r_2x^2 + \ldots + r_{s-1}x^{s-1}$, where r_i is the value that the output takes under pattern t_i, $0 \le i \le s$, and s is the total number of patterns. Then, this polynomial is divided by a selected polynomial $G(x) = g_0 + g_1x + g_2x^2 + \ldots + g_mx^m$ of degree m for some desired

value m, and the remainder of this division (referred to as *signature*) is compared against the remainder of the division by $G(x)$ of the corresponding fault-free response $C(x) = c_0 + c_1x + c_2x^2 + \ldots + c_{s-1}x^{s-1}$. Such a division is done efficiently in hardware by an LFSR structure such as that in Fig. 67.11(a). In practice, the responses of all outputs are handled together by an extension of the division circuit, known as *multiple-input signature register* (MISR). The general form of a MISR is shown in Fig. 67.11(b).

In all compression techniques, it is possible for the compressed forms of a faulty response and the correct one to be the same. This is known as *aliasing* or *fault masking*. For example, the effect of aliasing in ones count output response verification is that faults that cause the overall number of '1's in each output to be the same as in the fault-free circuit are not going to be detected after compression, although the appropriate test patterns for their detection have been applied. In general, signature analysis offers a very small probability of aliasing. This is due to the fact that an erroneous response $R(x) = C(x) = E(x)$, where $E(x)$ represents the error pattern (and addition is done mod 2), will produce the same signature as the correct response $C(x)$ and only if $E(x)$ is be a multiple of the selected polynomial $G(x)$.

BIST Architectures

BIST strategies for systems composed of combinational logic blocks and registers generally rely on partial modifications of the register structure of the system in order to economize on the cost of the required mechanisms for TPG and output response verification. For example, in the BILBO (Built-In Logic Block Observer) scheme,[10] each register that provides input to a combinational block and receives the output

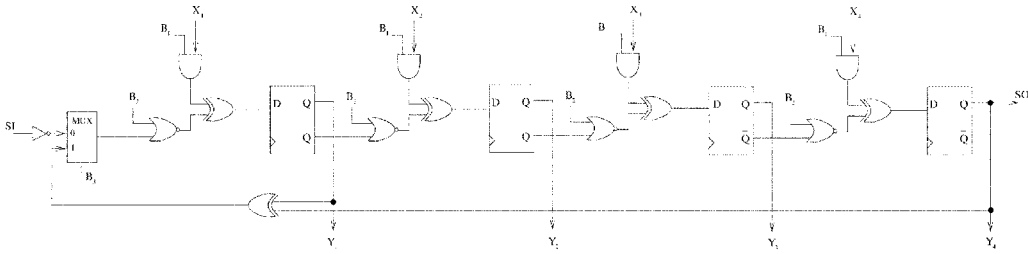

FIGURE 67.12 BILBO structure for a 4-bit register.

of another combinational block is transformed into a multipurpose structure that can act as an LFSR (for test pattern generation), as an MISR (for output response verification), as a shift register (for scan chain configurations), and also as a normal register. An implementation of the BILBO structure for a 4-bit register is shown in Fig. 67.12. In this example, the characteristic polynomial for the LFSR and MISR is $P(x) = x^4 + x + 1$.

By setting $B_1B_2B_3 = 001$, the structure acts like an LFSR. By setting $B_1B_2B_3 = 101$, the structure acts like an MISR. By setting $B_1B_2B_3 = 000$, the structure acts like a shift register (with serial input SI and serial output SO). By setting $B_1B_2B_3 = 11x$, the structure acts like a normal register, and by setting $B_1B_2B_3 = 01x$, the register can be cleared.

As two more representatives of system BIST architectures, we mention here the STUMPS scheme,[11] where each combinational block is interfaced to a scan path and each scan path is fed by one cell of the same LFSR and feeds one cell of the same MISR, and the LOCST scheme,[12] where there is a single boundary scan chain for inputs and a single boundary scan chain for outputs, with an initial portion of the input chain configured as an LFSR and a final portion of the output chain configured as an MISR.

CAD Tools for BIST/DFT and Delay Faults

Spyros Tragoudas
Southern Illinois University

68.1 Introduction

This chapter describes computer-aided design (CAD) tools and methodologies for improved design for testability (DFT), built-in self-test (BIST) mechanisms, and fault simulation. Section 68.2 presents CAD tools for the traditional stuck-at fault model which was examined in Chapters 66 and 67. Section 68.3 describes a fault model suitable for delay faults — the path delay fault model. The number of path delay faults in a circuit may be a non-polynomial quantity. Thus, this fault model requires sophisticated CAD tools not only for BIST and DFT, but also for ATPG and fault simulation.

68.2 CAD for Stuck-at Faults

In the traditional stuck-at model, each line in the circuit is associated to at most two faults, a stuck-at 0 and a stuck-at 1 fault. We distinguish between combinational and sequential circuits. In the former case, *computer-aided design* (CAD) tools target efficient synthesis of BIST schemes. The testing of sequential circuits is by far a more difficult problem and must be assisted by DFT techniques. The most popular DFT approach is the scan design. The following subsections present CAD tools for combinational logic and sequential logic, and then a review of advances in fault simulation.

Synthesis of BIST Schemes for Combinational Logic

The Pseudo-exhaustive Approach

In the pseudo-exhaustive approach, patterns are generated pseudorandomly and target all possible faults. A common circuit preprocessing routine for CAD tools is called *circuit segmentation.*

The idea in circuit segmentation is to insert a small number of storage elements in the circuit. These elements are bypassed in operation mode — that is, they function as wires — but in testing mode, they are part of the BIST mechanism. Due to their dual functionality, they are called *bypass storage elements* (*bses*). The hardware overhead of a *bse* amounts to that of a flip-flop and a two-to-one multiplexer. Each

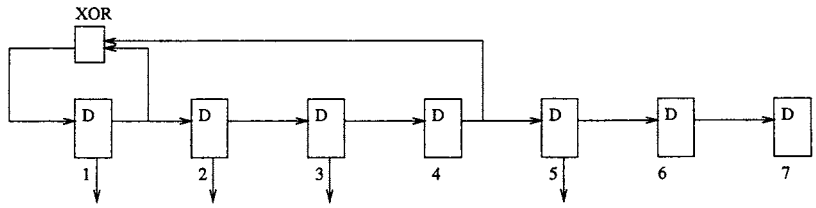

FIGURE 68.1 An observable point that depends on four controllable points.

bse is a controllable as well as an observable point, and must be inserted so that every observable point (primary output or *bse*) depends on at most k controllable points (primary inputs or *bses*), where k is an input parameter not larger than 25. This way, no more than 2^k patterns are needed to pseudo-exhaustively test the circuit.

The circuit segmentation problem is modeled as a combinational minimization problem. The objective function is to minimize the number of inserted *bses* so that each observable point depends on at most k controllable points. The problem is NP-hard in general.[1] However, efficient CAD tools have been proposed.[2-4] In Ref. 2, the *bse* insertion tool minimizes the hardware overhead using a *greedy methodology*. The CAD tool in Ref. 3 uses *iterative improvement*, and the one in Ref. 4 the concept of *articulation points*.

When the *test pattern generation* (TPG) is an LFSR/SR with a characteristic polynomial $P(x)$ with period $\mathcal{P}$, $\mathcal{P} \geq 2^k - 1$, *bse* insertion must be guided by a sophisticated CAD tools which guarantees that the $\mathcal{P}$ different patterns that are generated by the LFSR/SR suffice to test the circuit pseudo-exhaustively. This in turn implies that each observable point which depends on at most k controllable points must receive $2^k - 1$ patterns. (The all-zero input pattern is excluded because it cannot be generated by the LFSR/SR.) The example below illustrates the problem.

Example 1

Consider the LFSR/SR of Fig. 68.1, which has seven cells. In this case, the total number of primary inputs and inserted *bses* is seven. Consider a consecutive labeling of the LFSR/SR cells in the range [1…7], where the left-most element takes label 1. Assume that an observable point o in the circuit depends on elements 1, 2, 3, and 5 of the LFSR/SR. In this case, $k \geq 4$, and the input dependency of o is represented by the set $I_o = \{1, 2, 3, 5\}$.

Let the characteristic polynomial of the LFSR/SR be $P(x) = x^4 + x + 1$. This is a primitive polynomial and its period $\mathcal{P}$ is $\mathcal{P} = 2^4 - 1 = 15$. We list in Table 68.1 the patterns generated by $P(x)$ when the initial seed is 00010.

Any seed besides 00000 will return $2^4 - 1$ different patterns. Although 15 different patterns have been generated, the observable point o will received the set of subpatterns projected by columns 1, 2, 3, and 5 of the above matrix. In particular, o will receive patterns in Table 68.2.

TABLE 68.1

0	0	0	1	0

0	1	1	0	1
0	0	1	1	0
1	0	0	1	1
0	1	0	0	1
0	0	1	0	0

Although 15 different patterns have been generated by $P(x)$, point o receives only eight different patterns. This happens because there exists at least one linear combination in the set $\{x^1, x^2, x^3, x^5\}$, the set of monomials of o, which is divided by $P(x)$. In particular, the linear combination $x^5 + x^2 + 1$ is divisible by $P(x)$. If no linear combination is divisible by $P(x)$, then o will receive as many different patterns as the period of the characteristic polynomial $P(x)$.

For each linear combination in some set I_o which is divisible by the characteristic polynomial $P(x)$, we say that a *linear dependency* occurs. Avoiding linear dependencies in the set I_o sets is a fundamental problem in pseudo-exhaustive built-in TPG. The following describes CAD tools for avoiding linear dependencies.

The approach in Ref. 3 proposes that the elements of the LFSR/SR (inserted *bses* plus primary inputs) are assigned appropriate labels in the LFSR/SR. It has

been easily shown that no linear combination in some I_o is divisible by $P(x)$ if the largest label in I_o and the smallest label in I_o differ by less than k units.[3] We call this property the *k-distance property in set* I_o. Reference 3 presents a coordinated scheme that segments the circuit with *bse* insertion, and labels all the LFSR/SR cells so that the k-distance property is satisfied for each set I_o.

It is an NP-hard problem to minimize the number of inserted *bses* subject to the above constraints. This problem contains a special case the traditional circuit segmentation problem. Furthermore, Ref. 3 shows that it is NP-complete to decide whether an appropriate LFSR/SR cell labeling exists so that k-distance property is satisfied for each set I_o without considering the circuit segmentation problem, that is, after *bse* elements have been inserted so that for each set I_o it holds that $|I_o| \leq k$. However, Ref. 3 presents an efficient heuristic for the k-distance property problem. It is reduced to the bandwidth minimization problem on graphs for which many efficient polynomial time heuristics have been proposed.

The outline of the CAD tool in Ref. 3 is as follows. Initially, *bse* elements are inserted so that for each set I_o, we have that $|I_o| \leq k$. Then, a bandwidth-based heuristic determines whether all sets I_o could satisfy the k-distance property. For each I_o that violates the k-distance property, a modification is proposed by recursively applying a greedy *bse* insertion scheme, which is illustrated in Fig. 68.2.

The primary inputs (or inserted *bses*) are labeled in the range [1…6], as shown in the Fig. 68.2. Assume that the characteristic polynomial is $P(x) = x^4 + x + 1$, i.e., $k = 4$. Under the given labeling, sets I_e and I_d satisfy the k-distance property but set I_g violates it. In this case, the tool finds the closest front of predecessors of *g* that violate the k-distance property. This is node *f*. New *bses* are inserted on the incoming edges if *f*. (The tool may attempt to insert *bses* on a subset of the incoming edges.) These *bses* are assigned labels 7, 8. In addition, 4 is relabeled to 6, and 6 to 4. This way, I_g satisfies the k-distance requirement.

The CAD tool can also be executed so that instead of examining the k-distance, it examines instead if each set I_o has at least one linear dependency. In this case, it finds the closest front of predecessors that contain some linear dependency, and inserts *bse* elements on their incoming edges. This approach increases the time performance without significant savings in the hardware overhead.

The reason that primitive polynomials are traditionally selected as characteristic polynomials of LFSR/SRs is that they have large period $\mathcal{P}$. However, any polynomial could serve as a characteristic polynomial of the LFSR/SR as long as its period $\mathcal{P}$ is no less than $2^k - 1$. If P is less than $2^k - 1$, then no set I_o with $|I_o| = k$ can be tested pseudo-exhaustively.

A desirable characteristic polynomial would be one that has large period $\mathcal{P}$ and whose multiples obey a given pattern which we could try to avoid when relabeling the cells of the LFSR/SR so that appropriate I_o sets are formed. This is the idea of the CAD tool in Ref. 5.

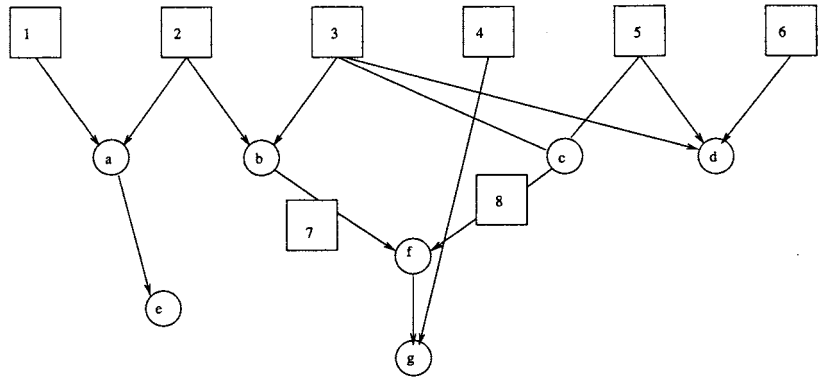

FIGURE 68.2 Enforcing the *k*-distance property with *bse* insertion.

In particular, Ref. 5 proposes that the characteristic polynomial is a product $P(x) = P_1(x) \cdot P_2(x)$ of two polynomials. $P_1(x)$ is a primitive polynomial of degree k which guarantees that the period of the characteristic polynomial $P(x)$ is at least $2^k - 1$. $P_2(x)$ is the polynomial $x^d + x^{d-1} + x^{d-2} + \ldots + x^1 + x^0$, whose degree d is determined by the CAD tool. $P_2(x)$ is called a *consecutive polynomial of degree d*. The CAD tool determines which primitive polynomial of degree d will be implemented in $P(x)$.

The multiples of consecutive polynomials have a given structure. Consider an $I_o = \{i_1, i_2, \ldots, i_k\}$ and $I'_o = \{i'_1, i'_2, \ldots, i'_{k'}\} \subseteq I_k$. Ref. 5 shows that there is no linear combination in set $I'o$ if the parity of all remainders of each $i'_j \in I'_o$ modulo d-1 is either even or odd. In more details, the algorithm groups all i'_j whose remainder modulo d-1 is x under list L_x, and then checks the parity of the list L_x. There are d lists labeled L_0 through L_{d-1}. If not all list parities agree, then there is no linear combination in I'_o. (If a list L_x is empty, it has even parity.) The example below illustrates the approach.

Example 2

Let $I_o = \{27, 16, 5, 3, 1\}$ and $P_2(x) = x^4 + x^3 + x^2 + x + 1$. Lists L_3, L_2, L_1 and L_0 are constructed, and their parities are examined. Set I_o contains linear dependencies because in subset $I'_o = \{27, 3\}$, there are even parities in all lists. In particular, list L_3 has two elements and all the remaining lists are empty.

However, there are no linear independencies in the subset $I'_o = \{16, 3, 1\}$. In this case, L_0, L_1, and L_3 have exactly one element each, and L_2 is empty. Therefore, there is no subset of I'_o where all L_i, $0 \le i \le 3$, have the same parity.

The performance of the approach in Ref. 5 is affected by the relative order of the LFSR/SR cells. Given a consecutive polynomial of degree d, one LFSR/SR cell labeling may give linear dependencies in some I_o whereas an appropriate relabeling may guarantee that no linear dependencies occur in any set I_o. Ref. 5 shows that it is an NP-complete problem to determine whether a relabeling exists so that no linear dependencies occur in any set I_o.

The idea of Ref. 5 is to label the LFSR/SR cells so that a small fraction of linear dependencies exist in each set I_o. In particular, for each set I_o, the approach returns a large subset I'_o with no linear dependencies with respect to polynomial $P_2(x)$. This is promise for pseudorandom built-in TPG. The objective is relaxed so that each set I_o receives many different test patterns. Experimentation in Ref. 5 shows that the smaller the fraction of linear dependencies in a set, the larger fraction of different patterns will receive. Also observe that many linear dependencies can be filtered out by the primitive polynomial $P_1(x)$.

A final approach for avoiding linear dependencies was proposed in Ref. 4. The idea is also to find a maximal subset I'_o of each I_o where no linear dependencies occur. The maximality of I'_o is defined with respect to linear independencies, that is, I'_o cannot be further expanded by adding another label a without introducing some linear dependencies. It is then proposed that cell a receives another label a' (as small as possible) which guarantees that there are no linear dependencies in $I'_o \cup \{a\}$. This may cause many "dummy" cells in the LFSR/SR (i.e., labels that do not belong to any I_o). Such dummy cells are subsequently removed by inserting XOR gates.

The Deterministic Approach

In this section we discuss BIST schemes for deterministic test pattern generation, where the generated patterns target a given list of faults. An initial set T of test patterns is traditionally part of the input instance. Set T has been generated by an ATPG tool and detects all the random resistant faults in the circuit.

The goal in deterministic BIST is to consult T and, within a short period of time, generate patterns on-chip which detect all random pattern resistant faults. The BIST scheme may be reproduced by a subset of the patterns in T as well as patterns not in T. If *all* the patterns of T are to be reproduced on-chip, then the mechanism is also called a *test set embedding scheme*. (In this case, only the patterns of T need to be reproduced on-chip.) The objective in test set embedding schemes is well defined, but the reproduction time or the hardware overhead may be less when we do not insist that all the patterns of T are reproduced on-chip.

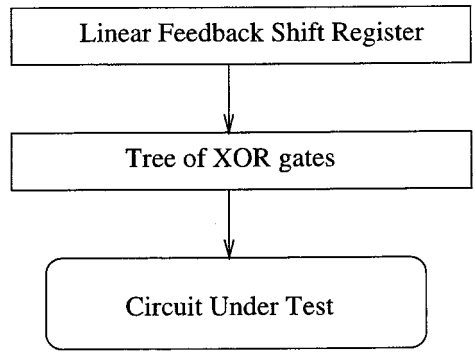

FIGURE 68.3 The schematic of a weighted random LFSR.

A very popular method for deterministic on-chip TPG is to use *weighted random LFSRs*. A weighted random LFSR consists of a simple LFSR/SR and a tree of XOR gates, which is inserted between the cells of the LFSR/SR and the inputs of the circuit under test, as Fig. 68.3 indicates. The tree of XOR gates guarantees that the test patterns applied to the circuit inputs are weighted with appropriate signal probabilities (probability of logic "1").

The idea is to weigh random test patterns with non-uniform probability distributions in order to improve detectability of random pattern resistant faults. The test patterns in T assist in assigning weights. The signal probability of an input is also referred to as the *weight* associated with that input. The collection of weights on all inputs of a circuit is called a *weight set*. Once a weight set has been calculated, the XOR tree of the weighted LFSR is constructed.

Many weighted random LFSR synthesis schemes have been proposed in the literature. Their syntheses mainly focuses on determining the weight set, thus the structure of the XOR tree. Recent approaches consider multiple weight sets. In Ref. 6, it has been shown that patterns with *small Hamming distance* are easier to be reproduced by the same weight set. This observation forms the basis of the approach which works in sessions.

A session starts by generating a weight set for a subset T' of patterns T with small *Hamming distance* from a given *centroid pattern in the subset*. Subsequently, the XOR tree is constructed and a characteristic polynomial is selected which guarantees high fault coverage. Next, fault simulation is applied and it is determined how many faults remain undetected. If there are still undetected faults, an *automatic test pattern generator* (ATPG) is activated, and a new set of patterns T is determined for the next session; otherwise, the CAD tool terminates.

For the test set embedding problem, weighted random LFSRs are not the only alternative. Binary counters may turn out to be a powerful BIST structure that requires very little hardware overhead. However, their design (synthesis) must be supported by sophisticated CAD tools that quickly and accurately determine the amount of time needed for the counter to reproduce a test matrix T on-chip. Such a CAD tool is described in Ref. 7, and recommends whether a counter may be suitable for the test embedding problem on a given circuit. The CAD tool in Ref. 7 designs a counter which reproduces T within a number of clock cycles that is within a constant factor from the smallest possible by a binary counter.

Consider a test matrix T of four patterns, consisting of eight columns, labeled 1 through 8. (The circuit under test has eight inputs.) A simple binary counter requires 125 clock cycles to reproduce these four patterns in a straightforward manner. The counter is seeded with the fourth pattern and incrementally will reach the second pattern, which is the largest, after 125 cycles. Instead, the

TABLE 68.3

1	0	1	0	1	1	0	1
1	0	1	1	1	1	0	1
1	0	1	0	1	1	1	1
0	1	0	0	0	0	0	0

CAD tool in Ref. 7 synthesizes the counter so that only 4 clock cycles are needed for reproducing on-chip these four patterns.

The idea is that matrix T can be manipulated appropriately. The following operations are allowed on T:

- Any constant columns (with all 0 or all 1) can be eliminated, since ground and power wires can be connected to the respective inputs.
- Merging of any two complimentary columns. This operation is allowed because the same counter cell (enhanced flip-flop) has two states Q and Q'. Thus, it can produce (over successive clock cycles) a column as well as its complement.
- Many identical columns (and respective complementary) can be merged into a single column since the output of a single counter cell can fan-out to many circuit inputs. However, due to delay considerations we do not allow more than a given number f of identical columns to be merged. Bound f is an input parameter in the CAD tool.
- Columns can be permuted. This corresponds to reordering of the counter cells.
- Any column can be replaced by its complementary column.

These five operations can be applied on T in order to reduce the number of clock cycles needed for reproducing it. The first three operations can be applied easily in a preprocessing step. In the presence of column permutation, the problem of minimizing the number of required clock cycles is NP-hard. In practice, the last two operations drastically reduce the reproduction time. The impact of column permutation is shown in the example in Table 68.4.

TABLE 68.4

1	0	1	0	1	1	0	1		0	1	1	1	1	1	0	0
1	0	1	1	1	1	0	1		0	1	1	1	1	1	0	0
1	0	1	0	1	1	1	1		0	1	1	1	1	1	0	1
0	1	0	0	0	0	0	0		1	0	0	0	0	0	0	0

The matrix on the left needs 125 cycles to be reproduced on-chip. The column permutation shown to the right reduces the reproduction time to only four cycles.

The idea of the counter synthesis CAD tool is to place as many identical columns as possible as the rightmost columns of the matrix. This set of columns can be preceded by a complementary column, if one exists. Otherwise, the first of the identical columns is complemented. The remaining columns are permuted so that a special condition is enforced, if possible.

The example in Table 68.5 illustrates the described algorithm. Consider matrix T given in Table 68.5.

TABLE 68.5

1	0	0	0	0	1	1	0	1	1	1	1
1	1	0	1	1	0	1	0	1	1	1	1
0	1	1	0	0	0	0	1	0	0	0	0
1	1	0	1	1	0	1	1	0	0	0	1
1	1	0	0	0	0	1	1	0	0	0	1
0	0	1	0	1	1	0	1	0	0	0	1

Assume that $f = 1$, that is, no fan-out stems are required. The columns are permuted as given in Table 68.6.

The leading (right-most) four columns are three identical columns and a complementary column to them. These four leading columns partition the vectors into two parts. Part 1 consists of the first two vectors with prefix 0111. Part 2 contains the remaining vectors. Consider the subvectors of both parts in the partition, induced when removing the leading columns. This set of subvectors (each has eight bits) will determine the relative order of the remaining columns of T.

TABLE 68.6

0	1	1	1	1	1	1	0	1	0	0	0
0	1	1	1	1	1	1	0	0	1	1	1
1	0	0	0	0	0	0	1	0	1	0	0
1	0	0	0	1	1	1	0	0	1	1	1
1	0	0	0	1	1	1	0	0	1	0	0
1	0	0	0	1	0	0	1	1	0	0	1

The unassigned eight columns are permuted and complemented (if necessary) so that the smallest subvector in part 1 is not smaller than the largest subvector in part 2. We call this conduction, the *low order condition*. The column permutation in Table 68.6 satisfies the low order condition. In this example, no column needs to be complemented in order for the low order condition to be satisfied.

The CAD tool in Ref. 7 determines in polynomial time whether the columns can be permuted or complemented so that the low order condition is satisfied. If it is satisfied, it is shown that the amount of required clock cycles for reproducing T is within a factor of two from the minimum possible. This also holds when the low order condition cannot be satisfied.

A test matrix T may contain don't-cares. Don't-cares are assigned so that we maximize the number of identical columns in T. This problem is shown to be NP-hard.[7] However, an assignment that maximizes the number of identical columns is guided by efficient heuristics for the maximum independent set problem on a graph $G = (V, E)$, which is constructed in the following way.

For each column c of T, there exists a node $v_c \in V$. In addition, there exists an edge between a pair of nodes if and only if there exists at least one column where one of the two columns has 1 and the other has 0. In other words, there exists an edge if and only if there is no don't-care assignment that makes the respective columns identical. Clearly, $G = (V, E)$ has an independent set of size k if and only if there exists a don't-care assignment that makes the respective columns of T identical. The operation of this CAD tool is illustrated in the example below.

Example 3

Consider matrix T with don't-cares and columns labeled c_1 through c_6 in Table 68.7. In graph $G = (V, E)$ of Fig. 68.4, node i corresponds to column c_i, $1 \le i \le 6$. Nodes 3, 4, 5, and 6 are independent. The matrix to the left below shows the don't-care assignment on columns c_3, c_4, c_5, and c_6. The don't-care assignment on the remaining columns (c_1 and c_2) is done as follows. First, it is attempted to find a don't-care assignment that makes either c_1 or c_2 complementary to the set of identical columns $\{c_3, c_4, c_5, c_6\}$. Column c_2 satisfies this condition. Then, columns c_2, c_3, c_4, c_5 and c_6 are assigned to the left-most positions of T. As described earlier, the test patterns of T are now assigned in two parts. Part 1 has patterns 1 and 3, and part 2 has patterns 2 and 4. The don't-cares of column c_1 are assigned so that the low order condition is satisfied. The resulting don't-care assignment and column permutation is shown in the matrix to the right in Table 68.8.

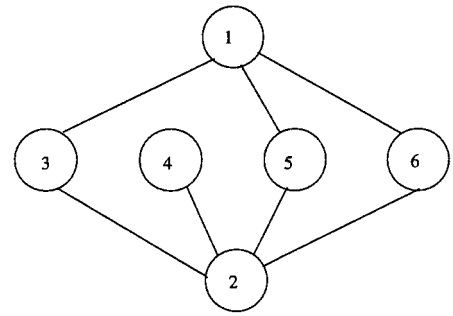

FIGURE 68.4 Graph construction with the don't-care assignment.

TABLE 68.7

c_1	c_2	c_3	c_4	c_5	c_6
0	0	1	x	1	1
x	1	0	0	x	0
1	x	x	1	x	x
0	x	x	x	0	x

TABLE 68.8

0	0	1	1	1	1	0	1	1	1	1	0
x	1	0	0	0	0	1	0	0	0	0	0
1	x	1	1	1	1	0	1	1	1	1	1
0	x	0	0	0	0	1	0	0	0	0	0

Extensions of the CAD tool involve partitioning of the patterns into submatrices where some or all of the above-mentioned operations are applied independently. For example, the columns of one submatrix can be permuted in a completely different way from the columns of another submatirx. Tradeoffs between hardware overhead and reproduction time have been analyzed among different variations (extensions) of the CAD tools. The tradeoffs are determined by the subset of operations that can be applied independently in each submatrix. The larger the set, the higher the hardware overhead is.

DFT and BIST for Sequential Logic

CAD Tools for Scan Designs

In the full scan design, all the flip-flops in the circuit must be scanned and inserted in the scan chain. The hardware overhead is large and the test application time is lengthy for circuits with a large number of flip-flops. Test application time can be drastically reduced by an appropriate reordering of the cells in the scan chain. This cell reordering problem has been formulated as a combinatorial optimization problem which is shown to be NP-hard. However, an efficient CAD tool for determining an efficient cell reordering is presented in Ref. 8.

One useful approach for reducing both of the above costs is to resynthesize the circuit by repositioning its flip-flops so that their number is minimized while the functionality of the design is preserved. We describe such a circuit resynthesis scheme.

Let us consider the circuit graph $G = (V, E)$ of the circuit, where each node $v \in V$ is either an input/output port or a combinational module. Each edge $(u, v) \in E$ is assigned a weight $ff(u, v)$ equal to the number of flip-flops on it. Ref. 9 has shown that flip-flops can be repositioned without changing the functionality of the circuit as follows.

Let IO denote the set of input/output ports. The flip-flop repositioning problem amounts to assigning $r()$ values to each node in V so that

$$\begin{aligned} &r(v) = 0, \ \forall v \in IO \\ &r(u) = r(v) \le ff(u,v), \ \forall (u,v) \in E \end{aligned} \tag{68.1}$$

Once an $r()$ value is assigned to each node at I/O port, the new number of flip-flops on each edge (u, v) is computed using the formula

$$ff_{new}(u,v) = ff(u,v) + r(u) - r(v) \tag{68.2}$$

The set of constraints in Eq. 68.1 is a set of difference constraints and forms a special case of linear programming which can be solved in polynomial time using Bellman–Ford shortest path calculations. The described resynthesis scenario is also referred to as *retiming* because flip-flop repositionings may affect the clock period.

The above set of difference constraints has an infinite number of solutions. Thus, there exists an infinite number of circuit designs with an equivalent functionality. One can benefit from these alternative designs, and resynthesis can be done in order to optimize certain objective functions. In full scan, the objective is to minimize the total number of flip-flops. The latter quantity is precisely

$$\sum_{(u,v)} ff_{new}(u,v)$$

which can be rewritten (using Eq. 68.2) as

$$\sum_{(u,v)}\left(ff(u,v)+r(u)-r(v)\right)=\sum_{(u,v)}ff(u,v)+\sum_{(u,v)}\left(r(u)-r(v)\right) \tag{68.3}$$

Since the first term in Eq. 68.3 is an invariant, the goal is to find $r()$ values that minimize $\sum_{(u,v)}(r(u)-r(v))$ subject to the constraints in Eq. 68.1. This special case of integer linear programming is polynomially solvable using min-cost flow techniques.[9] Once the $r()$ values are computed, Eq. 68.2 is applied to determine where the flip-flops will be repositioned. The resulting circuit has minimum number of flip-flops.[9]

Although full scan is widely used by the industry, its hardware overhead is often prohibitive. An alternative approach for scan designs is the *structural partial scan approach* where a minimum cardinality subset of the flip-flops must be scanned so that every cycle contains at least one scanned flip-flop. This is an NP-hard problem. Reference 10 has shown that minimizing the number of flip-flops subject to some constraints additional to Eq. 68.1 turns out to be a beneficial approach for structural partial scan. The idea here is that minimizing the number of flip-flops amounts to maximizing the average number of cycles per flip-flop. This leads to efficient heuristics for selecting a small number of flip-flops for breaking all cycles.

Other resynthesis schemes that reposition the flip-flops in order to reduce the partial scan overhead have been proposed in Refs. 11 and 12. Both schemes initially identify a set of lines L that forms a low cardinality solution for partial scan. L may have lines without flip-flops. Thus, the flip-flops must be repositioned so each line of L has a flip-flop which is then scanned.

Another important goal in partial scan is to minimize the *sequential depth of the scanned circuit*. This is defined as the maximum number of flip-flops along any path in the scanned circuit whose endpoints are either controllable or observable. The sequential depth of a scanned circuit is a very important quantity because it affects the upper bound on the length of the test sequences which need to be applied in order to detect the stuck-at faults. Since the scanned circuit is acyclic, the sequential depth can be determined in polynomial time by a simple topological graph traversal.

Figure 68.5 below illustrates the concept of the sequential depth. Cycles denote I/O ports, oval nodes represent combinational modules, solid square nodes indicate unscanned flip-flops, and empty square nodes are scanned flip-flops. The sequential depth of the circuit graph to the left is 2. The figure to the right shows an equivalent circuit where the sequential depth has been reduced to 1. In this figure, the unscanned (solid flip-flops) have been repositioned, while the scanned flip-flops remain at the original positions so that the scanned circuit is guaranteed to be acyclic. Flip-flop repositioning is done subject to the constraints in Eq. 68.1 so that the functionality of the design is preserved.

Let F be the set of observable/controllable points in the scanned circuit. Let $F(u, v)$ denote the maximum number of unscanned flip-flops between u and v, $u, v \in F$, and E' denote the set of edges in the scanned sequential graph that have a scanned flip-flop. Ref. 10 proves that the sequential depth is at most k if and only if there exists a set of $r()$ values that satisfy the following set of inequalities:

$$\begin{aligned} &r(u)-r(v)=0, \ \forall(u,v)\in E' \\ &r(v)-r(u)\le k-F(u,v), \ \forall u,v\in F \end{aligned} \tag{68.4}$$

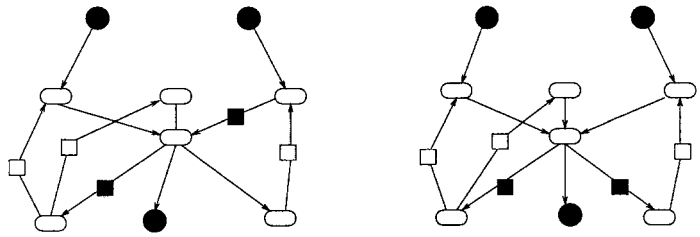

FIGURE 68.5 The impact of flip-flop repositioning on the sequential depth.

A simple hierarchy search can then be applied in order to find the smallest sequential depth that can be obtained with flip-flop repositioning.

A final objective in partial scan is to be able to *balance the scanned circuit.* In a balanced circuit, all paths between any pair of combinational modules have the same number of flip-flops. It has been shown that the TPG process for a balanced circuit reduces to TPG for combinational logic.[13] It has been proposed to balance a circuit by enhancing already existing flip-flops in the circuit and then bypassing them during testing mode.[13] A multiplexing circuitry needs to be associates with each selected flip-flop. Minimizing the multiplexer-related hardware overhead amounts to minimizing the number of selected flip-flops, which is an NP-hard problem.[13]

The natural question is whether flip-flop repositioning may help in balancing a circuit with less hardware overhead. Unfortunately, it has been shown that it cannot. It can however assist in inserting the minimum possible *bse* elements in order for the circuit to be balanced. Each inserted *bse* element is bypassed during operation mode but acts as a delay element in testing mode.

The algorithm consists of two steps. In the first step, *bses* are greedily inserted so that the scanned circuit becomes balanced. Subsequently, the number of the inserted *bse* elements is minimized by repositioning the inserted elements.

This is a variation of the approach that was described earlier for minimizing the number of flip-flops in a circuit. *Bses* are treated as flip-flops, but for every edge (u, v) with original circuit flip-flops, the set of constraints in Eq. 68.1 is enhanced with the additional constraint $r(u) - r(v) = 0$. This ensures that the flip-flops of the circuit will not be repositioned.

The correctness of the approach relies on the property that any flip-flop repositioning on a balanced circuit always maintains the balancing property. This can be easily shown as follows.

In an already balanced circuit, the number of flip-flops on any path $p_i(u, v)$ between any combinational nodes u, v has a number of flip-flops $c(u, v)$. When u and v are not adjacent nodes but the endpoints of a path p with two or more lines, a telescoping summation using Eq. 68.2 can be applied on the edges of the path to show that $ff_{new}p(u, v)$, the number of flip-flops on p after retiming, is

$$ff_{new}p(u,v) = c(u,v) + r(u) - r(v)$$

Observe now that quantity $ff_{new}p(u, v)$ is independent of the actual path $p(u, v)$, and remains invariant as long as we have a path between nodes u and v. This argument holds for all pairs of combinational nodes u, v. Thus, the circuit remains balanced after repositioning the flip-flops.

Test application time is a complex issue for designs that have been resynthesized for improved partial scan. Test sequences that have been precomputed for the circuit prior to its resynthesis cannot any more be applied to the resynthesized circuit. However, Ref. 14 shows that one can apply such recomputed test sequences after an initializing sequence of patterns brings the circuit to a given state s. State s guarantees that the precomputed patterns can be applied.

On-chip Schemes for Sequential Logic

Many CAD tools have been proposed in the literature for automating the design of BIST on-chip schemes for sequential logic. The first CAD tool of this section considers LFSR-based pseudo-exhaustive BIST. Then, a deterministic scheme that uses Cellular Automata is presented.

A popular LFSR-based approach for pseudorandom built-in self-test (BIST) of sequential proposes to enhance the scanned flip-flops of the circuit into either *Built-In Logic-Block Observation* (BILBO) cells or *Concurrent Built-In Logic-Block Observation* (CBILBO) cells. Additional BILBO cells and CBILBO cells that are transparent in normal mode can also be inserted into arbitrary lines in sequential circuits. The approach uses pseudorandom pattern generators (PRPGs) and *multiple-input signature registers* (MISRs).

There are two important differences between BILBO and CBILBO cells. (For the detailed structure of BILBO and CBILBO cells, see Ref. 15, Chapter 11.) First, in testing mode, a CBILBO cell operates both in the PRPG mode and the MISR mode, while a BILBO cell only can operate in one of the two modes.

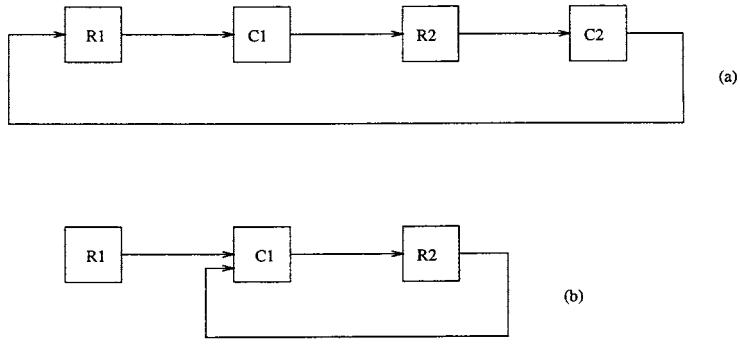

FIGURE 68.6 Illustration of the different hardware overheads.

The second difference is that CBILBO cells are more expensive than BILBO cells. Clearly, inserting a whole transparent test cell into a line is more expensive than enhancing an existing flip-flop regarding hardware costs.

The basic BILBO BIST architecture partitions a sequential circuit into a set of registers and blocks of combinational circuits with normal registers replaced by BILBO cells. The choice between enhancing existing flip-flops to BILBO cells or to insert transparent BILBO cells generates many alternative scenarios with different hardware overheads.

Consider the circuit in Fig. 68.6(a) with two BILBO registers R1 and R2 in a cycle. In order to test C1, register R1 is set in PRPG mode and R2 in MISR mode. Assuming that the inputs of register R1 are held at the value zero, the circuit is run in this mode for as many clock cycles as needed, and can be tested exhaustively for most cases — except for the all-zero pattern. At the end of this test process, the contents of R2 can be scanned out and the signature is checked. In the same way, C2 can be tested by configuring register R1 into MISR mode and R2 into PRPG mode.

However, the circuit in Fig. 68.6(b) does not conform to a normal BILBO architecture. This circuit has only one BILBO register R2 in a self-loop. In order to test C1, register R1 must be in PRPG mode, and register R2 must be in both MISR mode and PRPG mode, which is impossible due to the BILBO cell structure. This situation can be handled by either adding a transparent BILBO register in the cycle or by using a CBILBO that can operate simultaneously in both MISR and PRPG modes.

In order to make a sequential circuit self-testable, each cycle of the circuit must contain at least one CBILBO cell or two BILBO cells. This combinatorial optimization problem is stated as follows. The input is a sequential circuit, and a list of hardware overhead costs.

cB: The cost of enhancing a flip-flop to a BILBO cell.
cCB: The cost of enhancing a flip-flop to a CBILBO cell.
cBt: The cost of inserting a transparent BILBO cell.
cCBt: The cost of inserting a transparent CBILBO cell.

The goal is to find a minimum cost solution of this scan register placement problem in order to make every cycle in the circuit have at least one CBILBO cell or at least two BILBO cells.

The optimal solution for a circuit may vary, depending upon different cost parameter sets. For example, we can have three different solutions for the circuit in Fig. 68.7. The first is that both flip-flops FF1 and FF2 can be enhanced to CBILBO cells. The second is that one transparent CBILBO cell can be inserted at the output of gate G3 to break the two cycles. The third is that both flip-flops FF1 and FF2 can be enhanced to BILBO cells, together with one transparent BILBO cell inserted at the output of gate G3. Under the cost parameter set $cB = 20$, $cBt = 30$, $cCB = 40$, $cCBt = 60$, the hardware overhead of the three solutions are 80, 60, and 70, in that order. The second solution, using a transparent CBILBO cell, has the least hardware overhead.

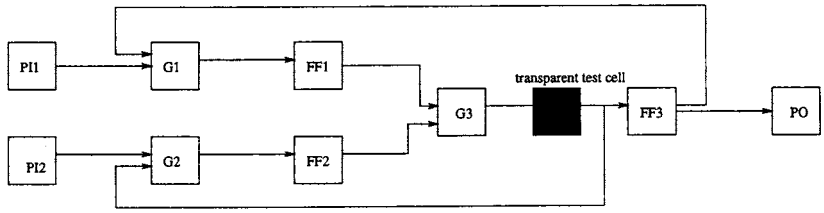

FIGURE 68.7 The solution depends on the cost parameter set.

However, under the cost parameter set $cB = 10$, $cBt = 30$, $cCB = 40$, $cCBt = 60$, the first solution, using both transparent and enhanced BILBO cells, yields the optimal solution with total hardware overhead of 50. Although a CBILBO cell is more expensive than a BILBO cell, and a transparent cell is more expensive than an enhanced one, in some situations using CBILBO cells and transparent test cells may be beneficial to the hardware overhead.

For this difficult combinatorial problem, Ref. 16 presents a CAD tool that finds the optimal hardware overhead using a branch and bound approach. The worst-case time complexity of the CAD tool is exponential and, in many instances, its time response is prohibitive. For this reason, Ref. 16 proposes an alternative branch and bound CAD tool that terminates the search whenever solutions close to the optimal are found. Although time complexity still remains exponential, the results reported in Ref. 16 show that branch and bound techniques are promising.

The remainder of this section presents a CAD tool for embedding test sequences on-chip. Checking for stuck-at faults in sequential logic requires the application of a sequence of test patterns to set the values of some flip-flops along with those values required for fault justification/propagation. Therefore, it is imperative that *all test patterns in each test sequence are applied in the specified order. Cellular automata* (CA) have been proposed as a TPG mechanism to achieve this goal, the advantage being mainly that they are a finite state machine (FSM) with a very regular structure.

References 17 and 18 propose that *hybrid CAs* are used for embedding test sequences on-chip. Hybrid CAs consist of a series of flip-flops $f_i 1 \le n$. The next state f_i^+ of flip-flop i is a function F_i of the present states of f_{i-1}, f_i, and f_{i+1}. (We call them the *3-neighborhood CAs.*) For the computation of f_1^+ and f_n^+, the missing neighbors are considered to be constant 0. A straightforward implementation of function F_i is by an 8-to-1 multiplexer.

Consider a $p \times w$ test matrix T comprising p ordered test vectors. The CAD tool in Ref. 18 presents a systematic methodology for this embedding problem. First, we give some definitions.[18]

Given a sequence of three columns (X_L, X, X_R), each row i, $1 \le i \le p-1$, is associated to a template $\tau_i = \begin{bmatrix} x_L^i & x^i & x_R^i \\ & x^{i+1} & \end{bmatrix}$. (No template is associated with the last row p). Let $H(\tau_i)$ denote the upper part $[x_L^i\, x^i\, x_R^i]$ of τ_i and let $L(\tau_i)$ denote the lower part, $[x^{i+1}]$.

Given a sequence of columns (X_L, X, X_R), two templates τ_i and τ_j, $1 \le i, j \le p-1$, are conflicting if and only if it happens that $H(\tau_i) = H(\tau_j)$ and $L(\tau_i) \ne L(\tau_j)$. A sequence of three columns (X_L, X, X_R) is a *valid triplet* if and only if there are no conflicting templates. This is imperative in order to have a properly defined F_i function for the corresponding CA cell that will generate column X of the test matrix, if column X is assigned between columns X_L and X_R in the CA cell ordering. If a valid triple cannot be formed from test matrix columns, a so-called "link column" must be introduced (corresponding to an extra CA cell) so as to make a valid triplet.

The goal in the studied on-chip embedding problem by a hybrid CA is to introduce the minimum number of link columns (extra CA cells) so as to generate the whole sequence. The CAD tool in Ref. 18 tackles this problem by a systematic procedure that uses *shift-up columns*. Given a column $X = (x^1, x^2, \ldots, x^p)^{tr}$, the shift-up column of X is the column $\hat{X} = (x^1, x^2, \ldots, x^p, d)^{tr}$, where d is a don't-care. Given a column X, the sequence of columns $(X_L, X, \hat{X})$ is a valid triplet for *any* column X_L.

Moreover, given two columns A and B of the test matrix, a *shifting sequence* from A to B to be a sequence of columns $(A, L_0, L_1, L_2, \ldots, L_j, B)$ such that $L_0 = \hat{A}$, $L_i = \hat{L}_{i-1}$, $1 \le i \le j$, and (L_{j-1}, L_j, B), is a valid triplet. A shifting sequence is always a valid sequence.

The important property of a shifting sequence $(A, L_0, L_1, L_2, \ldots, L_j, B)$ is that column A can be preceded by any other column X in a CA ordering, with the resulting sequence $(X, A, L_0, L_1, L_2, \ldots, L_j, B)$ being still valid. That is, for any two columns A and B of the test matrix, column B can always be placed after column A with some intervening link columns *without regard to what column is placed before A*. Given any two columns A and B of the test matrix, the goal of the CAD tool in Ref. 18 is to find a shifting sequence $(A, L_0, L_1, \ldots, L_{jAB}, B)$ of minimum length. This minimum number (denoted by m_{AB}) can be found by successive shift-ups of $L_0 = \hat{A}$ until a valid triplet ending with column B is formed.

Given an ordered test matrix T, the CAD tool in Ref. 18 reduces the problem of finding short length test shifting sequences to that of computing a Traveling Salesman (TS) solution on an auxiliary graph. Experimental results reported in Ref. 18 show that this hybrid CA-based approach is promising.

Fault Simulation

Explicit fault simulation is needed whenever the test patterns are generated using an ATPG tool. Fault simulation is needed in scan designs when an ATPG tool is used for TPG. Fault simulation procedures may also be used in the design of deterministic on-chip TPG schemes. On the other hand, pseudo-exhaustive/pseudorandom BIST schemes mainly use compression techniques for detecting whether the circuit is faulty. Compression techniques were covered in Chapter 67.[15] (Chapter 10 provides a more detailed discussion.)

This section reviews CAD tools proposed for fault simulation of stuck-at faults in single-output combinational logic. For a more extensive discussion on the subject, we refer the reader to Ref. 15 (Chapter 5).

The simplest form of simulation is called *single-fault propagation*. After a test pattern is simulated, the stuck-at faults are inserted one after the other. The values of every faulty circuitry are compared with the error-free values. A faulty value needs to be propagated from the line where the fault occurs. The propagation process continues line-by-line, in a topological search manner, until there is no faulty value that differs from the respective good one. If the latter condition is not satisfied, the fault is detected.

In an alternative approach, called *parallel-fault propagation*, the goal is to simulate n test patterns in parallel using n–bit memory. Gates are evaluated using boolean instructions operating on n–bit operands. The problem with this type of simulation is that events may occur only in a subset of the n patterns while at a gate. If one average α fraction of gates have events on their inputs in one test pattern, the parallel simulator will simulate $1/\alpha$ more gates than an event-driven simulator. Since n patterns are simulated in parallel, the approach is more efficient when $n \ge 1/\alpha$, and the speed-up is $n \cdot \alpha$. Single and parallel fault propagation are combined efficiently in a CAD tool proposed in Ref. 19.

Another approach for fault simulation is the *critical path tracing approach*.[20] For every test pattern, the approach first simulates the fault-free circuit and then determines the detected faults by determining which lines have *critical values*. A line has critical value 0 (1) in pattern t if and only if test pattern t detects the fault stuck-at 0 (1) at the line. Therefore, finding the lines that are critical in pattern t amounts to finding the stuck-at faults that are detected by t.

Critical lines are found by backtracking from the primary outputs. Such a backtracking process determines paths of critical lines that are called *critical paths*. The process of generating critical paths uses the concept of *sensitive inputs* of a gate with two or more inputs (for a test pattern t). This is determined easily: If only input l has the controlling value of a gate, then it is sensitive. On the other hand, if all the inputs of a gate have noncontrolling value, then they are all sensitive. There is no other condition for labeling some input line of a gate as sensitive. Thus, the sensitive inputs of a gate can be identified during the fault-free simulation of the circuit.

The operation of the critical path tracing algorithm is based on the observation that when a gate output is critical, then all its sensitive inputs are critical. On fan-out free circuits, critical path tracing is

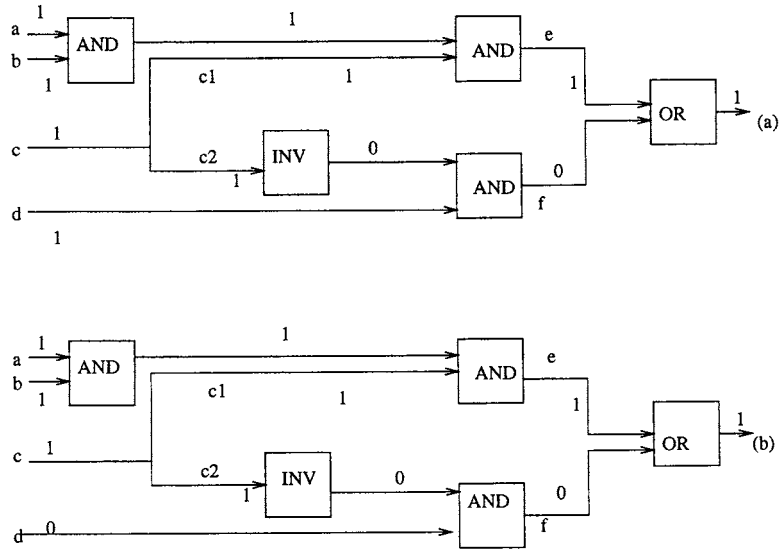

FIGURE 68.8 The solution depends on the cost parameter set.

a simple traversal that applies recursively to the above observation. The situation is more complicated when there exist reconvergent fan-outs. This is illustrated in Fig. 68.8.

In Fig. 68.8(a), starting from *g*, we determine critical lines *g*, *e*, *b*, and *c*1 as critical, in that order. In order to determine whether *c* is critical, we need additional analysis. The effects of the fault stuck-at 0 on line *c* propagate on reconvergent paths with different parities which cancel each other when they reconverge at gate *g*. This is called *self-masking*. Self-masking does not occur at Fig. 68.8(b) because the fault propagation from *c*2 does not reach the reconvergent point. In Fig. 68.8(b), *c* is critical.

Therefore, the problem is to determine whether self-masking occurs or not at the stem of the circuit. Let 0 (1) be the value of a stem *l* under test *t*. A solution is to explicitly simulate the fault stuck-at 1 (0) on *l*, and if *t* detects this fault, then *l* is marked as critical.

Instead, the CAD tool uses bottlenecks in the propagation of faults that are called *capture lines*. Let *a* be a line with topological level tl_a, sensitized to stuck-at fault *f* with a pattern *t*. If every path sensitized to *f* either goes through *a* or does not reach any other line with greater topological level greater than tl_a, then *a* is a capture line of *f* under pattern *t*. Such a line is common to all paths on which the effects of *f* can propagate to the primary output under pattern *t*.

The capture lines of a fault form a transitive chain. Therefore, a test *t* detects fault *f* if and only if all the capture lines of *f* under test pattern *t* are critical in *t*. Thus, in order to determine whether a stem is critical, the CAD tool does not propagate the effects of the fault step up to the primary output; it only propagates the fault effects up to the capture line that is closest to the stem.

68.3 CAD for Path Delays

CAD Tools for TPG

Fault Models and Non-enumerative ATPG

In the path delay fault problem, defects cause the propagation time along paths in the circuit under test to exceed the clock period. We assume here a fully scanned circuit where path delays are examined in combinational logic. A *path delay fault* is any path where either a rising ($0 \rightarrow 1$) or falling ($1 \rightarrow 0$) transition occurs on every line in the path. Therefore, for every physical path in the circuit, there exist two path delay faults. The first path delay fault is associated with a rising transition on the first line on

the path. The second path delay fault is associated with a falling transition on the first line on the path. In order to detect path delay faults, pairs of patterns must be applied rather than single test patterns.

One of the conditions that can be imposed on the tests for path delay faults is the *robust* condition. Robust tests guarantee the detection of the targeted path delay faults independent of any delays in the rest of the circuit. Table 68.9 lists the conditions for robust propagation of path delay faults in a circuit containing AND, OR, NAND, and NOR gates.

TABLE 68.9 Requirements for Robust Propagation

	Output Transition	
gate	$0 \rightarrow 1$	$1 \rightarrow 0$
AND	Any number of inputs	Single input
OR	Single input	Any number of inputs
NAND	Single input	Any number of inputs
NOR	Any number of inputs	Single input

Thus, when the output of a AND gate has been assigned, a rising transition multiple inputs are allowed to have rising transitions because rising transitions for an AND gate are transitions from a *controlling value* (*cv*) to a *noncontrolling value* (*ncv*). If, on the other hand, the output of an AND gate has a falling transition ($ncv \rightarrow cv$), then only one input is allowed to have a $ncv \rightarrow cv$ transition in order to satisfy the robustness.

Some definitions are necessary before we describe additional path delay fault families. Given a path delay fault p and a gate g on the p, the *on-input* of g with respect to path p is the input of g that is also on p. All other inputs of g are called *off-inputs* of g with respect to path p.

Robust path delay faults are a subset of the *non-robust path delay faults*. A non-robust test vector satisfies the conditions: (1) a transition is launched at the primary input of the target path, and (2) all off-inputs of the target path settle to non-controlling values under the second pattern in the vector. A robust test vector must satisfy the conditions of the non-robust tests, and whenever the transition at an on-input line a is $cv \rightarrow ncv$, each off-input of a is steady at ncv. The target faults detected by robust test vectors are called *robustly testable*, and are a subset of the target faults that are detected by non-robust test vectors. The target faults that are not robust testable and are detected by non-robust test vectors are called *non-robustly testable*. Non-robust test vectors cannot guarantee the detection of the target fault in the presence of other delay faults.

Functionally sensitizable test vectors allow for faults to be detected in the presence of multiple path delays. They detect a set of faults that is a superset of those detected by non-robust test vectors. A target fault is *functionally testable* (*FT*) if there is at least one gate with one or more off-inputs with $ncv \rightarrow ncv$ transition, where all of its off-inputs with $ncv \rightarrow cv$ transition are also delayed while its remaining off-inputs satisfy the conditions for non-robust test vectors. We say that each such gate satisfies the *functionally testable* (*FT*) *condition*. It has been shown that FT faults have better probability to be detected when the maximum off-input slack (or, simply, slack) is a small integer. (The slack of an off-input is defined as the difference between the stable time of the on-input signal and the stable time of the off-input signal.) Faults that are not detected by functionally sensitizable test vectors are called *functionally unsensitizable*. Table 68.10 summarizes the above-mentioned off-input conditions.[21]

TABLE 68.10 Off-input Signals for Two Input Gates and Fault Classification

	Off-input Transition	On-input Transition
$cv \rightarrow ncv$	Robust	Non-robustly testable
$ncv \rightarrow cv$	Funct. unsensitizable	Functionally testable
Stable *ncv*	Robust	Robust
Stable *cv*	Funct. unsensitizable	Funct. unsensitizable

Other classifications of path delay faults have been recently proposed in the literature, but they are not presented here.[22,23] Systematic path delay fault classification is very important when considering test pattern generation. For example, test pattern generation for robust path delay faults does not need to consider actual delays on the gates. However, delays have to be considered when generating pairs of patterns for non-robust and functionally testable faults. For the latter fault family, the generator must take into consideration that they are multiple faults, and that the slack is an important parameter for their detection.

The conventional approach for generating test patterns for path delay faults is a modification of the test pattern generation for stuck-at faults. It consists of a two-phase loop, each loop iteration resulting in a generated pair of patterns. Initially, transitions are assigned on the lines of path *P*. This is called the *path sensitization phase*. Then, a modified ATPG for stuck-at fault is executed twice. The first time, a test pattern must be generated so that every line of the selected path delay fault receives its initial transition value. The second execution of the modified ATPG generates another pattern, which assigns the final transition value on every line on the path. This is called the *line justification phase*.

The problem with this conventional approach is that the repeat loop will be executed as many times as the number of path delay faults, which is an exponential quantity to the size of the circuit. More explicitly, the difficulty of the path delay fault model is that the number of targeted faults is exponential, therefore we cannot afford to generate pairs of test patterns that detect one fault at a time.

Any practical ATPG tool must be able to generate a polynomial number of test patterns. Thus, in the case of path delay faults, the two-phase loop must be modified as follows. The first phase must be able to sensitize multiple paths. The second phase must be able to justify the assigned line transitions of as many sensitized paths as possible.

The goal in a *non-enumerative ATPG* is to generate a pair of patterns that sensitizes and justifies the transitions on all the lines of a subcircuit. Clearly, the average number of paths in each examined subcircuit must be an exponential quantity when the number of paths in the circuit is exponential. Thus, a necessary condition for the path sensitization phase is to generate, on average, subgraphs with large size.

The ATPG tools described in this section generate pairs of test patterns for robust path delay faults.[24,25] Both tools target an efficient path sensitization phase. A necessary condition for the paths of a subcircuit to be simultaneously sensitized is to be *structurally compatible* with respect to the parity (on the number of inverters) between any two reconvergent nodes in the subcircuit. This concept is illustrated in Fig. 68.9.

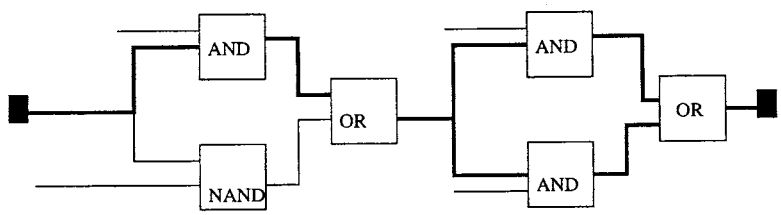

FIGURE 68.9 A graph consisting of structurally compatible paths.

Consider the circuit on the top portion of Fig. 68.9. The subgraph induced by the thick edges consists of two structurally compatible paths. These two paths share two OR gates. The two subpaths that share the same OR gate endpoints have even parity.

Any graph that constraints structurally compatible graphs is called a *structurally compatible* (SG) graph. The tools in Refs. 24 and 25 consider a special case of SG graphs with a single primary input and a single primary output. We call such an SG graph a primary compatible SG graph (PCG graph).

For the same pair of primary input and output nodes in the circuit, there may be many different PCG graphs, which are called sibling PCG graphs. Sibling PCG graphs contain mutually incompatible paths. The subgraph induced by the thick edges on the bottom portion of Fig. 68.9 shows a PCG that is sibling to the one on the top portion. This graph also contains two paths (the ones induced by the thick edges).

The ATPG tool in Ref. 25 generates large sibling PCGs for every pair of primary input and output nodes in the circuit. The size of each returned PCG is measured in terms of the number of structurally compatible paths that satisfy the requirements for robust propagation described earlier. Experimentation in Ref. 25 shows that the line justification phase satisfies the constraints along paths in a manner proportional to the size of the graph returned by the multiple path sensitization phase.

Given a pair of primary input and primary output nodes, Ref. 25 constructs large sibling PCGs as follows. Initially, a small number of lines in the circuit are removed so that the subcircuit between the selected primary inputs and outputs is a series-parallel graph. A polynomial time algorithm is applied on the series-parallel graph which finds the maximum number of structurally compatible paths that satisfy the conditions for robust propagation. An intermediate tree structure is maintained, which helps extract many such large sibling PCGs for the same pair of primary input and output nodes. Finally, many previously deleted edges are inserted so that the size of the sibling PCGs is increased further by considering paths that do not necessarily belong on the previously constructed series-parallel graph.

Once a pair of patterns is generated by the ATPG tool in Ref. 25, fault-simulation must be done so that the number of robust paths detected by the generated pair of patterns can be determined. The fault simulation problem for the path delay fault model is not as easy as for the stuck-at model. The difficulty relies on the fact that the number of path delay faults is not necessarily a polynomial quantity.

Each generated pair of patterns by the CAD tool in Ref. 25 targets robust path delay faults in a particular sibling PCG. It may, however, detect robust path delay faults in the portion of the circuit outside the targeted PCG. This complicates the fault simulation process. Thus, Ref. 25 suggests that faults are simulated only within the current PCG in which case a simple topological graph traversal suffices to detect them.

On-chip TPG Aspects

Many recent on-chip TPG schemes have been recently proposed for generating pairs of patterns. They are classified as either pseudo-exhaustive/pseudorandom or deterministic.

A pseudo-exhaustive scheme for generating pairs of patterns on-chip is proposed in Ref. 26. The method is based on a simple LFSR that has $2 \cdot w$ cells for a circuit with w inputs. Every other LFSR cell is connected to a circuit input. In particular, all the LFSR cells at even positions are connected to circuit inputs, and the remaining LFSR cells are used for "destroying" the shift dependency of the contents in the LFSR cells at even positions. The cells at odd positions are also called *separation cells*. Since the contents of the latter cells are independent, the scheme can generate all the possible two-input patterns. The schematic of the approach is given in Fig. 68.10.

Such an LFSR scheme is called a *full-input separation LFSR*.[26] It requires a significant hardware overhead and long wire feedback connections. A CAD tool is presented in Ref. 26 that reduces the size of the hardware overhead and the wire lengths by simply observing that separation cells must exist between any two LFSR cells that are connected to inputs that affect at least one circuit output. For each circuit output o, the I_o set which contains the labels of all the input cells of the *full separation LFSR* which affect o is constructed. Then, an LFSR cell relabeling CAD tool is proposed which minimizes the total number of separation cells so that the labels of all I_os are even numbers.[26]

Weighted random LFSRs can be used for on-chip deterministic TPG of pairs of patterns. Let us, for simplicity, consider the embedding problem. Here, the goal is to reproduce on-chip a matrix T consisting

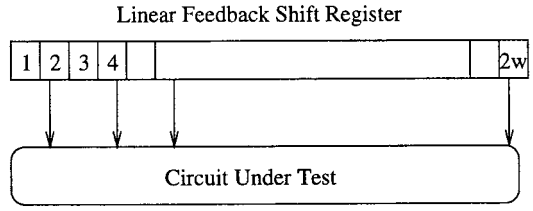

FIGURE 68.10 The schematic of an LFSR-based scheme for pseudo-exhaustive on-chip TPG.

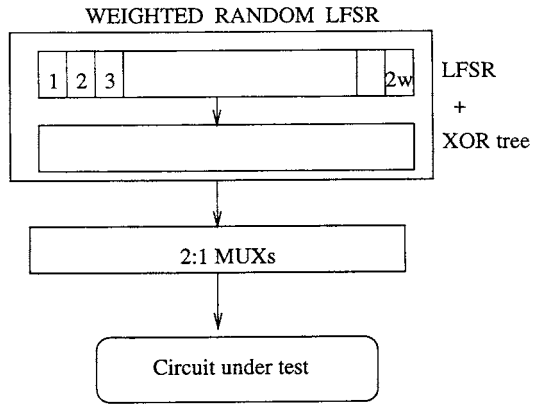

FIGURE 68.11 The schematic of a weighted random LFSR-based approach for deterministic on-chip TPG.

of n pairs of patterns (p_i^1, p_i^2), $1 \le i \le n$, each of size w, that have been generated by an ATPG tool such as the one described in the previous section.

A simple approach is to use a weighted random LFSR that n generates patterns p_i of size $2w$. Every pattern p_i is simply the concatenation of patterns p_i^1 and p_i^2. Once pattern p_i is generated, a simple circuit consisting of two-to-one multiplexers "splits" pattern p_i into its two pattern p_i^1 and p_i^2 and, in addition, guarantees that patterns p_i^1 are applied at even clock pulses and pattern p_i^2 are applied at odd clock pulses. The schematic of the approach is given in Fig. 68.11.

Fault Simulation and Estimation

Exact fault simulation for path delay faults is not a trivial aspect independent of the model used to propagate the delays (robust, non-robust, functionally testable path delay faults). The number of path delay faults remains, in the worst case, exponential, independent of propagation restrictions. Ref. 27 presents an exact simulation CAD tool for any type of path delay fault. The drawback of the approach in Ref. 27 is that it may require exponential time (and space) complexity, although experimentation has shown that in practice it is very efficient.

The following describes CAD tools for obtaining lower bounds on the number of detected path delay faults by a given set of n pairs of patterns. These approaches apply to any type of path delay fault and are referred to as fault estimation schemes.

In Ref. 28, every time a pair of patterns is applied, the CAD tool examines whether there exists at least one line where either a rising or falling transition has not been encountered by the previously applied pairs of test patterns. Let E_i, $1 \le i \le n$, denote the set of lines for which either a rising or a falling transition occurs for the first time when the pair of patterns P_i is applied.

When $|E_i| > 0$, a new set of path delay faults is detected by pattern P_i. These are the paths that contain lines in E_i. A simple topological search of the combinational circuit suffices to detect their number. If for some P_i, we have $|E_i| = 0$, the approach does not detect any path delay faults.

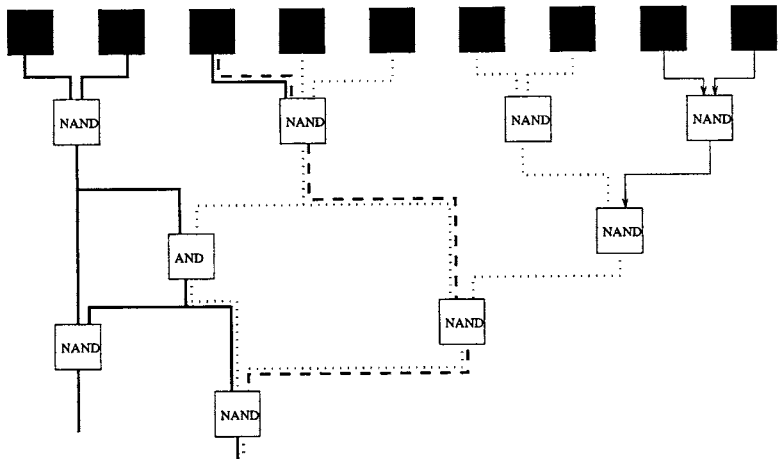

FIGURE 68.12 An undetected path delay fault.

The approach in Ref. 28 is non-enumerative but returns a conservative lower bound to the number of detected paths. Figure 68.12 illustrates a case where a path delay fault may not be counted.

Assume that the path delay faults in all three patterns start with a rising transition. Furthermore, assume that the first pair of patterns detects path delay faults along all the paths of the subgraph which is covered by thick edges. Let the second pair of patterns detect path delay faults on all the paths of the subgraph covered by dotted edges, and let the dashed path indicate a path delay fault detected by the third pair of patterns. Clearly, the latter path delay fault cannot be detected by the approach in Ref. 28.

For this reason, Ref. 28 suggests that fault simulation is done by virtually partitioning the circuit into subcircuits. The subcircuits should contain disjoint paths. One implementation for such a partitioning scheme is to consider lines that are independent in the sense that there is no physical path in the circuit that contains any two selected lines. Once a line is selected, we form a subcircuit that consists of all lines that depend on the selected line. In addition, the selected lines must form a cut separating the inputs from the outputs so that every physical path. This way, every path delay fault belongs to exactly one subcircuit. Figure 68.13 below shows three selected lines (the thick lines) of the circuit in Fig. 68.12 that are independent and also separate the inputs from the outputs.

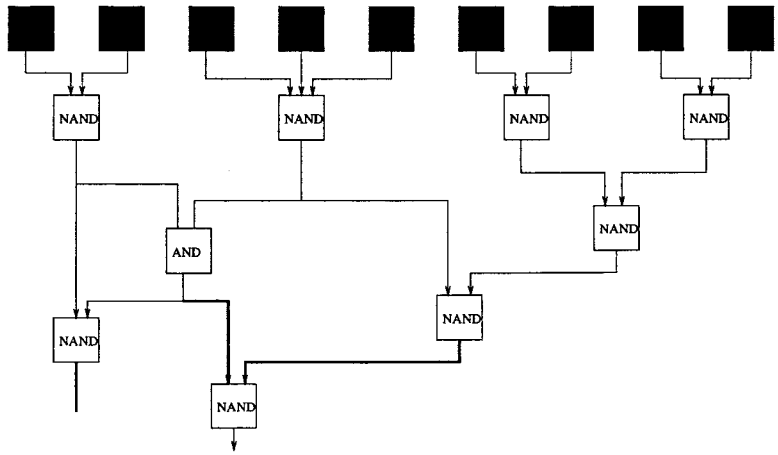

FIGURE 68.13 Three independent lines that form a cut.

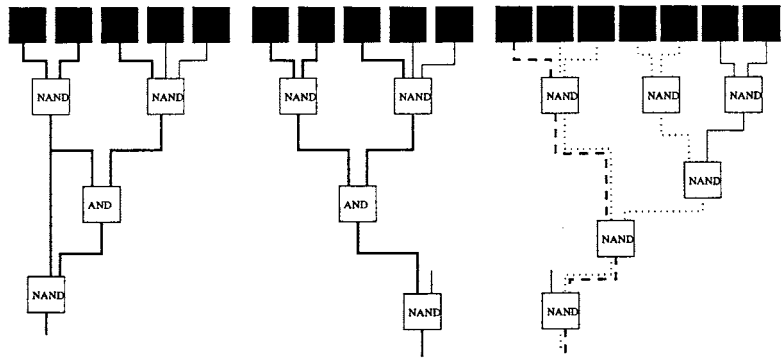

FIGURE 68.14 All paths are detected using three subcircuits.

Figure 68.14 contains the subcircuits corresponding to these lines. The first pattern detects path delay faults in the first two subcircuits, and the second pattern detects path delay faults in the third subcircuit. The missed path delay fault by the third pattern of Fig. 68.2 is detected on the third subcircuit because, in that subcircuit, its first line does not have a marked rising transition when the third pair of patterns is applied.

Reference 29 gives a new dimension to the latter problem. Such a cut of lines is called a *strong cut*. The idea is to find a maximum strong cut that allows for a maximum collection of subcircuits where fault coverage estimation can take place. A CAD tool is presented in Ref. 29 that returns such a maximum cardinality strong cut. The problem reduces to that of finding a maximum weighted independent set in a comparability graph, which is solvable in polynomial time using a minimum flow technique. There is no formal proof that the more the subcircuits, the better the fault coverage estimation is. However, experimentation verifies this assertion.[29]

Another CAD tool is given in Ref. 30. Every time a new pair of patterns is applied, the approach searches for sequences of rising and falling transitions on segments that terminate (or originate) at a given line. Therefore, if the CAD tool is implemented using segments of size two, every line can have up to four associated transitions. This enhances fault coverage estimation because new paths can be identified when a new sequence of transitions occurs through a line instead of a single transition.

69.1 Introduction

Very-high-speed digital integrated circuit design is a multidisciplinary challenge. First, there are several IC technologies available for very-high-speed applications. Each of these claims to offer unique benefits to the user. In order to choose the most appropriate or cost-effective technology for a particular application or system, the designer must understand the materials, the devices, the limitations imposed by process on yields, and the thermal limitations due to power dissipation.

Second, very-high-speed digital ICs present design challenges if the inherent performance of the devices is to be retained. At the upper limits of speed, there are no digital circuits, only analog. Circuit design techniques formerly thought to be exclusively in the domain of analog IC design are effective in optimizing digital IC designs for highest performance.

Finally, system integration when using the highest-speed technologies presents an additional challenge. Interconnections, clock and power distribution both on-chip and off-chip require much care and often restrict the achievable performance of an IC in a system.

The entire scope of very-high-speed digital design is much too vast to present in a single tutorial chapter. Therefore, we must focus the coverage in order to provide some useful tools for the designer. We will focus primarily on compound semiconductor technologies in order to restrict the scope. Silicon IC design tutorials can be found in other chapters in this handbook. This chapter gives a brief introduction to compound semiconductor materials in order to justify the use of non-silicon materials for the highest-speed applications. The transport properties of several materials are compared. Second, a technology-independent description of device operation for high-speed or high-frequency applications will be given in Chapter 70. The charge control methodology provides insight and connects the basic material properties and device geometry with performance. Chapter 71 describes the design basics of very-high-speed ICs. Static design methods are illustrated with compound semiconductor circuit examples, but are based on generic principles such as noise margin. The transient design methods emphasize analog circuit techniques and can be applied to any technology.

Finally, Chapter 72 describes typical circuit design approaches using FET and bipolar device technologies and presents applications of current interest.

69.2 Compound Semiconductor Materials

The compound semiconductor family is composed of the group III and group V elements shown in Table 69.1. Each semiconductor is formed from at least one group III and one group V element. Group IV

elements such as C, Si, and Ge are used as dopants, as are several group II and VI elements such as Be or Mg for p-type and Te and Se for n-type. Binary semiconductors such as GaAs and InP can be grown in large single-crystal ingot form using the liquid-encapsulated Czochralski method[1] and are the materials of choice for substrates. At the present time, GaAs wafers with a diameter of 100 and 150 mm are most widely used. InP is still limited to 75 mm diameter.

TABLE 69.1 Column III, IV, and V Elements Associated with Compound Semiconductors

B	C	N
Al	Si	P
Ga	Ge	As
In	Sn	Sb

Three or four elements are often mixed together when grown as thin *epitaxial* films on top of the binary substrates. The alloys thus formed allow electronic and structural properties such as bandgap and lattice constant to be varied as needed for device purposes. Junctions between different semiconductors can be used to further control charge transport as discussed in Section 69.4.

69.3 Why III-V Semiconductors?

The main motivation for using the III-V compound semiconductors for device applications is found in their electronic properties when compared with those of the dominant semiconductor material, silicon. Figure 69.1 is a plot of steady-state *electron velocity* of several n-type semiconductors versus electric field. From this graph, we see that at low electric fields the slope of the curves (*mobility*) is higher than that of silicon. High mobility means that the resistivity will be less for III-V n-type materials, and it may be easier to achieve lower access resistance. *Access resistance* is the series resistance between the device contacts and the internal active region. An example would be the base resistance of a bipolar transistor. Lower resistance will reduce some of the fundamental device time constants to be described in Chapter 70 that often dominate device high-frequency performance. Figure 69.1 also shows that the peak electron velocity is higher for III-V materials, and the peak velocity can be achieved at much lower electric fields. High velocity reduces *transit time*, the time required for a charge carrier to travel from its source to its destination, and improves device high-frequency performance, also discussed in Chapter 70. Achieving this high velocity at lower electric fields means that the devices will reach their peak performance at

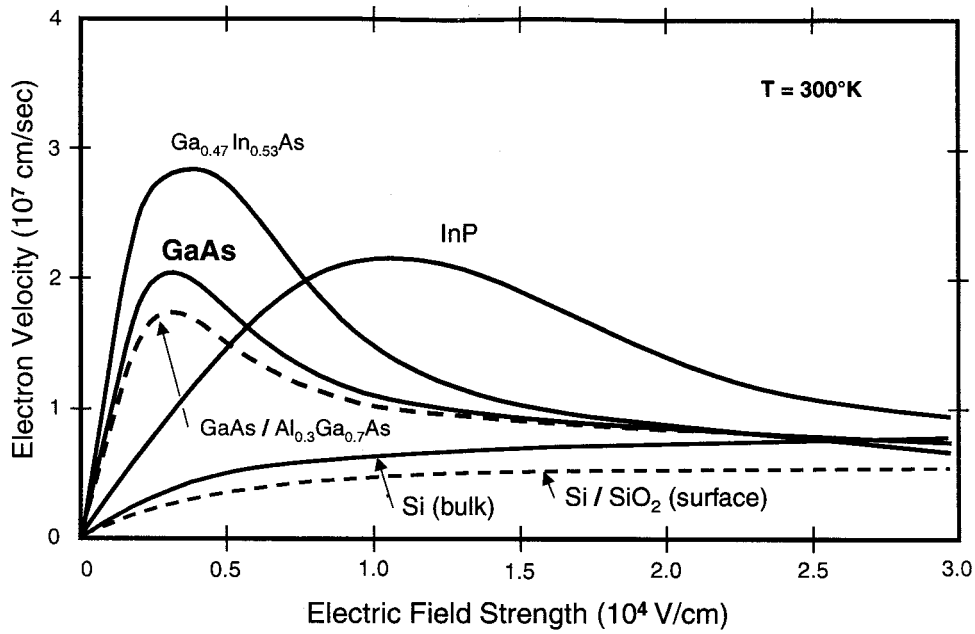

FIGURE 69.1 Electron velocity versus electric field for several n-type semiconductors.

TABLE 69.2 Comparison of Mobilities and Peak Velocities of Several n- and p-type Semiconductors

Semiconductor	E_G (eV)	ε_r	Electron Mobility (cm^2/V-s)	Hole Mobility (cm^2/V-s)	Peak Electron Velocity (cm/s)
Si (bulk)	1.12	11.7	1450	450	N.A.
Ge	0.66	15.8	3900	1900	N.A.
InP	1.35 D	12.4	4600	150	2.1×10^7
GaAs	1.42 D	13.1	8500	400	2×10^7
$Ga_{0.47}In_{0.53}As$	0.78 D	13.9	11,000	200	2.7×10^7
InAs	0.35 D	14.6	22,600	460	4×10^7
$Al_{0.3}Ga_{0.7}As$	1.80 D	12.2	1000	100	—
AlAs	2.17	10.1	280	—	—
$Al_{0.48}In_{0.52}As$	1.92 D	12.3	800	100	—

Note: In bandgap energy column, the symbol "D" indicates direct bandgap; otherwise, it is indirect bandgap. T = 300 K and "weak doping" limit.

lower voltages, which is useful for low-power, high-speed applications. Mobilities and peak velocities of several semiconductors are compared in Table 69.2.

On the other hand, as also shown in Table 69.2, p-type III-V semiconductors have rather poor hole mobility when compared with elemental semiconductor materials such as silicon or germanium. Holes also reach their peak velocities at much higher electric fields than electrons. Therefore, p-type III-V materials needed for the base of a bipolar transistor, for example, are used, but their thickness must be extremely small to avoid degradation in transit time. Lateral distances must also be small to avoid excessive series resistance. CMOS-like complementary FET technologies have also been developed,[2] but their performance has been limited by the poorer speed of the p-channel devices.

69.4 Heterojunctions

In the past, most semiconductor devices were composed of a single semiconductor element, such as silicon or gallium arsenide, and employed n- and p-type doping to control charge transport. Figure 69.2(a) illustrates an energy band diagram of a semiconductor with uniform composition that is in an applied electric field. Electrons will drift downhill and holes will drift uphill in the applied electric field. The electrons and/or holes could be produced by doping or by ionization due to light. In a *heterogeneous* semiconductor as shown in Fig. 69.2(b), the bandgap can be graded from wide bandgap on the left to narrow on the right by varying the composition. In this case, even without an applied electric field, a built-in quasi-electric field is produced by the bandgap variation that will transport both holes and electrons in the *same* direction.

The abrupt *heterojunction* formed by an atomically abrupt transition between AlGaAs and GaAs, shown in the energy band diagram of Fig. 69.3, creates discontinuities in the valence and conduction bands. The conduction band energy discontinuity is labeled ΔE_C and the valence band discontinuity, ΔE_V. Their sum equals the energy bandgap difference between the two materials. The potential energy steps caused by these discontinuities are used as barriers to electrons or holes. The relative sizes of these potential barriers depend on the composition of the semiconductor materials on each side of the heterojunction. In this example, an electron barrier in the conduction

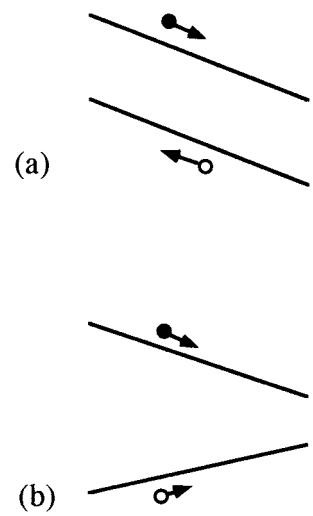

FIGURE 69.2 (a) Homogeneous semiconductor in uniform electric field, and (b) Heterogeneous semiconductor with graded energy gap. No applied electric field.

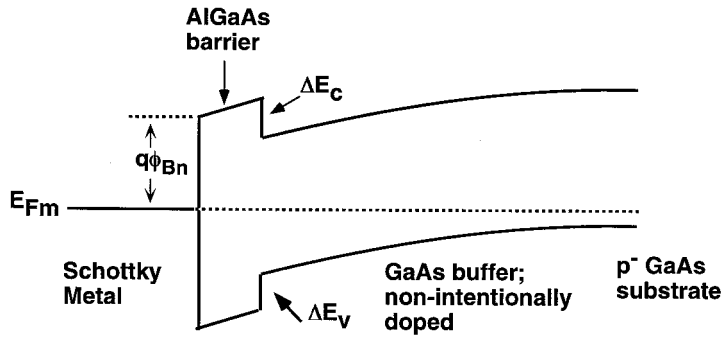

FIGURE 69.3 Energy band diagram of an abrupt heterojunction.

band is used to confine carriers into a narrow potential energy well with triangular shape. Quantum well structures such as these are used to improve device performance through two-dimensional charge transport channels, similar to the role played by the inversion layer in MOS devices. The structure and operation of heterojunctions in FETs and BJTs will be described in Chapter 70.

The overall principle of the use of heterojunctions is summarized in a *Central Design Principle*:

> "Heterostructures use energy gap variations in addition to electric fields as forces acting on holes and electrons to control their distribution and flow."[3,4]

The energy barriers can control motion of charge both across the heterojunction and in the plane of the heterojunction. In addition, heterojunctions are most widely used in light-emitting devices, since the compositional differences also lead to either stepped or graded index of refraction, which can be used to confine, refract, and reflect light. The barriers also control the transport of holes and electrons in the light-generating regions.

Figure 69.4 shows a plot of bandgap versus lattice constant for many of the III-V semiconductors.[3] Consider GaAs as an example. GaAs and AlAs have the same lattice constant (approximately 0.56 nm) but different bandgaps (1.4 and 2.2 eV, respectively). An alloy semiconductor, AlGaAs, can be grown

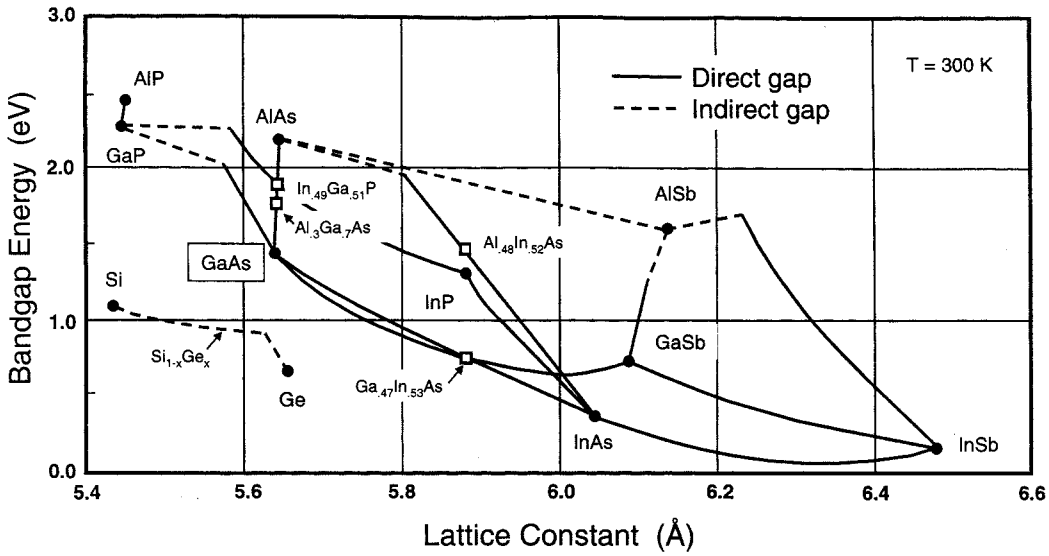

FIGURE 69.4 Energy bandgap versus lattice constant for compound semiconductor materials.

epitaxially on a GaAs substrate wafer using standard growth techniques. The composition can be selected by the Al-to-Ga ratio, giving a bandgap that can be chosen across the entire range from GaAs to AlAs. Since both lattice constants are essentially the same, very low lattice mismatch can be achieved for any composition of $Al_xGa_{1-x}As$. Lattice matching permits low defect density, high-quality materials to be grown that have good electronic and optical properties. It quickly becomes apparent from Fig. 69.4, however, that a requirement for lattice matching to the substrate greatly restricts the combinations of materials available to the device designer. For electron devices, the low mismatch GaAs/AlAs alloys, GaSb/AlSb alloys, $Al_{.48}In_{.52}As/InP/Ga_{.47}In_{.53}As$ and $GaAs/In_{.49}Ga_{.51}As$ combinations alone are available. Efforts to utilize combinations such as GaP on Si or GaAs on Ge that lattice match have been generally unsuccessful because of problems with interface structure, polarization, and autodoping.

For several years, lattice matching was considered to be a necessary condition if mobility-damaging defects were to be avoided. This barrier was later broken when it was discovered that high-quality semiconductor materials could still be obtained although lattice-mismatched if the thickness of the mismatched layer is sufficiently small.[5,6] This technique, called *pseudomorphic* growth, opened another dimension in III-V device technology, and allowed device structures to be optimized over a wider range of bandgap for better electron or hole dynamics and optical properties.

Two of the pseudomorphic systems that have been very successful in high-performance millimeter-wave FETs are the InAlAs/InGaAs/GaAs and InAlAs/InGaAs/InP systems. The $In_xGa_{1-x}As$ layer is responsible for the high electron mobility and velocity which both improve as the In concentration x is increased. Up to $x = 0.25$ for GaAs substrates and $x = 0.80$ for InP substrates have been demonstrated and result in great performance enhancements when compared with lattice-matched combinations.

Compound Semiconductor Devices for Digital Circuits

Donald B. Estreich
Hewlett-Packard Company

70.1 Introduction

An *active device* is an electron device, such as a transistor, capable of delivering power amplification by converting dc bias power into time-varying signal power. It delivers a greater energy to its load than if the device were absent. The *charge control* framework[7-9] discussed below presents a unified understanding of the operation of all electron devices and simplifies the comparison of the several active devices used in digital integrated circuits.

70.2 Unifying Principle for Active Devices: Charge Control Principle

Consider a generic electron device as represented in Fig. 70.1. It consists of three electrodes encompassing a charge *transport region*. The transport region is capable of supporting charge flow (electrons as shown in the figure) between an *emitting electrode* and a *collecting electrode*. A third electrode, called the *control electrode*, is used to establish the electron concentration within the transport region. Placing a *control charge*, Q_C, on the control electrode establishes a *controlled charge*, denoted as $-Q$, in the transport region. The operation of active devices depends on the *charge control principle*[7]:

> Each charge placed upon the control electrode can at most introduce an equal and opposite charge in the transport region between the emitting and collecting electrode.

At most, we have the relationship, $|-Q| = |Q_C|$. Any parasitic coupling of the control charge to charge on the other electrodes, or remote parts of the device, will decrease the controlled charge in the transport region, that is $|-Q| < |Q_C|$ more generally. For example, charge coupling between the control

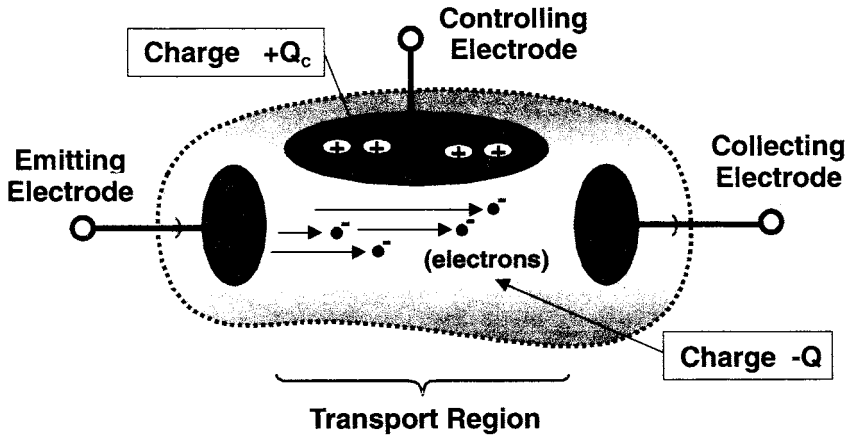

FIGURE 70.1 Generic charge control device consisting of three electrodes embedded around a charge transport region.

electrode and the collecting electrode forms a feedback or output capacitance, say $\mathbf{C_o}$. Time variation of Q_C leads to the modulation of the current flow between emitting and collecting electrodes.

The generic structure in Fig. 70.1 could represent any one of a number of active devices (e.g., vacuum tubes, unipolar transistors, bipolar transistors, photoconductors, etc.). Hence, charge control analysis is very broad in scope, since it applies to all electronic transistors.

Starting from the charge control principle, we associate two characteristic time constants with an active device, thereby leading to a first-order description of its behavior. Application of a potential difference between the emitting and collecting electrodes, say V_{CC}, establishes an electric field in the transport region. Electrons in the transport region respond to the electric field and move across this region with a *transit time* τ_r. The transit time[1] is the first of the two important characteristic times used in charge control modeling. With charge $-Q$ in the transit region, the static (dc) current I_o between emitting and collecting electrodes is

$$I_o = -Q/\tau_r = Q_c/\tau_r \tag{70.1}$$

A simple interpretation of τ_r is as follows: τ_r is equal to the length l of the transport region, divided by the average velocity of transit (i.e., $\tau_r = l/\langle v \rangle$). From this perspective, a charge of $-Q$ (coulombs) is swept out the collecting electrode every τ_r seconds.

Now consider Fig. 70.2, showing the common-emitting electrode connection of the active device of Fig. 70.1 connected to input and output (i.e., load) resistances, say R_{in} and R_L, respectively. The second characteristic time of importance can now be defined: It is the *lifetime time constant*, and we denote it by τ. It is a measure of how long a charge placed on the control electrode will remain on the control terminal. The lifetime time constant is established in one of several ways, depending on the physics of the active device and/or its connection. The controlling charge may "leak away" by (1) discharging through the external resistor R_{in} as typically happens with FET devices, (2) recombining with intermixed oppositely charged carriers within the device (e.g., base recombination in a bipolar transistor), or (3) discharging through an internal shunt leakage path within the device. The dc current flowing to replenish the lost control charge is given by

$$I_{in} = -Q/\tau = Q_c/\tau \tag{70.2}$$

The *static* (*dc*) *current gain* G_I of a device is defined as the current delivered to the output, divided by the current replenishing the control charge during the same time period. Where in τ seconds charge $-Q$

[1]The transit time τ_r is best interpreted as an average transit time per carrier (electron). We note that $1/\tau_r$ is common to all devices — it is related to a device's ultimate capability to process information.

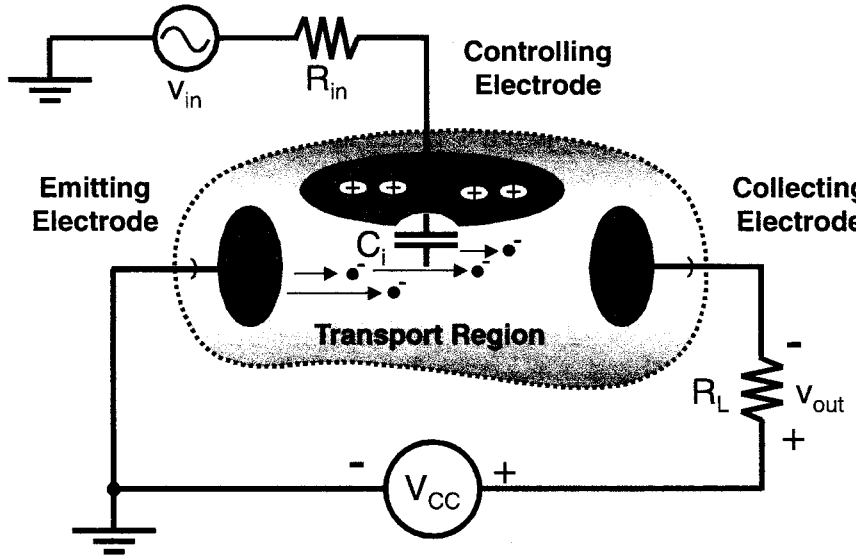

FIGURE 70.2 Generic charge control device of Fig. 70.1 connected to input and output resistors, R_{in} and R_L, respectively, with bias voltage and input signal applied.

is both lost and replenished, charge Q_c times the ratio τ/τ_r has been supplied to the output resistor R_L. In symbols, the static current gain is

$$G_I = I_o/I_{in} = \tau/\tau_r \tag{70.3}$$

provided $|-Q| = |Q_C|$ holds.

In the dynamic case, the process of *small-signal amplification* consists of an incremental variation of the control charge Q_c directly resulting in an incremental change in the controlled charge, $-Q$. The resulting variation in output current flowing in the load resistor translates into a time-varying voltage v_o. The charge control formalism holds just as well for large-signal situations. In the large-signal case, the changes in control charge are no longer small incremental changes. Charge control analysis under large charge variations is less accurate due to the simplicity of the model, but still very useful for approximate switching calculations in digital circuits.

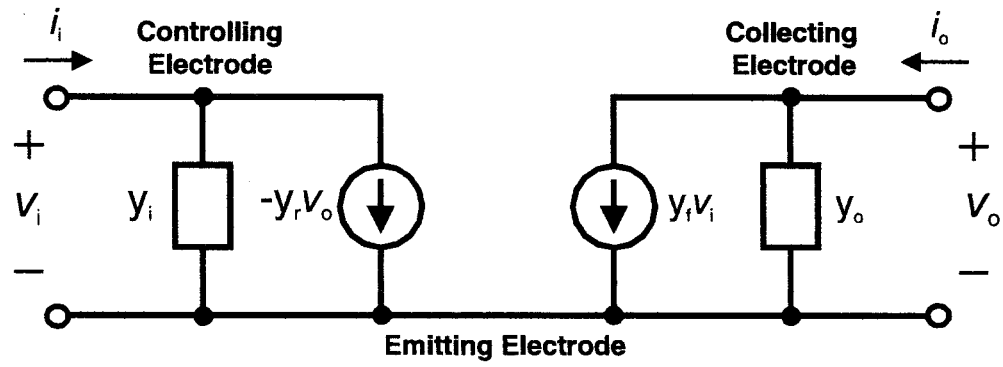
An important dynamic parameter is the *input capacitance* C_i of the active device. Capacitance C_i is a measure of the work required to introduce a charge carrier in the transport region. Capacitance C_i is given by the change in charge Q for a corresponding change in input voltage v_{in}. It is desirable to maximize C_i in an active device. The *transconductance* g_m is calculated from

$$g_m = \left(\frac{\partial I_o}{\partial v_{in}}\right)_{v_o} = \left(\frac{\partial I_o}{\partial Q}\right) \cdot \left(\frac{\partial Q}{\partial v_{in}}\right) \tag{70.4}$$

The first partial derivative on the right-hand side of Eq. 70.4 is simply $(1/\tau_r)$, and the second partial derivative is C_i. Hence, the transconductance g_m is the ratio

$$g_m = \frac{C_i}{\tau_i} \tag{70.5}$$

A physical interpretation of g_m is the ratio of the work required to introduce a charge carrier to the average transit time of a charge carrier in the transport region. The transconductance is one of the most commonly used device parameters in circuit design and analysis.



$$y_i = \frac{C_i}{\tau} \qquad y_f \cong g_m = \frac{C_i}{\tau_r}$$

$$y_r = -\frac{C_o}{\tau} \qquad y_o = \frac{C_o}{\tau_r}$$

FIGURE 70.3 Two-port, small-signal, admittance charge control model with the emitting electrode selected as the common terminal to both input and output.

In addition to C_i, another capacitance, say C_o, is introduced and associated with the collecting electrode. Capacitance C_o accounts for charge on the collecting electrode coupled to either static charge in the transport region or charge on the control electrode. A non-zero C_o indicates that the coupling between the controlling electrode and the charge in transit is less than unity (i.e., $|-Q| < |Q_C|$).

For small-signal analysis the capacitance parameters are usually taken at fixed numbers evaluated about the device's bias state. When using charge control in the large-signal case, the capacitance parameters must include the voltage dependencies. For example, the input capacitance C_i can be strongly dependent upon the control electrode to emitting electrode and collecting electrode potentials. Hence, during the change in bias state within a device, the magnitude of the capacitance C_i is time varying. This variation can dramatically affect the switching speed of the active device. Parametric dependencies on the instantaneous bias state of the device are at the heart of accurate modeling of large-signal or switching behavior of active devices.

We introduce the *small-signal admittance charge control model* shown in Fig. 70.3. This model uses the emitting electrode as the common terminal in a two-port connection. The transconductance g_m is the magnitude of the real part of the *forward admittance* y_f and is represented as a voltage-controlled current source positioned from collecting-to-emitting electrode. The *input admittance*, denoted by y_i, is equivalent to (C_i/τ), where τ is the control charge lifetime time constant. Parameter y_i can be expressed in the form $(g_i + sC_i)$ where $s = j\omega$. An *output admittance*, similarly denoted by y_o, is given by (C_o/τ_r) where τ_r is the transit time and, in general $y_o = (g_o + sC_o)$. Finally, the *output-to-input feedback admittance* y_r is included using a voltage-controlled current source at the input. Often, y_r is small enough to approximate as zero (the model is then said to be *unilateral*).

Consider the frequency dependence of the *dynamic* (*ac*) *current gain* G_i. The low-frequency current gain is interpreted as follows: an incremental charge q_c is introduced on the control electrode with lifetime τ. This produces a corresponding incremental charge –q in the transport region. Charge –q is swept across the transport region every transit time τ_r seconds. In time τ, charge –q crosses the transit region τ/τ_r times, which is identically equal to the low-frequency current gain.

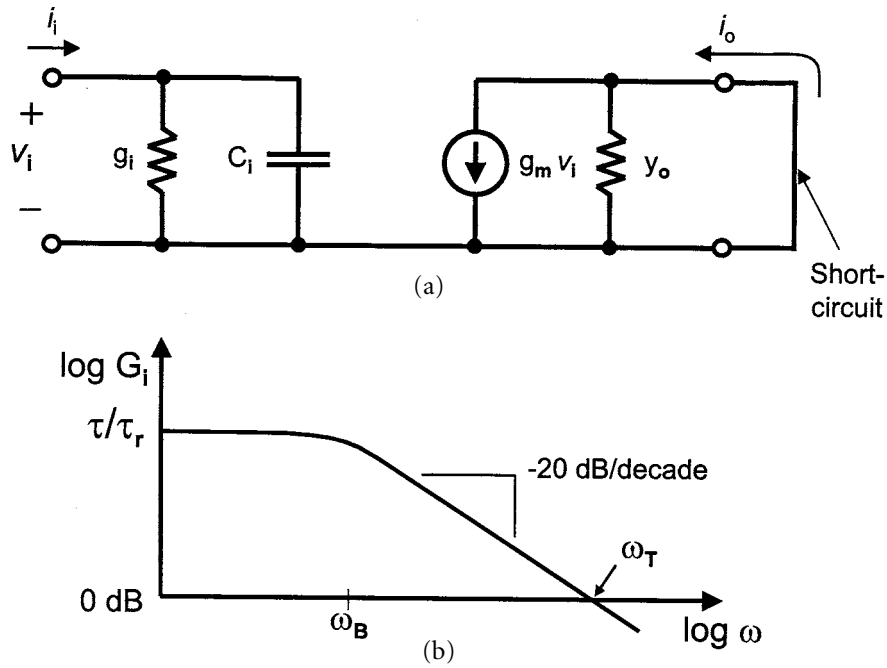


FIGURE 70.4 (a) Small-signal admittance model with output short-circuited, and (b) magnitude of the small-signal current gain G_i plotted as a function of frequency. The unity current gain crossover (i.e., $G_i = 1$) defines the parameter f_T (or ω_T).

The lifetime τ associated with the control electrode arises from charge "leaking off" the controlling electrode. This is modeled as an RC time constant at the input of the equivalent circuit shown in Fig. 70.4(a) with τ equal to $R_{eq}C_i$. R_{eq} is the equivalent resistance presented to capacitor C_i. That is, R_{eq} is determined by the parallel combination of $1/g_i$ and any external resistance at the input. The *break frequency* ω_B associated with the control electrode is

$$\omega_B = \frac{1}{\tau} = \frac{1}{R_{eq}C_i} \tag{70.6}$$

When the charge on the control electrode varies at a rate ω less than ω_B, G_i is given by τ/τ_r because charge "leaks off" the controlling electrode faster than $1/\omega$. Alternatively, when ω is greater than ω_B, G_i decreases with increasing ω because the applied signal charge varies upon the control electrode more rapidly than $1/\tau$. In this case, G_i is inversely proportional to ω, that is,

$$G_i = \frac{1}{\omega\tau_r} = \frac{\omega_T}{\omega} \tag{70.7}$$

where ω_T is the common-emitter *unity current gain frequency.* At $\omega = \omega_T$ ($= 2\pi f_T$), the ac current gain equals unity, as illustrated in Fig. 70.4(b).

Consider the *current gain-bandwidth product* $G_i\Delta f$. A purely capacitive input impedance cannot define a bandwidth. However, a finite real impedance always appears at the input terminal in any practical application. Let R_i be the *effective input resistance* of the device (i.e., R_i will be equal to $(1/g_i)$ in parallel with the external resistance R_{in}). Since the input current is equal to q_c/τ and the output current is equal to q/τ_r, the current gain-bandwidth product becomes

$$G_i \cdot \Delta f = \frac{q/\tau_r}{q_c/\tau} \frac{\omega}{2\pi} \tag{70.8}$$

For $\omega \gg \omega_B$, at $\tau = 1/\omega$, and assuming $|q_c| = |-q|$,

$$G_i \cdot \Delta f = \frac{1}{2\pi\tau_r} = \frac{\omega_T}{2\pi} = f_T \tag{70.9}$$

f_T (or ω_T) is a widely quoted parameter used to compare or "benchmark" active devices. Sometimes, f_T (or ω_T) is interpreted as a measure of the maximum speed a device can drive a replica of itself. It is easy to compute and historically has been easy to measure with bridges and later using S-parameters. However, f_T does have interpretative limitations because it is defined as current into a short-circuit output. Hence, it ignores input resistance and output capacitance effects upon actual circuit performance.

Likewise, voltage and power gain expressions can be derived. It is necessary to define the output impedance before either can be quantified. Let R_o be the *effective output resistance* at the output terminal of the active device. Assuming both the input and output RC time constants to be identical (i.e., $R_iC_i = R_oC_o$), the *voltage gain* G_v can be expressed in terms of G_i as

$$G_v = G_i \frac{R_o}{R_i} = G_i \frac{C_i}{C_o} \tag{70.10}$$

where R_o is the parallel equivalent output resistance from all resistances at the output node.

The *power gain* G_p is computed from the product of $G_i \cdot G_v$ along with the *power gain-bandwidth product*. These results are listed in Table 70.1 as summarized from Johnson and Rose.[7] These simple expressions are valid for all devices as interpreted from the charge control perspective. They provide for a first-order comparison, in terms of a few simple parameters, among the active devices commonly

TABLE 70.1 Charge Control Relations for All Active Devices

Parameter	Symbol	Expression
Transconductance	g_m	$\frac{C_i}{\tau_r} \Leftrightarrow \omega_T C_i$
Current amplification	G_i	$\frac{1}{\omega\tau_r} \Leftrightarrow \frac{\omega_T}{\omega}$
Voltage amplification	G_v	$\frac{1}{\omega\tau_r}\frac{C_i}{C_o} \Leftrightarrow \frac{\omega_T}{\omega}\frac{C_i}{C_o}$
Power amplification	$G_p = G_iG_v$	$\frac{1}{\omega^2\tau_r^2}\frac{C_i}{C_o} \Leftrightarrow \frac{\omega_T^2}{\omega^2}\frac{C_i}{C_o}$
Current gain-bandwidth product	$G_i \cdot \Delta f$	$\frac{1}{\tau_r} \Leftrightarrow \omega_T$
Voltage gain-bandwidth product	$G_v \cdot \Delta f$	$\frac{1}{\tau_r}\frac{C_i}{C_o} \Leftrightarrow \omega_T\frac{C_i}{C_o}$
Power gain-bandwidth product	$G_p \cdot \Delta f^2$	$\frac{1}{\tau_r^2}\frac{C_i}{C_o} \Leftrightarrow \omega_T^2\frac{C_i}{C_o}$

Note: Table assumes $R_iC_i = R_oC_o$. (After Johnson and Rose (Ref. 7), March 1959. © 1959 IEEE, reproduced with permission of IEEE.)

available. From an examination of Table 70.1, it is evident that maximizing C_i and minimizing τ_r leads to higher transconductance, higher parametric gains, and greater frequency response. This is an important observation in understanding how to improve upon the performance of any active device.

Whereas f_T has limitations, the frequency at which the maximum power gain extrapolates to unity, denoted by ω_{max}, is often a more useful indicator of device performance. The primary limitation of ω_{max} is that it is very difficult to calculate and is usually extrapolated from S-parameter measurements in which the extrapolation is approximate at best.

70.3 Comparing Unipolar and Bipolar Transistors

Unipolar transistors are active devices that operate using only a single charge carrier type, usually electrons, in their transport region. *Field-effect transistors* fall into the unipolar classification. In contrast, *bipolar transistors* depend on positive and negative charged carriers (i.e., both majority and minority carriers) within the transport region. A fundamental difference arises from the relative locations of the control electrode and transport region — in unipolar devices, they are physically separated, whereas in bipolar devices, they are merged into the same physical region (i.e., base region). Before reviewing the physical operation of each, transport in semiconductors is briefly reviewed.

Charge Transport in Semiconductors[10-12]

Bulk semiconducting materials are useful because their conductivity can be controlled over many orders of magnitude by changing the doping level. Both electrons and holes[10] can conduct current in semiconductors. In integrated circuits metal, semiconductor, and insulator layers are used together in precisely positioned shapes and thicknesses to form useful device and circuit functions.

Fig. 69.1 illustrates the behavior of electron velocity as a function of local electric field strength for several important semiconducting materials. Two characteristic regions of behavior can be identified: a *linear* or *ohmic* region at low electric fields, and a *velocity-saturated* region at high fields. At low fields, current transport is proportional to the carrier's mobility. Mobility is a measure of how easily carriers move through a material.[10] At high fields, carriers saturate in velocity; hence, current levels will correspondingly saturate in active devices. The data in Fig. 69.1 assumes low doping levels (i.e., $N_x < 10^{15}$ cm^{-3}). The dashed curve represents transport in a GaAs quantum well formed adjacent an $Al_{0.3}Ga_{0.7}As$ layer — in this case, *interface scattering* lowers the mobility. A similar situation is found for transport in silicon at a semiconductor–oxide interface such as found in metal-oxide-semiconductor (MOS) devices.

Several general conclusions can be extracted from this data:

1. Compound semiconductors generally have higher electron mobilities than silicon.
2. At high fields (say E > 20,000 V/cm), saturated electron velocities tend to converge to values close to 1×10^7 cm/s.
3. Many compound semiconductors show a transition region between low and high electric field strengths with a *negative differential mobility* due to electron transfer from the Γ ($\mathbf{k} = 0$) valley to conduction band valleys with higher effective masses (this gives rise to the *Gunn Effect*[13]).

Hole mobilities are much lower than electron mobilities in all semiconductors. Saturated velocities of holes are also lower at higher electric fields. This is why n-channel field-effect transistors have higher performance than p-channel field-effect transistors, and why npn bipolar transistors have higher performance than pnp bipolar transistors. Table 69.2 compares electron and hole mobilities for several semiconducting materials.

Field-Effect (Unipolar) Transistor[14-16]

Fig. 70.5(a) shows a conceptual view of an n-channel field-effect transistor (FET). As shown, the n-type channel is a homogeneous semiconducting material of thickness b, with electrons supporting the drain-to-source current. A p-type channel would rely on mobile holes for current transport and all voltage polarities would be exactly reversed from those shown in Fig. 70.5(a). The control charge on the gate

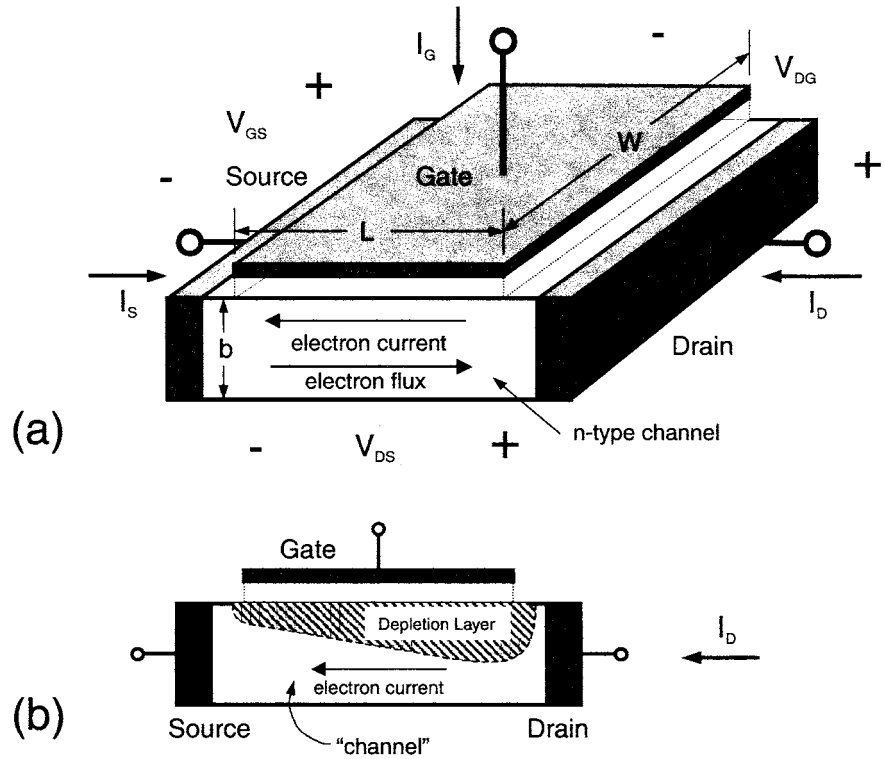

FIGURE 70.5 (a) Conceptual view of a field-effect transistor with the channel sandwiched between source and drain ohmic contacts and a gate control electrode in close proximity; and (b) cross-sectional view of the FET with a depletion layer shown such as would be present in a compound semiconductor MESFET.

region (of length L and width W) establishes the number of conduction electrons per unit area in the channel by electrostatic attraction or exclusion. The cross-section on the FET channel in Fig. 70.5(b) shows a *depletion layer*, a region void of electrons, as an intermediary agent between the control charge and the controlled charge. This depletion region is present in *junction* FET and *Schottky barrier junction* (i.e., *metal-semiconductor junction*) MESFET structures.

In all FET structures, the gate is physically separated from the channel. By physically separating the control charge from the controlled charge, the gate-to-channel impedance can be very large at low frequencies. The gate impedance is predominantly capacitive and, typically, very low gate leakage currents are observed in high-quality FETs. This is a distinguishing feature of the FET — its high input impedance is desirable for many circuit applications.

The channel, positioned between the source and drain ohmic contacts, forms a resistor whose resistance is modulated by the applied gate-to-channel voltage. We know the gate potential controls the channel charge by the charge control relation. Time variation of the gate potential translates into a corresponding time variation of the drain current (and the source current also). Therefore, transconductance g_m is the natural parameter to describe the FET from this viewpoint.

Fig. 70.6(a) shows the I_D-V_{DS} characteristic of the n-channel FET in the common-source connection with constant electron mobility and a long channel assumed. Two distinct operating regions appear in Fig. 70.6(a) — the *linear* (i.e., *non-saturated*) region, and the *saturated* region, separated by the dashed parabola. The origin of current saturation corresponds to the onset of *channel pinch-off* due to carrier exclusion at the drain end of the channel. Pinch-off occurs when the drain voltage is positive enough to deplete the channel completely of electrons at the drain end; this corresponds to a gate-to-source voltage equal to the *pinch-off voltage*, denoted as $-V_p$ in Figs. 70.6(b) and (c). For constant V_{DS} in the saturated region, the I_D vs. V_{GS} *transfer curve* approximates "square law" behavior; that is,

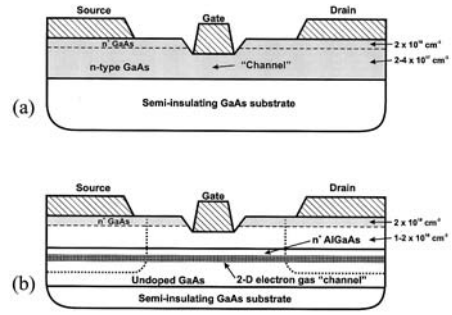

FIGURE 70.6 (a) Field-effect transistor drain current (I_D) versus drain-to-source voltage (V_{DS}) characteristic with the gate-to-source voltage (V_{GS}) as a stepped parameter; (b) I_D versus V_{GS} "transfer curve" for a constant V_{DS} in the saturated region of operation, revealing its "square-law" behavior; (c) transconductance g_m versus V_{GS} for a constant V_{DS} in saturated region of operation corresponding to the transfer curve in (b). These curves assume constant mobility, no velocity saturation, and the "long-channel FET approximation."

$$I_D = I_{D,sat} = I_{DSS}\left[1 - \frac{V_{GS}}{\left(-V_P\right)}\right]^2 \quad \text{for } -V_P \le V_{GS} \le \varphi \tag{70.11}$$

where I_{DSS} is the drain current when $V_{GS} = 0$, and φ is a built-in potential associated with the gate-to-channel junction or interface (e.g., a metal-semiconductor Schottky barrier as in the MESFET). The symbol $I_{D,sat}$ denotes the drain current in the saturated region of operation. Transconductance g_m is linear with V_{GS} for the saturation transfer characteristic of Eq. (70.11) and is approximated by

$$g_m = \frac{\partial I_D}{\partial V_{GS}} \cong 2\frac{D_{DSS}}{V_P}\left[1 - \frac{V_{GS}}{\left(-V_P\right)}\right] \quad \text{for } -V_P \le V_{GS} \le \varphi \tag{70.12}$$

Equations 70.11 and 70.12 are plotted in Figs. 70.6(b) and (c), respectively.

Bipolar Junction Transistors (Homojunction and Heterojunction)[13-17]

In the *bipolar junction transistor* (BJT), both the control charge and the controlled charge occupy the same region (i.e., the *base region*). A control charge is injected into the base region (i.e., this is the base current flowing in the base terminal), causing the emitter-to-base junction's potential barrier to be lowered. Barrier lowering results in majority carrier diffusion across the emitter-to-base junction. Electrons diffuse into the base and holes into the emitter in the npn BJT shown in Fig. 70.7. By controlling the emitter-to-base junction's physical structure, the dominant carrier diffusion across this n-p junction should be injection into the base region. For our npn transistor, the dominant carrier transport is electron diffusion into the base region where the electrons are minority carriers. They transit the base region, of base width W_b, by both diffusion and drift. When collected at the collector-to-base junction, they establish the collector current I_C. The base width must be short to minimize recombination in the base region (this is reflected in the current gain parameter commonly used with BJT and HBT devices).

In *homojunction* BJT devices, the emitter and base regions have the same bandgap energy. The respective carrier injection levels are set by the ratio of the emitter-to-base doping levels. For high emitter efficiency, that is, the number of carriers diffusing into the base being much greater than the number of carriers simultaneously diffusing into the emitter, the emitter must be much more heavily doped than the base region. This places a limit on the maximum doping level allowed in the base of the homojunction

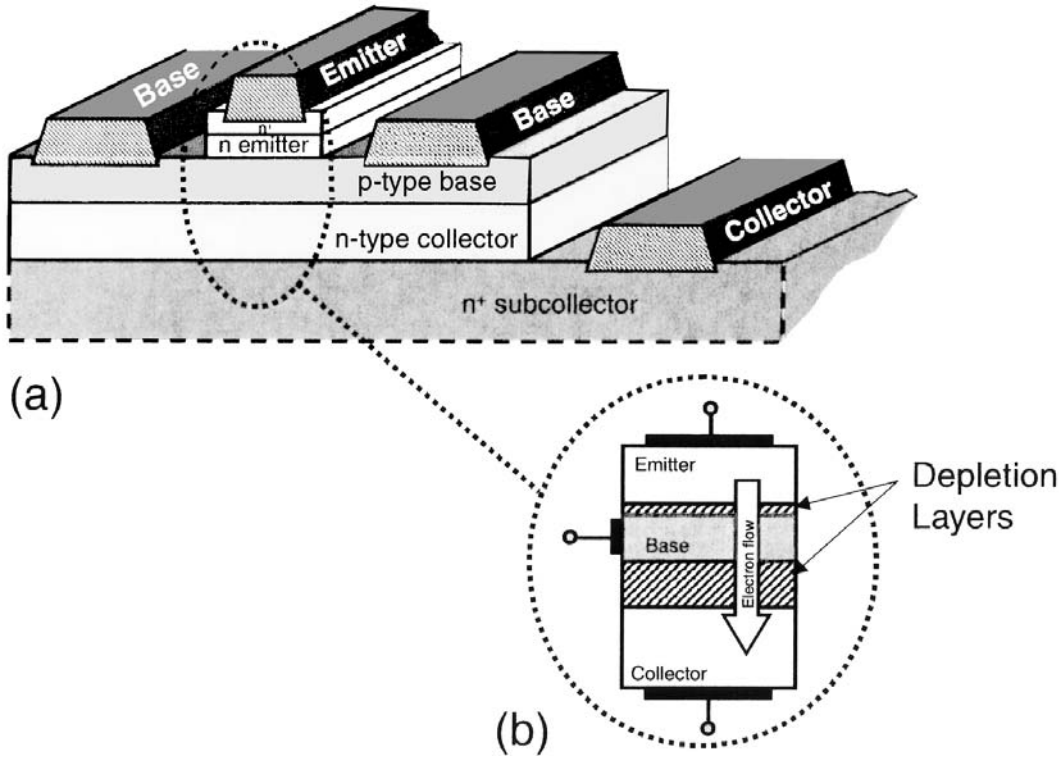

FIGURE 70.7 (a) Conceptual view of a bipolar junction transistor with the base region sandwiched between emitter and collector regions. Structure is representative of a compound semiconductor heterojunction bipolar transistor. (b) Simplified cross-sectional view of a vertically structured BJT device with primary electron flow represented by large arrow.

BJT, thereby leading to higher base resistance than the device designer would normally desire.[16] In contrast, the *heterojunction bipolar transistor* (HBT) uses different semiconducting materials in the base and emitter regions to achieve high emitter efficiency. A wider bandgap emitter material allows for high emitter efficiency while allowing for higher base doping levels which in turn lowers the parasitic base resistance. An example of a wider bandgap emitter transistor is shown in Fig. 70.8. In this example, the emitter is AlGaAs whereas the base and collector are formed with GaAs. Figure 70.8 shows the band diagram under normal operation with the emitter–base junction forward-biased and the collector–base junction reverse-biased. The discontinuity in the valence band edge at the emitter–base heterojunction is the origin of the reduced diffusion into the emitter region. The injection ratio determining the emitter efficiency depends exponentially on this discontinuity. If ΔE_g is the valence band discontinuity, the injection ratio is proportional to the exponential of ΔE_g normalized to the thermal energy kT[4]:

$$\frac{J_n}{J_p} \propto \exp\left(-\Delta E_g / kT\right) \tag{70.13}$$

For example, ΔE_g equal to 8kT gives an exponential factor of approximately 8000, thereby leading to an emitter efficiency of nearly unity, as desired. The use of the emitter-base band discontinuity is a very efficient way to hold high emitter efficiencies.

In bipolar devices, the collector current I_C is given by the exponential of the *base-emitter forward voltage* V_{BE} normalized to the *thermal voltage* kT/q

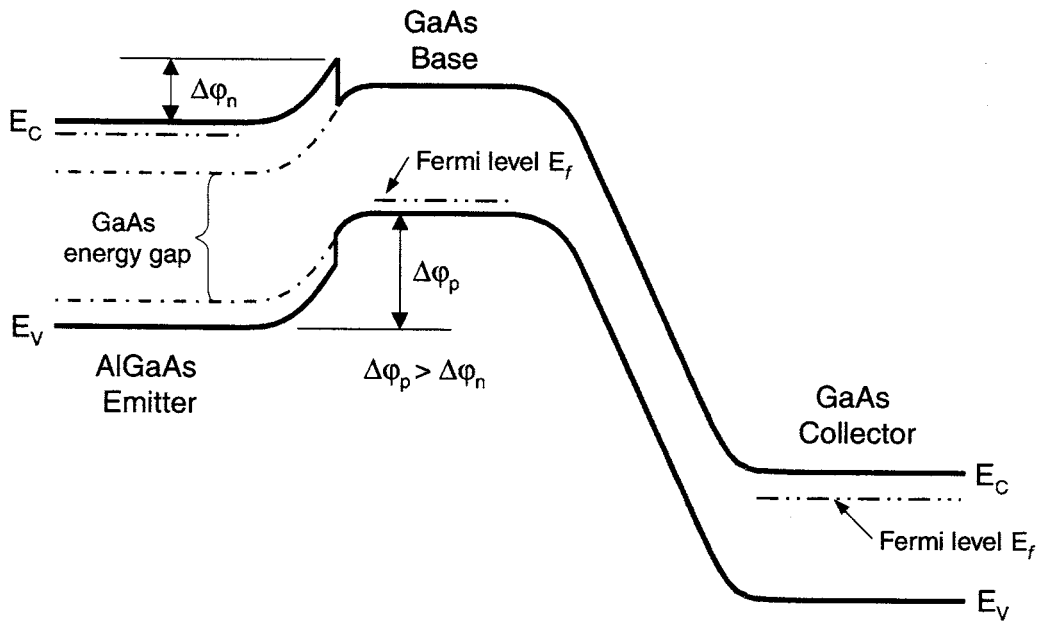

FIGURE 70.8 The bandgap diagram for an HBT AlGaAs/GaAs device with the wider bandgap for the AlGaAs emitter (solid line) compared with a homojunction GaAs BJT emitter (dot-dash line). The double dot-dashed line represents the Fermi level in each region.

$$I_C = I_S \exp\left(qV_{BE}/kT\right) \tag{70.14}$$

The saturation current I_S is given by a quantity that depends on the structure of the device; it is inversely proportional to the base doping charge Q_{BASE} and proportional to the device's area A, namely

$$I_S = \frac{qADn_i^2}{Q_{BASE}} \tag{70.15}$$

where the other symbols have their usual meanings (D is the minority carrier *diffusion constant* in the base, n_i is the *intrinsic carrier concentration* of the semiconductor, and q is the *electron's charge*).

A typical collector current versus collector-emitter voltage characteristic, for several increasing values of (forward-biased) emitter-base voltages, is shown in Fig. 70.9(a). Note the similarity to Fig. 70.6(a), with the BJT having a quicker turn-on for low V_{CE} values compared with the softer knee for the FET. The transconductance of the BJT and HBT is found by taking the derivative of Eq. 70.14, thus

$$g_m = \frac{\partial I_C}{\partial V_{BE}} = \frac{qI_S}{kT}\exp\left(qV_{BE}/kT\right) \tag{70.16}$$

Both I_C and g_m are of exponential form, as observed in Fig. 70.9; Eqs. 70.14 and 70.16 are plotted in Figs. 70.9(b) and (c), respectively. The transconductance of the BJT/HBT is generally much larger than that of the best FET devices (this can be verified by comparing Eq. (70.12) with Eq. (70.16) with typical parameter values inserted). This has significant circuit design advantages for the BJT/HBT devices over the FET devices because high transconductance is needed for high current drive to charge load capacitance

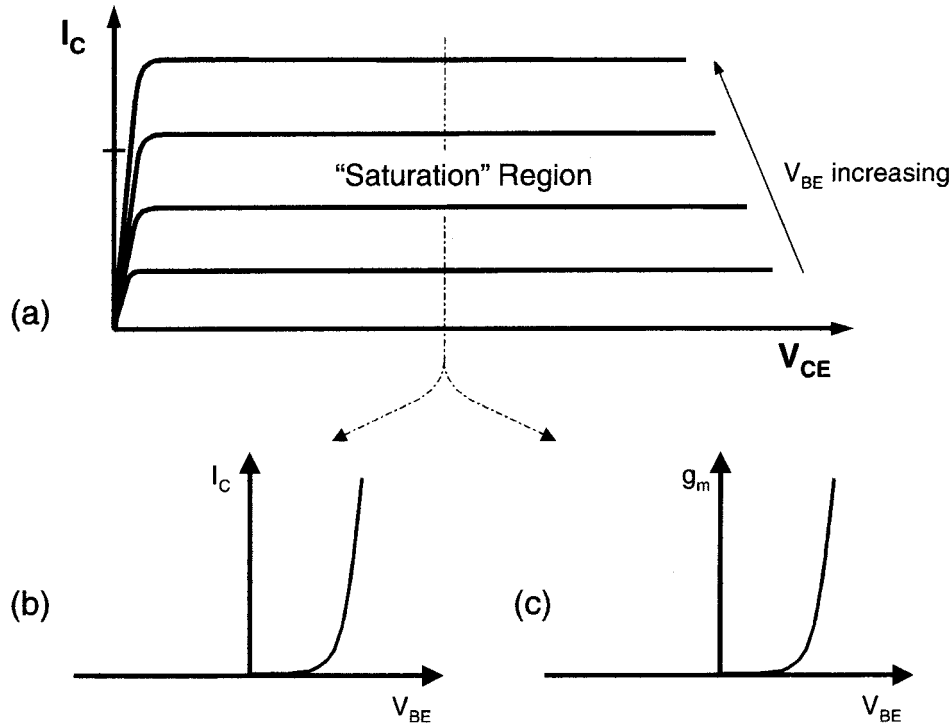

FIGURE 70.9 (a) Collector current (I_C) versus collector-to-emitter voltage (V_{CE}) characteristic curves with the base-to-emitter voltage (V_{BE}) as stepped parameter; (b) I_C versus V_{BE} "transfer curve" for a constant V_{CE} in saturated region of operation shows exponential behavior; and (c) transconductance g_m versus V_{BE} for a constant V_{CE} in the saturated region of operation corresponding to the transfer curve in (b).

in digital circuits. In general, higher g_m values allow a designer to use feedback to a greater extent in design and this provides for greater tolerance to process variations.

Comparing Parameters

Table 70.2 compares some of the more important features and parameters of the BJT/HBT device with the FET device. For reference, a common-source FET configuration is compared with a common-emitter BJT/HBT configuration. One of the most striking differences is the input impedance parameter. A FET has a high input impedance at low to mid-range frequencies because it essentially is a capacitor. As the frequency increases, the magnitude of the input impedance decreases as $1/\omega$ because a capacitive reactance varies as $|C_{gs}/\omega|$. The BJT/HBT emitter-base is a forward-biased pn junction, which is inherently a low impedance structure because of the lowered potential barrier to carriers. The BJT/HBT input is also capacitive (i.e., a large diffusion capacitance due to stored charge), but a large conductance (or small resistance) appears in parallel assuring a low input impedance even at low frequencies.

BJT/HBT devices are known for their higher transconductance g_m, which is proportional to collector current. An FET's g_m is proportional to the saturated velocity v_{sat} and its input capacitance C_{gs}. Thus, device structure and material parameters set the performance of the FET whereas thermodynamics play the key role in establishing the magnitude of g_m in a BJT/HBT.

Thermodynamics also establishes the magnitude of the *turn-on voltage* (this follows simply from Eq. 70.14) in the BJT/HBT device. For digital circuits, turn-on voltage (or *threshold voltage*) is important in terms of repeatability and consistency for circuit robustness. The BJT/HBT is clearly superior to the FET in this regard because doping concentration and physical structure establish an FET's turn-on voltage. In general, these variables are less controllable. However, the forward turn-on voltage in the AlGaAs/GaAs

TABLE 70.2 Comparing Electrical Parameters for BJT/HBT vs. FET

Parameter	BJT/HBT	FET
Input impedance Z	Low Z due to forward-biased junction; large diffusion capacitance C_{be}	High Z due to reverse biased junction or insulator; small depletion layer capacitance C_{gs}
Turn-on Voltage	Forward voltage V_{BE} highly repeatable; set by thermodynamics	Pinch-off voltage V_P not very repeatable; set by device design
Transconductance	High g_m [$= I_C/(kT/q)$]	Low g_m [$\cong v_{sat}C_{gs}$]
Current gain	β (or h_{FE}) = 50 to 150; β is important due to low input impedance	Not meaningful at low frequencies and falls as $1/\omega$ at high frequencies
Unity current gain cutoff frequency f_T	$f_T = g_m/2\pi C_{BE}$ is usually lower than for FETs	$f_T = g_m/2\pi C_{gs}$ ($= v_{sat}/2\pi L_g$) higher for FETs
Maximum frequency of oscillation f_{max}	$f_{max} = [f_T/(8\pi r_b C_{bc}]^{1/2}$	$f_{max} = f_T [r_{ds}/R_{in}]^{1/2}$
Feedback capacitance	C_{bc} large because of large collector junction	Usually C_{gd} is much smaller than C_{bc}
1/*f* Noise	Low in BJT/HBT	Very high 1/*f* noise corner frequency
Thermal behavior	Thermal runaway and second breakdown	No thermal runaway
Other		Backgating is problem in semi-insulating substrates

HBT is higher (~1.4 V) because of the band discontinuity at the emitter–base heterojunction. For InP-based HBTs, the forward turn-on voltage is lower (~0.8 V) than that of the AlGaAs/GaAs HBT and comparable to the approximate 0.7 V found in silicon BJTs. This is important in digital circuits because reducing the signal swing allows for faster circuit speed and lowers power dissipation by allowing for reduced power supply voltages.

For BJT/HBT devices, *current gain* (often given the symbol of β or h_{FE}) is a meaningful and important parameter. Good BJT devices inject little current into the emitter and, hence, operate with low base current levels. The current gain is defined as the collector current divided by the base current and is therefore a measure of the quality of the device (i.e., traps and defects, both surface and bulk, degrade the current gain due to higher recombination currents). At low to mid-range frequencies, current gain is not especially meaningful for the high input impedance FET device because of the capacitive input.

The intrinsic gain of an HBT is higher because of its higher *Early voltage* V_A. The Early voltage is a measure of the intrinsic output conductance of a device. In the HBT, the change in the collector voltage has very little effect on the modulation of the collector current. This is true because the band discontinuity dominates the establishment of the current collected at the collector–base junction. A figure of merit is the *intrinsic voltage gain* of an active device, given by the product $g_m V_A$, and the HBT has the highest values compared to silicon BJTs and compound semiconductor FETs.

It is important to have a dynamic figure of merit or parameter to assess the usefulness of an active device for high-speed operation. Both the unity current gain cutoff frequency f_T and maximum frequency of oscillation f_{max} have been discussed in the charge control section above. Both of these figures of merit are used because they are simple and can generally be correlated to circuit speed. The higher the value of both parameters, the better the high-speed circuit performance. This is not the whole story because in digital circuits other factors such as output node-to-substrate capacitance, external load capacitances, and interconnect resistance also play an important role in determining the speed of a circuit.

Generally, 1/*f* noise is much higher in FET devices than in the BJT/HBT devices. This is usually of more importance in analog applications and oscillators however. Thermal behavior in high-speed devices is important as designers push circuit performance. Bipolar devices are more susceptible to thermal runaway than FETs because of the positive feedback associated with a forward-biased junction (i.e., a smaller forward voltage is required to maintain the same current at higher temperatures). This is not true in the FET; in fact, FETs generally have negative feedback under common biases used in digital circuits. Both GaAs and InP have poorer thermal conductivity than silicon, with GaAs being about one-third of silicon and InP being about one-half of silicon.

Finally, circuits built on GaAs or InP semi-insulating substrates are susceptible to *backgating*. Backgating is similar to the backgate-bias effects in MOS transistors, only it is not as predictable or repeatable as the well-known *backgate-bias effect* is in silicon MOSFETs on silicon lightly doped substrates. Interconnect traces with negatively applied voltages and located adjacent to devices can change their threshold voltage (or turn-on voltage). It turns out that HBT devices do not suffer from backgating, and this is one of their advantages. Of course, semi-insulating substrates are nearly ideal for microstrip transmission lines on top of the substrates because of their very low loss. Silicon substrates are much more lossy in comparison and this is a decided advantage in GaAs and InP substrates.

70.4 Typical Device Structures

In this section, a few typical device structures are described. We begin with FET structures and then follow with HBT structures. There are many variants on these devices and the reader is referred to the literature for more information.[15,16,19-22]

FET Structures

In the silicon VLSI world, the MOSFET (*metal-oxide-semiconductor field-effect transistor*) dominates. This device forms a channel at the oxide–semiconductor interface upon applying a voltage to the gate to attract carriers to this interface.[23] The thin layer of mobile carriers forms a two-dimensional sheet of carriers. One of the limitations with the MOSFET is that the oxide–semiconductor interface scatters the carriers in the channel and degrades the performance of the MOSFET. This is evident in Fig. 69.1 where the lower electron velocity at the Si-SiO_2 interface is compared with electron velocities in compound semiconductors. For many years, device physicists have looked for device structures and materials which increase electron velocity. FET structures using compound semiconductors have led to much faster devices such as the MESFET and the HEMT.

The MESFET (*metal-semiconductor FET*) uses a thin doped channel (almost always n-type because electrons are much more mobile in semiconductors) with a reverse-biased Schottky barrier for the gate control.[15] The cross-section of a typical MESFET is shown in Fig. 70.10(a). A recessed gate is used along with a highly doped n^+ layer at the surface to reduce the series resistance at both the source and drain connections. The gate length and electron velocity in the channel dominate in determining the high-speed performance of a MESFET. Much work has gone into developing processes that form shorter gate structures. For digital devices, lower breakdown voltages are permissible, and therefore shorter gate lengths and higher channel doping is more compatible with such devices. For a given semiconductor material, a device's breakdown voltage BV_{GD} times its unity current gain cutoff frequency f_T is a constant. Therefore, it is possible to tradeoff BV_{GD} for f_T in device design. A high f_T is required in high-speed digital circuits because devices with a high f_T over their logic swing will have a high g_m/C ratio for large-signal operation. A high g_m/C ratio translates into a device's ability to drive load capacitances.

It is also desirable to maximize the charge in the channel per unit gate area. This allows for higher currents per unit gate width and greater ability to drive large capacitive loads. The higher current per unit gate width also favors greater IC layout density. In the MESFET, the doping level of the channel sets this limit. MESFET channels are usually ion-implanted and the added lattice damage further reduces the electron mobility.

To achieve still higher currents per gate width and even higher figures of merit (such as f_T and f_{max}), the HEMT (*high electron mobility transistor*) structure has evolved.[16,22] The HEMT is similar to the MESFET except that the doped channel is replaced with a *two-dimensional quantum well* containing electrons (sometimes referred to as a *2-D electron gas*). The quantum well is formed by a discontinuity in conduction band edges between two different semiconductors (such as AlGaAs and GaAs in Fig. 69.3). From Fig. 69.4 we see that GaAs and $Al_{0.3}Ga_{0.7}As$ have nearly identical lattice constants but with somewhat different bandgaps. One compound semiconductor can be grown (i.e., using *molecular beam epitaxy* or *metalo-organic chemical vapor deposition* techniques) on a different compound semiconductor if the

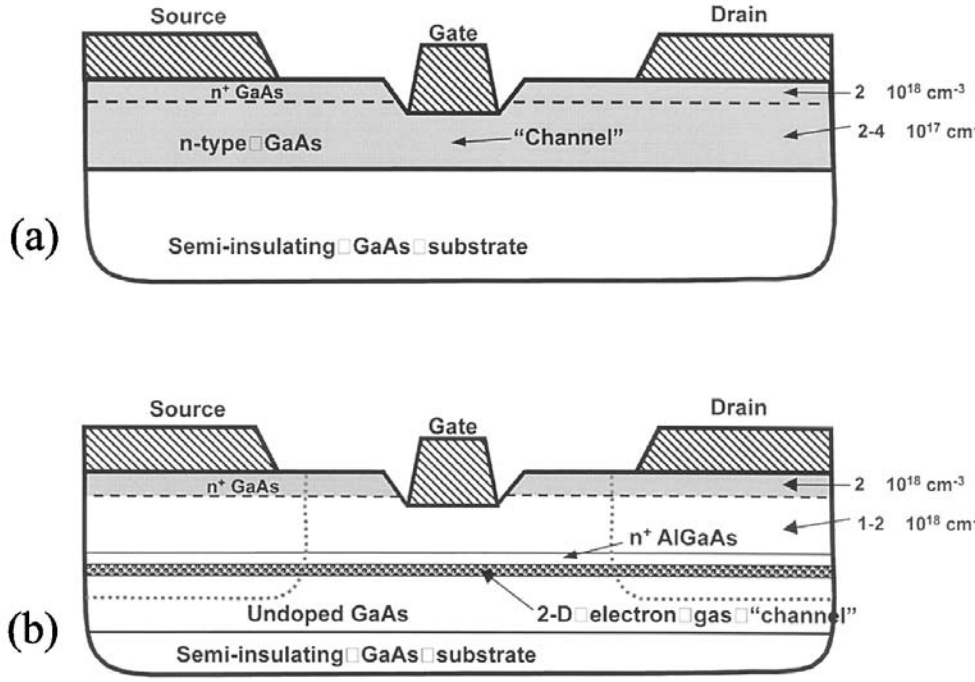

FIGURE 70.10 Typical FET cross-sections for (a) GaAs MESFET device with doped channel, and (b) AlGaAs/GaAs HEMT device with single quantum well containing and two-dimensional electron gas.

lattice constants are identical. Another example is $Ga_{0.47}In_{0.53}As$ and InP, where they are lattice matched. The difference in conduction band edge alignment leads to the formation of a quantum well. The greater the edge misalignment, the deeper the quantum well can be, and generally the greater the number of carriers the quantum well can hold. The charge per unit area that a quantum well can hold directly translates into greater current per unit gate width. Thus, the information in Fig. 69.4 can be used to *bandgap engineer* different materials that can be combined in lattice matched layers.

A major advantage of the quantum well comes from being able to use semiconductors that have higher electron velocity and mobility than the substrate material (e.g., GaAs) and also avoid charge impurity scattering in the quantum well by locating the donor atoms outside the quantum well itself. Figure 70.10(b) shows a HEMT cross-section where the dopant atoms are positioned in the wider bandgap AlGaAs layer. When these donors ionize, electrons spill into the quantum well because of its lower energy. Higher electron mobility is possible because the ionized donors are not located in the quantum well layer. A recessed gate is placed over the quantum well, usually on a semiconductor layer such as the AlGaAs layer in Fig. 70.10(b), allowing modulation of the charge in the quantum well.

There are only a few lattice-matched structures possible. However, semiconductor layers for which the lattice constants are not matched are possible if the layers are thin enough (of the order of a few nanometers). Molecular beam epitaxy and MOCVD make it possible to grow layers of a few atomic layers. Such structures are called *pseudomorphic HEMT* (PHEMT) devices.[16,22] This gives more flexibility in selecting quantum well layers which hold greater charge and have higher electron velocities and mobilities. The highest performance levels are achieved with pseudomorphic HEMT devices.

FET Performance

All currently used FET structures are n-channel because hole velocities are very low compared with electron velocities. Typical gate lengths range from 0.5 microns down to about 0.1 microns for the fastest devices. The most critical fabrication step in producing these structures is the gate recess width and depth.

The GaAs MESFET (ca. 1968) was the first compound semiconductor FET structure and is still used today because of its simplicity and low cost of manufacture. GaAs MESFET devices have f_T values in the 20 GHz to 50 GHz range corresponding to gate lengths of 0.5 microns down to 0.2 microns, and g_m values of the order of 200 to 400 mS/mm, respectively. These devices will typically have I_{DSS} values of 200 to 400 mA/mm, where parameter I_{DSS} is the common-source, drain current with zero gate voltage applied in a saturated state of operation.

In comparison, the first HEMT used an AlGaAs/GaAs material structure. These devices are higher performance than the GaAs MESFET (e.g., given an identical gate length, the AlGaAs/GaAs HEMT has an f_T about 50% to 100% higher, depending on the details of the device structure and quality of material). Correspondingly higher currents are achieved in the AlGaAs/GaAs HEMT devices.

Higher performance still is achieved using InP based HEMTs. For example, the $In_{0.53}Ga_{0.47}As/In_{0.52}Al_{0.48}As$ on InP lattice-matched HEMT have reported f_T numbers greater than 250 GHz with gate lengths of the order of 0.1 microns. Furthermore, such devices have I_{DSS} values approaching 1000 mA/mm and very high transconductances of greater than 1500 mS/mm.[22,24] These devices do have low breakdown voltages of the order of 1 or 2 V because of the small bandgap of InGaAs. Changing the stoichiometric ratios to $In_{0.15}Ga_{0.85}As/In_{0.70}Al_{0.30}As$ on a GaAs substrate produces a pseudomorphic HEMT structure. The $In_{0.15}Ga_{0.85}As$ is a strained layer when grown on GaAs. The use of strained layers gives the device designer more flexibility in accessing a wider variety of quantum wells depths and electronic properties.

Heterojunction Bipolar Structures

Practical heterojunction bipolar transistors (HBT) devices[19,21] are still evolving. Molecular beam epitaxy (MBE) is used to grow the doped layers making up the vertical semiconductor structure in the HBT. In fact, HBT structures were not really practical until the advent of MBE, although the idea behind the HBT goes back to around 1950 (Shockley). The vastly superior compositional control and layer thickness control with MBE is what made HEMTs and HBTs possible. The first HBT devices used an AlGaAs/GaAs junction with the wider bandgap AlGaAs layer forming the emitter region. Compound semiconductor HBT devices are typically mesa structures, as opposed to the more nearly planar structures used in silicon bipolar technology, because top surface contacts must be made to the collector, base, and emitter regions. Molecular beam epitaxy grows the stack of layers over the entire wafer, whereas, in silicon VLSI processes, selective implantations and oxide masking localize the doped regions. Hence, etching down to the respective layers allows for contact to the base and collector regions. An example of such a mesa HBT structure[20] is shown in Fig. 70.11. The HBT shown uses an InGaP emitter primarily for improved reliability over the AlGaAs emitter and a carbon-doped p^+ base GaAs layer.

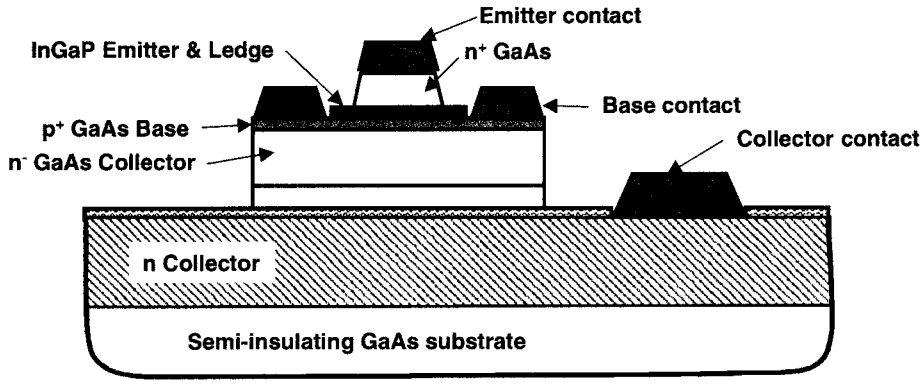

FIGURE 70.11 Cross-section of an HBT device with carbon-doped p^+ base and an InGaP emitter.[20] Note the commonly used mesa structure, where selective layer etching is required to form contacts to the base and collector regions.

Recently, InP-based HBTs[21] have emerged as candidates for use in high-speed circuits. The two dominant heterojunctions are InP/InGaAs and AlInAs/InGaAs in InP devices. The small but significant bandgap difference between AlInAs directly on InP greatly limits its usefulness. InP-based HBT device structures are similar to those of GaAs-based devices and the reader is referred to Chapter 5 of Jalali and Pearton[16] for specific InP HBT devices. Generally, InP has advantages of lower surface recombination (higher current gain results), better electron transport, lower forward turn-on voltage, and higher substrate thermal conductivity.

HBT Performance

Typical current gain values in production-worthy HBT devices range from 50 at the low range to 150 at the high range. Cutoff frequency f_T values are usually quoted under the best (i.e., peak) bias conditions. For this reason f_T values must be carefully interpreted because in digital circuits, the bias state varies widely over the entire switching swing. For this reason, probably an averaged f_T value would be better, but it is difficult to determine. Typical f_T values for HBT processes in manufacturing (say 1998) are in the 50 to 150 GHz range. For example, for the HBT example in Fig. 70.11 with a 2 μm × 2 μm emitter f_T is approximately 65 GHz at a current density of 0.6 mA/μm^2 and its dc current gain is around 50. Of course, higher values for f_T have been reported for R&D or laboratory devices. In HBT devices, the parameter f_{max} is often lower than its f_T value (e.g., for the device in Fig. 70.11, f_{max} is about 75 GHz). Base resistance (refer to Table 70.2 for equation) is the dominant limiting factor in setting f_{max}. The best HBT devices have f_{max} values only slightly higher than their f_T values. In comparison, MESFET and HEMT devices typically have higher f_{max}/f_T ratios, although in digital circuits this may be of little importance.

Where the HBT really excels is in being able to generate much higher values of transconductance. This is a clear advantage in driving larger loading capacitances found in large integrated circuits. Biasing the HBT in the current range corresponding to the highest transconductance is essential to take advantage of the intrinsically higher transconductance.

Logic Design Principles and Examples

Stephen I. Long
University of California at Santa Barbara

71.1 Introduction

The logic circuits used in high-speed compound semiconductor digital ICs must satisfy the same essential conditions for design robustness and performance as digital ICs fabricated in other technologies. The static or dc design of a logic cell must guarantee adequate voltage and/or current gain to restore the signal levels in a chain of similar cells. A minimum *noise margin* must be provided for tolerance against process variation, temperature, and induced noise from ground bounce, crosstalk, and EMI so that functional circuits and systems are produced with good electrical yield. Propagation delays must be determined as a function of loading and power dissipation.

Compound semiconductor designs emphasize speed, so logic voltage swings are generally low, τ_r low so that transconductances and f_T are high, and device access resistances are made as low as possible in order to minimize the lifetime time constant τ. This combination makes circuit performance very sensitive to parasitic R, L, and C, especially when the highest operation frequency is desired. The following sections will describe the techniques that can be used for static and dynamic design of high-speed logic.

71.2 Static Logic Design

A basic requirement for any logic family is that it must be capable of *restoring* the logic voltage or current swing. This means that the voltage or current gain with loading must exceed 1 over part of the transfer characteristic. Figure 71.1 shows a typical V_{out} vs. V_{in} *dc transfer characteristic* for a static ratioed logic inverter as is shown in the schematic diagram of Fig. 71.2. It can be seen that a chain of such inverters will restore steady-state logic voltage levels to V_{OL} and V_{OH} because the high-gain transition region around $V_{in} = V_{TH}$ will result in voltage amplification. Even if the voltage swing is very small, if centered on the *inverter threshold* voltage V_{TH}, defined as the intersection between the transfer characteristic and the $V_{in} = V_{out}$ line, the voltage will be amplified to the full swing again by each successive stage.

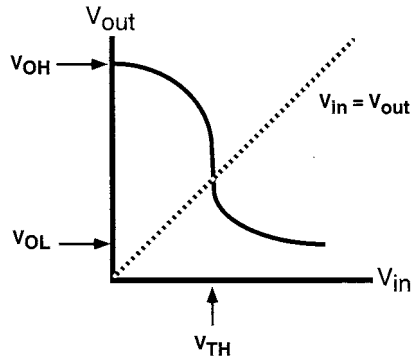

FIGURE 71.1 Typical voltage transfer characteristic for the logic inverter shown in Fig. 71.2.

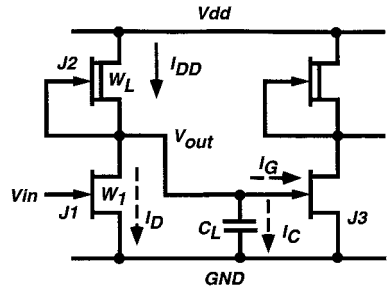

FIGURE 71.2 Schematic diagram of a direct-coupled FET logic (DCFL) inverter.

Ratioed logic implies that the *logic high and low voltages* V_{OH} and V_{OL} shown in Fig. 71.1 are a function of the widths W_1 and W_L of the FETs in the circuit shown in Fig. 71.2. In III-V technologies, this circuit is implemented with either MESFETs or HEMTs. The circuit in Fig. 71.2 is called *Direct Coupled FET Logic* or DCFL.

The logic levels of *non-ratioed* logic are independent of device widths. Non-ratioed logic typically occurs when the switching transistors do not conduct any static current. This is typical of logic families such as static CMOS or its GaAs equivalent *CGaAs*[2] which make use of complementary devices. Dynamic logic circuits such as precharged logic[25] and pass transistor logic[26,27] also do not require static current in pull-down chains. Such circuits have been used with GaAs FETs in order to reduce static power dissipation. They have not been used, however, for the highest speed applications.

Direct-Coupled FET Logic

DCFL is the most widely used logic family for the high-complexity, low-power applications that will be discussed in Chapter 72. The operation of DCFL shown in Fig. 71.2 is easily explained using a load line analysis. Currents are indicated by arrows in this figure. Solid arrows correspond to currents that are nearly constant. Dashed arrows represent currents that depend on the state of the output of the inverter. Figure 71.3 presents an I_D–V_{DS} characteristic of the enhancement mode (normally-off with threshold voltage $V_T > 0$) transistor J1. A family of characteristic curves is drawn representing several V_{GS} values. In this circuit, $V_{GS} = V_{in}$ and $V_{DS} = V_{out}$.

A load line representing the I–V characteristic of the active load ($V_{GS} = 0$) depletion-mode (normally-on with $V_T < 0$) transistor J2 is also superimposed on this drawing. Note that the logic low level V_{OL} is determined by the intersection of the two curves when $I_D = I_{DD}$. Load line 1 corresponds to a load device with narrow width; load line 2 for a wider device. It is evident that the narrow, weaker device will provide a lower V_{OL} value and thus will increase the logic swing. However, the weaker device will also have less

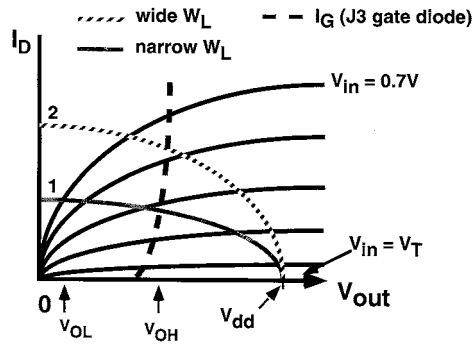

FIGURE 71.3 Drain current versus drain-source voltage characteristic of J1. The active load, J2, is also shown superimposed over the J1 characteristics as a load line. Two load lines corresponding to wide and narrow J2 widths are shown. In addition, the gate current I_G of J3 versus V_{out} limits the logic high voltage.

current available to drive any load capacitance, so the inverter with load line 1 will therefore be slower than the one with load line 2. There is therefore a tradeoff between speed and logic swing. So far, the analysis of this circuit is the same as that of an analogous nMOS E/D inverter.

In the case of DCFL logic inverters implemented with GaAs-based FETs, the Schottky barrier gate electrode of the next stage will limit the maximum value of V_{OH} to the forward voltage drop across the gate-source diode. This is shown by the gate diode I_G–V_{GS} characteristic also superimposed on Fig. 71.3. V_{OH} is given by the point of intersection between the load current I_{DD} and the gate current I_G, because a logic high output requires that the switch transistor J1 is off. V_{OH} will therefore also depend on the load transistor current. Effort must be made not to overdrive the gate since excess gate current will flow through the internal parasitic source resistance of the driven device J3, degrading V_{OL} of this next stage.

Source-Coupled FET Logic

A second widely used type of logic circuit — source-coupled FET Logic or SCFL is shown in Fig. 71.4. SCFL, or its bipolar counterpart, ECL, is widely used for very high-speed applications, which will be discussed in Chapter 72. The core of the circuit consists of a differential amplifier, J_1 and J_2, a current source J_3, and pull-up resistors R_L on the drains. The differential topology is beneficial for rejection of common-mode noise. The static design procedure can be illustrated again by a load-line analysis. A maximum current I_{CS} can flow through either J_1 or J_2.

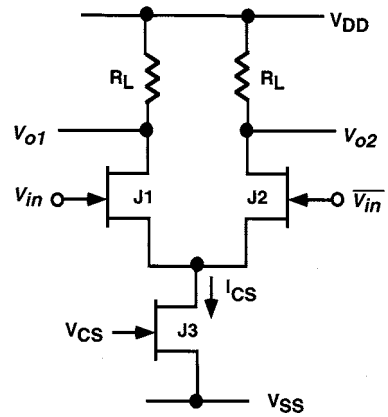

FIGURE 71.4 Schematic of differential pair J1,J2 used as a source-coupled FET logic (SCFL) cell.

Figure 71.5 shows the I_D–V_{DS} characteristic of J_1 for example. The maximum current I_{CS} is shown by a dotted line. The output voltage V_{O1} is either V_{DD} or $V_{DD} - I_{CS}R_L$; therefore, the maximum differential voltage swing, $\Delta V = 2\ I_{CS}R_L$, is determined by the choice of R_L. Next, the width of J_1 should be selected so that the change in V_{GS} needed to produce the voltage drop $I_{CS}R_L$ at the drain is less than $I_{CS}R_L$. This will ensure that the voltage gain is greater than 1 (needed to compensate for the source followers described below) and that the device is biased in its saturation region or cutoff at all times. The latter requirement is necessary if the maximum speed is to be obtained from the SCFL stage, since device capacitances are minimized in saturation and cutoff.

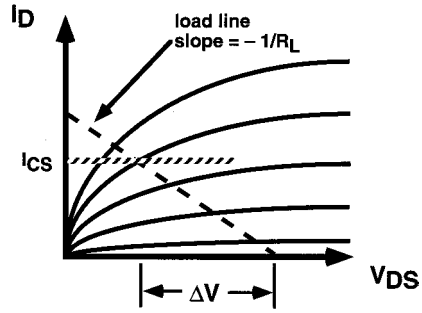

FIGURE 71.5 Load-line analysis of the SCFL inverter cell.

Source followers are frequently used on the output of an SCFL stage or at the inputs of the next stage. Figure 71.6(a) shows the schematic diagram of the follower circuit. The follower can serve two functions: level shifting and buffering of capacitive loads. When used as a level shifter, a negative or positive voltage offset can be obtained between input and output. The only requirement is that the V_{GS} of the source follower must be larger than the FET threshold voltage. If the source follower is at the output of an SCFL cell, it can be used as a buffer to reduce the sensitivity of delay to load capacitance or fanout.

The voltage gain of a source follower is always less than 1. This can be illustrated by another load-line analysis. Figure 71.6(b) presents the I_{D1}–V_{DS1} characteristic of the source follower FET, J1. A constant V_{GS1} is applied for every curve plotted in the figure. The load line (dashed line) of a depletion-mode, active current source J2 is also superimposed. In this circuit, the output voltage is $V_{out} = V_{DD} - V_{DS1}$. The V_{out} is determined by the intersection of the load line with the I_{D1} characteristic curves. The current of the pull-down current source is selected according to the amount of level shifting needed. A high current will result in a greater amount of level shift than a small load current. If the devices have high output resistance, and are accordingly very flat, very little change in V_{GS1} will be required to change V_{out} over the

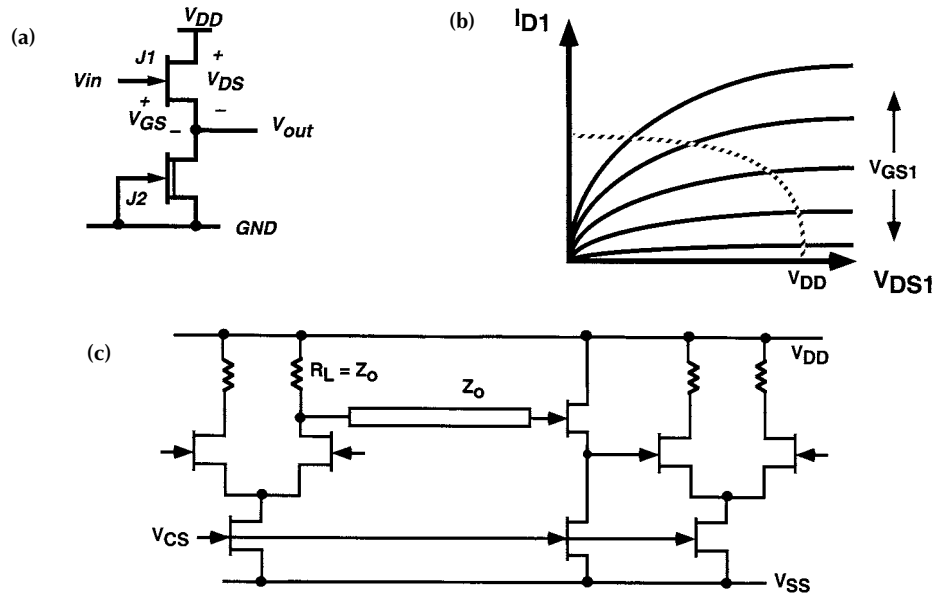

FIGURE 71.6 (a) Schematic of source follower, (b) load-line analysis of source follower, and (c) source follower buffer between SCFL stages.

full range from V_{OL} to V_{DD}. If V_{GS1} remains nearly constant, then V_{out} follows V_{in}, hence the name of the circuit. Since the input voltage to the source follower stage is $V_{in} = V_{GS1} + V_{out}$, a small change in V_{GS1} would produce an incremental voltage gain close to unity. If the output resistance is low, then the characteristic curves will slope upward and a larger range of V_{GS1} will be necessary to traverse the output voltage range. This condition would produce a low voltage gain. Small signal analysis shows that

$$A_v = \frac{1}{1 + 1 \Big/ \left[g_{m1} \left(r_{ds1} \| r_{ds2} \right) \right]} \tag{71.1}$$

The buffering effect of the source follower is accomplished by reducing the capacitive loading on the drain nodes of the differential amplifier because the input impedance of a source follower is high. Since the output tries to follow the input, the change in V_{GS} will be less than that required by a common source stage. Therefore, the input capacitance is dominated by C_{GD}, typically quite small for compound semiconductor FETs biased in saturation. The effective small-signal input capacitance is

$$C_G = C_{GD} + C_{GS}\left(1 - A_v\right) \tag{71.2}$$

where $A_v = dV_{out}/dV_{in}$ is the incremental voltage gain.

The source follower also provides a low output impedance, whose real part is approximately $1/g_m$ at low frequency. The current available to charge and discharge the load capacitance can be adjusted by the width ratio of J1 and J2. If the load is capacitive, V_{out} will be delayed from V_{in}. This will cause V_{GS1} to temporarily increase, providing excess current I_{D1} to charge the load capacitance. Ideally, for equal rise and fall times, the peak current available from J1 should equal the steady-state current of J2.

Source followers can also be used at the input of an SCFL stage to provide level shifting as shown in Fig. 71.6(c). In this case, the drain resistors, R_L, should be chosen to provide the proper termination resistance for the on-chip interconnect transmission line. These resistors provide a reverse termination to absorb signals that reflect from the high input impedance of the source follower. Alternatively, the drain resistors can be located at the gate of the source follower, thereby providing a shunt termination at the destination end of the interconnect. This practice results in good signal integrity, but because the practical values of characteristic impedance are less than 100-Ω, the current swing in the differential amplifier core must be large. This will increase power dissipation per stage.

SCFL logic structures generally employ more than one level of differential pairs so that complex logic functions (XOR, latch, and flip-flop) that require multiple gates to implement in logic families such as DCFL can be implemented in one stage. More details on SCFL gate structures and examples of their usage will be given in Chapter 72.

Static and Dynamic Noise Margin and Noise Sources

Noise margin is a measure of the ability of a logic circuit to provide proper functionality in the presence of noise.[28] There are many different definitions of noise margin, but a simple and intuitive one for the static or dc noise margin is illustrated by Fig. 71.8. Here, the transfer characteristic from Fig. 71.1 is plotted again. In order to evaluate the ability of a chain of such inverters to reject noise, a loop consisting of two identical inverters is considered. This might be representative of the positive feedback core of a bistable latch. Because the inverters are connected in a loop, an infinite chain of inverters is represented. The transfer characteristic of inverter 2 in Fig. 71.7 is plotted in gray lines. For inverter 2, $V_{out\,1} = V_{in2}$ and $V_{out2} = V_{in1}$. Therefore, the axes are reversed for the characteristic plotted for inverter 2. If a series noise source V_N were placed within the loop as shown, the maximum static noise voltage allowed will be represented by the *maximum width* of the loops formed by the transfer characteristic.[28] These widths, labeled V_{NL} and V_{NH}, respectively, for the low and high noise margins, are shown in the figure. If the voltage V_N exceeds V_{NL} or V_{NH}, the latch will be set into the opposite state and will remain there until

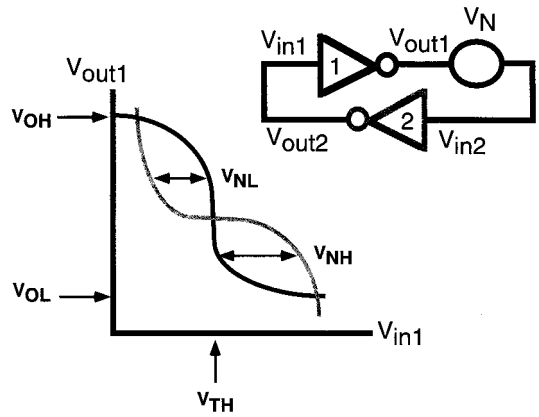

FIGURE 71.7 Voltage transfer characteristics of an inverter pair connected in a loop. Noise margins are shown as V_{NH} and V_{NL}.

reset. This would constitute a logic failure. Therefore, we must insist that any viable logic circuit provide noise margins well in excess of ambient noise levels in the circuit.

The static noise margin defined above utilized a dc voltage source V_N in series with logic inverters to represent static noise. This source might represent a static offset voltage caused by IR drop along IC power and ground distribution networks. The DCFL inverter, for example, would experience a shift in V_{TH} that is directly proportional to a ground voltage offset. This shift would skew the noise margins. The smallest noise margin would determine the circuit electrical yield. The layout of the power and ground distribution networks must consider this problem. The width of power and ground buses on-chip must be sufficient to guarantee a maximum IR drop that does not compromise circuit operation. It is important to note that this width is frequently much greater than what might be required by electromigration limits. It is essential that the designer consider IR drop in the layout. Some digital IC processes allow the topmost metal layer to form a continuous sheet, thereby minimizing voltage drops.

The static noise voltage source V_N might also represent static threshold voltage shifts on the active devices due to statistical process variation or backgating effects. Therefore, the noise margin must be several times greater than the variance in device threshold voltages provided by the fabrication process so that electrical yields will not be compromised.[29]

The above definition of maximum width noise margin has assumed a steady-state condition. It does not account for transient noise sources and the delayed response of the logic circuit to noise pulses. Unfortunately, pulses of noise are quite common in digital systems. For example, the ground potential can often be modified dynamically by simultaneous switching events on the IC chip.[30] Any ground distribution bus can be modeled as a transmission line with impedance Z_0 where

$$Z_0 = \sqrt{\frac{L_o}{C_o}} \tag{71.3}$$

Here, L_o is the equivalent series inductance per unit length and C_o the equivalent shunt capacitance per unit length. Since the interconnect exhibits a series inductance, there will be transient voltage noise ΔV induced on the line by current transients as predicted by

$$\Delta V = L\frac{dI}{dt} \tag{71.4}$$

This form of noise is often called *ground bounce*. The ground bounce ΔV is particularly severe when many devices are being switched synchronously, as would be the case in many applications involving

flip-flops in shift registers or pipelined architectures. The high peak currents that result in such situations can generate large voltage spikes. For example, output drivers are well-known sources of noise pulses on power and ground buses unless they are carefully balanced with fully differential interconnections and are powered by power and ground pins separate from the central logic core of the IC.

Designing to minimize ground bounce requires minimization of inductance. Bakoglu[30] provides a good discussion of power distribution noise in high-speed circuits. There are several steps often used to reduce switching noise. First, it is standard practice to make extensive use of multiple ground pins on the chip to reduce bond-wire inductance and package trace inductance when conventional packaging is used. Bypass capacitance off-chip can be useful if it can be located inside the package and can have a high series resonant frequency. On-chip bypass capacitance is also helpful, especially if enough charge can be supplied from the capacitance to provide the current during clock transitions. The objective is to provide a low impedance between power and ground on-chip at the clock frequency and at odd multiples of the clock frequency. Finally, as mentioned above, high-current circuits such as clock drivers and output drivers should not share power and ground pins with other logic on-chip.

Crosstalk is another common source of noise pulses caused by electromagnetic coupling between adjacent interconnect lines. A signal propagating on a driven interconnect line can induce a crosstalk voltage and current in a coupled line. The duration of the pulse depends on the length of interconnect; the amplitude depends on the mutual inductance and capacitance between the coupled lines.[31]

In order to determine how much noise is acceptable in a logic circuit, the noise margin definition can be modified to accommodate the transient noise pulse situation. The logic circuit does not respond instantaneously to the noise pulse at the input. This delay in the response is attributed to the device and interconnect capacitances and the device current limitations which will be discussed extensively in Section 71.3. Consider the device input capacitance. Sufficient charge must be transferred during the noise pulse to the input capacitance to shift the control voltage either above or below threshold. In addition, this voltage must be maintained long enough for the output to respond if a logic upset is to occur. Therefore, a logic circuit can withstand a larger noise pulse amplitude than would be predicted from the static noise margin if the pulse width is much less than the propagation delay of the circuit. This increased noise margin for short pulses is called the dynamic noise margin (DNM). The DNM approaches the static NM if the pulse width is wide compared with the propagation delay because the circuit can charge up to the full voltage if not constrained by time.

The DNM can be predicted by simulation. Figure 71.8(a) shows the loop connection of the set-reset NOR latch similar to that which was used for the static NM definition in Fig.10.7. The inverter has been modified to become a NOR gate in this case. An input pulse train $V_1(t)$ of fixed duration but with

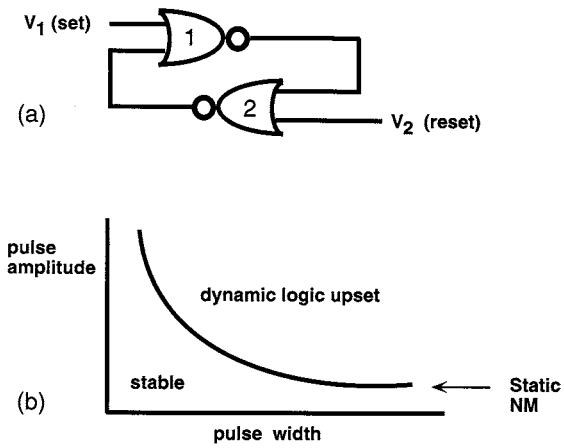

FIGURE 71.8 (a) Set-reset latch used to describe dynamic noise margin simulation, and (b) plot of the pulse amplitude applied to the set input in (a) that results in a logic upset.

gradually increasing amplitude can be applied to the set input. The latch was initialized by applying an initial condition to the reset input $V_2(t)$. The output response is observed for the input pulse train. At some input amplitude level, the output will be set into the opposite state. The latch will hold this state until it is reset again. The cross-coupled NOR latch thus becomes a logic upset detector, dynamically determining the maximum noise margin for a particular pulse width. The simulation can be repeated for other pulse widths, and a plot of the pulse amplitude that causes the latch to set for each pulse duration can be constructed, as shown in Fig. 71.8(b). Here, any amplitude or duration that falls on or above the curve will lead to a logic upset condition.

Power Dissipation

Power dissipation of a static logic circuit consists of a static and a dynamic component as shown below.

$$P_D = V_{DD}\bar{I}_{DD} + C_L \Delta V^2 \; f\eta \tag{71.5}$$

In the case of DCFL, the current I_{DD} from the pull-up transistor J2 is relatively constant, flowing either in the pull-down (switch) device J1 or in the gate(s) of the subsequent stage(s). Taking its average value, the static power is $V_{DD}\overline{I_{DD}}$. The dynamic power $C_L\Delta V^2 f\eta$ depends on the frequency of operation f, the load capacitance C_L, and the duty factor η. η is application dependent. Since the voltage swing is rather small for the DCFL inverter under consideration (about 0.6 V for MESFETs), the dynamic power will not be significant unless the load capacitance is very large, such as in the case of clock distribution networks. The V_{DD} power supply voltage is traditionally 2 V because of compatibility with the bipolar ECL V_{TT} supply, but a V_{DD} as low as 1 V can be used for special low-power applications. Typical power dissipation per logic cell (inverter, NOR) depends on the choice of supply voltage and on I_{DD}. Power is typically determined based on speed and is usually in the range of 0.1 to 0.5 mW/gate. DCFL logic circuits are often used when the application requires high circuit density and very low power.

71.3 Transient Analysis and Design for Very-High-Speed Logic

Adequate attention must be given to static or dc design, as described in the previous section, in order to guarantee functionality under the worst-case situations. In addition, since the only reason to use the compound semiconductor devices for digital electronics at all is their speed, attention must be given to the dynamic performance as well. In this section, we will describe three methods for estimating the performance of high-speed digital logic circuit functional blocks. Each of these methods has its strengths and weaknesses.

The most effective methods for guiding the design are those that provide insight that helps to identify the dominant time constants that determine circuit performance. These are not necessarily the most accurate methods, but are highly useful because they allow the designer to determine what part of the circuit or device is limiting the speed. Circuit simulators are far more accurate (at least to the extent that the device models are valid), but do not provide much insight into performance limitations. Without simple analytical techniques to guide the design, performance optimization becomes a trial-and-error exercise.

Zero-Order Delay Estimate

The first technique, which uses the simple relationship between voltage and current in a capacitor,

$$I = C_L \frac{dV}{dt} \tag{71.6}$$

is relevant when circuit performance is dominated by wiring or fan-out capacitance. This will be the case if the delay predicted by Eq. 71.6 due to the total loading capacitance, C_L, significantly exceeds the intrinsic delay of a basic inverter or logic gate. To apply this approach, determine the average current available from the driving logic circuit for charging (I_{LH}) and discharging (I_{HL}) the load capacitance. The logic swing ΔV is known, so low-to-high (t_{PLH}) and high-to-low (t_{PHL}) propagation delays can be determined from Eq. 71.6. These delays represent the time required to charge or discharge the circuit output to 50% of its final value. Thus, t_{PLH} is given by

$$t_{PLH} = \frac{C_L \Delta V}{2 I_{LH}} \tag{71.7}$$

where I_{LH} is the average charging current during the output transition from V_{OL} to $V_{OL} + \Delta V/2$. The net propagation delay is given by

$$t_P = \frac{t_{PLH} + t_{PHL}}{2} \tag{71.8}$$

At this limit, where speed is dominated by the ability to drive load capacitance, we see that increasing the currents will reduce t_p. In fact, the product of power (proportional to current) and delay (inversely proportional to current) is nearly constant under this situation. Increases in power lead to reduction of delay until the interconnect distributed RC delays or electromagnetic propagation delays become comparable to t_p.

The equation also shows that small voltage swing ΔV is good for speed if the noise margin and drive current are not compromised. This means that the devices must provide high transconductance.

For example, the DCFL inverter of Fig. 71.2 can be analyzed. Figure 71.9 shows equivalent circuits that represent the low-to-high and high-to-low transitions. The current available for the low-to-high transition, I_{PLH}, shown in Fig. 71.9(a), is equal to the average pullup current, I_{DD}. If we assume that $V_{OL} = 0.1$ V and $V_{OH} = 0.7$ V, then the ΔV of interest is 0.6 V. This brings the output up to 0.4 V at $V_{50\%}$. In this range of V_{out}, the active load transistor J2 is in saturation at all times for $V_{DD} > 1$ V, so I_{DD} will be relatively constant, and all of the current will be available to charge the capacitor.

The high-to-low transition is more difficult to model in this case. V_{out} will begin at 0.7 V and discharge to 0.4 V. The discharge current through the drain of J1 is going to vary with time because the device is below saturation over this range of V_{out}. Looking at the Vin = 0.7 V characteristic curve in Fig. 71.3, we see that its I_D–V_{DS} characteristic is resistive. Let's approximate the slope by $1/R_{on}$. Also, the discharge current I_{PHL} is the difference between I_{DD} and $I_{D1} = V_{out}/R_{on}$, as shown in Fig. 71.9(b). The average current available to discharge the capacitor can be estimated by

$$I_{HL} = \frac{V_{OH} + V_{50\%}}{2 R_{on}} - I_{DD} \tag{71.9}$$

Then, t_{PHL} is estimated by

$$t_{PHL} = \frac{C_L \Delta V}{2 I_{HL}} \tag{71.10}$$

Time Constant Delay Methods: Elmore Delay and Risetime

Time constant delay estimation methods are very useful when the wiring capacitance is quite small or the charging current is quite high. In this situation, typical of very-high-speed SSI and MSI circuits that

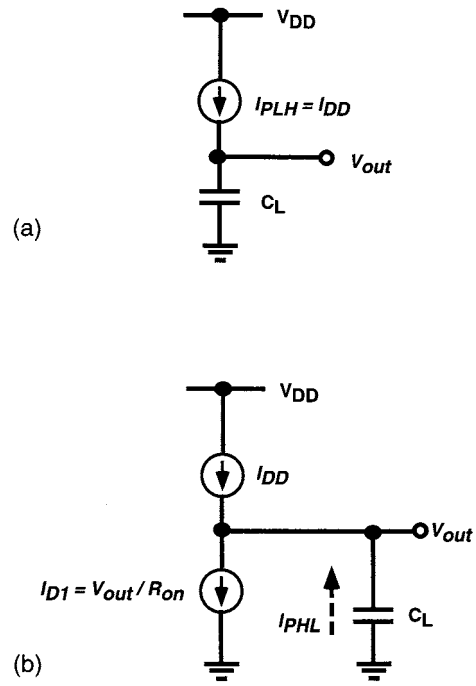

FIGURE 71.9 (a) Equivalent circuit for low-to-high transition; and (b) Equivalent circuit for high-to-low transition.

push the limits of the device and process technology, the circuit delays are dominated by the devices themselves. Both methods to be described rely on a large-signal equivalent circuit model of the transistors, an approximation dubious at best. But, the objective of these techniques is not absolute accuracy. That is much less important than being able to identify the dominant contributors to the delay and risetime, since more accurate but less intuitive solutions are easily available through circuit simulation. The construction of the large signal equivalent circuit requires averaging of non-linear model elements such as transconductance and certain device capacitances over the appropriate voltage swing.

The propagation delay definition described above, the delay required to reach 50% of the logic swing, must be relaxed slightly to apply methods based on linear system analysis. It was first shown by Elmore in 1948[32] and apparently rediscovered by Ashar in 1964[33] that the delay time t_D between an impulse function $\delta(0)$ applied at $t = 0$ to the input of a network and the centroid or "center-of-mass" of the impulse response (output) is quite close to the 50% delay. This definition of delay t_D is illustrated in Fig. 71.10. Two conditions must be satisfied in order to use this approach. First, the step response of the network is monotonic. This implies that the impulse response is purely a positive function. Monotonic step response is valid only when the circuit poles are all negative and real, or the circuit is heavily damped. Due to feedback through device capacitances, this condition is seldom completely correct. Complex poles often exist. However, strongly underdamped circuits are seldom useful for reliable logic circuits because their transient response will exhibit ringing, so efforts to compensate or damp such oscillations are needed in these cases anyway. Then, the circuit becomes heavily damped or at least dominated by a single pole and fits the above requirement more precisely.

Second, the correspondence between t_D and t_{PLH} is improved if the impulse response is symmetric in shape, as in Fig. 71.10(b). It is shown in Ref. 33 that cascaded stages with similar time constants have a tendency to approach a Gaussian-shaped distribution as the number of stages becomes large. Most logic systems require several cascaded stages, so this condition is often true as well.

Assuming that these conditions are approximately satisfied, we can make use of the fact that the impulse response of a circuit in the frequency domain is given by its transfer (or network) function F(s) in the complex frequency $s = \sigma + j\omega$. Then, the propagation delay, t_D, can be determined by

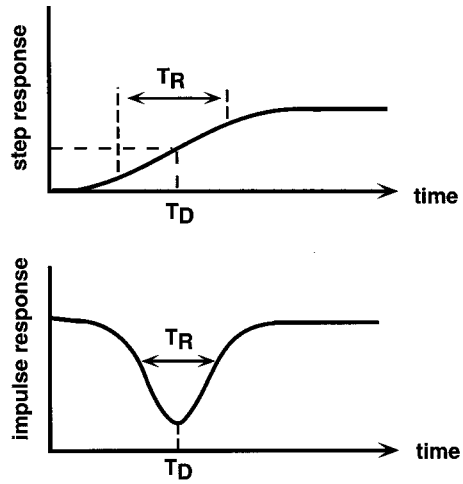

FIGURE 71.10 (a) Monotonic step response of a network; (b) corresponding impulse response. The delay t_D is defined as the centroid of the impulse response.

$$t_D = \frac{\int_0^\infty tf(t)dt}{\int_0^\infty f(t)dt} = \lim_{s\to 0}\frac{\int_0^\infty tf(t)e^{-st}dt}{\int_0^\infty f(t)e^{-st}dt} = \left[\frac{-\frac{d}{ds}F(s)}{F(s)}\right]_{s=0} \tag{71.11}$$

Fortunately, the integration never needs to be performed. t_D can be obtained directly from the network function F(s) as shown. But, the network function must be calculated from the large-signal equivalent circuit of the device, including all important parasitics, driving impedances, and load impedances. This is notoriously difficult if the circuit includes a large number of capacitances or inductances.

Fortunately, in most cases, circuits of interest can be subdivided into smaller networks, cascaded, and the presumed linearity of the circuits can be employed to simplify the task. In addition, the evaluation of the function at s = 0 eliminates many terms in the equations that result. In particular, Tien[34] shows that two corollaries are particularly useful in cascading circuit blocks:

1. If the network function F(s) = A(s)/B(s), then

$$t_D = \left[\frac{-\frac{d}{ds}A(s)}{A(s)}\right]_{s=0} + \left[\frac{\frac{d}{ds}B(s)}{B(s)}\right]_{s=0} \tag{71.12}$$

2. If F(s) = A(s)B(s)C(s), then

$$t_D = \left[\frac{-\frac{d}{ds}A(s)}{A(s)}\right]_{s=0} + \left[\frac{-\frac{d}{ds}B(s)}{B(s)}\right]_{s=0} + \left[\frac{-\frac{d}{ds}C(s)}{C(s)}\right]_{s=0} \tag{10.13}$$

This shows that the total delay is just the sum of the individual delays of each circuit block. When computing the network functions, care must be taken to include the driving point impedance of the

previous stage and to represent the previous stage as a Thevenin-equivalent open-circuit voltage source. A good description and illustration of the use of this approach in the analysis of bipolar ECL and CML circuits can be found in Ref. 34.

Risetime: the standard definition of risetime is the 10 to 90% time delay of the step response of a network. While convenient for measurement, this definition is analytically unpleasant to derive for anything except simple, first-order circuits. Elmore demonstrated that the standard deviation of the impulse response could be used to estimate the risetime of a network.[32] This definition provides estimates that are close to the standard definition. The standard deviation of the impulse response can be calculated using

$$T_R^2 = 2\pi\left[\int_0^\infty t^2 f(t)dt - t_D^2\right] \tag{71.14}$$

Since the impulse response frequently resembles the Gaussian function, the integral is easily evaluated.

Once again, the integration need not be performed. Lee[35] has pointed out that the transform techniques can also be used to obtain the Elmore risetime directly from the network function F(s).

$$T_R^2 = 2\pi\left[\frac{\frac{d^2}{ds^2}F(s)}{F(s)}\right]_{s=0} - 2\pi\left[\frac{\frac{d}{ds}F(s)}{F(s)}\right]^2_{s=0} \tag{71.15}$$

This result can also be used to show that the risetimes of cascaded networks add as the square of the individual risetimes. If two networks are characterized by risetimes T_{R1} and T_{R2}, the total risetime $T_{R,total}$ is given by the RMS sum of the individual risetimes

$$T_{R,total}^2 = T_{R1}^2 + T_{R2}^2 \tag{71.16}$$

Time Constant Methods: Open Circuit Time Constants

The frequency domain/transform methods for finding delay and risetime are particularly valuable for design optimization because they identify dominant time constants. Once the time constants are found, the designer can make efforts to change biases, component values, or optimize the design of the transistors themselves to improve the performance through addressing the relevant bottleneck in performance. The drawback in the above technique is that a network function must be derived. This becomes tedious and time-consuming if the network is of even modest complexity. An alternate technique was developed[36,37] that also can provide reasonable estimates for delay, but with much less computational difficulty. The open-circuit time constant (OCTC) method is widely used for the analysis of the bandwidth of analog electronic circuits just for this reason. It is just as applicable for estimating the delay of very-high-speed digital circuits.

The basis for this technique again comes from the transfer or network function F(s) = Vo(s)/Vi(s). Considering transfer functions containing only poles, the function can be written as

$$F(s) = \frac{a_0}{b_n s^n + b_{n-1}s^{n-1} + \cdots + b_1 s + 1} \tag{71.17}$$

The denominator comes from the product of n factors of the form $(\tau_j s + 1)$, where τ_j is the time constant associated with the *j*-th pole in the transfer function. The b_1 coefficient can be shown to be equal to the sum

$$b_1 = \sum_{j=1}^{n} \tau_j \tag{71.18}$$

of the time constants and b_2 the product of all the time constants. Often, the first-order term dominates the frequency response. In this case, the 3-dB bandwidth is then estimated by $\omega_{3dB} = 1/b_1$. The higher-order terms are neglected. The accuracy of this approach is good, especially when the circuit has a dominant pole. The worst error would occur when all poles have the same frequency. The error in this case is about 25%. Much worse errors can occur however if the poles are complex or if there are zeros in the transfer function as well. We will discuss this later.

Elmore has once again provided the connection we need to obtain delay and risetime estimates from the transfer function. The Elmore delay is given by

$$D = b_1 - a_1 \tag{71.19}$$

where a_1 is the corresponding coefficient of the first-order zero (if any) in the numerator. The risetime is given by

$$T_R^2 = b_1^2 - a_1^2 + 2\left(a_2 - b_2\right) \tag{71.20}$$

In Eq. 71.20, a_2 and b_2 correspond to the coefficients of the second-order zero and pole, respectively.

At this point, it would appear that we have gained nothing since finding that the time constants associated with the poles and zeros is well known to be difficult. Fortunately, it is possible to obtain the b_1 and b_2 coefficients directly by a much simpler method: open-circuit time constants. It has been shown that[35,36]

$$b_1 = \sum_{j=1}^{n} R_{jo} C_j = \sum_{j=1}^{n} \tau_{jo} \tag{71.21}$$

that is, the sum of the time constants τ_{jo}, defined as the product of the effective open-circuit resistance R_{jo} across each capacitor C_j when all other capacitors are open-circuited, equals b_1. These time constants are very easy to calculate since open-circuiting all other capacitors greatly simplifies the network by decoupling many other components. Dependent sources must be considered in the calculation of the R_{jo} open-circuit resistances. Note that these open-circuit time constants are not equal to the pole time constants, but their sum gives the same result for b_1. It should also be noted that the individual OCTCs give the time constant of the network if the j-th capacitor were the only capacitor. Thus, each time constant provides information about the relative contribution of that part of the circuit to the bandwidth or the delay.[35] If one of these is much larger than the rest, this is the place to begin working on the circuit to improve its speed.

The b_2 coefficient can also be found by a similar process,[38] taking the sum of the product of time constants of all possible pairs of capacitors. For example, in a three-capacitor circuit, b_2 is given by

$$b_2 = R_{1o} C_1 R_{2s}^1 C_2 + R_{1o} C_1 R_{3s}^1 C_3 + R_{2o} C_2 R_{3s}^2 C_3 \tag{71.22}$$

where the R_{js}^i resistance is the resistance across capacitor Cj calculated when capacitor C_i is *short*-circuited and all other capacitors are open-circuited. The superscript indicates which capacitor is to be shorted. So, R_{3s}^2 is the resistance across C_3 when C_2 is short-circuited and C_1 is open-circuited. Note that the first time constant in each product is an open-circuit time constant that has already been calculated. In

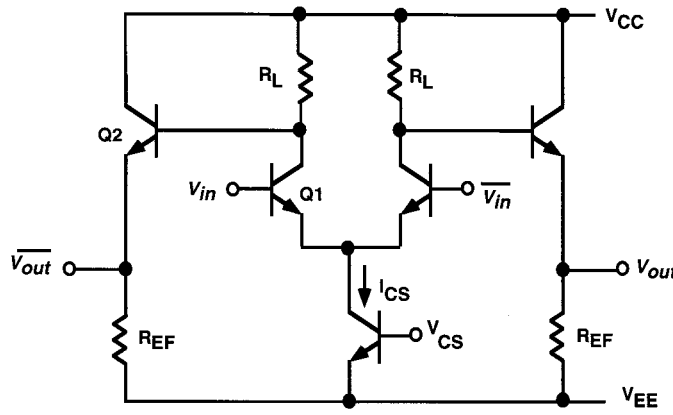

FIGURE 71.11 Schematic of basic ECL inverter.

addition, for any pair of capacitors in the network, we can find an OCTC for one and a SCTC for the other. The order of choice does not matter because

$$R_{io}C_iR_{js}^iC_j = R_{jo}C_jR_{is}^jC_i \tag{71.23}$$

so we are free to choose whichever combination minimizes the computational effort.[38]

At this stage, it would be helpful to illustrate the techniques described above with an example. An ECL inverter whose schematic is shown in Fig. 71.11 is selected for this purpose. The analysis is based on work described in more detail in Ref. 39.

The first step is to construct the large-signal equivalent circuit. We will discuss how to evaluate the large-signal component values later. Figure 71.12 shows such a model applied to the ECL inverter, where

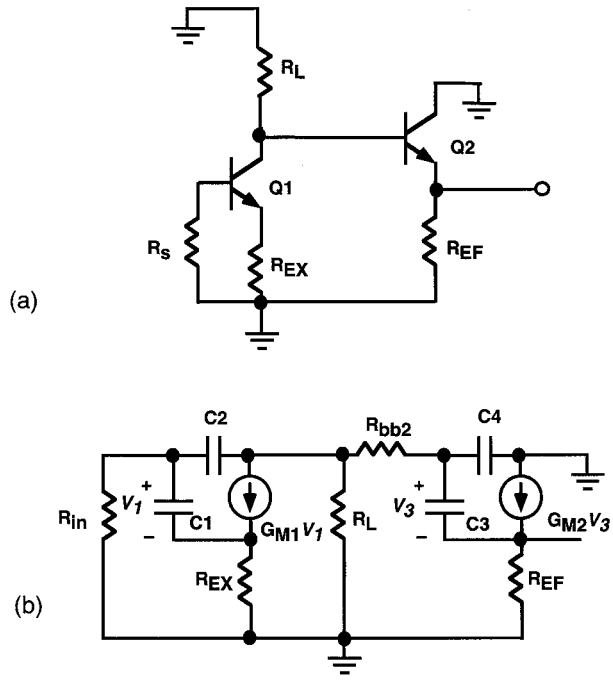

FIGURE 71.12 (a) Large-signal half-circuit model of ECL inverter; and (b) large-signal equivalent circuit of (a).

the half-circuit approximation has been used in Fig. 71.12(a) due to the inherent symmetry of differential circuits.[40] The hybrid-pi BJT model shown in Fig. 71.12(b) has been used with several simplifications. The dynamic input resistance, r_π, has been neglected because other circuit resistances are typically much smaller. The output resistance, r_o, has also been neglected for the same reason. The collector-to-substrate capacitance, C_{CS}, has been neglected because in III-V technologies, semi-insulating substrates are typically used. The capacitance to substrate is quite small compared to other device capacitances. Retained in the model are resistances R_{bb}, the extrinsic and intrinsic base resistance, and R_{EX}, the parasitic emitter resistance. Both of these are very critical for optimizing high-speed performance.

In the circuit itself, R_{IN} is the sum of the driving point resistance from the previous stage, probably an emitter follower output, and R_{bb1} of Q_1. R_L is the collector load resistor, whose value is determined by half of the output voltage swing and the dc emitter current, I_{CS}. $R_L = \Delta V/2I_{CS}$. The R_{EX} of the emitter follower is included in R_{EF}.

We must calculate open-circuit time constants for each of the four capacitors in the circuit. First consider C_1, the base-emitter diffusion and depletion capacitance of Q_1. C_2 is the collector-base depletion capacitance of Q_1. C_3 and C_4 are the corresponding base-emitter and base-collector capacitances of Q_2. Figure 71.13 represents the equivalent circuit schematic when $C_2 = C_3 = C_4 = 0$. A test source, V_1, is placed at the C_1 location. $R_{1o} = V_1/I_1$ is determined by circuit analysis to be

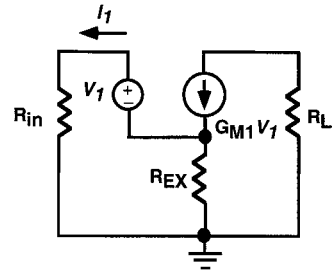

FIGURE 71.13 Equivalent large-signal half-circuit model for calculation of R_{1o}.

$$R_{1o} = \frac{R_{IN} + R_{EX}}{1 + G_{M1}R_{EX}} \tag{71.24}$$

Table 71.1 shows the result of similar calculations for R_{2o}, R_{3o}, and R_{4o}. The b_1 coefficient (first-order estimate of t_D) can now be found from the sum of the OCTCs:

$$b_1 = R_{1o}C_1 + R_{2o}C_2 + R_{3o}C_3 + R_{4o}C_4 \tag{71.25}$$

Considering the results in Table 71.1, one can see that there are many contributors to the time constants and that it will be possible to determine the dominant terms after evaluating the model and circuit parameters.

Next, estimates must be made of the non-linear device parameters, G_{Mi} and C_i. The large signal transconductances can be estimated from

$$G_M = \frac{\Delta I_C}{\Delta V_{BE}} \tag{71.26}$$

For the half-circuit model of the differential pair, the current ΔI_C is the full value of I_{CS} since the device switches between cutoff and I_{CS}. The ΔV_{BE} corresponds to the input voltage swing needed to switch the device between cutoff and I_{CS}. This is on the order of $3V_T$ (or 75 mV) for half of a differential input. So, $G_{M1} = I_{CS}/0.075$ is the large-signal estimate for transconductance of Q_1.

The emitter follower Q_2 is biased at I_{EF} when the output is at V_{OL}. Let us assume that an identical increase in current, I_{EF}, will provide the logic swing needed on the output of the inverter to reach V_{OH}. Thus, $\Delta I_{C2} = I_{EF}$ and $R_{EF} = (V_{OH} - V_{OL})/I_{EF}$. The difference in V_{BE} at the input required to double the collector current can be calculated from

TABLE 71.1 Effective Zero-Frequency Resistances for Open-Circuit Time-Constant Calculation for the Circuit of Fig. 71.12 ($G'_{MI} = G_{MI}/(1 + G_{MI}\,R_{EX})$)

R_{1o}	$\dfrac{R_{IN} + R_{EX}}{1 + G_{M1}R_{EX}}$
R_{2o}	$R_{IN} + R_L + G'_{M1}R_{IN}R_L$
R_{3o}	$\dfrac{R_{bb} + R_L + R_{EF}}{1 + G_{M2}R_{EF}}$
R_{4o}	$R_{bb} + R_L$

$$\Delta V_{BE} = V_T \ln(2) = 0.7 V_T = 17.5\,\text{mV} \tag{71.27}$$

Thus, $G_{M2} = I_{EF}/0.0175$.

C_1 and C_3 consist of the parallel combination of the *depletion* (*space charge*) *layer capacitance*, C_{be}, and the *diffusion capacitance*, C_D. C_2 and C_4 are the base-collector depletion capacitances. Depletion capacitances are voltage varying according to

$$C(V) = C(0)\left(1 - \frac{V}{\phi}\right)^{-m} \tag{71.28}$$

where C(0) is the capacitance at zero bias, ϕ is the built-in voltage, and m the grading coefficient. An equivalent large-signal capacitance can be calculated by

$$C = \frac{Q_2 - Q_1}{V_2 - V_1} \tag{71.29}$$

Q_i is the charge at the initial (1) or final (2) state corresponding to the voltages V_i. $Q_2 - Q_1 = \Delta Q$ and

$$\Delta Q = \int_{V_1}^{V_2} C(V)\,dV \tag{71.30}$$

The large-signal diffusion capacitance can be found from

$$C_D = G_M \tau_f \tag{71.31}$$

where τ_f is the forward transit delay (τ_r) as defined in Section 70.2.

Finally, the Elmore risetime estimate requires the calculation of b_2. Since there are four capacitors in the large-signal equivalent circuit, six terms will be necessary:

$$b_2 = R_{1o}C_1R_{2s}^1C_2 + R_{1o}C_1R_{3s}^1C_3 + R_{1o}C_1R_{4s}^1C_4 + R_{2o}C_2R_{3s}^2C_3 + R_{2o}C_2R_{4s}^2C_4 + R_{3o}C_3R_{4s}^3C_4 \tag{71.32}$$

R_{2s}^1 will be calculated to illustrate the procedure. The remaining short-circuit equivalent resistances are shown in Table 71.2. Referring to Fig. 71.14, the equivalent circuit for calculation of R_{2s}^1 is shown. This is the resistance seen across C_2 when C_1 is shorted. If C_1 is shorted, $V_1 = 0$ and the dependent current source is dead. It can be seen from inspection that

$$R_{2s}^1 = R_{IN} \| R_{EX} + R_L \tag{71.33}$$

Time Constant Methods: Complications

As attractive as the time constant delay and risetime estimates are computationally, the user must beware of complications that will degrade the accuracy by a large margin. First, consider that both methods have depended on a restrictive assumption regarding monotonic risetime. In many cases, however, it is not unusual to experience complex poles. This can occur due to feedback which leads to inductive input or output impedances and emitter or source followers which also have inductive output impedance. When

TABLE 71.2 Effective Resistances for Short Circuit Time Constant Calculation for the Circuit of Fig. 71.12

R_{2s}^{1}	$R_{IN} \Vert R_{EX} + R_L$
R_{3s}^{1}	R_{3o}
R_{4s}^{1}	R_{4o}
R_{3s}^{2}	$\dfrac{\left(\dfrac{1}{G'_{M1}} \Vert R_{IN} \Vert R_L\right) + R_{bb} + R_{EF}}{1 + G_{M2} R_{EF}}$
R_{4s}^{2}	$\left(\dfrac{1}{G'_{M1}} \Vert R_{IN} \Vert R_L\right) + R_{bb}$
R_{4s}^{3}	$\left(R_L + R_{bb}\right) \Vert R_{EF}$

combined with a predominantly capacitive input impedance, complex poles will generally result unless the circuit is well damped. The time constant methods ignore the complex pole effects which can be quite significant if the poles are split and $\sigma \ll j\omega$. In this case, the circuit transient response will exhibit ringing, and time constant estimates of bandwidth, delay, and risetime will be in serious error. Of course, the ringing will show up in the circuit simulation, and if present, must be dealt with by adding damping resistances at appropriate locations.

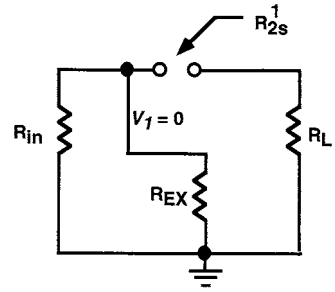

FIGURE 71.14 Equivalent circuit model for calculation of R_{2s}^{1}.

An additional caution must be given for circuits that include zeros. Although Elmore's equations can modify the estimates for t_D and T_R when there are zeros, the OCTC method provides no help in finding the time constants of these zeros. Zeros often occur in wideband amplifier circuits that have been modified through the addition of inductance for shunt peaking, for example. The addition of inductance, either intentionally or accidentally, can also produce complex pole pairs. Zeros are intentionally added for the optimization of speed in very-high-speed digital ICs as well; however, the large area required for the spiral inductors when compared with the area consumed by active devices tends to discourage the use of this method in all but the simplest (and fastest) designs.[35]

72.1 Design of MESFET and HEMT Logic Circuits

The basis of dc design, definition of logic levels, noise margin, and transfer characteristics were discussed in Chapter 71 using a DCFL and SCFL inverter as examples. In addition, methods for analysis of high-speed performance of logic circuits were presented. These techniques can be further applied to the design of GaAs MESFET, HEMT, or P-HEMT logic circuits with depletion-mode, enhancement-mode, or mixed E/D FETs. Several circuit topologies have been used for GaAs MESFETs, like direct-coupled FET logic (DCFL), source-coupled FET logic (SCFL), as well as dynamic logic families,[41] and have been extended for use with heterostructure FETs. Depending on the design requirements, whether it be high speed or low power, the designer can adjust the power-delay product by choosing the appropriate device technology and circuit topology, and making the correct design tradeoffs.

Direct-Coupled FET Logic (DCFL)

Among the numerous GaAs logic families, DCFL has emerged as the most popular logic family for high-complexity, low-power LSI/VLSI circuit applications. DCFL is a simple enhancement/depletion-mode GaAs logic family, and the circuit diagram of a DCFL inverter was shown in Fig. 71.2. DCFL is the only static ratioed GaAs logic family capable of VLSI densities due to its compactness and low power dissipation. An example demonstrating DCFL's density is Vitesse Semiconductor's 350K sea-of-gates array. The array uses a two-input DCFL NOR as the basic logic structure. The number of usable gates in the array is 175,000. A typical gate delay is specified at 95 ps with a power dissipation of 0.59 mW for a buffered two-input NOR gate with a fan-out of three, driving a wire load of 0.51 mm.[42] However, a drawback of DCFL is its low noise margin, the logic swing being approximately 600 mV. This makes the logic sensitive to changes in threshold voltage and ground bus voltage shifts.

DCFL NOR and NAND Gate

The DCFL inverter can easily be modified to perform the NOR function by placing additional enhancement-mode MESFETs in parallel as switch devices. A DCFL two-input NOR gate is shown in Fig. 72.1. If any input rises to V_{OH}, the output will drop to V_{OL}. If n inputs are high simultaneously, then V_{OL} will be decreased because the width ratio W_I/W_L in Fig. 71.2 has effectively increased by a factor of n. There is a limit to the number of devices that can be placed in parallel to form very wide NOR functions. The

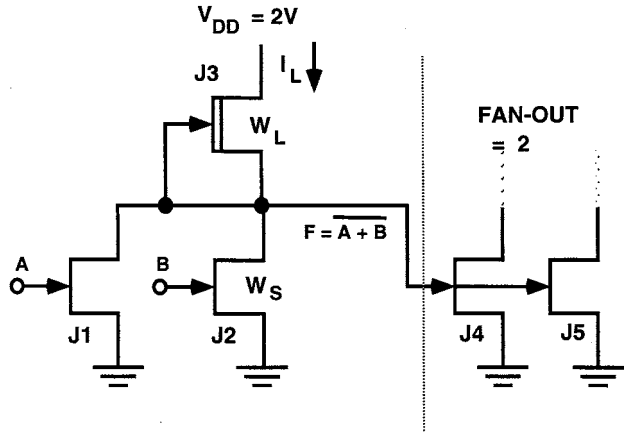

FIGURE 72.1 DCFL two-input NOR gate schematic.

drain capacitance will increase in proportion to the number of inputs, slowing down the risetime of the gate output. Also, the subthreshold current contribution from n parallel devices could become large enough to degrade V_{OH}, and therefore the noise margin. This must be evaluated at the highest operating temperature anticipated because the subthreshold current will increase exponentially with temperature according to[43,44]:

$$I_D = I_S\left[1-\exp\left(\frac{cV_{DS}}{V_T}\right)\right]\left[\exp\left(\frac{bV_{DS}}{V_T}\right)\right]\left[\exp\left(\frac{aV_{GS}}{V_T}\right)\right] \tag{72.1}$$

The parameters a, b, and c are empirical fitting parameters. The first term arises from the diffusion component of the drain current which can be fit from the subthreshold I_D–V_{DS} characteristic at low drain voltage. The second and third terms represent thermionic emission of electrons over the channel barrier from source to drain. The parameters can be obtained by fitting the subthreshold I_D–V_{DS} and I_D–V_{GS} characteristics, respectively, measured in saturation.[45] For the reasons described above, the fan-in of the DCFL NOR is seldom greater than 4.

In addition to the subthreshold current loading, the forward voltage of the Schottky gate diode of the next stage drops with temperature at the rate of approximately –2mV/degree. Higher temperature operation will therefore reduce V_{OH} as well, due to this thermodynamic effect.

A NAND function can also be generated by placing enhancement-mode MESFETs in series rather than in parallel for the switch function. However, the low voltage swing inherent in DCFL greatly limits the application of the NAND function because V_{OL} will be increased by the second series transistor unless the widths of the series devices are increased substantially from the inverter prototype. Also, the switching threshold V_{TH} shown in Fig. 71.1 will be slightly different for each input even if width ratios are made different for the two inputs. The combination of these effects reduces the noise margin even further, making the DCFL NAND implementation generally unsuitable for VLSI applications.

Buffering DCFL Outputs

The output (drain) node of a DCFL gate sources and sinks the current required to charge and discharge the load capacitance due to wiring and fan-out. Excess propagation delay of the order of 5 ps per fan-out is typically observed for small DCFL gates. Sensitivity to wiring capacitance is even higher, such that unbuffered DCFL gates are never used to drive long interconnections unless speed is unimportant. Therefore, an output buffer is frequently used in such cases or when fan-out loading is unusually high.

The superbuffer shown in Fig. 72.2(a) is often used to improve the drive capability of DCFL. It consists of a source follower J_3 and pull-down J_4. The low-to-high transition begins when $V_{IN} = V_{OL}$. J_4 is cut off

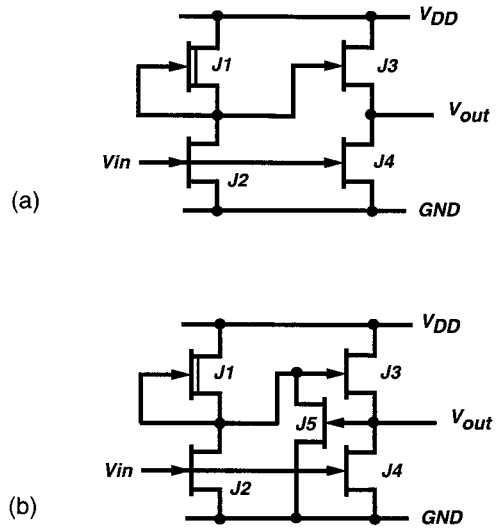

FIGURE 72.2 (a). Superbuffer schematic, and (b) modified superbuffer with clamp transistor. J5 will limit the output current when $V_{out} > 0.7$ V.

and J_3 becomes active, driving the output to V_{OH}. V_{OUT} follows the DCFL inverter output. For the output high-to-low transition, J_4 is driven into its linear region, and the output can be pulled to $V_{OL} = 0$ V in steady state. J_3 is cut off when the DCFL output (drain of J_1) switches from high to low. Since this occurs one propagation delay after the input switched from low-to-high, it is during this transition that the superbuffer can produce a current spike between V_{DD} and ground. J_4 attempts to discharge the load capacitance before the DCFL gate output has cut off J_3. Thus, superbuffers can become an on-chip noise source, so ground bus resistance and inductance must be controlled.

There is also a risk that the next stage might be overdriven with too much input current when driven by a superbuffer. This could happen because the source follower output is capable of delivering high currents when its V_{GS} is maximum. This occurs when $V_{out} = V_{OH} = 0.7$ V, limited by forward conduction of the gate diodes being driven. For a supply voltage of 2 V, a maximum $V_{GS} = 0.7$ V is easily obtained on J_3, leading to the possibility of excess static current flowing into the gates. This would degrade V_{OL} of the subsequent stage due to voltage drop across the internal source resistance. Figure 72.2(b) shows a modified superbuffer design that prevents this problem through the addition of a clamp transistor, J_5. J_5 limits the gate potential of J_3 when the output reaches V_{OH}, thus preventing the overdriving problem.

Source-Coupled FET Logic (SCFL)

SCFL is the preferred choice for very-high-speed applications. An SCFL inverter, a buffered version of the basic differential amplifier cell shown in Fig. 71.4, is shown in Fig. 72.3. The high-speed capability of SCFL stems from four properties of this logic family: small input capacitance, fast discharging time of the differential stage output nodes, good drive capability, and high F_t.

In addition to higher speed, SCFL is characterized by high functional equivalence and reduced sensitivity to threshold voltage variations.[29] The current-mode approach used in SCFL ensures an almost constant current consumption from the power supplies and, therefore, the power supply noise is greatly reduced as compared to other logic families. The differential input signaling also improves the dc, ac, and transient characteristics of SCFL circuits.[46]

SCFL, however, has two drawbacks. First, SCFL is a low-density logic family due to the complex gate topology. Second, SCFL dissipates more power than DCFL, even with the high functional equivalence taken into account.

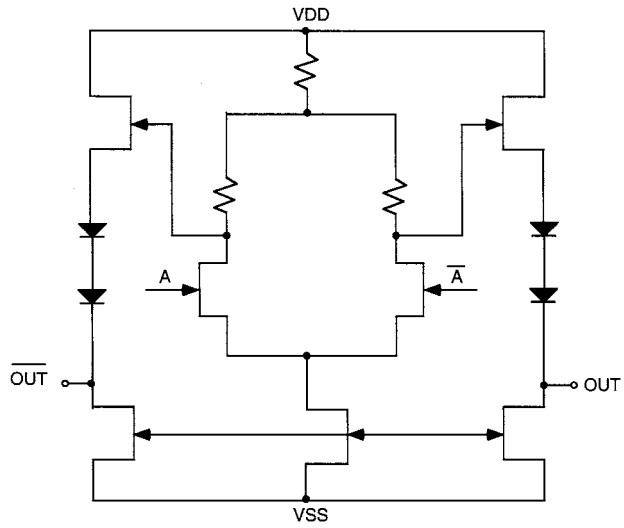

FIGURE 72.3 Schematic diagram of SCFL inverter with source follower output buffering.

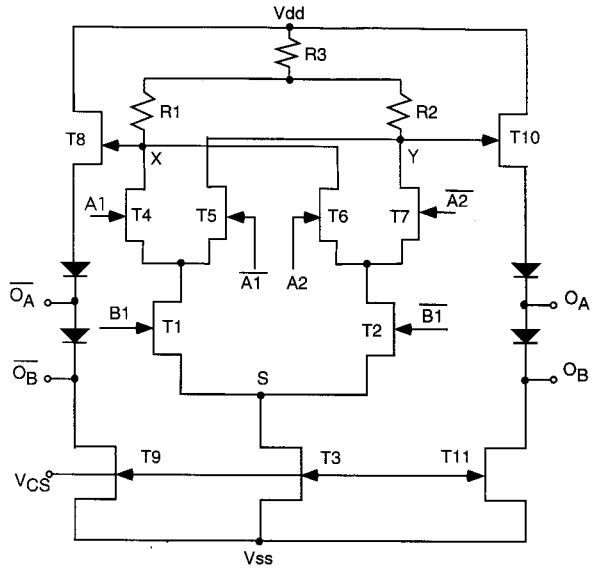

FIGURE 72.4 SCFL two-level series-gated circuit.

SCFL Two-Level Series-Gated Circuit

A circuit diagram of a two-level series-gated SCFL structure is shown in Fig. 72.4 2-to-1 MUXs, XOR gates, and D-latches and flip-flops can be configured using this basic structure. If the A inputs are tied to the data signals and the B inputs are tied to the select signal, the resulting circuit is a 2-to-1 MUX. If the data is fed to the A1 input, the clock is connected to B and the A outputs ($O_A, \overline{O_A}$) are fed back to the A2 inputs, the resulting circuit is a D-latch as seen in Fig. 72.5. Finally, an XOR gate is created by connecting $A_1 = \bar{A}_2$, forming a new input A_{IN} and $\bar{A}_1 = A_2$ to complementary new input $\bar{A}_{IN}$.

The inputs to the two levels require different dc offsets in order for the circuit to function correctly, thus level-shifting networks using diodes or source followers are required. Series logic such as this also requires higher supply voltages in order to keep the devices in their saturation region. This will increase the power dissipation of SCFL.

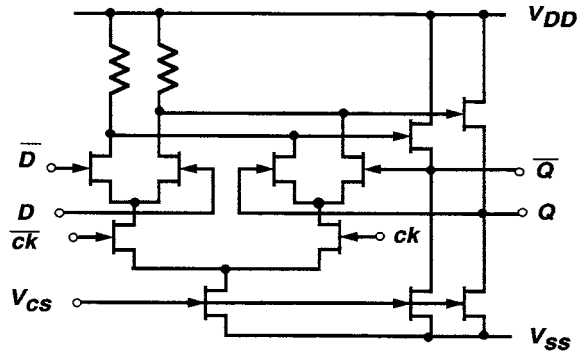

FIGURE 72.5 SCFL D latch schematic. Two cascaded latch cells with opposite clock phasing constitute a master-slave flip-flop.

The logic swing of the circuit shown in Fig. 72.4 is determined by the size of the current source T3 and the load resistors R1 and R2 (R1 = R2). Assuming T3 is in saturation, the logic swing on nodes X and Y is

$$\Delta V_{X,Y} = I_{ds3}\ R1 = I_{dss3}\ R1 \tag{72.2}$$

where I_{dss3} is the saturation current of T3 at Vgs = 0 V. The logic high and low levels on node X ($V_{X,H}$, $V_{X,L}$) are determined from the voltage drop across R3 and Eq. 72.2.

$$V_{X,H} = V_{dd} - (I_{dss3}\ R3) \tag{72.3}$$

$$V_{X,L} = V_{dd} - [I_{dss3}\ (R1 + R3)] \tag{72.4}$$

The noise margin is the difference between the minimum voltage swing required on the inputs to switch the current from one branch to the other (V_{SW}) and the logic swing $\Delta V_{X,Y}$. V_{SW} is set by the ratio between the sizes of the switch transistors (T1,T2, T4-T7) and T3. For symmetry reasons, the sizes of all the switch transistors are kept the same size. Assuming the saturation drain-source current of an FET can be described by the simplified square-law equation:

$$I_{ds} = \beta W(V_{gs} - V_T)^2 \tag{72.5}$$

where V_T is the threshold voltage, W is the FET width, and β is a process-dependent parameter. V_{SW} is calculated assuming all the current from T3 flows only through T2.

$$V_{SW} = \left|V_T\right|\sqrt{\left(W3/W2\right)} \tag{72.6}$$

For a fixed current source size (W3), the larger the size of the switch transistors, the smaller the voltage swing required to switch the current and, hence, a larger noise margin. Although a better noise margin is desirable, it needs to be noted that the larger switch transistors means increased input capacitance and decreased speed. Depending on the design specifications, noise margin and speed need to be traded off.

Since all FETs need to be kept in the saturation region for the correct operation of an SCFL gate, level-shifting is needed between nodes A and B and the input to the next gate, in order to keep T1, T2, and T4-T7 saturated. T3 is kept in saturation if the potential at node S is higher than $V_{SS} + V_{ds,sat}$. The potential at node S is determined by the input voltages to T1 and T2. V_S settles at a potential such that the drain-source current of the conducting transistor is exactly equal to the bias current, I_{dss3}, since no current flows through the other transistor. The minimum logic high level at the output node B ($V_{OB,H}$) is

$$V_{OB,H} \geq V_{ss} + V_{ds,sat} + V_{gs} = V_{ss} + V_{ds,sat} + V_{SW} + V_{th} \tag{72.7}$$

To keep T9 and T11 in saturation, however, requires that

$$V_{OB,H} \geq V_{ss} + V_{ds,sat} + V_{SW} \tag{72.8}$$

As with the voltage on node S, the drain voltages of T1 and T2 are determined by the voltage applied to the A inputs. The saturation condition for T1 and T2 is

$$V_{OA,H} - V_{SW} - V_{th} - V_S = V_{OA,H} - V_{OB,H} \geq V_{ds,sat} \tag{72.9}$$

Equation 72.9 shows that the lower switch transistors are kept in saturation if the level-shifting difference between the A and B outputs is larger than the FET saturation voltage. Since diodes are used for level-shifting, the minimum difference between the two outputs is one diode voltage drop, V_D. If $V_{ds,sat} > V_D$, more diodes are required between the A and B outputs.

The saturation condition for the upper switch transistors, T4 to T7, is determined by the minimum voltage at nodes A and B and the drain voltage of T1 and T2.

$$V_{A,min} - (V_{OA,H} - V_{SW} - V_{th}) \geq V_{ds,sat} \tag{72.10}$$

Substituting Eq. 72.4 into Eq. 72.10 yields

$$\left(V_{dd} - I_{dss3} * \left(R1 + R3\right)\right) - \left(V_{OA,H} - V_{SW} - V_{th}\right) \geq V_{ds,sat} \tag{72.11}$$

Rewriting Eq. 72.11 using Eq. 72.8 gives the minimum power supply range

$$V_{dd} - V_{ss} \geq I_{dss3} * (R1+R3) + 3V_{ds,sat} \tag{72.12}$$

Equation 72.11 allows the determination of the minimum amount of level-shifting required between nodes A and B to the outputs

$$V_{A,H} - V_{OA,H} \geq V_{ds,sat} + I_{dss3} * R1 - V_{th} - V_{SW} \tag{72.13}$$

Equations 72.8 to 72.13 can be used for designing the level shifters. The design parameters available in the level-shifters are the widths of the source followers (W8, W10), the current sources (W9, W11), and the diode (W_D). Assuming the current source width (W9) is fixed, the voltage drop across the diodes is partially determined by the ratio (W_D/W9). This ratio should not be made too small. Operating Schottky diodes at high current density will result in higher voltage drop, but this voltage will be partially due to the $I_D R_S$ drop across the parasitic series resistance. Since this resistance is often process dependent and difficult to reproduce, poor reproducibility of V_D will result in this case.

The ratio between the widths of the source follower and the current source (W8/W9) determines the gate-source voltage of the source follower (V_{gs8}). V_{gs8} should be kept below 0.5 V to prevent gate-source conduction.

The dc design of the two-level series-gated SCFL gate in Fig. 72.4 can be accomplished by applying Eqs. 72.2 to 72.13. Ratios between most device sizes can be determined by choosing the required noise margin and logic swing. Only W3 in the differential stage and W9 among the level-shifters are unknown at this stage. All other device sizes can be expressed in terms of these two transistor widths.

The relation between W3 and W9 can be determined only by considering transient behavior. For a given total power dissipation, the ratio between the power dissipated in the differential stage and the output buffers determines how fast the outputs are switched. If fast switching at the outputs is desired, more power needs to be allocated to the output buffers and, consequently, less power to the differential

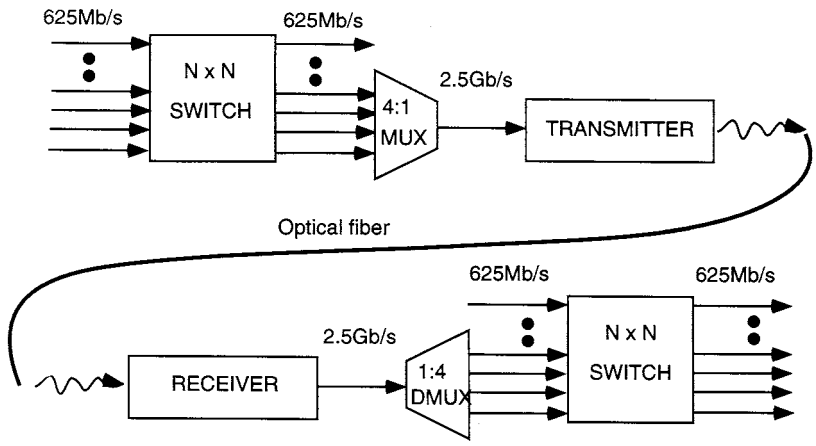

FIGURE 72.6 2.5-Gb/s optical communication system.

stage. While this allocation will ensure faster switching at the output, the switching speed of the differential stage is reduced because of the reduced current available to charge and discharge the large input capacitance of the output buffers.

Finally, it is useful to note that scaling devices to make a speed/power tradeoff is simple in SCFL. If twice as much power is allocated to a gate, all transistors and diodes are made twice as wide while all resistors are reduced by half.[46]

Advanced MESFET/HEMT Design Examples

High-Speed TDM Applications

The need for high bandwidth transmission systems continues to increase as the number of bandwidth-intensive applications in the areas of video imaging, multimedia and data communication (such as database sharing and database warehousing) continues to grow. This has led to the development of optical communication systems with transmission bit rates, for example, of 2.5 Gb/s and 10 Gb/s. A simplified schematic of a 2.5 Gb/s communication system is shown in Fig. 72.6.

As seen in Fig. 72.6, MUXs, DMUXs, and switches capable of operating in the Gb/s range are crucial for the operation of these systems. GaAs MESFET technology has been employed extensively in the design of these high-speed circuits because of the excellent intrinsic speed performance of GaAs. SCFL is especially well suited for these circuits where high speed is of utmost importance and power dissipation is not a critical factor.

The design strategies employed in the previous subsection can now be further applied to a high-speed 4:1 MUX, as shown in Fig. 72.7. It was shown that the two-level series gated SCFL structure could be easily configured into a D-latch. The MSFF in the figure is simply a master-slave flip-flop containing two D-latches. The PSFF is a phase-shifting flip-flop that contains three D-latches and has a phase shift of 180° compared with an MSFF.

The 4:1 MUX is constructed using a tree-architecture in which two 2:1 MUXs merge two input lines each into one output operating at twice the input bit rate. The 2:1 MUX at the second stage takes the two outputs of the first stage and merges it into a single output at four times the primary input bit rate. The architecture is highly pipelined, ensuring good timing at all points in the circuit. The inherent propagation delay of the flip-flops ensures that the signals are passed through the selector only when they are stable.[46]

The interface between the two stages of 2:1 MUXs is timing-critical, and care needs to be taken to obtain the best possible phase margin at the input of the last flip-flop. To accomplish this, a delay is added between the CLK signal and the clock input to this flip-flop. The delay is usually implemented

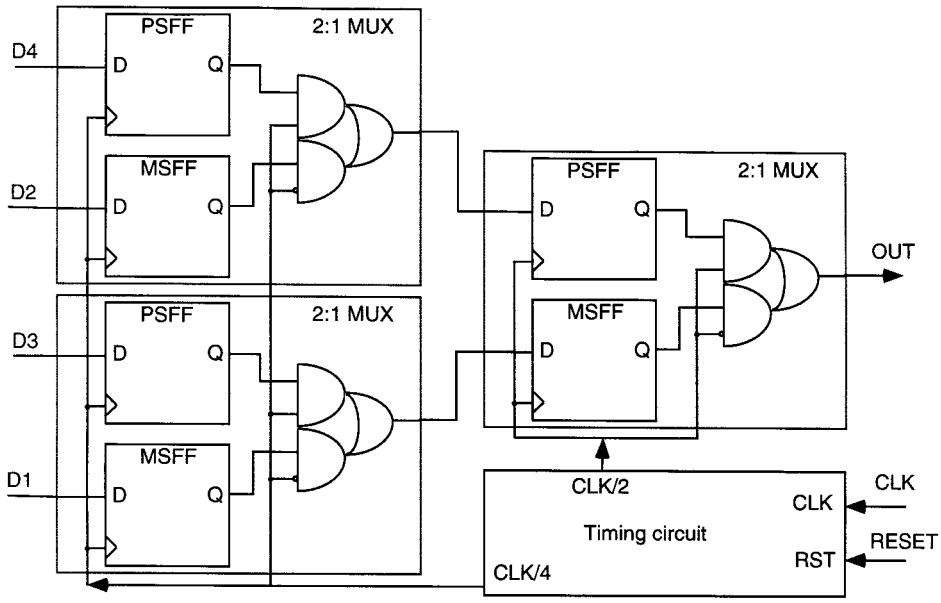

FIGURE 72.7 High-speed 4:1 multiplexer (MUX).

using logic gates because their delays are well-characterized in a given process. Output jitter can be minimized if 50% duty-cycle clock signals are used. Otherwise, a retiming MSFF will be needed at the output of the 4:1 MUX.

The 4:1 MUX is a good example of an application of GaAs MESFETs with very-high-speed operation and low levels of integration. Vitesse Semiconductor has several standard products operating at the Gb/s range fabricated in GaAs using their own proprietary E/D MESFET process. For example, the 16×16 crosspoint switch, VSC880, has serial data rates of 2.0 Gb/s. The VS8004 4-bit MUX is a high-speed, parallel-to-serial data converter. The parallel inputs accept data at rates up to 625 Mb/s and the differential serial data output presents the data sequentially at 2.5 Gb/s, synchronous with the differential high-speed clock input.[42]

While the MESFET technologies have proven capable at 2.5 and 10 Gb/s data rates for optical fiber communication applications, higher speeds appear to require heterojunction technologies. The 40-Gb/s TDM application is the next step, but it is challenging for all present semiconductor device IC technologies. A complete 40-Gb/s system has been implemented in the laboratory with 0.1-μm InAlAs/InGaAs/InP HEMT ICs as reported in Refs. 47 and 48. Chips were fabricated that implemented multiplexers, photodiode preamplifiers, wideband dc 47-GHz amplifiers, decision circuits, demultiplexers, frequency dividers, and limiting amplifiers. The high-speed static dividers used the super-dynamic FF approach.[49]

A 0.2-μm AlGaAs/GaAs/AlGaAs HEMT quantum well device technology has also demonstrated 40-Gb/s TDM system components. A single chip has been reported that included clock recovery, data decision, and a 2:4 demultiplexer circuit.[50] The SCFL circuit approach was employed.

Very-High-Speed Dynamic Circuits

Conventional logic circuits using static DCFL or SCFL NOR gates such as those described above are limited in their maximum speed by loaded gate delays and serial propagation delays. For example, a typical DCFL NOR-implemented edge-triggered DFF has a maximum clock frequency of approximately $1/5\tau_D$ and the SCFL MSFF is faster, but it is still limited to $1/2\tau_D$ at best. Frequency divider applications that require clock frequencies above 40 GHz have occasionally employed alternative circuit approaches which are not limited in the same sense by gate delays and often use dynamic charge storage on gate

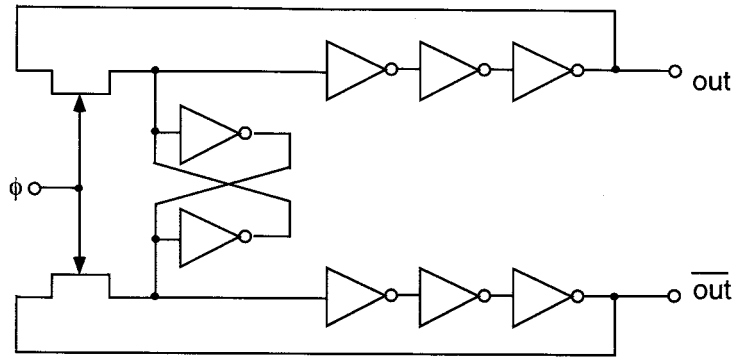

FIGURE 72.8 Dynamic frequency divider (DFD) divide-by-2 circuit. (Ref. 51, ©1989 IEEE, with permission.)

nodes for temporarily holding a logic state. These approaches have been limited to relatively simple circuit functions such as divide-by-2 or -4.

The dynamic frequency divider (DFD) technique is one of the well-known methods for increasing clock frequency closer to the limits of a device technology. For an example, Fig. 72.8 shows a DFD circuit using a single-phase clock, a cross-coupled inverter pair as a latch to reduce the minimum clock frequency, and pass transistors to gate a short chain of inverters.[51,52] These have generally used DCFL or DCFL superbuffers for the inverters. The cross-coupled inverter pair can be made small in width, since its serial delay is not in the datapath. But the series inverter chain must be designed to be very fast, generally requiring high power per inverter in order to push the power-delay product to its extreme high-speed end. Since fan-out is low, the intrinsic delays of an inverter in a given technology can be approached.

The maximum and minimum clock frequencies of this circuit can be calculated from the gate delays of the n series inverters as shown in Eqs. 72.14 and 72.15. An odd number n is required to force an inversion of the data so that the circuit will divide-by-2. Here, t_1 is the propagation delay of the pass transistor switches, J1 and J2, and t_D is the propagation delay of the DCFL inverters. The parameter "a" is the duty cycle of the clock. For a 50% clock duty cycle, the range of minimum to maximum clock frequency is about 2 to 1.

$$f_{\phi\max} = \frac{1}{t_1 + nt_D} \tag{72.14}$$

$$f_{\phi\min} = \frac{a}{t_1 + nt_D} \tag{72.15}$$

Clock frequencies as high as 51 GHz have been reported using this approach with a GaAs/AlGaAs P-HEMT technology.[52] The power dissipation was relatively high, 440 mW. Other DFD circuit approaches can also be found in the literature.[53-55]

A completely different approach, as shown in Fig. 72.9, utilizes an injection-locked push-pull oscillator (J1 and J2) whose free running frequency is a subharmonic of the desired input frequency.[56] FETs J3 and J4 are operating in their ohmic regions and act as variable resistors. The variation in V_{GS1} and V_{GS2} cause the oscillator to subharmonically injection-lock to the input source. Here, a divide-by-4 ratio was demonstrated with an input frequency of 75 GHz and a power dissipation of 170 mW using a 0.1-μm InP-based HEMT technology with f_T = 140 GHz and f_{max} = 240 GHz. This divider also operated in the 59–64 GHz range with only –10 dBm RF input power. The frequency range is limited by the tuning range of the oscillator. In this example, about 2 octaves of frequency variation was demonstrated.

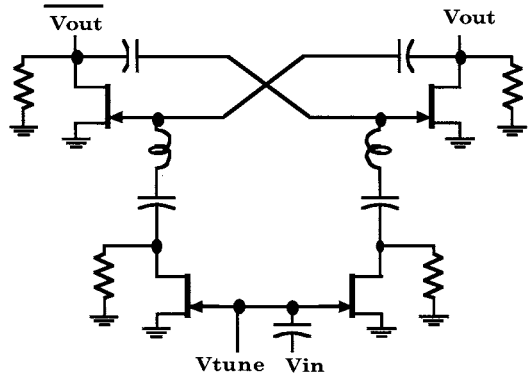

FIGURE 72.9 Injection-locked oscillator divide-by-4 (Ref. 56, ©1996 IEEE. With permission.)

Finally, efforts have also been made to beat the speed limitations of a technology by dynamic design methods while still maintaining minimum power dissipation. The quasi-dynamic FF[48,49] and quasi-differential FF[57] are examples of circuit designs emphasizing this objective. The latter has achieved 16-GHz clock frequency with approximately 2 mW of power per FF.

72.2 HBT Logic Design Examples

From a circuit topology perspective, both III-V HBTs and silicon BJTs are interchangeable, with myriad similarities and a few essential differences. The traditional logic families developed for the Si BJTs serve as the starting point for high-speed logic with III-V HBTs. During the period of intense HBT development in the 1980s and early 1990s, HBTs have implemented ECL, CML, DTL, and, I^2L logic topologies as well as novel logic families with advanced quantum devices (such as resonant tunneling diodes[1]) in the hopes of achieving any combination of high-speed, low-power, and high-integration level. During that time, III-V HBTs demonstrated their potential integration limits with an I^2L 32-bit microprocessor[58] and benchmarked its high-speed ability with an ECL 30-GHz static master/slave flip-flop based frequency divider. During the same time, advances in Si based technology, especially CMOS, have demonstrated that parallel circuit algorithms implemented in a technology with slower low-power devices capable of massive integration will dominate most applications. Consequently, III-V-based technologies such as HBTs and MESFET/HEMT have been relegated to smaller but lucrative niche markets.

As HBT technology evolved into a mature production technology in the mid-1990s, it was clear that III-V HBT technology had a clear advantage in high-speed digital circuits, microwave integrated circuits, and power amplifier markets. Today, in the high-speed digital arena, III-V HBTs have found success in telecom and datacom lightwave communication circuits for SONET/ATM-based links that operate from 2.5 to 40 Gb/s. HBTs also dominate the high-speed data conversion area with Nyquist-rate ADCs capable of gigabit/gigahertz sampling rates/bandwidths, sigma-delta ADCs with very high oversampling rates, and direct digital synthesizers with gigahertz clock frequencies and ultra-low spurious outputs. In these applications, the primary requirement is ultra-high-speed performance with LSI (10 K transistors) levels of integration. Today, the dominant logic type used in HBT designs is based on non-saturating emitter coupled pairs such as ECL and current-mode logic (CML), which is the focus of this chapter.

III-V HBT for Circuit Designers

III-V HBTs and Si BJTs are inherently bipolar in nature. Thus, from a circuit point of view, both share many striking similarities and some important differences. The key differences between III-V HBT

technology and Si BJT technology, as discussed below, can be traced to three essential aspects: (1) heterojunction vs. homojunction, (2) III-V material properties, and (3) substrate properties.

First, the primary advantage of a base–emitter heterojunction is that the wide bandgap emitter allows the base to be doped higher than the emitter (typically 10 to 50X in GaAs/AlGaAs HBTs) without a reduction in current gain. This translates to lower base resistance for improved f_{max} and reduces base width modulation with V_{ce} for low output conductance. Alternatively, the base can be made thinner for lower base-transit time (τ_b) and higher f_t without having R_b too high. If the base composition is also graded from high bandgap to low, an electric field can be established to sweep electrons across the base for reduced τ_b and higher f_t. With a heterojunction B-E and a homojunction B-C, the junction turn-on voltage is higher in the B-E than it is in the B-C. This results in a common-emitter I–V curve offset from the off to saturation transition. This offset is approximately 200 mV in GaAs/AlGaAs HBTs. With a highly doped base, base punch-through is not typically observed in HBTs and does not limit the f_t-breakdown voltage product as in high-performance Si BJTs and SiGe HBT with thin bases. Furthermore, if a heterojunction is placed in the base–collector junction, a larger bandgap material in the collector can increase the breakdown voltage of the device and reduce the I–V offset.

Second, III-V semiconductors typically offer higher electron mobility than Si for overall lower τ_b and collector space charge layer transit times (τ_{cscl}). Furthermore, many III-V materials exhibit velocity overshoot in the carrier drift velocity. When HBTs are designed to exploit this effect, significant reductions in τ_{cscl} can result. With short collectors, the higher electron mobility can result in ultra-high f_t; however, this can also be used to form longer collectors with still acceptable τ_{cscl}, but significantly reduced C_{bc} for high f_{max}. The higher mobility in the collector can also lead to HBTs with lower turn on resistance in the common emitter I–V curves.

Since GaAs/AlGaAs and GaAs/InGaP have wider bandgaps than Si, the turn-on voltage of the B–E ($V_{be,on}$) junction is typically on the order of 1.4 V vs. 0.9 V for advanced high-speed Si BJT. InP-based HBTs can have $V_{be,on}$ on the order of 0.7 V; however, most mature production technologies capable of LSI integration levels are based on AlGaAs/GaAs or InGaP/GaAs. The base–collector turn-on voltage is typically on the order of 1 V in GaAs-based HBTs. This allows V_{ce} to be about 600 mV lower than V_{be} without placing the device in saturation. The wide bandgap material typically results in higher breakdown voltages, so III-V HBTs typically have a high Johnson figure of merit (f_t * breakdown voltage) compared with Si- and SiGe-based bipolar transistors.

The other key material differences between III-V vs. silicon materials are the lack of a native stable oxide in III-V, the extensive use of poly-Si in silicon-based processes, and the heavy use of implants and diffusion for doping silicon devices. III-V HBTs typically use epitaxial growth techniques, and interconnect step height coverage issues limit the practical structure to one device type, so PNP transistors are not typically included in an HBT process. These key factors contribute to the differences between HBTs and BJTs in terms of fabrication.

Third, the GaAs substrate used in III-V HBTs is semi-insulating, which minimizes parasitic capacitance to ground through the substrate, unlike the resistive silicon substrate. Therefore, the substrate contact as in Si BJTs is unnecessary with III-V HBTs. In fact, the RF performance of small III-V HBT devices can be measured directly on-wafer without significant de-embedding of the probe pads below 26 GHz. For interconnects, the line capacitance is typically dominated by parallel wire-to-wire capacitance, and the loss is not limited by the resistive substrate. This allows for the formation of high-Q inductors, low-loss transmission lines, and longer interconnects that can be operated in the 10's of GHz. Although BESOI and SIMOX Si wafers are insulating, the SiO_2 layer is typically thin resulting in reduced but still significant capacitive coupling across this thin layer.[59]

Most III-V substrates have a lower thermal conductivity than bulk Si, resulting in observed self-heating effects. For a GaAs/AlGaAs HBT, this results in observed negative output conductance in the common-emitter I–V curve measured with constant I_b. The thermal time constant for GaAs/AlGaAs HBTs is on the order of microseconds. Since thermal effects cannot track above this frequency, the output conductance

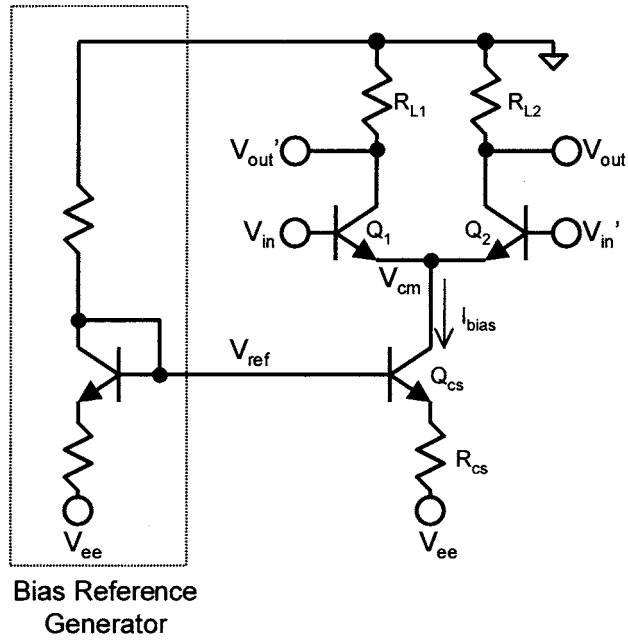

FIGURE 72.10 Standard differential CML buffer with a simple reference generator.

of HBTs at RF (> 10 MHz) is low but positive. This effect does result in a small complication for HBT models based on the standard Gummel Poon BJT model.

Current-Mode Logic

The basic current-mode logic (CML) buffer/inverter cell is shown in Fig. 72.10. The CML buffer is a differential amplifier that is operated with its outputs clipped or in saturation. The differential inputs (V_{in} and V_{in}') are applied to the bases of Q_1 and Q_2. The difference in potential between V_{in} and V_{in}' determines which transistor I_{bias} is steered through, resulting in a voltage drop across either load resistance R_{L1} or R_{L2}. If $V_{in} = V_{OH}$ and $V_{in}' = V_{OL}$ ($V_{in,High} > V_{in,Low}$), Q_1 is on and Q_2 is off. Consequently, I_{bias} completely flows through R_{L1}, causing V_{out}' to drop for a logic low. With Q_2 off, V_{out} floats to ground for a logic high. If the terminal assignment of V_{out} and V_{out}' were reversed, this CML stage would be an inverter instead of a buffer

The logic high V_{OH} of a CML gate is 0 V. The logic low output is determined by $V_{OL} = -R_{L1}I_{bias}$. With R_{L1}/R_{L2} = 200-Ωs, and I_{bias} = 2 mA, the traditional logic low of a CML gate is –400 mV. As CML gates are cascaded together, the outputs of one stage directly feed the inputs of another CML gate. As a result, the base-collector of the "on" transistor is slightly forward-biased (by 400 mV in this example). For high-speed operation, it is necessary to keep the switching transistors out of saturation. With a GaAs base-collector turn-on voltage near 1V, 500 to 600 mV forward-bias is typically tolerated without any saturation effects. In fact, this bias shortens the base-collector depletion region, resulting in the highest f_t vs. V_{ce} (f_{max} suffers due to increase in C_{bc}). As a result, maximum logic swing of a CML gate is constrained by the need to keep the transistors out of saturation. As the transistor is turned on, the logic high is actively pulled to a logic low; however, as the transistor is turned off, the logic low is pulled up by a RC time constant. With a large capacitive loading, it is possible that the risetime is slower than the falltime, and that may result in some complications with high-speed data.

A current mirror (Q_{cs} and R_{cs}) sets the bias (I_{bias}) of the differential pair. This is an essential parameter in determining the performance of CML logic. In HBTs, the f_t dependence on I_c is as follows:

$$1/2\pi f_t = \tau_{ec} = nkT/\left(qI_c\left(C_{bej} + C_{bc} + C_{bed}\right)\right) + R_c\left(C_{bej} + C_{bc}\right) + \tau_b + \tau_{cscl} \tag{72.16}$$

where τ_{ec} is the total emitter-to-collector transit time, qI_c/nkT is the transconductance (g_m), C_{bc} is the base-collector capacitance, C_{bej} is the base–emitter junction capacitance, C_{bed} is the B–E diffusion capacitance, R_c is the collector resistance, τ_b is the base transit time, and τ_{cscl} is the collector space charge layer transit time. At low currents, the transit time is dominated by the device g_m and device capacitance. As the bias increases, τ_{ec} is eventually limited by τ_b and τ_{cscl}. As this limit approaches, Kirk effect typically starts to increase τ_b/τ_{cscl}, which decreases f_t. In some HBTs, the peak f_{max} occurs a bit after the peak f_t. With this in mind, optimal performance is typically achieved when I_{bias} is near $I_{c,maxft}$ or $I_{c,maxfmax}$. In some HBT technologies, the maximum bias may be constrained by thermal or reliability concerns. As a rule of thumb, the maximum current density of HBTs is typically on the order of 5×10^4 A/cm^2.

The bias of CML and ECL logic is typically set with a bias reference generator, where the simplest generator is shown in Fig. 72.10. Much effort has been invested in the design of the reference generator to maintain constant bias with power supply and temperature variation. In HBT, secondary effects of heterojunction design typically result in slightly varying ideality factor with bias. This makes the design of bandgap reference circuits quite difficult in most HBT technologies, which complicates the design of the reference generator. Nevertheless, the reference generators used today typically result in a 2% variation in bias current from –40 to 100C with a 10% variation in power supply. In most applications, the voltage drop across R_{cs} is set to around 400 mV. With V_{ee} set at –5.2 V, V_{ref} is typically near –3.4 V. With constant bias, as V_{ee} moves by ±10%, then the voltage drop across R_{cs} remains constant, so V_{ref} moves by the change in power supply (about ±0.5 V). Since the logic levels are referenced to ground, the average value of V_{cm} (around –1.4 V) remains constant. This implies that changes in the power supply are absorbed by the base–collector junction of Q_{cs}, and it is important that this transistor is not deeply saturated.

Since the device goes from the cutoff mode to the forward active mode as it switches, the gate delay is difficult to predict analytically with small-signal analysis. Thus, large-signal models are typically used to numerically compute the delay in order to optimize the performance of a CML gate. Nevertheless, the small-signal model, frequency-domain approach described in Chapter 71.3 (Elmore) leads to the following approximation of a CML delay gate with unity fan-out[33]:

$$\tau_{d,cml} = \left(1 + g_m R_L\right)R_b C_{bc} + R_b\left(C_{be} + C_d\right) + \left(2C_{bc} + 1/2C_{be} + 1/2C_d\right)/g_m \tag{72.17}$$

where C_d is the diffusion capacitance of $g_m(\tau_b + \tau_{cscl})$. Furthermore, by considering the difference in charge storage at logic high and logic low, divided by the logic swing, the effective CML gate capacitance can be expressed[19] as

$$C_{cml} = C_{be}/2 + 2C_{bc} + C_s + \left(\tau_b + \tau_{cscl}\right)/R_L \tag{72.18}$$

where C_s is collector-substrate and interconnect capacitances. Both equations show that the load resistor and bias (which affects g_m and device capacitors) have a strong effect on performance.

For a rough estimate of the CML maximum speed without loading, one can assume that f_t is the gain bandwidth product. With the voltage gain set at $g_m R_L$, the maximum speed is $f_t/(g_m R_L)$. In the above example, at 1 mA average bias, $g_{m,int}$ = 1/26 S at room temperature. Assuming the internal parasitic emitter resistance R_E is 10 ohms and using the fact that $g_{m,ext} = g_{m,int}/(1 + R_E g_{m,int})$, the effective extrinsic g_m is 1/36 mhos. With a 200-ohm load resistor, the voltage gain is approximately 5.5. With a 70-GHz f_t HBT process, the maximum switching rate is about 13 GHz. Although this estimate is quite rough, it does show that high-speed CML logic desires high device bias and low logic swing. In most differential circuits, only 3 to 4 kT/q is needed to switch the transistors and overcome the noise floor. With such low levels

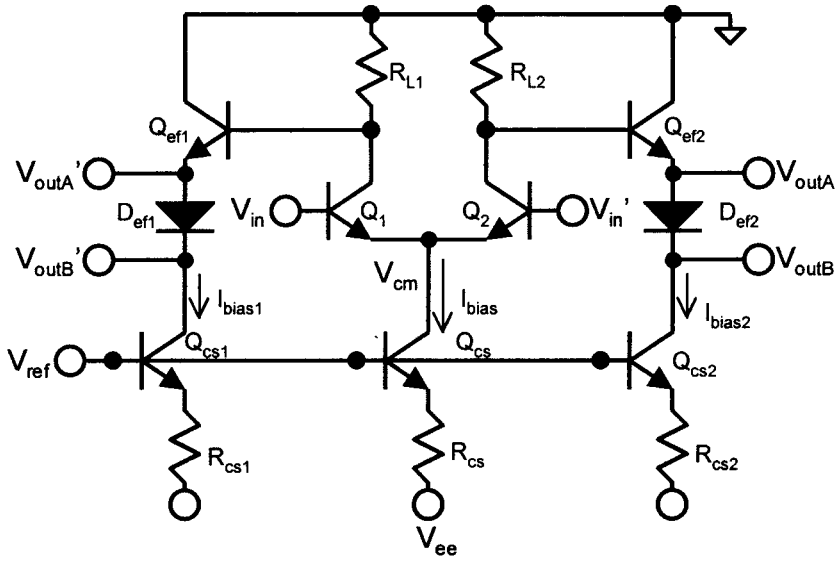

FIGURE 72.11 Standard differential ECL buffer with outputs taken at two different voltage levels.

and limited gain, the output may not saturate to the logic extremes, resulting in decreasing noise margin. In practice, the differential logic level should not be allowed to drop below 225 mV. With a 225-mV swing vs. 400 mV, the maximum gate bandwidth improves to 23 GHz from 13 GHz.

Emitter-Coupled Logic

By adding emitter followers to the basic HBT CML buffer, the HBT ECL buffer is formed in Fig. 72.11. From a dc perspective, the emitter followers (Q_{ef1} and Q_{ef2}) shift the CML logic level down by V_{be}. With the outputs at V_{outA}/V_{outA}' and 400 mV swing from the differential pair, the first level ECL logic high is –1.4 V and the ECL logic low is –1.8 V. For some ECL logic gates, a second level is created through a Schottky diode voltage shift (D_{ef1}/D_{ef2}). The typical Schottky diode turn-on voltage for GaAs is 0.7 V, so the output at V_{outB}/V_{outB}' is –2.1 V for a logic high and –2.5 V for a logic low. In general, the HBT ECL levels differ quite a bit from the standard Si ECL levels. Although resistors can be used to bias Q_{ef1}/Q_{ef2}, current mirrors (Q_{cs1}/Q_{cs2} and R_{cs1}/R_{cs2}) are typically used. Current mirrors offer stable bias with logic level at the expense of higher capacitance, while resistors offer lower capacitance but the bias varies more and may be physically quite large.

From an ac point of view, emitter followers have high input impedance (approximately β times larger than an unbuffered input) and low output impedance (approx. $1/g_m$), which makes it an ideal buffer. In comparison with CML gates, since the differential pair now drives a higher load impedance, the effect of loading is reduced, yielding increased bandwidth, faster edge rates, and higher fan-out. The cost of this improvement is the increase in power due to the bias current of the emitter followers. For example, in a 50 GHz HBT process, a CML buffer (fan-out = 1, I_{bias} = 2mA, R_{L1}/R_{L2} = 150 Ω), the propagation delay (t_D) is 14.8 ps with a risetime [20 to 80%] (t_r) of 31 ps and a falltime [20 to 80%] (t_f) of 21 ps. In comparison, an ECL buffer with level 1 outputs (fan-out = 1, I_{bias} = 2 mA, I_{bias1}/I_{bias2} = 2 mA, R_{L1}/R_{L2} = 150 Ω) has t_d = 14 ps, t_f = 9 ps, and t_r = 17 ps. With a threefold increase in P_{diss}, the impedance transformation of the EF stage results in slightly reduced gate delays and significant improvements in the rise/falltimes. With the above ECL buffer modified for level 2 (level shifted) outputs, the performance is only slightly lower with t_D = 14.2 ps, t_f = 11 ps, and t_r = 22 ps.

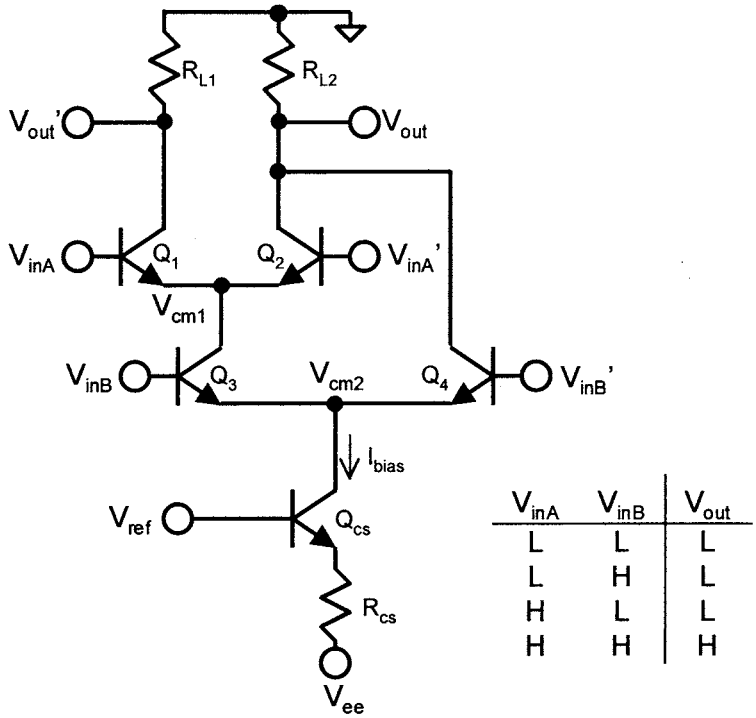
In general, emitter followers tend to have bandwidths approaching the f_t of the device, which is significantly higher than the differential pair. Consequently, it is possible to obtain high-speed operation with the EF biased lower than would be necessary to obtain the maximum device f_t. With the ECL level 1

buffer, if the I_{bias1}/I_{bias2} is lowered to 1 mA from 2mA, the performance is still quite high, with t_d = 15 ps, t_f = 13 ps, and t_r = 18 ps. Although t_D approaches the CML case, the t_f and t_r are still significantly better.

As the EF bias is increased, its driving ability is also increased; however, at some point with high bias, the output impedance of the EF becomes increasingly inductive. When combined with large load capacitance (as in the case of high fan-out or long interconnect), it may result in severe ringing in the output that can result in excessive jitter on data edges. The addition of a series resistor between the EF output and the next stage can help to dampen the ringing by increasing the real part of the load. This change, however, increases the RC time constant, which usually results in a significant reduction in performance. In practice, changing the impedance of the EF bias source (high impedance current source or resistor bias) does not have a significant effect on the ringing. As a result, the primary method to control the ringing is through the EF bias, which places a very real constraint on bandwidth, fan-out, and jitter that needs to be considered in the topology of real designs. In some FET DCFL designs, several source followers are cascaded together to increase the input impedance and lower the output resistance between two differential pairs for high-bandwidth drive. Due to voltage headroom limits, it is very difficult to cascade two HBT emitter followers without causing the current source to enter deep saturation. In general, ECL gates are typically used for the high-speed sections due to significant improvement in rise/falltimes (bandwidth) and drive ability, although the power dissipation is higher.

ECL/CML Logic Examples

Typically, ECL and CML logic is mixed throughout high-speed GaAs/AlGaAs HBT designs. As a result, there are three available logic levels that can be used to interconnect various gates. The levels are CML (0/–400 mV), ECL1 (–1.4/–1/8 V), and ECL2 (–2.1/–2.5 V). To form more complex logic functions, typically two levels of transistors are used to steer the bias current. Figure 72.12 shows an example of an CML AND/NAND gate. For the ECL counterpart, it is only necessary to add the emitter followers. The top input is V_{inA}/V_{inA}'. The bottom input is V_{inB}/V_{inB}'. In general, the top can be driven with either the



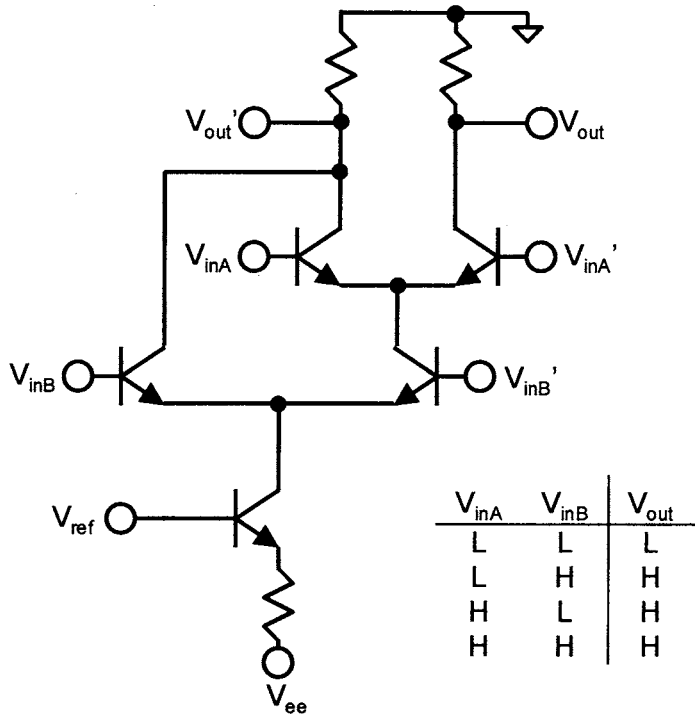
V_{inA}	V_{inB}	V_{out}
L	L	L
L	H	L
H	L	L
H	H	H

FIGURE 72.12 Two-level differential CML AND gate.

CML or the ECL1 inputs, and the bottom level can be driven by ECL1 and ECL2 levels. The choice of logic input levels are typically dictated by the design tradeoff between bandwidth, power dissipation, and fan-out. As seen in Fig. 72.12, only when V_{inA} and V_{inB} are high, will I_{bias} current be steered into the load resistor that makes $V_{out} = V_{OH}$. All other combinations will make $V_{out} = V_{OL}$, as required by the AND function. Due to the differential nature, if the output terminal labels were reversed, this would be a NAND gate.

For the worst-case voltage headroom, V_{inA}/V_{inA}' is driven with ECL1 levels, resulting in V_{cm1} of –2.8 V. With an ECL2 high on V_{inB} (–2.1 V), the lower stage (Q_3/Q_4) has a B-C forward-bias of 0.7 V, which may result in a slight saturation. This also implies that V_{cm2} is around –3.5 V, which results in an acceptable nominal 100 mV forward-bias on the current source transistor (Q_{cs}). As V_{ee} becomes less negative, the change in V_{ee} is absorbed across Q_{cs}, which places Q_{cs} closer into saturation. In saturation, the current source holds I_e in Q_{cs} constant; so if I_b increases (due to saturation), then I_c decreases. For some current source reference designs that cannot source the increased I_b, the increased loading due to saturated I_b may lower V_{ref}, which would have a global effect on the circuit bias. If the current source reference can support the increase in I_b, then the bias of only the local saturated differential pair starts to decrease leading to the potential of lower speed and lower logic swing. For HBTs, the worst-case Q_{cs} saturation occurs at low temperature, and the worst-case saturation for Q_3/Q_4 occurs at high temperature since V_{be} changes by –1.4 mV/C and V_{diode} = –1.1 mV/C (for constant-current bias). It is possible to decrease the forward-bias of the lower stage by using the base-emitter diode as the level shift to generate the second ECL levels; however, the power supply voltage needs to increase from –5.2 to possibly –6 V.

With the two-level issues in mind, Fig. 72.13 illustrates the topology for a two-level OR/NOR gate. This design is similar to an AND gate except that $V_{out} = V_{OL}$ if both V_{inA} and V_{inB} are low. Otherwise, Vout = V_{OH}. By using the bottom differential pair to select one of the two top differential pairs, many other prime logic functions can be implemented. In Fig. 72.14, the top pairs are wired such that $V_{out} = V_{OL}$ if $V_{inA} = V_{inB}$, forming the XOR/XNOR block. If the top differential pairs are thought of as selectable



V_{inA}	V_{inB}	V_{out}

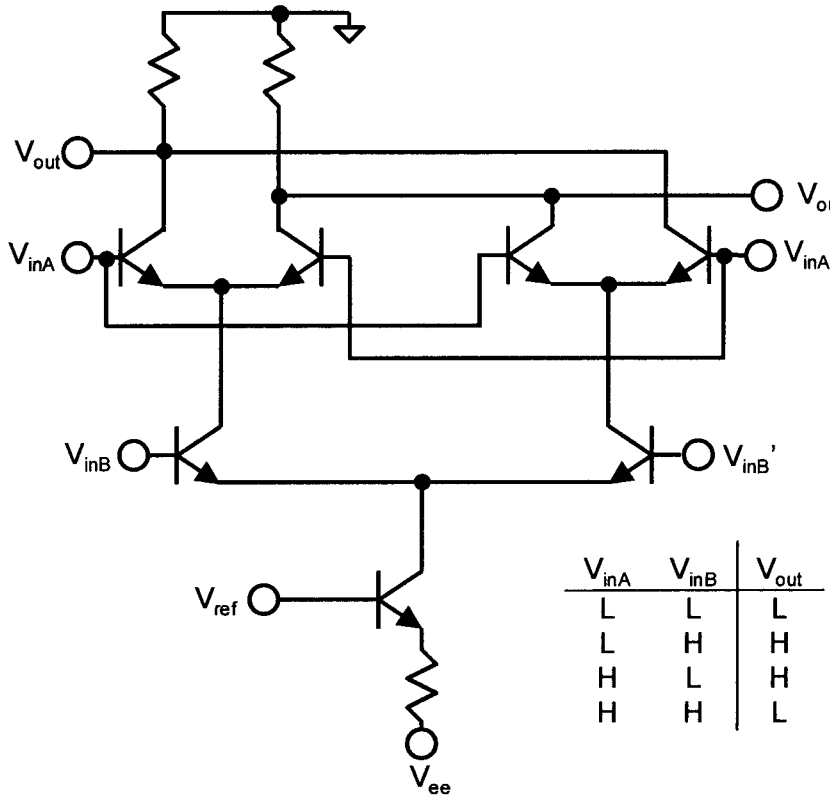

FIGURE 72.14 Two-level differential CML XOR gate.

buffers with a common output as shown in Fig. 72.15, then a basic 2:1 MUX cell is formed. Here, V_{inB}/V_{inB}' determines which input (V_{inA1}/V_{inA1}' or V_{inA2}/V_{inA2}') is selected to the output. This concept can be further extended to a 4:1 MUX if the top signals are CML and the control signals are ECL1 and ECL2, as shown in Fig. 72.16. Here, the MSB (ECL1) and LSB (ECL2) determine which of the four inputs are selected. With the 2:1 MUX in mind, if each top differential pair had separate output resistors with a common input, a 1:2 DEMUX is formed as shown in Fig. 72.17.

The last primary cell of importance is the latch. This is shown in Fig. 72.18. Here, the first differential pair is configured as a buffer. The second pair is configured as a buffer with positive feedback. The positive feedback causes any voltage difference between the input transistors to be amplified to full logic swing and that state is held as long as the bias is applied. With this in mind, as the first buffer is selected ($V_{inB} = V_{OH}$), the output is transparent to the input. As $V_{inB} = V_{OL}$, the last value stored in the buffer is held, forming a latch, which in this case, is triggered on the falling edge of the ECL2 level. When two of these blocks are connected together in series, it forms the basic master-slave flip-flop.

Advanced ECL/CML Logic Examples

With small signal amplifiers, the cascode configuration (common base on top of a common emitter stage) typically reduces the Miller capacitance for higher bandwidth. With the top-level transistor on, the top transistor forms a cascode stage with the lower differential amplifier. This can lead to higher bandwidths and reduced rise/falltimes. However, in large-signal logic, the bottom transistor must first turn on the top cascode stage before the output can change. This added delay results in a larger propagation delay from for the bottom pair vs. the top switching pair. In the case of the OR/NOR, as in Fig. 72.12, if Q_1 or Q_2 switches with Q_3 on or if Q_4 switches, the propagation delay is short. If Q_3 switches, it must first turn

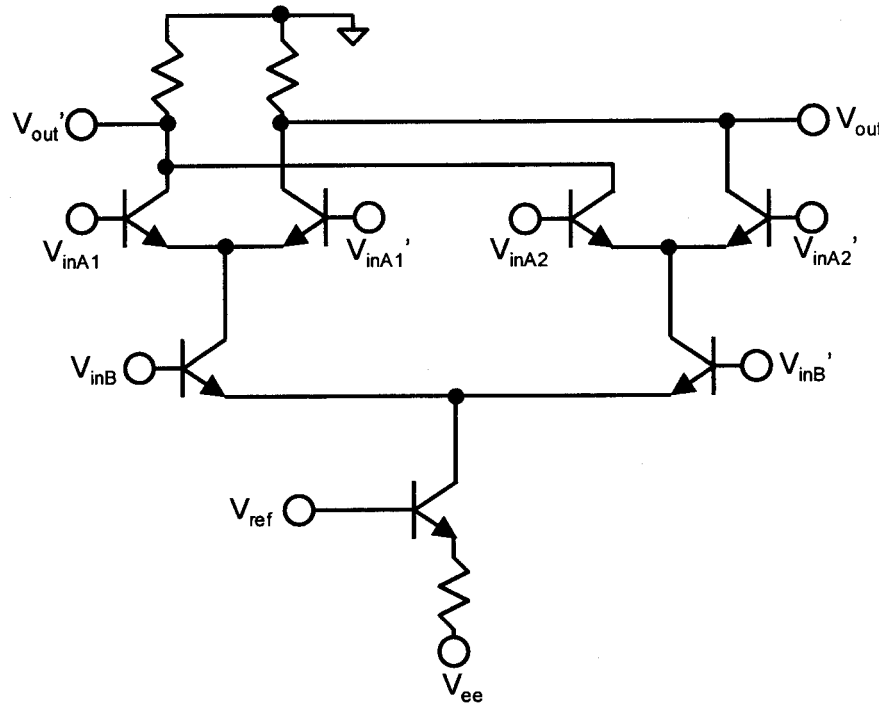

FIGURE 72.15 Two-level 2:1 differential CML MUX gate.

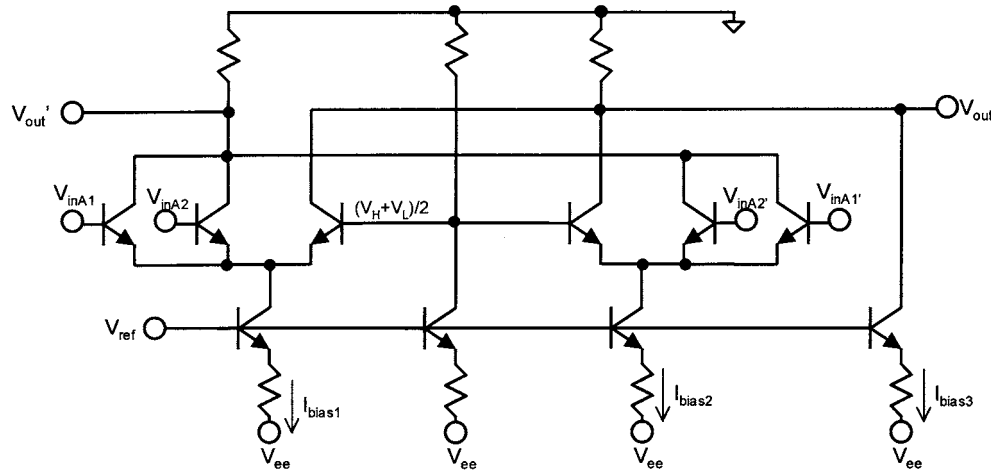
on either Q_1/Q_2, leading to the longest propagation delay. In this case, the longest delay limits the usable bandwidth of the AND gate. Likewise, in the XOR case, the delay of the top input is shorter than the lower input, which results in asymmetric behavior and reduced bandwidth. For a 10-GHz flip-flop, this can result in as much as a 10-ps delay from rising edge of the clock to the sample point of the data. This issue must be taken into account in determining the optimal input data phase for lowest bit errors when dealing with digital data.

One solution to the delay issue is to use a quasi-differential signal. In Fig. 72.19, a single-ended single-level OR/NOR gate is shown. Here, a reference generator of $(V_H + V_L)/2$ is applied to V_{inA}'. If either of the V_{inA1} or V_{inA2} is high, then $V_{out} = V_{OH}$. This design has more bandwidth than the two-level topology shown in Fig. 72.12, but some of the noise margin may be sacrificed.

Figure 72.20 shows an example of a single-level XOR gate with a similar input level reference. In this case, $I_{bias1} = I_{bias2} = I_{bias3}$. The additional I_{bias3} is used to make the output symmetric. Ignoring I_{bias3}, when V_{inA} is not equal to V_{inB}, I_{bias1} and I_{bias2} are used to force $V_{out}' = V_{OL}$. When $V_{inA} = V_{inB}$, $V_{out} = V_{out}'$ since both are lowered by I_{bias}, resulting in an indeterminate state. To remedy this, I_{bias3} is added to V_{out} to make the outputs symmetric. This design results in higher speed due to the single-level design; however, the noise margin is somewhat reduced due to the quasi-differential approach and the outputs have a common-mode voltage offset of $R_L I_{bias}$.

In a standard differential pair, the output load capacitance can be broken into three parts. The base-collector capacitance of the driving pair, the interconnect capacitance, and the input capacitance of the next stage. The interconnect capacitance is on the order of 5 to 25 fF for adjacent to nearby gates. The base-collector depletion capacitance is on the order of 25 fF. Assuming that the voltage gain is 5.5, the effective C_{bc} or Miller capacitance is about 140 fF. $C_{be,j}$, when the transistor is off, is typically less than 6 fF. The $C_{be,d}$ capacitance when the transistor is on is of the order of 50 to 200 fF. These rough numbers show that the Miller effect has a significant effect on the effective load capacitance. For the switching transistor, the Miller effect increases both the effective internal C_{bc} as well as the external load. In these situations, a cascode stage may result in higher bandwidth and sharper rise/falltimes with a slight increase in propagation delay. Figure 72.21 shows a CML gate with an added cascode stage. Due to the 400-mV logic swing, the cascode bases are connected to ground. For higher swings, the cascode bases can be biased to a more negative voltage to avoid saturation. The cascode requires that the input level be either



V_{inA1}	V_{inA2}	I_{out}	$I_{out'}$	V_{out}	$V_{out'}$
L	L	$2I_{bias}$	I_{bias}	L	H
L	H	I_{bias}	$2I_{bias}$	H	L
H	L	I_{bias}	$2I_{bias}$	H	L
H	H	$2I_{bias}$	I_{bias}	L	H

FIGURE 72.20 Single-level CML quasi-differential XOR gate.

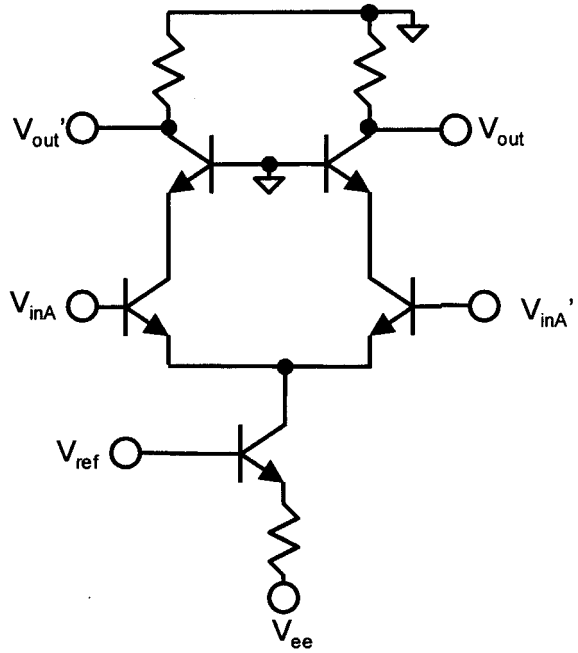


FIGURE 72.21 CML buffer with a cascode output stage.

ECL1 or ECL2 to account for the V_{be} drop of the cascode. Since the base of the cascode is held at ac ground, the Miller effect is not seen at the input of the common-base stage as the output voltage swings. From the common-emitter point of view, the collector swings only about 60 mV per decade change in I_c, thus the Miller effect is greatly reduced. The reduction of the Miller effect through cascoding reduces

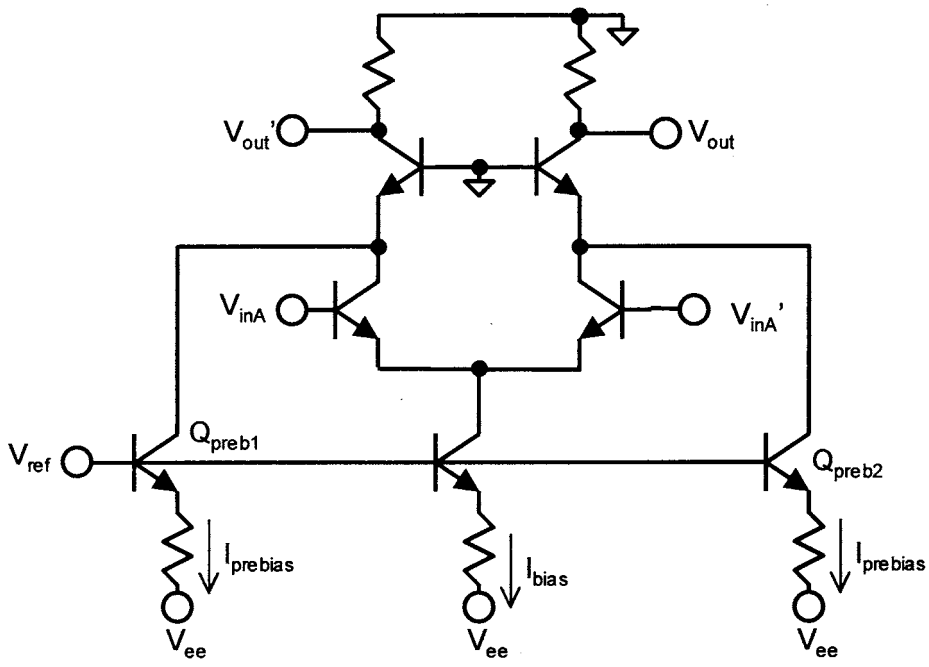

FIGURE 72.22 CML buffer with a cascode output stage and bleed current to keep the cascode "on".

the effect of both the internal transistor C_{bc} and load capacitance due to C_{bc} of the other stages, which results in the reduced rise/falltimes, especially at the logic transition region.

As both of the transistors in a cascode turn off, the increased charge stored in both transistors that has to discharge through an RC time constant may result in a slower edge rate near the logic high of a rising edge. In poorly designed cascode stages, the corner point between the fast-rising edge to the slower-rising edge may occur near the 20/80% point, canceling out some of the desired gains. Furthermore, with the emitter node of the off common-base stage floating in a high-impedance state, its actual voltage varies with time (large RC discharge compared to the switching time). This can result in some "memory" effects where the actual node voltage depends on the previous bit patterns. In this case, as the transistor is turns on, the initial voltage may vary, which can result in increased jitter with digital data. With these effects in mind, the cascoded CML design can be employed with performance advantages in carefully considered situations.

One way to remedy the off cascode issues is to use prebias circuits as shown in Fig. 72.22. Here, the current sources formed with Q_{preb1} and Q_{preb2} ($I_{prebias} \ll I_{bias}$) ensures that the cascode is always slightly on by bleeding a small bias current. This results in improvements in the overall rise- and falltimes, since the cascode does not completely turn off. This circuit does, however, introduce a common-mode offset in the output that may reduce the headroom in a two-level ECL gate that it must drive. Furthermore, a series resistor can be introduced between the bleed point and the current source to decouple the current source capacitance into the high-speed node. This design requires careful consideration to the design tradeoffs involving the ratio of $I_{bias}/I_{prebias}$ as well as the potential size of the cascode transistor vs. the switch transistors for optimal performance. When properly designed, the bleed cascode can lead to significant performance advantages.

In general, high-speed HBT circuits require careful consideration and design of each high-speed node with respect to the required level of performance, allowable power dissipation, and fan-out. The primary tools the designer has to work with are device bias, device size, ECL/CML gate topology, and logic level to optimize the design. Once the tradeoff is understood, CML/ECL HBT-based circuits have formed

some of the faster circuits to date. The performance and capability of HBT technology in circuit applications are summarized below.

HBT Circuit Design Examples

A traditional method to benchmark the high-speed capability of a technology is to determine the maximum switching rate of a static frequency divider. This basic building block is employed in a variety of high-speed circuits, which include frequency synthesizers, demultiplexers, and ADCs. The basic static frequency divider consists of a master/slave flip-flop where the output data of the slave flip-flop is fed back to the input data of the master flip-flop. The clock of the master and the clock of the slave flip-flop are connected together, as shown in Fig. 72.23. Due to the low transistor count and importance in many larger high-speed circuits, the frequency divider has emerged as the primary circuit used to demonstrate the high-speed potential of new technologies. As HBT started to achieve SSI capability in 1984, a frequency divider with a toggle rate of 8.5 GHz[6] was demonstrated. During the transition from research to pilot production in 1992, a research-based AlInAs/GaInAs HBT (f_t of 130 GHz and f_{max} of 90 GHz) was able to demonstrate a 39.5 GHz divide-by 4.[60] Recently, an advanced AlInAs/GaInAs HBT technology (f_t of 164 GHz and f_{max} of 800 GHz) demonstrated a static frequency divider operating at 60 GHz.[61] This HBT ECL-based design, to date, reports the fastest results for any semiconductor technology, which illustrates the potential of HBTs and ECL/CML circuit topology for high-speed circuits.

Besides high-speed operation, production GaAs HBTs have also achieved a high degree of integration for LSI circuits. For ADCs and DACs, the turn-on voltage of the transistor (V_{be}) is determined by material constants, thus there is significantly less threshold variation when compared to FET-based technologies. This enables the design of high-speed and accurate comparators. Furthermore, the high linearity characteristics of HBTs enable the design of wide dynamic range and high linearity sample-and-hold circuits. These paramount characteristics result in the dominance of GaAs HBTs in the super-high performance/high-speed ADCs. An 8-bit 2 gigasamples/s ADC has been fabricated with 2500 transistors. The input bandwidth is from dc to 1.5 GHz, with a spur-free dynamic range of about 48 dB.[62]

Another lucrative area for digital HBTs is in the area of high-speed circuits that are employed in fiber-optic based telecommunications systems. The essential circuit blocks (such as a 40-Gb/s 4:1 multiplexers[63]

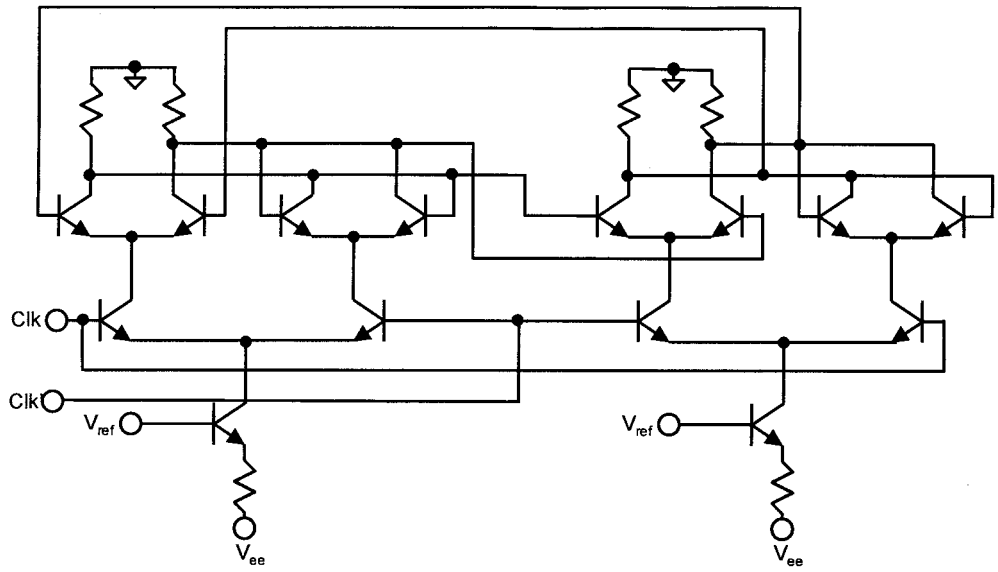

FIGURE 72.23 2:1 Frequency divider based on two CML latches (master/slave flip-flop).

and 26-GHz variable gain-limiting amplifiers[64]) have been demonstrated with HBTs in the research lab. In general, the system-level specifications (SONET) for telecommunication systems are typically very stringent compared with data communication applications at the same bit rate. The tighter specifications in telecom applications are due to the long-haul nature and the need to regenerate the data several times before the destination is reached. Today, there are many ICs that claim to be SONET-compliant at OC-48 (2.5 Gb/s) and some at OC-192 (10 Gb/s) bit rates. Since the SONET specifications apply on a system level, in truth, there are very few ICs having the performance margin over the SONET specification for use in real systems. Due the integration level, high-speed performance, and reliability of HBTs, some of the first OC-48 (2.5 Gb/s) and OC-192 (10 Gb/s) chip sets (e.g., preamplifiers, limiting amplifiers, clock and data recovery circuits, multiplexers, demultiplexers, and laser/modulator drivers) deployed are based on GaAs HBTs. A 16 × 16 OC-192 crosspoint switch has been fabricated with a production 50 GHz f_t and f_{max} process.[65] The LSI capability of HBT technology is showcased with this 9000 transistor switch on a 6730 × 6130 μm^2 chip. The high-speed performance is illustrated with a 10 Gb/s eye diagram shown in Fig. 72.24. With less than 3.1 ps of RMS jitter (with four channels running), this is the lowest jitter 10-Gb/s switch to date. At this time, only two 16 × 16 OC-192 switches have been demonstrated[65,66] and both were achieved with HBTs. With a throughput of 160,000 Mb/s, these HBT parts have the largest amount of aggregate data running through it of any IC technology.

In summary, III-V HBT technology is a viable high-speed circuit technology with mature levels of integration and reliability for real-world applications. Repeatedly, research labs have demonstrated the world's fastest benchmark circuits with HBTs with ECL/CML-based circuit topology. The production line has shown that current HBTs can achieve the both the integration and performance level required for high-performance analog, digital circuits, and hybrid circuits that operate in the high gigahertz range. Today, the commercial success of HBTs can be exemplified by that fact that HBT production lines ship several million HBT ICs every month and that several new HBT production lines are in the works. In the future, it is expected that advances in Si based technology will start to compete in the markets currently held by III-V technology; however, it is also expected that III-V technology will move on to address ever higher speed and performance issues to satisfy our insatiable demand for bandwidth.

73.1 Introduction

As the complexity of VLSI systems continues to increase, the micro-electronic industry must possess an ability to reconfigure design and manufacturing resources and integrate design activities so that it can quickly adapt to the market changes and new technology. Gaining this ability imposes a two-fold challenge: (1) to coordinate design activities that are geographically separated and (2) to represent an immense amount of knowledge from various disciplines in a unified format. The Internet can provide the catalyst by abridging many design activities with the resources around the world not only to exchange information but also to communicate ideas and methodologies.

In this chapter, we present a collaborative engineering framework that coordinates distributed design activities through the Internet. Engineers can represent, exchange, and access the design knowledge and carry out design activities. The crux of the framework is the formal representation of process flow using the process grammar, which provides the theoretical foundation for representation, abstraction, manipulation, and execution of design processes. The abstraction of process representation provides mechanisms to represent hierarchical decomposition and alternative methods, which enable designers to manipulat e the process fl ow diag ram and se lect the best method. In the fram e work, the process inf orm at ion

is layered into separate specification and execution levels so that designers can capture processes and execute them dynamically. As the framework is being executed, a designer can be informed of the current status of design such as updating and tracing design changes and be able to handling exception. The framework can improve design productivity by accessing, reusing, and revising the previous process for a similar. The cockpit of our framework interfaces with engineers to perform design tasks and to negotiate design tradeoff. The framework has the capability to launch whiteboards that enable the engineers in a distributed environment to view the common process flows and data and to concurrently execute dynamic activities such as process refinement, selection of alternative process, and design reviews. The proposed framework has a provision for various browsers where the tasks and data used in one activity can be organized and retrieved later for other activities.

One of the predominant challenges for micro-electronic design is to handle the increased complexity of VLSI systems. At the turn of the century, it is expected that there will be 100 million transistors in a single chip with 0.1 micron features, which will require an even shorter design time (Spiller, 1997). This increase of chip complexity has given impetus to trends such as system on a chip, embedded system, and hardware/software co-design. To cope with this challenge, industry uses custom-off- the-shelf (COTS) components, relies on design reuse, and practices outsourcing design. In addition, design is highly modularized and carried out by many specialized teams in a geographically distributed environment. Multi-facets of design and manufacturing, such as manufacturability and low power, should be considered at the early stage of design. It is a major challenge to coordinate these design activities (Fair, 94). The difficulties are caused by due to the interdependencies among the activities, the delay in obtaining distant information, the inability to respond to errors and changes quickly, and general lack of communications. At the same time, the industry must contend with decreased expenditures on manufacturing facilities while maintaining rapid responses to market and technology changes.

To meet this challenge, the U.S. government has launched several programs. The Rapid Prototyping of Application Specific Signal Processor (RASSP) Program was initiated by the Department of Defense to bring about the timely design and manufacturing of signal processors. One of the main goals of the RASSP program was to provide an effective design environment to achieve a four-time improvement in the development cycle of digital systems (Chung, 1996). DARPA also initiated a program to develop and demonstrate key software elements for Integrated Product and Process Development (IPPD) and agile manufacturing applications. One of the foci of the earlier program was the development of infrastructure for distributed design and manufacturing. Recently, the program is continued to Rapid Design Exploration & Optimization (RaDEO) to support research, development, and demonstration of enabling technologies, tools, and infrastructure for the next generation of design environments for complex electro-mechanical systems. The design environment of RaDEO is planned to provide cognitive support to engineers by vastly improving their ability to explore, generate, track, store, and analyze design alternatives (Lyons, 1997).

The new information technologies, such as the Internet and mobile computing, are changing the way we communicate and conduct business. More and more design centers use PCs, and link them on the Internet/intranet. The web-based communication allows people to collaborate across space and time, between humans, humans and computers, and computers in a shared virtual world (Berners-Lee, 1994). This emerging technology holds the key to enhance design and manufacturing activities. The Internet can be used as the medium of a virtual environment where concepts and methodologies can be discussed, accessed, and improved by the participating engineers. Through the medium, resources and activities can be reorganized, reconfigured, and integrated by the participating organizations. This new paradigm certainly impacts the traditional means for designing and manufacturing a complex product. Using Java, programs can be implemented in a platform-independent way so that they can be executed in any machine with a Web browser. Common Object Request Broker Architecture (CORBA) (Yang, 1996) provides distributed services for tools to communicate through the Internet (Vogel). Designers may be able to execute remote tools through the Internet and see the visualization of design data (Erkes, 1996; Chan, 1998; Chung, 1998).

Even though the potential impact of this technology will be great on computer aided design, Electronic Design Automation (EDA) industry has been slow in adapting this new technology (Spiller, 1997). Until

recently, EDA frameworks used to be a collection of point tools. These complete suites of tools are integrated tightly by the framework using their proprietary technology. These frameworks have been suitable enough to carry out a routine task where the process of design is fixed. However, new tools appear constantly. To mix and match various tools outside of a particular framework is very difficult. Moreover, tools, expertise, and materials for design and manufacturing of a single system are dispersed geographically. Now we have reached the stage where a single tool or framework is not sufficient enough to handle the increasing complexity of a chip and emerging new technology. A new framework is necessary which is open and scalable. It must support collaborative design activities so that designers can add new tools to the framework, and interface them with other CAD systems. There are two key functions of the framework: (1) managing the process and (2) maintaining the relationship among many design representations. For design data management, refer to (Katz, 1987). In this chapter, we will focus on the process management aspect.

To cope with the complex process of VLSI system design, we need a higher level of viewing of a complete process, i.e., the abstraction of process by hiding all details that need not to be considered for the purpose at hand. As pointed out in National Institute of Standards and Technology reports (Schlenoff, 1996; Knutilla, 1998), a "unified process specification language" should have the following major requirements: abstraction, alternative task, complex groups of tasks, and complex sequences.

In this chapter we first review the functional requirements of the process management in VLSI system design. We then present the Internet-based Micro-Electronic Design Automation (IMEDA) System. IMEDA is a web-based collaborative engineering framework where engineers can represent, exchange, and access design knowledge and perform the design activities through the Internet. The crux of the framework is a formal representation of process flow using process grammar. Similar to the language grammar, production rules of the process grammar map tasks into admissible process flows (Baldwin, 1995a). The production rules allow a complex activity to be represented more concisely with a small number of high-level tasks. The process grammar provides the theoretical foundation for representation, abstraction, manipulation, and execution of design and manufacturing processes. It facilitates the communication at an appropriate level of complexity. The abstraction mechanism provides a natural way of browsing the process repository and facilitates process reuse and improvement. The strong theoretical foundation of our approach allows users to analyze and predict the behavior of a particular process. The cockpit of our framework interfaces with engineers to perform design tasks and to negotiate design tradeoff. The framework guides the designer in selecting tools and design methodologies, and it generates process configurations that provide optimal solutions with a given set of constraints. The just-in-time binding and the location transparency of tools maximize the utilization of company resources. The framework is equipped with whiteboards so that engineers in a distributed environment can view the common process flows and data and concurrently execute dynamic activities such as process refinement, selection of alternative processes, and design reviews. With the grammar, the framework gracefully handles exceptions and alternative productions. A layered approach is used to separate the specification of design process and execution parameters. One of the main advantages of this separation is freeing designers from the overspecification and graceful exception handling. The framework, implemented using Java, is open and extensible. New process, tools, and user-defined process knowledge and constraints can be added easily.

73.2 Functional Requirements of Framework

Design methodology is defined as a collection of principles and procedures employed in the design of engineering systems. Baldwin and Chung (Baldwin, 1995a) define design methodology management as selecting and executing methodologies so that the input specifications are transformed into desired output specifications. Kleinfeldt (1994), states that "design methodology management provides for the definition, presentation, execution, and control of design methodology in a flexible, configured way." Given a methodology, we can select a process or processes for that particular methodology.

Each design activity, whether big or small, can be treated as a task. A complex design task is hierarchically decomposed into simpler subtasks, and each subtask in turn may be further decomposed. Each

task can be considered as a transformation from input specification to output specification. The term *workflow* is used to represent the details of a process including its *structure in terms of all the required tasks and their interdependencies*. Some process may be ill-structured, and capturing it as a workflow may not be easy. Exceptions, conditional executions, and human involvement during the process make it difficult to model the process as a workflow.

There can be many different tools or alternative processes to accomplish a task. Thus, a design process requires design decisions such as selecting tools and processes as well as selecting appropriate design parameters. At a very high level of design, the input specifications and constraints are very general and may even be ill-structured. As we continue to decompose and perform the tasks based on design decisions, the output specifications are refined and the constraints on each task become more restrictive. When the output of a task does not meet certain requirements or constraints, a new process, tools, or parameters must be selected. Therefore, the design process is typically iterative and based on previous design experience. Design process is also a collaborative process, involving many different engineering activities and requiring the coordination among engineers, their activities, and the design results.

Until recently, it was the designer's responsibility to determine which tools to use and in what order to use them. However, managing the design process itself has become difficult, since each tool has its own capabilities and limitations. Moreover, new tools are developed and new processes are introduced continually. The situation is further aggravated because of incompatible assumptions and data formats between tools. To manage the process, we need a framework to monitor the process, carry out design tasks, support cooperative teamwork, and maintain the relationship among many design representations (Chiueh, 1990; Katz, 1987). The framework must support concurrent engineering activities by integrating various CAD tools and process and component libraries into a seamless environment. Figure 73.1 shows the RASSP enterprise system architecture (Welsh, 1995). It integrates tools, tool frameworks, and data management functions into an enterprise environment. The key functionality of the RASSP system is managing the RASSP design methodology by "process automation", that is, controlling CAD program execution through workflow.

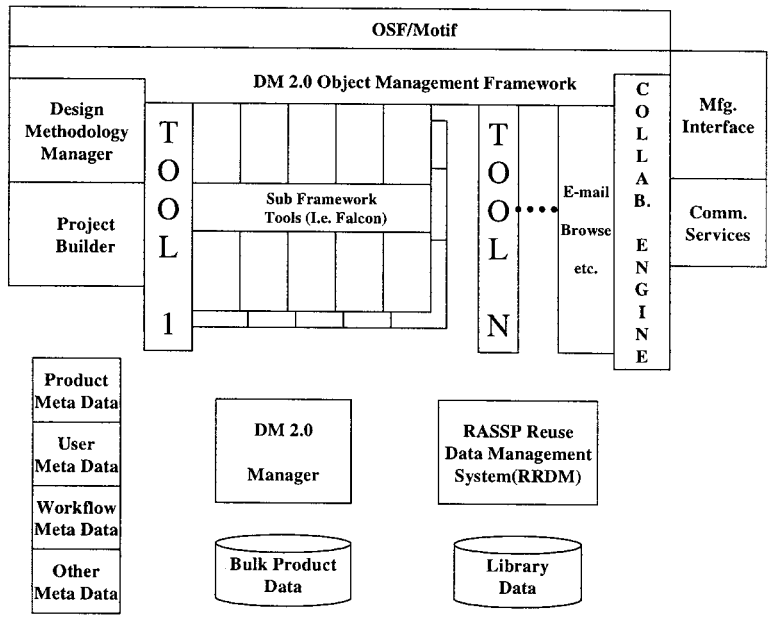

FIGURE 73.1 RASSP enterprise system architecture.

The Building Blocks of Process

The lowest level of a building block of a design process is a tool. A *tool* is an unbreakable unit of a CAD program. It usually performs a specific task by transforming given input specifications into output specifications. A *task* is defined as design activities that include information about what tools to use and how to use them. It can be decomposed into smaller subtasks. The simplest form of the task, called an *atomic task*, is the one that cannot be decomposed into subtasks. In essence, an atomic task is defined as an encapsulated tool. A task is called *logical* if it is not atomic. A workflow of a logical task describes the details of how the task is decomposed into subtasks, and the data and control dependencies such as the relationship between design data used in the subtasks. For a given task, there can be several workflows, each of which denotes a possible way of accomplishing the task. A *methodology* is a collection of workflow supported together with information on which workflow should be selected in a particular instance.

Functional Requirements of Workflow Management

To be effective, a framework must integrate many design automation tools and allow the designer to specify acceptable methodologies and tools together with information such as when and how they may be used. Such a framework must not only guide the designer in selecting tools and design methodologies, but also aid the designer in constructing a workflow that is suitable to complete the design under given constraints. The constructed workflow should guarantee that required steps are not skipped; built-in design checks are incorporated into the workflow. The framework must also keep the relationships between various design representations, maintain the consistency between designs and support cooperative teamwork, and allow the designer to interact with the system to adjust design parameters or to modify the previous design process. The framework must be extendible to accommodate rapidly changing technologies and emerging new tools. Such a framework can facilitate developing new hardware systems as well as redesigning a system from a previous design.

During a design process, a particular methodology or workflow selected by a designer must be based on available tools, resources (computing and human), and design data. For example, a company may impose a rule that if input is a VHDL behavioral description, then designers should use Model Technology's VHDL simulator, but if the input is Verlig, they must use ViewLogic simulator. Or, if a component uses Xilinx, then all other components must also use Xilinx. Methodology must be driven by local expertise and individual preference, which in turn, are based on the designer's experience.

The process management should not constrain the designer. Instead, it must free designers from routine tasks, and guide the execution of workflow. User interaction and a designer's freedom are especially important when exceptions are encountered during the execution of flows, or when designers are going to modify the workflow locally. The system must support such activities through "controlled interactions" with designers.

Process management can be divided into two parts:

- A formal specification of supported methodologies and tools that must show the tasks and data involved in a workflow and their relationships.
- An execution environment that helps designers to construct workflow and execute them.

Process Specification

Methodology management must provide facilities to specify design processes. Specification of processes involves tasks and their structures (i.e., workflow). The task involved and the flow of process, that is the way the process can be accomplished in terms of its subtasks, must be defined. Processes must be encapsulated and presented to designers in a usable way. Designers want an environment to guide them in building a workflow and to help them execute it during the design process. Designers must be able to browse related processes, and compare, analyze, and modify them.

Tasks

Designers should be able to define the tasks that can be logical or atomic, organize the defined tasks, and retrieve them. Task abstraction refers to using and viewing a task for specific purposes and ignoring the irrelevant aspects of the task. In general, object-oriented approaches are used for this purpose. Abstraction of the task may be accomplished by defining tasks in terms of "the operations the task is performing" without detailing the operations themselves. Abstraction of tasks allows users to clearly see the behavior of them and use them without knowing the details of their internal implementations. Using the generalization–specialization hierarchy (Chung, 1990), similar tasks can be grouped together. In the hierarchy, a node in the lower level inherits its attributes from its predecessors. By inheriting the behavior of a task, the program can be shared, and by inheriting the representation of a task (in terms of its flow), the structure (workflow) can be shared. The Process Handbook (Malone, in press) embodies concepts of specialization and decomposition to represent processes.

There are various approaches associated with binding a specific tool to an atomic task. A tool can be bound to a task statically at the compile time, or dynamically at the run time based on available resources and constraints. When a new tool is installed, designers should be able to modify the existing bindings. The simplest approach is to modify the source code or write a script file and recompile the system. The ideal case is plug and play, meaning that CAD vendors address the need of tool interoperability, e.g., the Tool Encapsulation Specification (TES) proposed by CFI (CFI, 1995).

Workflow

To define a workflow, we must specify the tasks involved in the workflow, data, and their relationship. A set of workflows defined by methodology developers enforces the user to follow the flows imposed by the company or group. Flows may also serve to guide users in developing their own flows. Designers would retrieve the cataloged flows, modify them, and use them for their own purposes based on the guidelines imposed by the developer. It is necessary to generate legal flows. A blackboard approach was used in (Lander, 1995) to generate a particular flow suitable for a given task. In Nelsis (Bosch, 1991), branches of a flow are explicitly represented using "or" nodes and "merge" nodes. A task can be accomplished in various ways. It is necessary to represent alternative methodologies for the task succinctly so that designers can access alternative methodologies and select the best one based on what-if analysis. IDEF3.X (IDEF) is used to graphically model workflow in RASSP environment. Figure 73.2 shows an example of workflow using IDEF3.X. A node denotes a task. It has inputs, outputs, mechanism, and conditions. IDEF definition that has been around for 20 years mainly to capture flat modeling such as a shop floor process. IDEF specification, however, requires complete information such as control mechanisms and scheduling at the specification time, making the captured process difficult to understand. In IDEF, "or" nodes are used to represent the alternative paths. It does not have an explicit mechanism to represent alternative workflow. IDEF is ideal only for documenting the current practice and not suitable for executing iterative process which is determined during the execution of the process. Perhaps, the most important aspect missing from most process management systems is the abstraction mechanism (Schlenoff, 1996).

Execution Environment

The execution environment provides dynamic execution of tasks and tools and binds data to tools, either manually or automatically. Few frameworks separate the execution environment from the specification of design process. There are several modes in which a task can be executed (Kleinfeldth, 1994): manual mode, manual execution of flow, automatic flow execution, and automatic flow generation. In manual flow execution, the environment executes a task in the context of a flow. In an automatic flow execution environment, tasks are executed based on the order specified on the flow graph. In automatic flow generation, the framework generates workflow dynamically and executes them without the guidance of designers. Many frameworks use blackboard- or knowledge-based approaches to generate workflow. However, it is important for designers to be able to analyze the workflow created and share it with others.

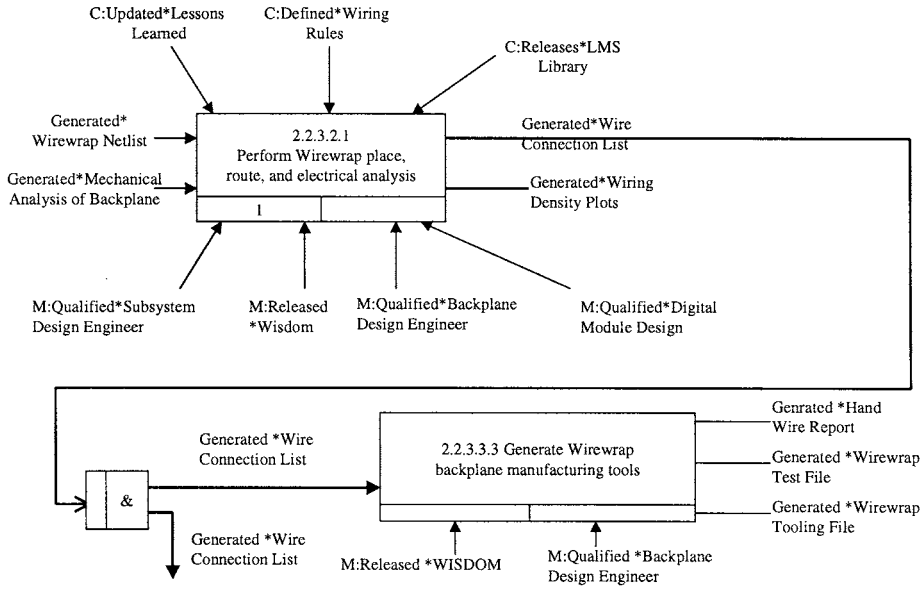

FIGURE 73.2 Workflow example using IDEF definition.

That is, repeatability and predictability are important factors if frameworks support dynamic creation of workflow.

Each task may be associated with pre- and post-conditions. Before a task is executed, the pre-condition of the task is evaluated. If the condition is not satisfied, the framework either waits until the condition is met, or aborts the task and selects another alternative. After the task is executed, its post-condition is evaluated to determine if the result meets the exit criteria. If the evaluation is unsatisfactory, another alternative should be tried.

When a task is complex involving many subtasks and each subtask in turn has many alternatives, generating a workflow for the task that would successfully accomplish the task is not easy. If the first try of an alternative is not successful, another alternative should be tried. In some cases, backtrack occurs which nullifies all the executions of previous workflow.

Literature Surveys

Many systems have been proposed to generate design process (Knapp, 1991) and manage workflow (Dellen, 1997; Lavana, 1997; Schurmann, 1997; Sutton, 1998). Many of them use the web technology to coordinate various activities in business (Andreoli, 1997), manufacturing (Berners-Lee, 1994; Cutkosy, 1996; Erkes, 1996), and micro-electronic design (Rastogi, 1993, Chan, 1998). WELD (Chan, 1998) is a network infrastructure for a distributed design system that offers users the ability to create a customizable and adaptable virtual design system that can couple tools, libraries, design, and validation services. It provides support not only for designing but also for manufacturing, consulting, component acquisition, and product distribution, encompassing the developments of companies, universities, and individuals throughout the world. Lavana et al. (1997) proposed an Internet-based collaborative design. They use Petri nets as a modeling tool for describing and executing workflow. User teams, at different sites, control the workflow execution by selection of its path. Minerva II (Sutton, 1998) is a software tool that provides design process management capabilities serving multiple designers working with multiple CAD frameworks. The proposed system generates design plan and realizes unified design process management across multiple CAD frameworks and potentially across multiple design disciplines. ExPro (Rastogi, 1993) is an expert-system-based process management system for the semiconductor design process.

There are several systems that automatically determine what tools to execute. OASIS (OASIS, 1992) uses Unix make file style to describe a set of rules for controlling individual design steps. The Design Planning Engine of the ADAM system (Knapp, 1986; Knapp, 1991) produces a plan graph using a forward chaining approach. Acceptable methodologies are specified by listing pre-conditions and post-conditions for each tool in a lisp-like language. Estimation programs are used to guide the chaining. Ulysses (Bushnell, 1986) and Cadweld (Daniel, 1991) are blackboard systems used to control design processes. A knowledge source, which encapsulates each tool, views the information on the blackboard and determines when the tool would be appropriate. The task management is integrated into the CAD framework and Task Model is interpreted by a blackboard architecture instead of a fixed inference mechanism. Minerva (Jacome, 1992) and the OCT task manager (Chiu, 1990) use hierarchical strategies for planning the design process. Hierarchical planning strategies take advantage of knowledge about how to perform abstract tasks which involve several subtasks.

To represent design process and workflow, many languages and schema have been proposed. NELSIS (Bosch, 1991) framework is based on a central, object-oriented database and on a flow management. It uses a dataflow graph as Flow Model and provides the hierarchical definition and execution of design flow. PLAYOUT (Schurmann, 1997) framework is based on separate Task and Flow Models which are highly interrelated among themselves and the Product Model. In (Barthelmann, 1996), graph grammar is proposed in defining the task of software process management. Westfechtel (1996) proposed "process-net" to generate the process flow dynamically. However, in many of these systems, the relationship between task and data is not explicitly represented. Therefore, representing the case in which a task generates more than one datum and each of them goes to a different task is not easy. In (Schurmann, 1997), Task Model (describing the I/O behavior of design tools) is used as a link between the Product Model and the Flow Model. The proposed system integrates data and process management to provide traceability. Many systems use IDEF to represent a process (Chung, 1996; IDEF; Stavas). IDEF specification, however, requires complete information such as control mechanisms and scheduling at the specification time, making the captured process difficult to understand.

Although there are many other systems that address the problem of managing process, most proposed system use either a rule-based approach or a hard-coded process flow. They frequently require source code modification for any change in process. Moreover, they do not have mathematical formalism. Without the formalism, it is difficult to handle the iterative nature of the engineering process and to simulate the causal effects of any changes in parameters and resources. Consequently, coordinating the dynamic nature of processes is not well supported in most systems. It is difficult to analyze the rationale how an output is generated and where a failure has occurred. They also lack a systematic way of generating all permissible process flows at any level of abstraction while providing means to hide the details of the flow when they are not needed. Most systems have the tendency to over-specify the flow information, requiring complete details of a process flow before executing the process. In most real situations, the complete flow information may not be known after the process has been executed: they are limited in their ability to address the underlying problem of process flexibility. They are rather rigid and not centered on users, and do not handle exceptions gracefully. Thus, the major functions for the collaborative framework such as adding new tools and sharing and improving the process flow cannot be realized. Most of them are weak in at least one of the following criteria suggested by NIST (Schlenoff et al., 1996): process abstraction, alternative tasks, complex groups of tasks, and complex sequences.

73.3 IMEDA System

The Internet-based Micro-Electronic Design Automation (IMEDA) System is a general management framework for performing various tasks in design and manufacturing of complex micro-electronic systems. It provides a means to integrate many specialized tools such as CAD and analysis packages, and allows the designer to specify acceptable methodologies and tools together with information such as when and how they may be used. IMEDA is a collaborative engineering framework that coordinates

design activities distributed geographically. The framework facilitates the flow of multimedia data sets representing design process, production, and management information among the organizational units of a virtual enterprise. IMEDA uses process grammar (Baldwin, 1995) to represent the dynamic behavior of the design and manufacturing process. In a sense, IMEDA is similar to agent-based approach such as Redux (Petrie, 1996). Redux, however, does not provide process abstraction mechanism or facility to display the process flow explicitly.

The major functionality of the framework includes

- Formal representation of the design process using the process grammar that captures a complex sequence of activities of micro-electronic design.
- Execution environment that selects a process, elaborates the process, invokes tools, pre- and post-evaluates the productions if the results meet the criterion, and notifies designers.
- User interface that allows designers to interact with the framework, guides the design process, and edits the process and productions.
- Tool integration and communication mechanism using Internet Socket and HTTP.
- Access control that provides a mechanism to secure the activity and notification and approval that provide the mechanisms to disperse design changes to, and responses from, subscribers

IMEDA is a distributed framework. design knowledge, including process information, manager programs, etc., are maintained in a distributed fashion by local servers. The following Fig. 73.3 illustrates how IMEDA links tools and sites for distributed design activities. The main components of IMEDA are

- **System Cockpit**: It controls all interactions between the user and the system and between the system components. The cockpit will be implemented as a Java applet and may be executable on any platform for which a Java enabled browser is available. It keeps track of the current design status and informs the user of possible actions. It allows users to collaboratively create and edit process flows, production libraries, and design data.
- **Manager Programs:** These encapsulate design knowledge. Using pre-evaluation functions, managers estimate the possibility of success for each alternative. They invoke tools and call post-evaluation functions to determine if a tool's output meets the specified requirements. The interface servers allow cockpits and other Java-coded programs to view and manipulate production, task

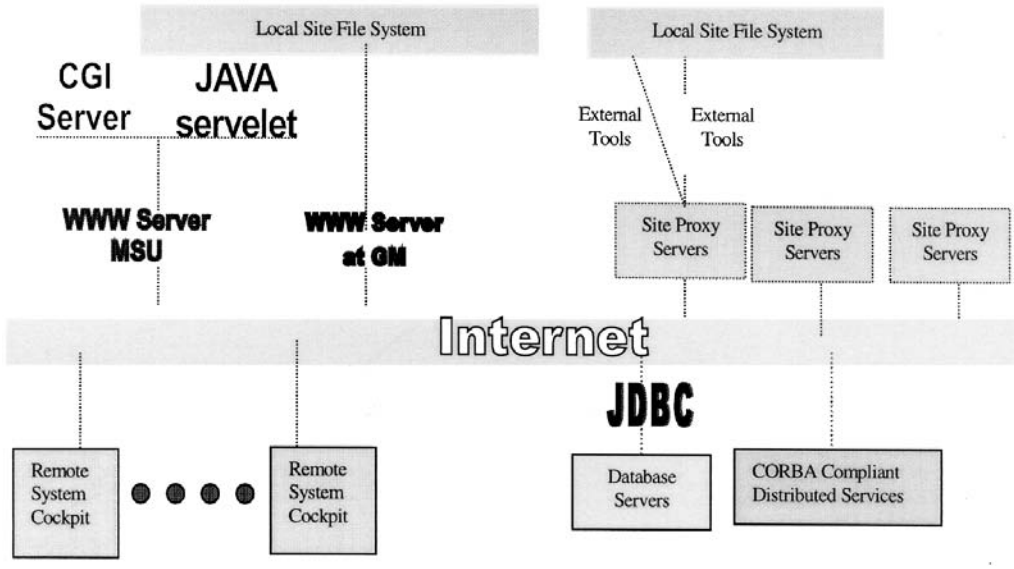

FIGURE 73.3 The architecture of IMEDA.

and design data libraries. Manager programs must be maintained by tool integrators to reflect site-specific information such as company design practices and different ways of installing tools.

- **Browsers:** The task browser organizes the tasks in a generalization-specialization (GS) hierarchy and contains all the productions available for each task. The data-specification browser organizes the data-specifications in a GS hierarchy and contains all the children.
- **External Tools**. These programs are the objects invoked by the framework during DM activities. Each atomic task in a process flow is bound to an external tool. External tools are written typically by the domain experts.
- **Site Proxy Server:** Any physical site that will host external tools must have a site proxy server running. These servers provide an interface between the cockpit and the external tools. The site server receives requests from system cockpits, and invokes the appropriate tool. Following the tool completion, the site server notifies the requesting cockpit, returning results, etc.
- **CGI Servers and Java Servlets:** The system cockpit may also access modules and services provided by CGI servers or the more recently introduced Java servlets. Currently, the system integrates modules of this type as direct components of the system (as opposed to external tools that may vary with the flow).
- **Database Servers:** Access to component data is a very important function. Using an API called JBDC, the framework can directly access virtually any commercially available database server remotely.
- **Whiteboard:** The shared cockpit, or "whiteboard" is a communication medium to share information among users in a distributed environment. It allows designers to interact with the system and guides the design process collaboratively. Designers will be able to examine design results and current process flows, post messages, and carry out design activities both concurrently and collaboratively. Three types of whiteboards are the process board, the chat board, and the freeform drawing board. Their functionality includes: (i) process board to the common process flow graph indicating the current task being executed and the intermediate results arrived at before the current task; (ii) drawing board to load visual design data, and to design and simulate process; and (iii) chat board to allow participants to communicate with each other via text-based dialog box.

IMEDA uses a methodology specification based on a process flow graphs and process grammars (Baldwin, 1995). Process grammars are the means for transforming high-level process flow graphs into progressively more detailed graphs by applying a set of substitution rules, called productions, to nodes that represent logical tasks. It provides not only the process aspect of design activities but also a mechanism to coordinate them. The formalism in process grammar facilitates abstraction mechanisms to represent hierarchical decomposition and alternative methods, which enable designers to manipulate the process flow diagram and select the best method. The formalism provides the theoretical foundations for the development of IMEDA.

IMEDA contains the database of admissible flows, called process specifications. With the initial task, constraints, and execution environment parameters, including personal profile, IMEDA guides designers in constructing process flow graphs in a top-down manner by applying productions. It also provides designers with the ability to discover process configurations that provide optimal solutions. It maintains consistency among designs and allows the designer to interact with the system and adjust design parameters, or modify the previous design process. As the framework is being executed, a designer can be informed of the current status of design such as updating and tracing design changes and be able to handling exception.

Real-world processes are typically very complex by their very nature; IMEDA provides designers the ability to analyze, organize, and optimize processes in a way never before possible. More importantly, the framework can improve design productivity by accessing, reusing, and revising the previous process for a similar design.

The unique features of our framework include

Process Abstraction/Modeling — Process grammars provide abstraction mechanism for modeling admissible process flows. The abstraction mechanism allows a complex activity to be represented

more concisely with a small number of higher-level tasks, providing a natural way of browsing the process repository. The strong theoretical foundation of our approach allows users to analyze and predict the behavior of a particular process. With the grammar, the process flow gracefully handles exceptions and alternative productions. When a task has alternative productions, backtracking occurs to select other productions.

Separation of Process Specification and Execution Environment — Execution environment information such as complex control parameters and constraints is hidden from the process specification. The information of these two layers is merely linked together to show the current task being executed on a process flow. The represented process flow can be executed in both automatic and manual modes. In the automatic mode, the framework executes all possible combinations to find a solution. In the manual mode, users can explore design space.

Communication and Collaboration — To promote real-time collaboration among participants, the framework is equipped with the whiteboard, a communication medium to share information. Users can browse related processes, compare them with other processes, analyze, and simulate them. Locally managed process flows and productions can be integrated by the framework in the central server. The framework manages the production rules governing the higher level tasks, while lower level tasks and their productions are managed by local servers. This permits the framework to be effective in orchestrating a large-scale activity.

Efficient Search of Design Process and Solution — IMEDA is able to select the best process and generate a process plan, or select a production dynamically and create a process flow. The process grammar easily captures design alternatives. The execution environment selects and executes the best one. If the selected process does not meet the requirement, then the framework backtracks and selects another alternative. This backtrack occurs recursively until a solution is found. If you allow a designer to select the best solution among many feasible ones, the framework may generate many multiple versions of the solution.

Process Simulation — The quality of a product depends on the tools (maturity, speed, and special strength of the tool), process (or workflow selected), and design data (selected from the reuse library). Our framework predicts the quality of results (product) and assesses the risk and reliability. This information can be used to select the best process/work flow suitable for a project.

Parallel Execution of Several Processes and Multiple Versions — To reduce the design time and risk, it is necessary to execute independent tasks in parallel whenever they are available. Sometimes, it is necessary to investigate several alternatives simultaneously to reduce the design time and risk. Or the designer may want to execute multiple versions with different design parameters. The key issue in this case is scheduling the tasks to optimize the resource requirements.

Life Cycle Support of Process Management — The process can be regarded as a product. A process (such as airplane designing or shipbuilding) may last many years. During this time, it may be necessary for the process itself to be modified because of new tools and technologies. Life cycle support includes updating the process dynamically, and testing/validating the design process, version history and configuration management of the design process. Tests and validations of the design processes, the simulation of processes, and impact analysis are necessary tools.

73.4 Formal Representation of Design Process[1]

IMEDA uses a methodology specification based on a process flow graphs and process grammars (Baldwin, 1995). The grammar is an extension of graph grammar originally proposed by Ehrig (1979) and has been applied to interconnection network (Derk, 1998) and software engineering (Heiman, 1997).

[1]Materials in this section are excerpted from R. Baldwin and M.J. Chung, *IEEE Computer,* Feb. 1995. With permission.

Process Flow Graph

A process flow graph depicts tasks, data, and the relationships among them, describing the sequence of tasks for an activity. Three basic symbols are used to represent a process flow graph. Oval nodes represent Logical Tasks, two-concentric oval nodes represent Atomic Tasks, rectangular nodes represent Data Specifications and diamond nodes represent Selectors. A task that can be decomposed into subtasks is called *logical*. Logical task nodes represent abstract tasks that could be done with several different tools or tool combinations. A task that cannot be decomposed is *atomic*. An atomic task node, commonly called a tool invocation, represents a run of an application program.

A *selector* is a task node that selects data or parameter. Data specifications are design data, where the output specification produced by a task can be consumed by another task as an input specification. Each data specification node, identified by a rectangle, is labeled with a data specification type. Using the graphical elements of the flow graph, engineers can create a process flow in a top-down fashion. These elements can be combined into a process flow graph using directed arcs. The result is a bipartite acyclic directed graph that identifies clearly the task and data flow relationships among the tasks in a design activity. The set of edges indicates those data specifications used and produced by each task. Each specification must have at most one incoming edge. Data specifications with no incoming edges are inputs of the design exercise. $T(G)$, $S(G)$, and $E(G)$ are the sets of task nodes, specification nodes, and edges of graph G, respectively. Figure 73.4 shows a process flow graph that describes a possible rapid

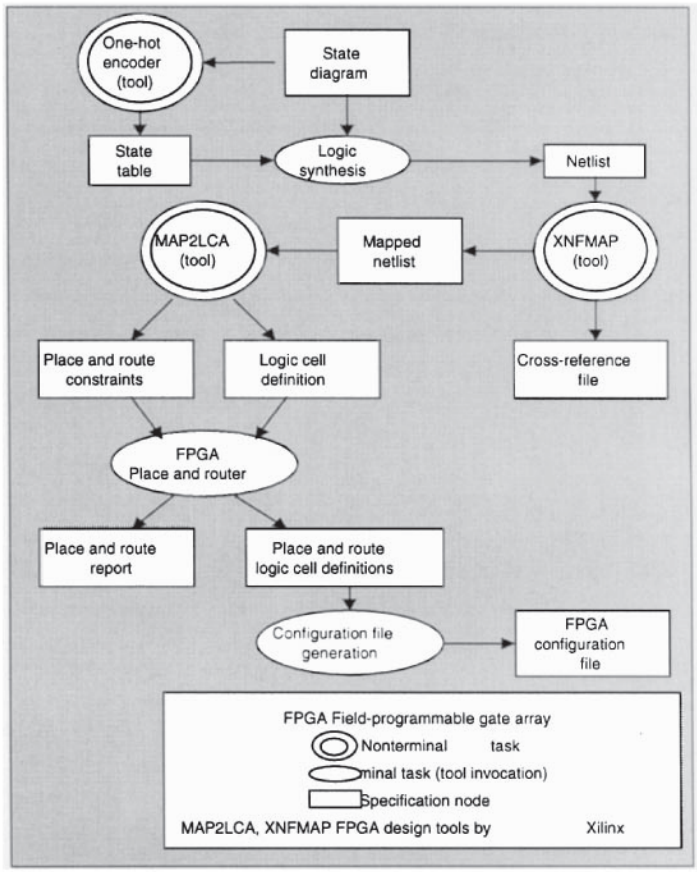

FIGURE 73.4 A sample process flow graph in which a state diagram is transformed into a field-programmable gate array configuration file.

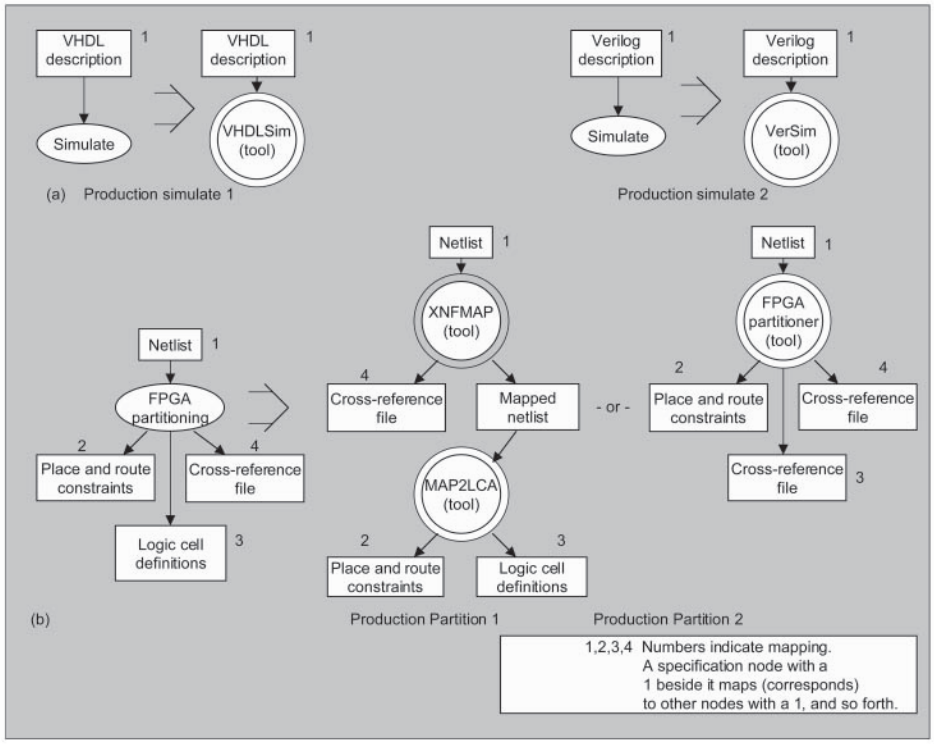

FIGURE 73.5 Graph production from a design process grammar. Two simulation alternatives based on input format are portrayed in (a); two partition alternatives representing different processes for an abstract task are protrayed in (b).

prototyping design process, in which a state diagram is transformed into a field-programmable gate array (FPGA) configuration file.

The various specification types form a class hierarchy where each child is a specialization of the parent. There may be several incompatible children. For example, VHDL and Verilog descriptions are both children of simulation models. We utilize these specification types to avoid data format incompatibilities between tools (see Fig. 73.5a). Process flow graphs can describe design processes to varying levels of detail. A graph containing many logical nodes abstractly describes what should be done without describing how it should be done (i.e., specifying which tools to use). Conversely, a graph in which all task nodes are atomic completely describes a methodology.

In our prototype, we use the following definitions: $In(N)$ is the set of input nodes of node N: $In(N) = \{ M \mid (M,N) \in E\}$. Out(N) is the set of output nodes of node N: $OUT(N) = \{ M \mid (N,M) \in E\}$. $I(G)$ is the set of input specifications of graph G: $\{ N \in S(G) \mid In(N) = \varnothing \}$.

Process Grammars

The designer specifies the overall objectives with the initial graph that lists available input specifications, desired output specifications, and the logical tasks to be performed. By means of process grammars, logical task nodes are replaced by the flows of detailed subtasks and intermediate specifications. The output specification nodes are also replaced by nodes that may have a child specification type.

The productions in a graph grammar permit the replacement of one subgraph by another. A production in a design process grammar can be expressed formally as a tuple $P = (G_{LHS}, G_{RHS}, \sigma_{in}, \sigma_{out})$, where G_{LHS} and G_{RHS} are process flow graphs for the left side and the right side of the production, respectively, such that (i) G_{LHS} has one logical task node representing the task to be replaced, (ii) σ_{in} is a mapping

from the input specifications $I(G_{LHS})$ to $I(G_{RHS})$, indicating the relationship between two input specifications (each input specification of $I(G_{RHS})$ *is* a subtype of $I(G_{LHS})$), and (iii) σ_{out} is a mapping from the output specifications of G_{LHS} to output specifications of G_{RHS} indicating the correspondence between them. (each output specification must be mapped to a specification with the same type or a subtype). Figure 73.5 illustrates productions for two tasks, `simulate` and `FPGA partitioning`. The mappings are indicated by the numbers beside the specification nodes. Alternative productions may be necessary to handle different input specification types (as in Fig. 73.5a), or because they represent different processes- separated by the word "or" — for performing the abstract task (as in Fig. 73.5b).

Let A be the logical task node in $G_{LHS,}$ and A' be a logical task node in the original process flow graph G such that A has the same task label as A'. The production rule P can be applied to A', which means that A' can be replaced with G_{RHS} only if each input and output specifications of A' matches to input and output specifications of G_{LHS}, respectively. If there are several production rules with the same left side flow graph, it implies that there are alternative production rules for the logical task. Formally, the production matches A' if

(i) A' has the same task label as A.
(ii) There is a mapping ρ_{in}, from $In(A)$ to $In(A')$, indicating how the inputs should be mapped. For all nodes $N \in In(A)$, $\rho_{in}(N)$ should have the same type as N or a subtype.
(iii) There is a mapping, ρ_{out}, from $Out(A')$ to $Out(A)$, indicating how the outputs should be mapped. For all nodes $N \in Out(A')$, $\rho_{out}(N)$ should have the same type as N or a subtype.

The mappings are used to determine how edges that connected the replaced subgraph to the remainder should be redirected to nodes in the new subgraph. Once a match is found in graph G, the production is applied as follows:

(i) Insert G_{RHS}–$I(G_{RHS})$ into G. The inputs of the replaced tasks are not replaced.
(ii) For every N in $I(G_{RHS})$ and edge (N,M) in G_{RHS}, add edge $(\rho_{in}(\sigma_{in}(N)),M)$ to G. That is to connect the inputs of A' to the new task nodes that will use them.
(iii) For every N in Out(A') and edge (N,M) in G, replace edge (N,M) with edge $(\sigma_{out}(\rho_{out}(N)),M)$. That is to connect the new output nodes to the tasks that will use them.
(iv) Remove A' and Out(A') from G, along with all edges incident on them.

Figure 73.6 illustrates a derivation in which the FPGA partitioning task is planned, using a production from Fig. 73.5b.

The process grammar provides mechanism of specifying alternative methods for a logical task. A high-level flow graph can then be decomposed into detailed flow graphs by applying *production rules* to a logical task. A *production rule* is a substitution that permits the replacement of a logical task node with a flow graph that represents a possible way of performing the task. The concept of applying productions to logical tasks is somewhat analogous to the idea of productions in traditional (i.e., non-graph) grammars. In this sense, logical tasks correspond to *logical symbols* in grammar, and atomic tasks correspond to *terminal symbols*.

73.5 Execution Environment of the Framework

Figure 73.7 illustrates the architecture of our proposed system, which applies the theory developed in the previous section. Decisions to select or invoke tools are split between the designers and a set of manager programs, where manager programs are making the routine decisions and the designers make decisions that requires higher-level thinking. A program called Cockpit coordinates the interaction among manager programs and the designers. Tool sets and methodology preferences will differ among sites and over time. Therefore, our assumption is that each unit designates a person (or group) to act as system integrator, who writes and maintains the tool-dependent code in the system. We provide the tool-independent code and template to simplify the task of writing tool-dependent code.

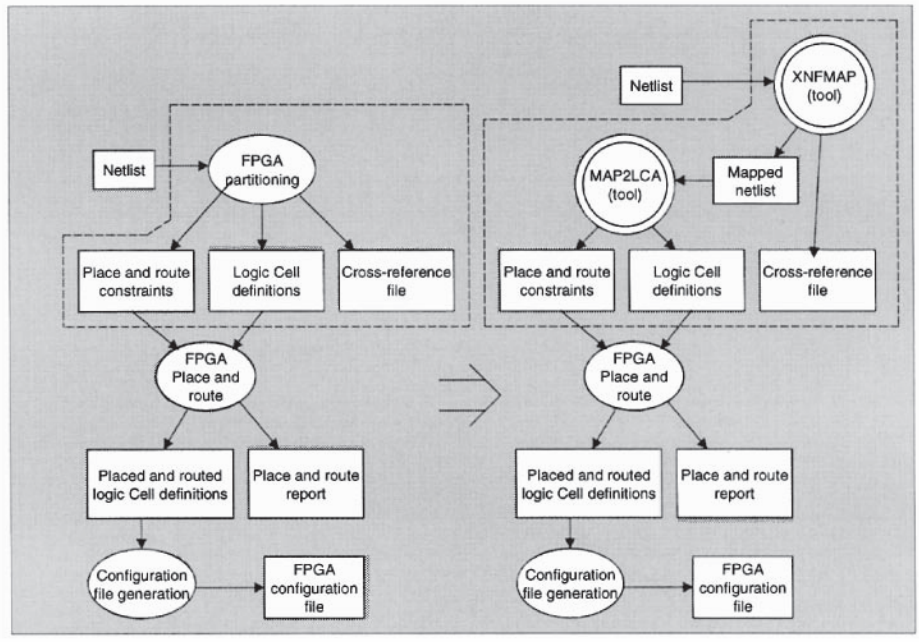

FIGURE 73.6 A sample graph dertivation. Nodes in the outlined region, left, are replaced with nodes in the outlined region, right, according to production partition 1 in Fig. 73.5.

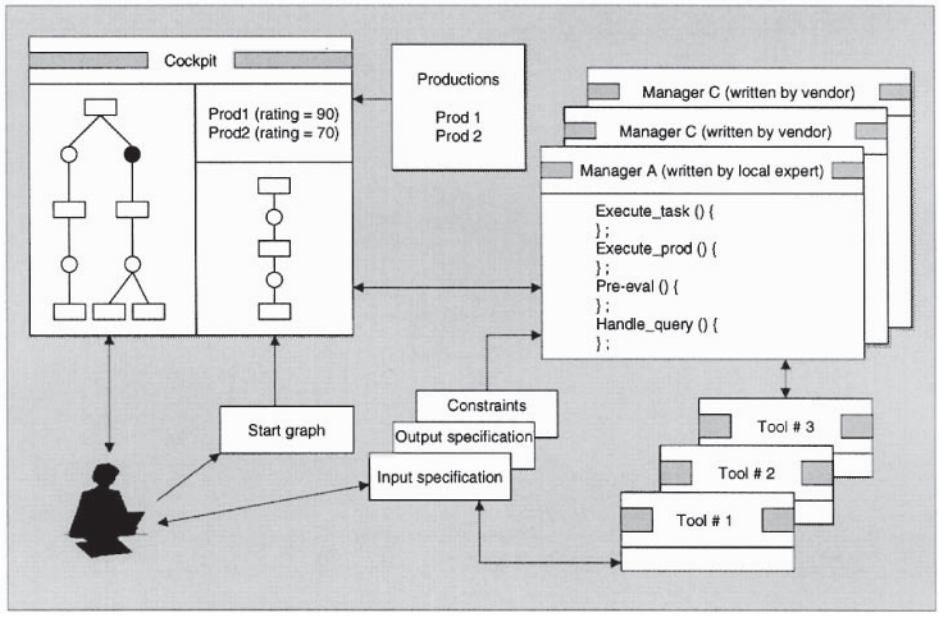

FIGURE 73.7 The proposed system based on Cockpit.

The Cockpit Program

The designer interacts with Cockpit, a program which keeps track of the current process flow graph and informs the designer of possible actions such as productions that could be applied or tasks that could be executed. Cockpit contains no task-specific knowledge; its information about the design process comes

entirely from a file of graph productions. When new tools are acquired or new design processes are developed, the system integrator modifies this file by adding, deleting, and editing productions.

To assist the designer in choosing an appropriate action, Cockpit interacts with several manager programs which encapsulate design knowledge. There are two types of manager programs: task managers and production managers. Task managers invoke tools and determine which productions to execute for logical task nodes. Production managers provide ratings for the productions and schedule the execution of tasks on the right-had side of the production. Managers communicate with each other using messages issued by Cockpit.

Our prototype system operates as follows. Cockpit reads the initial process flow graph from an input file generated by using a text editor. Cockpit then iteratively identifies when productions can be applied to logical task nodes and requests that the production managers assign the ratings to indicate how appropriate the productions are for those tasks. The process flow graph and the ratings of possible production applications are displayed for the designer, who directs Cockpit through a graphical user interface to apply a production or execute a task at any time. When asked to execute a task, Cockpit sends a message to a task manager. For an atomic task node, the task manager simply invokes the corresponding tool. For a logical task, the task manager must choose one or more productions, as identified by a Cockpit. The Cockpit applies the production and requests that the production manager executes it.

Manager Programs

Manager programs must be maintained by system integrators to reflect site-specific information, such as company design practices and tool installation methods. Typically, a manager program has its own thread. A Cockpit may have several manager programs, and therefore multi-threads. We define a communication protocol between Cockpit and manager programs and provide templates for manager programs. The manager programs provide five operations: pre-evaluation, tool invocation, logical task execution, production execution, and query handling. Each operation described below corresponds to a C++ or Java function in the templates, which system integrators can customize as needed.

Pre-evaluation: Production managers assign ratings to help designers and task managers select the most appropriate productions. The rating indicates the likelihood of success from applying this production. The strategies used by the system integrator provide most of the code to handle the rating. In some cases, it may be sufficient to assign ratings statically, based on the success of past productions. These static ratings can be adjusted downward when the production has already been tried unsuccessfully on this task node (which could be determined using the query mechanism). Alternatively, the ratings may be an arbitrarily complex function of parameters obtained through the query mechanism or by examining the input files. Sophisticated manager programs may continuously gather and analyze process metrics that indicate those conditions leading to success, adjust adjusting ratings accordingly.

Tool Invocation: Atomic task mangers must invoke the corresponding software tool when requested by Cockpit, then determine whether the tool completed successfully. In many cases, information may be predetermined and entered in a standard template, which uses the tool's result status to determine success. In other cases, the manager must determine tool parameters using task-specific knowledge or determine success by checking task-specific constraints. Either situation would require further customization of the manager program.

Logical Task Execution: Logical task managers for logical tasks must select productions to execute the logical task. Cockpit informs the task manager of available productions and their ratings. The task manager can either direct Cockpit to apply and execute one or more productions, or it can decide that none of the productions is worthwhile and report failure. The task manager can also request that the productions be reevaluated when new information has been generated that might influence the ratings, such as a production's failure. If a production succeeds, the task manager checks any constraints; if they are satisfied, it reports success.

Production Execution: Production managers execute each task on the right-hand side of the production at the appropriate time and possibly check constraints. If one of the tasks fails or a constraint is violated, backtracking can occur. The production manager can use task-specific knowledge to determine which tasks to repeat. If the production manager cannot handle the failure itself, it reports the failure to Cockpit, and the managers of higher level tasks and productions attempt to handle it.

Query Handling: Both production and task managers participate in the query mechanism. A production manager can send queries to its parent (the task manager for the logical task being performed) or to one of its children (a task manager of a subtask). Similarly, a task manager can send a query to its parent production manager or to one of its children (a production manager of the production it executed). The manager templates define C functions, which take string arguments, for sending these queries. System integrators call these functions but do not need to modify them. The manager templates also contain functions which are modified by system integrators for responding to queries. Common queries can be handled by template code; for example, a production manager can frequently ask its parent whether the production has already been attempted for that task and whether it succeeded. The manager template handles any unrecognized query from a child manager by forwarding it to the parent manager. Code must be added to handle queries for task-specific information such as the estimated circuit area or latency.

Execution Example

Now we describe a synthesis scenario that illustrates our prototype architecture in use. In this scenario, the objective is to design a controller from a state diagram, which will ultimately be done following the process flow graph in Fig. 73.4. There are performance and cost constraints on the design, and the requirement to produce a prototype quickly. The productions used are intended to be representative but not unique. For simplicity, we assume that a single designer is performing the design with, therefore, only one Cockpit.

The start graph for this scenario contains only the primary task, chip synthesis, and specification nodes for its inputs and outputs (like the graph in the left in Fig. 73.8). Cockpit tells us that the production of Fig. 73.8 can be applied. We ask Cockpit to apply it. The chip synthesis node is then replaced by nodes for state encoding, logic synthesis, and physical synthesis, along with intermediate specification nodes. Next, we want to plan the physical synthesis task. Tasks can be planned in an order other than they are to be performed. Cockpit determines that any of the productions shown in Fig. 73.9 may be applied, then queries each production's task manager program asking it to rate the production's appropriateness in the current situation. Based on the need to implement the design quickly, the productions for standard cell synthesis and full custom synthesis are rated low while the production for FPGA synthesis is rated high. Ratings are displayed to help us decide.

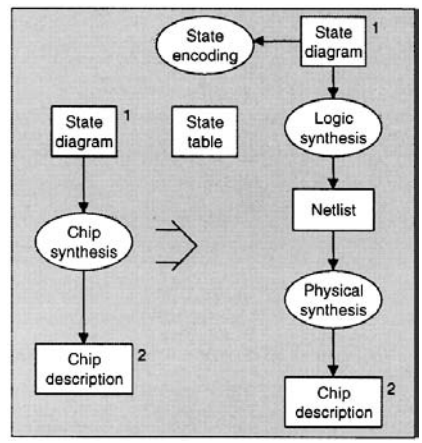

FIGURE 73.8 Productions for chip synthesis.

When we plan the state encoding task, Cockpit finds two productions: one to use the tool Min-bits Encoder and the other to use the tool One-hot Encoder. One-hot Encoder works well for FPGAs, while Minbits Encoder works better for other technologies. To assign proper ratings to these productions, their production managers must find out which implementation technology will be used. First, they send a query to their parent manager, the state encoding task manager. This manager forwards the message to

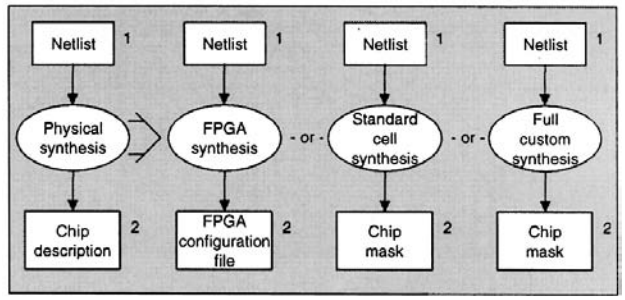

FIGURE 73.9 Productions for physical synthesis.

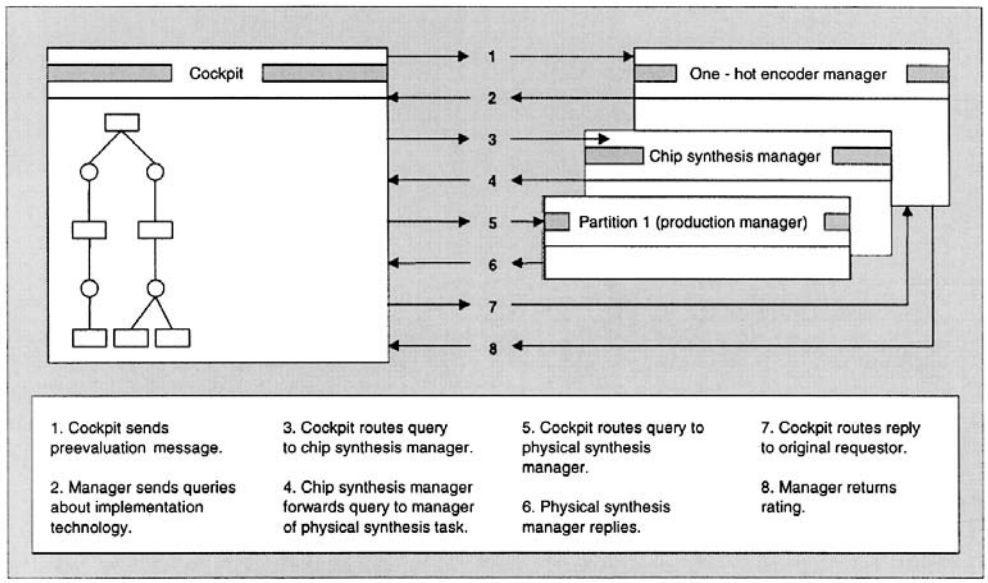

FIGURE 73.10 Sequence of actions for query handling.

its parent, the chip synthesis production manager. In turn, this manager forwards the query to the physical synthesis task manager for an answer. All messages are routed by Cockpit, which is aware of the entire task hierarchy. This sequence of actions is illustrated in Fig. 73.10.

After further planning and tool invocations, a netlist is produced for our controller. The next step is the FPGA synthesis task. We apply the production in Fig. 73.11 and proceed to the FPGA partitioning task. The knowledge to automate this task has already been encoded into the requisite manager programs, so we direct Cockpit to execute the FPGA partitioning task. It finds the two productions illustrated in Fig. 73.5b and requests their ratings, Next, Cockpit sends an execute message, along with the ratings, to the FPGA partitioning task manager. This manager's strategy is to always execute the highest-rated production, which in this case is production Partition 1. (Other task managers might have asked that both productions be executed or, if neither were promising, immediately reported failure.) This sequence of actions is shown in Fig. 73.12.

Because the Partition 1 manager used an as-soon-as-possible task scheduling strategy, it asks Cockpit to execute XNFMAP immediately. The other subtask, MAP2LCA, is executed when XNFMAP complete successfully. After both tasks complete successfully, Cockpit reports success to the FPGA partitioning task manager. This action sequence is illustrated in Fig. 73.13.

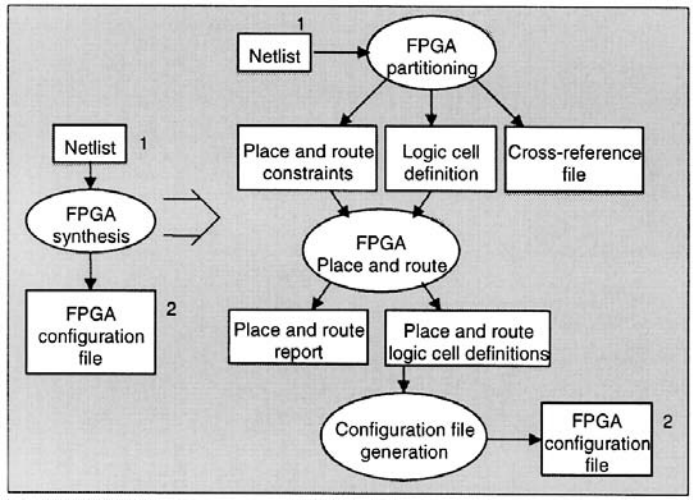

FIGURE 73.11 Production for field-programmable gate array synthesis.

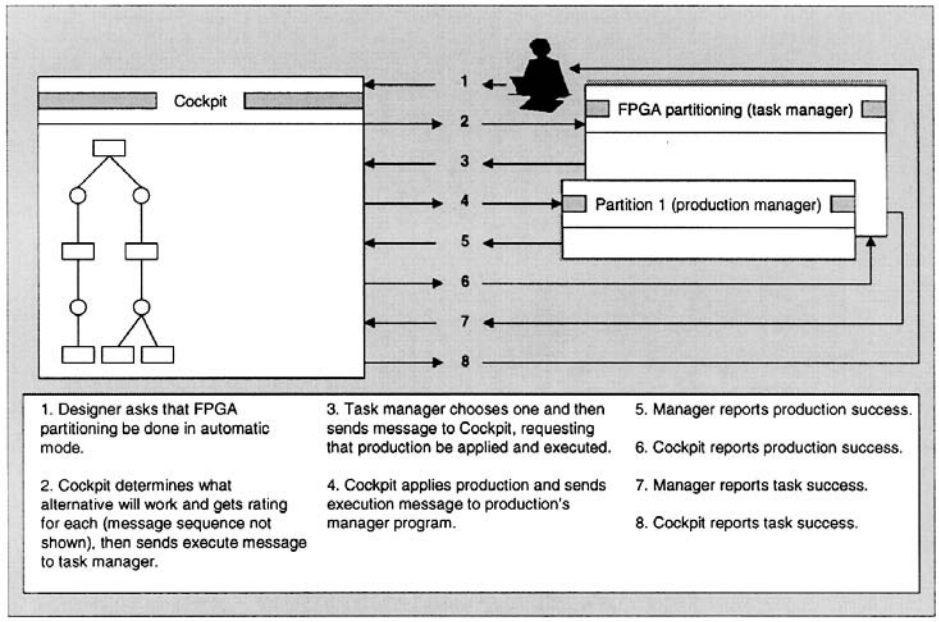

FIGURE 73.12 Sequence of action during automatic task execution.

Scheduling

In this subsection, we describe a detailed description and discussion of auto-mode scheduling, including the implementation of the *linear scheduler*. The ability to search through the configuration space of a design process for a design configuration that meets user-specified constraints is important. For example, assume that a user has defined a process for designing a digital filter with several different alternative ways of performing logical tasks such as "FPGA Partitioning" and "Select the Filter Architecture." One constraint that an engineer may wish to place on the design might be: "Find a process configuration that produces a filter that has maximum delay at most 10 nanoseconds." Given such a constraint, the framework must search through the configuration space of the filter design process, looking for a sequence of valid atomic

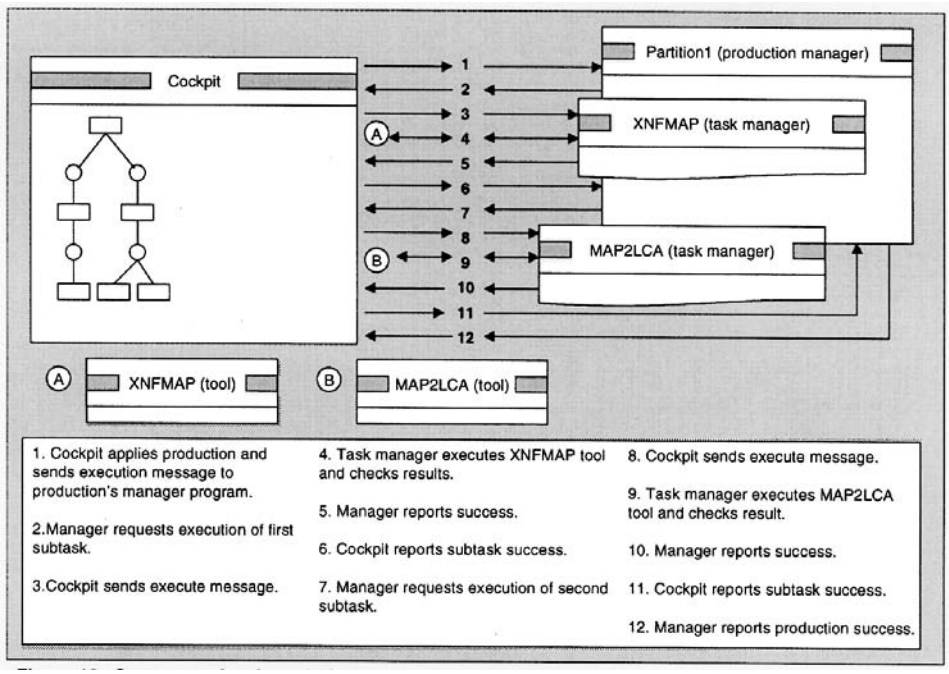

FIGURE 73.13 Sequence of actions during automatic production execution.

tasks that produces a filter with "maximum delay at most 10 nanoseconds." We call the framework component that performs this search a *scheduler*. There are, of course, many different ways of searching through the design process configuration space. In general, a successful scheduler will provide the following functionality:

- **Completeness (Identification of Successful Configurations):** Given a particular configuration of a process, the correct scheduler will be able to conclusively determine whether the configuration meets user-specified constraints. The scheduler must guarantee that before reporting failure, all possible process configurations have been considered, and if there is a successful configuration, the algorithm must find it.
- **Reasonable Performance:** The configuration space of a process grows exponentially (in the number of tasks). Ideally, a scheduler will be able to search the configuration space using an algorithm that requires less than exponential time.

The Linear Scheduling Algorithm is very simple yet complete and meets most of the above criteria. In this algorithm, for each process flow graph (corresponding to an initial process flow graph or a production), it has a scheduler. Each scheduler is a separate thread with a *Task Schedule List* (TSL) representing the order in which tasks are to be executed. The tasks in a scheduler's TSL are called its children tasks. A scheduler also has a *task pointer* to indicate the child task being executed in the TSL. The algorithm is recursive such that with each new instantiation of a production of a given task, a new scheduler is created to manage the flow graph representing the production selected. A liner scheduler creates a TSL by performing a topological sort of the initial process flow graph and executes its children tasks in order. If a child task is atomic, the scheduler executes the task without creating a new scheduler; otherwise, it selects a new alternative, creates a new child scheduler to manage the selected alternative, and waits for a signal from the child scheduler indicating success or failure. When a child task execution is successful, the scheduler increments the *task pointer* in its TSL and proceeds to execute the next task. If a scheduler reaches the end of its TSL, it signals success to its own parent, and awaits signals from its parent if it should terminate itself (all successful) or rollback (try another to find new configurations).

If a child task fails, the scheduler tries another alternative for the task. If there is no alternatives left, it rolls back (by decrementing the task pointer) until it finds a logical task that has another alternative to try. If a scheduler rolls back to the beginning of the TSL and cannot find an alternative, then its flow has failed. In this case, it signals a failure to its parent and terminates itself.

In the linear scheduling algorithm, each scheduler can send or receive any of five signals: `PROCEED`, `ROLLBACK`, `CHILD-SUCCESS`, `CHILD-FAILURE`, and `DIE`. These signals comprise scheduler-to-scheduler communication, including self-signaling. Each of the five signals is discussed below.

- **PROCEED:** This signal tells the scheduler to execute the next task in the `TSL`. It can be self-sent or received from a parent scheduler. For example, a scheduler increments its task pointer and sends itself a `PROCEED` signal when a child task succeeds, whereas it sends a `PROCEED` signal to its children to start its execution
- **ROLLBACK:** This is signaled when a task execution has failed. This signal may be self-sent or received from a parent scheduler. Scheduler self-signals `ROLLBACK` whenever a child task fails. A Rollback can result in either trying the next alternative of a logical task, or decrementing the task pointer and trying the previous task in the TSL. If rollback results in decrementing the task pointer to point to a child task node which has received a success-signal, the parent scheduler will send a rollback signal to that child task scheduler.
- **CHILD-SUCCESS:** A child scheduler sends a `CHILD-SUCCESS` to its parent scheduler if it has successfully completed the execution of all of the tasks in its `TSL`. After sending the child-success signal, the scheduler remains active, listening for possible rollback signals from the parent. After receiving a child-success signal, parent schedulers self-send a proceed signal.
- **CHILD-FAILURE:** A child-failure signal is sent from a child scheduler to its parent in the event that the child's managed flow fails. After sending a child-failure signal, children schedulers terminate. Upon receiving child-failure signals, parent scheduler self-send a rollback signal.
- **DIE:** This signal may be either self-sent, or sent from parent schedulers to their children schedulers.

73.6 Implementation

In this section, a high level description of the major components of IMEDA and their organization and functionality will be presented. Detailed explanations of the key concepts involved in the architecture of the Process Management Framework will also be discussed, including external tool integration, the tool invocation process, the Java File System, and state properties.

The System Cockpit

The System Cockpit, as its name suggests, is where nearly all user interaction with the framework takes place. It is here that users create, modify, save, load, and simulate process flow graphs representing design processes. This system component has been implemented as a Java applet. As such, it is possible to run the cockpit in any Java-enabled Web browser such as Netscape's Navigator or Microsoft's Internet Explorer. It is also possible to run the cockpit in some Java-enabled operating systems such as IBM's OS/2.

Each cockpit component also has the following components:

- **Root Flow.** Every cockpit has a Root Flow. The Root Flow is the flow currently being edited in the Cockpit's Flow Edit Panel. Notice that the Root Flow may change as a result of applying a production to a flow graph, in which case the Root Flow becomes a derivation of itself.
- **Flow Edit Panel.** The Flow Edit Panel is the interactive Graphical User Interface for creating and editing process flow graphs. This component also acts as a display for animating process simulations performed by various schedulers such as the manual or automode linear scheduler.
- **Class Directory.** The Cockpit has two Class Directories: Task Directory and the Specification Directory. These directories provide the "browser" capabilities of the framework, allowing users to create reusable general-to-specific hierarchies of task classes. Class Directories are implemented using a *tree* structure.

- **Production Database.** The Production Database acts as a warehouse for logical task productions. These productions document the alternative methods available for completing a logical task. Each Production Database has a list of Productions. The Production Database is implemented as a tree-like structure, with Productions being on the root trunk, and Alternatives being leaves.
- **Browser**. Browsers provide the tree-like graphical user interface for users to edit both Class Directories and Databases. There are three Browsers: Database Browser for accessing the Production Database, Directory Browser for accessing the Task Directory, and Directory Browser for accessing the Spec Browser. Both Database Browsers and Directory Browsers inherit properties from object Browser, and offer the user nearly identical editing environments and visual representations. This deliberate consolidation of Browser interfaces allowed us to provide designers with an interface that was consistent and easier to learn.
- **Menu.** A user typically performs and accesses most of the system's key function from the cockpit's Menu.
- **Scheduler.** The cockpit has one or more schedulers. Schedulers are responsible for searching the configuration space of a design process for configurations that meet user specified design constraints. The Scheduler animates its process simulations by displaying them in the Flow Edit Panel of the Cockpit.

External Tools

External Tools are the concrete entities to which atomic tasks from a production flow are bound. When a flow task object is expanded in the Cockpit Applet (during process simulation), the corresponding external tool is invoked. The external tool uses a series of inputs and produces a series of outputs (contained in files). These inputs and outputs are similarly bound to specifications in a production flow. Outputs from one tool are typically used as inputs for another. IMEDA can handle the transfer of input and output files between remote sites. The site proxy servers, in conjunction with a remote file server (also running at each site) automatically handle the transfer of files from one system to another. External tools may be implemented using any language, and on any platform that has the capability of running a site server. While performing benchmark tests of IMEDA, we used external tools written in C, Fortran, Perl, csh (a Unix shell script), Java applications, and Mathematica scripts.

External Tool Integration

One of the primary functionality of IMEDA is the integration of user-defined external tools into an abstract process flow. IMEDA then uses these tools both in simulating the process flow to find a flow configuration that meets specific constraints, and in managing selected flow configurations during actual design execution.

There are two steps to integrating tools with a process flow defined in IMEDA: *association* and *execution.* Association involves "linking" or "binding" an abstract flow item (e.g., an atomic task) to an external tool. Execution describes the various steps that IMEDA takes to actually invoke the external tool and process the results.

Binding Tools

External tools may be bound to three types of flow objects: Atomic Tasks, Selectors, and Multiple Version Selectors. Binding an external tool to a flow object is a simple and straightforward job, involving simply defining certain properties in the flow object.

The following properties must be defined in an object that is to be bound to an external tool:

- **SITE.** Due to the fact that IMEDA can execute tools on remote systems, it is necessary to specify the site where the tool is located on. Typically, a default SITE will be specified in the system defaults, and making it unnecessary to define the site property unless the default is to be overridden. Note that the actual site ID specified by the SITE property must refer to a site that is running a Site Proxy Server listening on that ID. See the "Executing External Tools" section below for more details.

- **CMDLINE.** The CMDLINE property specifies the command to be executed at the specified remote site. The CMDLINE property should include any switches or arguments that will always be sent to the external tool. Basically, the CMDLINE argument should be in the same format that would be used if the command were executed from a shell/DOS prompt.
- **WORKDIR.** The working directory of the tool is specified by the WORKDIR property. This is the directory in which IMEDA will actually execute the external tool, create temporary files, etc. This property is also quite often defined in the global system defaults, and thus may not necessarily have to be defined for every tool.
- **WRAPPERPATH.** The JDK 1.0.2 does not allow Java Applications to execute a tool in an arbitrary directory. To handle remote tool execution, a wrapper is provided. It is a "go-between" program that would simply change directories and then execute the external tool. This program can be as simple as a DOS/NT batch file, a shell script, or a perl program. The external tool is wrapped in this simple script, and executed. Since IMEDA can execute tools at remote and heterogeneous sites, it was very difficult to create a single wrapper that would work on all platforms (WIN32, Unix, etc.). Therefor, the wrapper program may be specified for each tool, defined as global default, or a combination of the two.

Once the properties above have been defined for a flow object, the object is said to be "bound" to an external tool. If no site, directory, or filename is specified for the outputs of the flow object, IMEDA automatically creates unique file names, and stores the files in the working directory of the tool on the site that the tool was run. If a tool uses as inputs data items that are not specified by any other task, then the data items must be bound to static files on some site.

Executing External Tools

Once flow objects have been bound to the appropriate external tools, IMEDA can be used to perform process simulation or process management. IMEDA actually has several "layers" that lie between the Cockpit (a Java applet) and the external tool that is bound to a flow being viewed by a user in the Cockpit. A description of each of IMEDA components for tool invocations is listed below.

- **Tool Proxy.** The tool proxy component acts as a liaison between flow objects defined in Cockpits and the Site Proxy Server. All communication is done transparently through the communication server utilizing TCP/IP sockets. The tool proxy "packages" information from Cockpit objects (atomic tasks, selectors, etc.) into string messages that the Proxy Server will recognize. It also listens for and processes messages from the Proxy Server (through the communications server) and relays the information back to the Cockpit object that instantiated the tool proxy originally.
- **Communications Server.** Due to various security restrictions in the 1.0.2 version of Sun Microsystem's Java Development Kit (JDK), it is impossible to create TCP/IP socket connections between a Java applet and any IP address other than the address from which the applet was loaded. Therefore, it was necessary to create a "relay server" in order to allow cockpit applets to communicate with remote site proxy servers. The sole purpose of the communications server is to receive messages from one source and then to rebroadcast them to all parties that are connected and listening on the same channel.
- **Site Proxy Server.** Site Proxy Servers are responsible for receiving and processing invocation requests from tool proxies. When an invocation request is received, the site proxy server checks to see that the request is formatted correctly, starts a tool monitor to manage the external tool invocation, and returns the exit status of the external tool after it has completed.
- **Tool Monitors.** When the site proxy server receives an invocation request and invokes an external tool, it may take a significant amount of time for the tool to complete. If the proxy server had to delay the handling of other requests while waiting for each external tool to complete, IMEDA would become very inefficient. For this reason, the proxy server spawns a tool monitor for each external tool that is to be executed. The tool monitor runs as a separate thread, waiting on the tool, storing its stdout and stderr, and moving any input or output files that need moving to their appropriate

site locations, and notifying the calling site proxy server when the tool has completed. This allows the site proxy server to continue receiving and processing invocation requests in a timely manner.

- **Tool Wrapper.** Tool wrapper changes directories into the specified `WORKDIR`, and then executes the `CMDLINE`.
- **External Tool.** External tools are the actual executable programs that run during a tool invocation. There is very little restriction on the nature of the external tools.

Communications Model

The Communications Model of IMEDA is perhaps the most complex portion of the system in some respects. This is where truly *distributed* communications come into play. One system component is communicating with another via network messages rather than function calls.

The heart of the communications model is the Communications Server. This server is implemented as a broadcast server. All incoming messages to the server are simply broadcast to all other connected parties. FlowObjects communicate with the Communications Server via ToolProxys. A ToolProxy allows a FlowObject to abstract all network communications and focus on the functionality of invoking tasks. A ToolProxy takes care of constructing a network message to invoke an external tool. That message is then sent to the Communications Server via a Communications Client. The Communication Client takes care of the low-level socket based communication complexities. Finally, the Communications Client sends the message to the Communications Server, which broadcasts the message to all connected clients. The client for which the message was intended (typically a Site Proxy Server) decodes the message and, depending on its type, creates either a ToolMonitor (for an Invocation Message) or an External Redraw Monitor (for a Redraw Request).

The Site Proxy Server creates these monitors to track the execution of external programs, rather than monitoring them itself. In this way, the Proxy Server can focus on its primary job – receiving and decoding network messages. When the Monitors invoke an external tool, they must do so within a Wrapper. Once the Monitors have observed the termination of an external program, they gather any output on *stdout* or *stderr* and return these along with the exit code of the program to the Site Proxy Server. The Proxy Server returns the results to the Communications Server, then the Communications Client, then the ToolProxy, and finally to the original calling FlowObject.

User Interface

The Cockpit provides both the user interface and core functionality of IMEDA. While multiple users may use different instances of the Cockpit simultaneously, there is currently no provision for direct collaboration between multiple users. Developing efficient means of real-time interaction between IMEDA users is one of the major thrusts of the next development cycle.

Currently the GUI of the cockpit provides the following functionality:

- **Flow editing.** Users may create and edit process flows using the flow editor module of the Cockpit. The flow editor provides the user with a simple graphical interface that allows the use of a template of tools for "drawing" a flow. Flows can be optimally organized via services provided by a remote Layout Server written in Perl.
- **Production Library Maintenance.** The Cockpit provides functionality for user maintenance of collections of logical task productions, called libraries. Users may organize productions, modify input/output sets, or create/edit individual productions using flow editors.
- **Class Library Maintenance.** Users are provided with libraries of task and specification classes that are organized into a generalization-specialization hierarchy. Users can instantiate a class into an actual task, specification, selector, or database when creating a flow by simply dragging the appropriate class from a class browser and dropping it onto a flow editor's canvas. The Cockpit

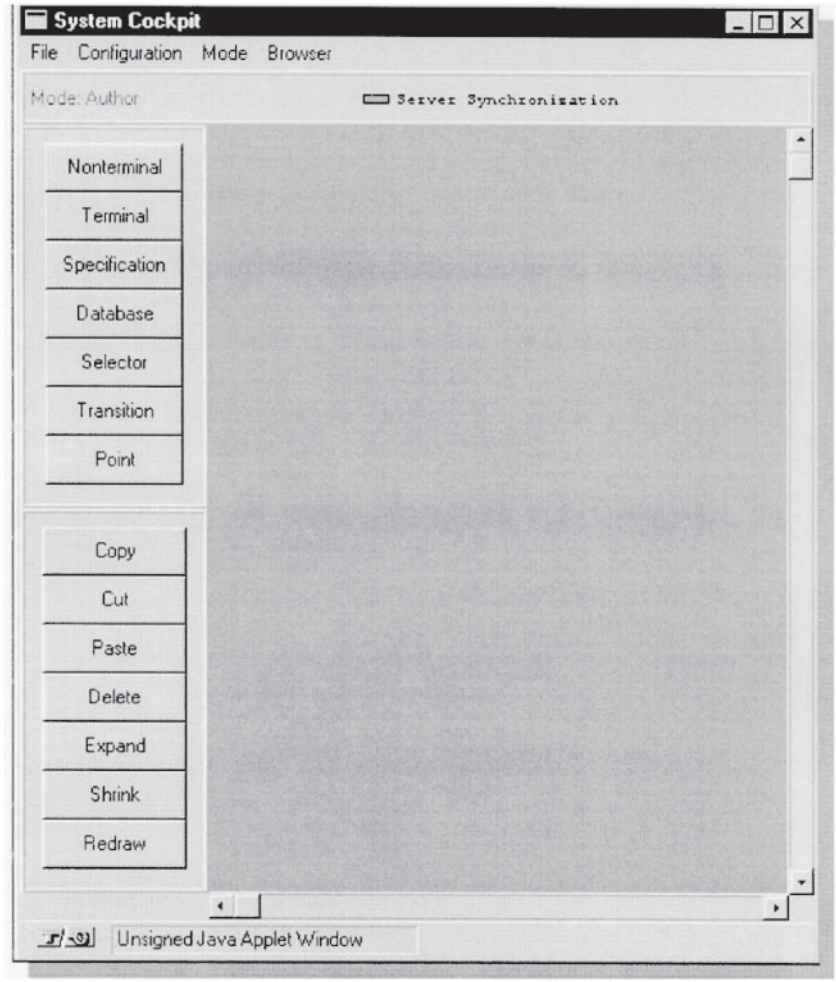

FIGURE 73.14 A system cockpit window.

provides the user with a simple tree structure interface to facilitate the creation and maintenance of class libraries.

- **Process Simulation.** Processes may be simulated using the Cockpit. The Cockpit provides the user with several scheduler modules that determine how the process configuration space will be explored. The schedulers control the execution of external tools (through the appropriate site proxy servers) and simulation display (flow animation for user monitoring of simulation progress). There are multiple schedulers for the user to choose from when simulating a process, including the manual scheduler, comprehensive linear scheduler, etc.
- **Process Archival.** The Cockpit allows processes to be archived on a remote server using the Java File System (JFS). The Cockpit is enabled by a JFS client interface to connect to a remote JFS server where process files are saved and loaded. While the JFS system has its clear advantages, it is also awkward to not allow users to save process files, libraries, etc. on their local systems. Until version 1.1 of the Java Development Kit, local storage by a Java applet was simply not an option — the browser JVM definition did not allow access to most local resources. With version 1.1 of the JDK, however, comes the ability to electronically sign an applet. Once this has been done, users can grant privileged resource access to specific applets after a signature has been verified.

Design Flow Graph Properties

Initially, a flow graph created by a user using GUI is not associated with any system-specific information. For example, when a designer creates an atomic task node in a flow graph, there is initially no association with any external tool. The framework must provide a mechanism for users to bind flow graph entities to the external tools or activities that they represent.

We have used the concept of *properties* to allow users to bind flow graph objects to external entities. In an attempt to maintain flexibility, properties have been implemented in a very generic fashion. Users can define any number of properties for flow object. There are a number of key properties that the framework recognizes for each type of flow object. The user defines these properties to communicate needed configuration data to the framework.

A property consists of a *property label* and *property contents.* The label identifies the property, and consists of an alpha-numeric string with no white space. The contents of a property is any string. Currently users define properties using a freeform text input dialog, with each line defining a property. The first word on a line represents the property label, and the remainder of the line constitutes the property contents.

Property Inheritance

To further extend the flexibility of flow object properties, the framework requires that each flow object be associated with a *flow object class.* Classes allow designers to define properties that are common to all flow objects that inherit from that flow object class. Furthermore, classes are organized into a general-to-specific hierarchy, with children classes inheriting properties from parent classes.

Therefore, the properties of a particular class consist of any properties defined locally for that object, in addition to properties defined in the object's inherited class hierarchy. If a property is defined in both the flow object and one of its parent classes, the property definition in the flow object takes precedence. If a property is defined in more than one class in a class hierarchy, the "youngest" class (e.g., the child in a parent-child relationship) takes precedence.

Classes are defined in the Class Browsers of IMEDA. Designers that have identified a clear general-to-specific hierarchy of flow object classes can quickly create design flow graphs by dragging and dropping from class browsers onto flow design canvases. The user would then need only to overload those properties in the flow objects that are different from their respective parent classes.

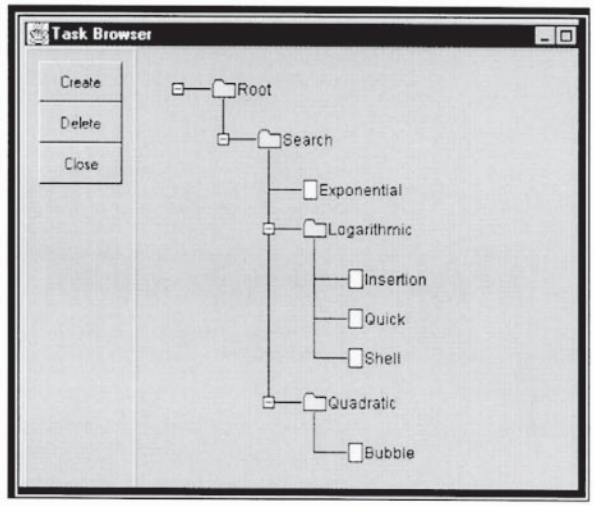

FIGURE 73.15 A task browser.

For example, consider a class hierarchy of classes that all invoke the same external sort tool, but pass different flags to the tool, based on the context. It is likely that all of these tools will have properties in common, such as a common working directory and tool site. By defining these common properties in a common ancestor of all of the classes, such as *Search*, it is unnecessary to redefine the properties in the children classes.

Of course, children classes can define new properties that are not contained in the parent classes, and may also overload property definitions provided by ancestors. Following these rules, class *Insertion* would have the following properties defined: `WORKDIR`, `SITE`, `WRAPPERPATH`, and `CMDLINE`.

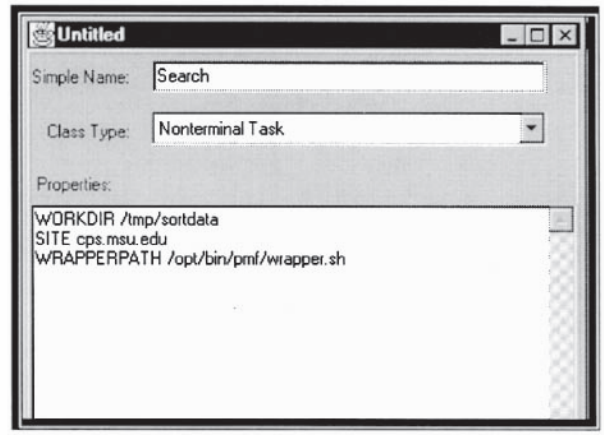

FIGURE 73.16 A property window and property inheritance.

Macro Substitution

While performing benchmarks on IMEDA, one cumbersome aspect of the framework that users often pointed out was the need to re-enter properties for tasks or specifications if, for example, a tool name or working directory changed. Finding every property that needed to be changed was a tedious job, and prone to errors.

In an attempt to deal with this problem, we came up with the idea of *property macros*. That is, a property macro is any macro that is not a key system macro. A macro is a textual substitution rule that can be created by users. By using macros in the property databases of flow objects, design flows can be made more flexible and more amiable to future changes.

As an example, consider a design flow that contains many atomic tasks bound to an external tool. Our previous example using searches is one possible scenario. On one system, the path to the external tool may be "/opt/bin/sort," while on another system the path is "`/user/keyesdav/public/bin/sort`." Making the flow object properties flexible is easy if a property macro named `SORTPATH` is defined in an ancestor of all affected flow objects. Children flow objects can then use that macro in place of a static path when specifying the flow object properties. As a further example, consider a modification to the previous "Search task hierarchy" where we define a macro `SORTPATH` in the Search class, and then use that macro in subsequent children classes, such as the Insertion class.

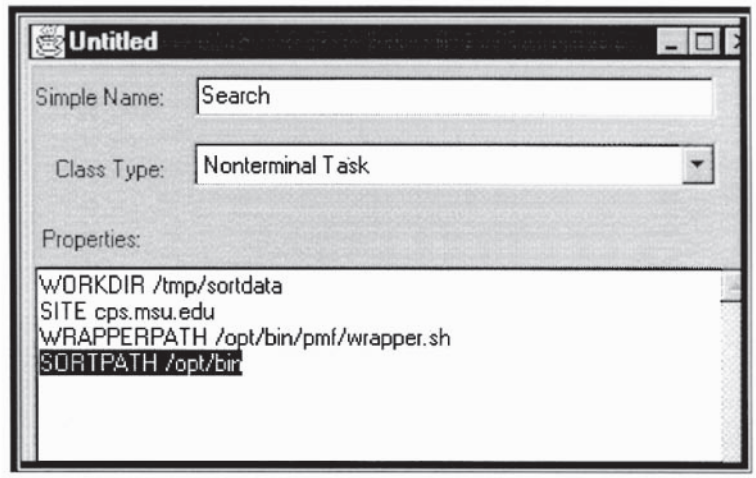

FIGURE 73.17
Macro definition.

In the highlighted portion of the Property Database text area, a macro called "SORTPATH" is defined. In subsequent class' Property Databases, this macro can be used in place of a static path. This makes it easy to change the path for all tools that use the SORTPATH property macro — just the property database dialog where SORTPATH is originally defined needs to be modified.

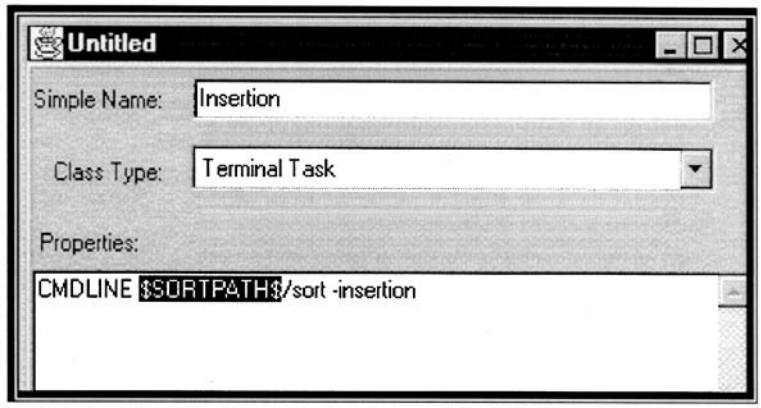

FIGURE 73.18 Macro substitution.

Key Framework Properties

In our current implementation of IMEDA, there are a number of key properties defined. These properties allow users to communicate needed information to the framework in a flexible fashion. Most importantly, it allows system architects to define or modify system properties quickly. This is an important benefit when working with evolving software such as IMEDA.

73.7 Conclusion

Managing the design process is the key factor to improve the productivity in the micro-electronic industry. We have presented an *I*nternet-based *M*icro-*E*lectronic *D*esign *A*utomation (IMEDA) framework to manage the design process. IMEDA uses a powerful formalism, called design process grammars, for representing design processes. We have also proposed an execution environment that utilizes this formalism to assist designers in selecting and executing appropriate design processes. The proposed approach is applicable not only in rapid prototyping but also in any environment where a design is carried out hierarchically and many alternative processes are possible.

The primary advantages of our system are

- *Formalism*: A strong theoretical foundation enables us to analyze how our system will operate with different methodologies.
- *Parallelism*: In addition to performing independent tasks within a methodology in parallel, our system also allows multiple methodologies to be executed in parallel.
- *Extensibility*: New tools can be integrated easily by adding productions and manager programs.
- *Flexibility*: Many different control strategies can be used. They can even be mixed within the same design exercise.

The prototype of IMEDA is implemented using Java. We are currently integrating more tools into our prototype system and developing manager program templates that implement more sophisticated algorithms for pre-evaluation, logical task execution, and query handling. Our system will become more useful as CAD vendors to adapt open software systems and allow greater tool interoperability.

74.1 Introduction

The term **system**, when used in the digital design domain, implies many different entities. A system can consist of a processor, memory, and input/output, all on a single integrated circuit, or it can consist of a network of processors, geographically distributed, each performing a specific application. There can be a single clock, with modules communicating synchronously, multiple clocks with asynchronous communication, or an entirely asynchronous operation. The design can be general, or specific to a given application, i.e., application-specific. Together, the previously mentioned variations constitute the system style. To a great extent, system style selection is determined by the physical technologies used, the environment in which the system operates, designer experience, and corporate culture, and is not automated to any great extent.

System-level design covers a wide range of design activities and design situations. It includes the more specific activity system engineering, that involves the requirements development, test planning, subsystem interfacing, and end-to-end analysis of systems. System-level design is sometimes called system architecting, a term used widely in the aerospace industry.

General-purpose system-level design involves the design of programmable digital systems, including the basic modules containing storage, processors, input/output, and system controllers. At the system level, the design activities include determining the following:

- the power budget (the amount of power allocated to each module in the system);
- the cost and performance budget allocated to each module in the system;
- the interconnection strategy;
- the selection of commercial off-the-shelf modules (COTS);
- the packaging of each module;
- the overall packaging strategy;
- the number of processors, storage units, and input/output interfaces required; and
- the overall characteristics of each processor, storage unit, and input/output interface.

For example, memory system design focuses on the number of memory modules required, how they are organized, and the capacity of each module. A specific system-level issue in this domain can be the question of how to partition the memory between the processor chip and the off-chip memory. At a higher level, a similar issue might involve configuration of the complete storage hierarchy, including memory, disk drives, and archival storage.

For each general-purpose system designed, many systems are designed to perform specific applications. Application-specific system design involves the same activities as described previously, but can involve many more issues, since there are usually more custom logic modules involved. Specifications for application-specific systems contain not only requirements on general capabilities but also the functionality required in terms of specific tasks to be executed. Major application-specific, system-level design activities include not only the general-purpose system design activities, but the following activities as well:

- partitioning an application into multiple functional modules;
- scheduling the application tasks on shared functional modules;
- allocating functional modules to perform the application tasks;
- allocating and scheduling storage modules to contain blocks of data as it is processed;
- determining the implementation styles of functional modules;
- determining the word lengths of data necessary to achieve a given accuracy of computation; and
- predicting resulting system characteristics once the system design is complete.

Each of the system design tasks given in the previous two lists will be described in subsequent detail. Since the majority of system design activities are application-specific, this section will focus on system-level design of application-specific systems. Related activities, hardware-software co-design, verification, and simulation are covered in other sections.

Design Philosophies and System-Level Design

Many design tools have been constructed with a top-down design philosophy. Top-down design represents a design process whereby the design becomes increasingly detailed until final implementation is complete. Considerable prediction of resulting system characteristics is required in order to make the higher-level decisions with some degree of success.

Bottom-up design, on the other hand, relies on designing a set of primitive elements and forming more complex modules from those elements. Ultimately, the modules are assembled into a system. At each stage of the design process there is complete knowledge of the parameters of the lower-level elements. However, the lower-level elements may be inappropriate for the tasks at hand.

Industry system designers describe the design process as being much less organized and considerably more complex than the top-down and bottom-up philosophies suggest. There is a mixture of top-down and bottom-up activities, with major bottlenecks of the system receiving detailed design consideration while other parts of the system still exist only as abstract specifications. For this reason, the system-level design activities presented in detail here support such a complex design situation. Modules, elements, and components used to design at the system level might exist or might only exist as abstract estimates along with requirements. The system can be designed after all modules have been designed and manufactured, prior to any detailed design, or with a mixture of existing and new modules.

The System Design Space

System design, like data path design, is quite straightforward as long as the constraints are not too severe. However, most modern system designs must solve harder problems than problems solved by existing systems; moreover, designers must race to produce working systems faster than competitors. More variations in design are possible than ever before, and such variations require that a large design space be explored. The dimensions of the design space (its axes) are system properties such as cost, power, design time, and performance. The design space contains a population of designs, each of which possesses different values of these system properties. There are literally millions of system designs for a given specification, each of which exhibits different cost, performance, power consumption, and design time. Straightforward solutions that do not attempt to optimize system properties are easy to obtain but may be inferior to designs that require use of system-level design tools and perhaps many iterations of design. The complexity of system design is not due to the fact that system design is an inherently difficult activity, but that so many variations in design are possible and time does not permit exploration of all of them.

74.2 System Specification

Complete system specifications contain a wide range of information including

- constraints on the system power, performance, cost, weight, size, and delivery time;
- required functionality of the system components;
- any required information about the system structure;
- required communication between system components;
- the flow of data between components;
- the flow of control in the system; and
- the specification of input precision and desired output precision.

Most systems specifications that are reasonably complete exist first in a natural language. Such natural language interfaces are not currently available with commercial, system-level design tools.

More conventional system-specification methods, used to drive system-level design tools, include formal languages, graphs, or a mixture of the two. Each of the formal system-specification methods described here contains some of the information found in a complete specification, i.e., most specification methods are incomplete. The remaining information necessary for full system design can be provided interactively by the designer, can be entered later in the design process, or can be provided in other forms at the same time the specification is processed. The required design activities determine the specification method used for a given system design task.

There are no widely adopted formal languages for system-level hardware design although SLDL (System-Level Design Language) is currently being developed by an industry group. Hardware descriptive languages such as VHDL[1] and Verilog[2] are used to describe the functionality of modules in an application-specific system. High-level synthesis tools can then synthesize such descriptions to produce register-transfer designs. Extensions of VHDL have been proposed to encompass more system-level design properties. Apart from system constraints, VHDL specifications can form complete system descriptions. However, the level of detail required in VHDL, and to some extent in Verilog, requires the designer to make some implementation decisions. In addition, some information explicit in more abstract specifications, such as the flow of control between tasks, is implicit in HDLs.

Graphical tools have been used for a number of years to describe system behavior and structure. Block diagrams are often used to describe system structure. Block diagrams assume that tasks have already been assigned to basic blocks and that their configuration in the system has been specified. They generally cannot represent the flow of data or control, or design constraints. The PMS (Processor Memory Switch) notation invented by Bell and Newell was an early attempt to formalize the use of block diagrams for system specification.[3]

Petri nets have been used for many years to describe system behavior using a token-flow model. A token-flow model represents the flow of control with tokens, which flow from one activity of the system to another. Many tokens can be active in a given model concurrently, representing asynchronous activity and parallelism, important in many system designs. Timed Petri nets have been used to model system performance, but Petri nets cannot easily be used to model other system constraints, system behavior, or any structural information.

State diagrams and graphical tools such as State Charts[4] provide alternative methods for describing systems. Such tools provide mechanisms to describe the flow of control, but they do not describe system constraints, system structure, data flow, or functionality.

Task-flow graphs, an outgrowth from the Control/Data-Flow Graphs (CDFG) used in high-level synthesis, are often used for system specification. These graphs describe the flow of control and data between tasks. When used in a hierarchical fashion, task nodes in the task-flow graph can contain detailed functional information about each task, often in the form of a CDFG. Task flow graphs contain no mechanisms for describing system constraints or system structure.

Spec Charts[5] incorporate VHDL descriptions into State-Chart-like notation, overcoming the lack of functional information found in State Charts.

Figure 74.1 illustrates the use of block diagrams, Petri nets, task flow graphs, and spec charts.

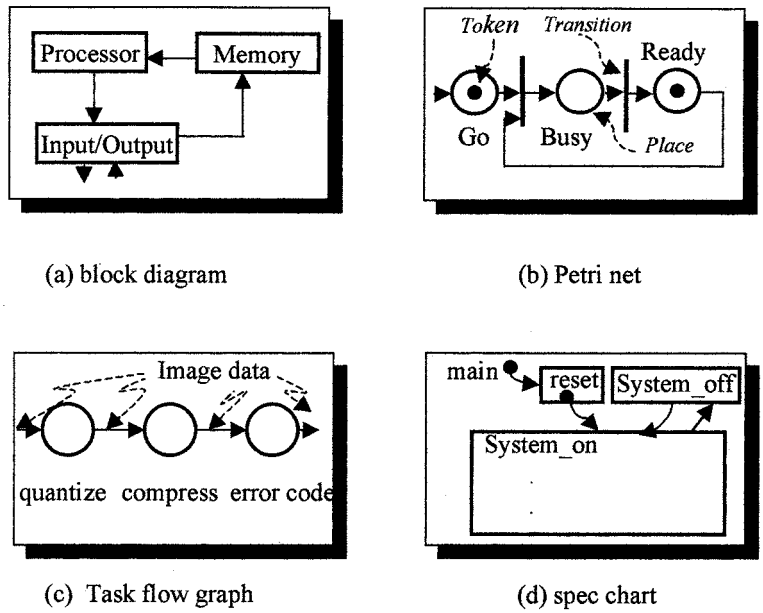

FIGURE 74.1 The use of block diagrams, Petri nets, task flow graphs, and spec charts, shown in simplified form.

74.3 System Partitioning

Most systems are too large to fit on a single substrate. If the complexity of the system tasks and the capacity of the system modules are of the same order, then partitioning is not required. All other systems must be partitioned so that they fit into the allowed substrates, packages, boards, multi-chip modules, and cases. Partitioning determines the functions, tasks, or operations in each partition of a system. Each partition can represent a substrate, package, multi-chip module, or larger component. Partitioning is performed with respect to a number of goals, including minimizing cost, design time, or power, or maximizing performance. Any of these goals can be reformulated as specific constraints, like meeting given power requirements.

When systems are partitioned, resulting communication delays must be taken into account, affecting performance. Limitations on interconnection size must be taken into account, affecting performance as well. Pin and interconnection limitations force the multiplexing of inputs and outputs, reducing performance, and sometimes affecting cost. Power consumption must also be taken into account. Power balancing between partitions and total power consumption might both be considerations. In order to meet market windows, system partitions can facilitate the use of COTS, programmable components, or easily fabricated components such as gate arrays. In order to meet cost constraints, functions that are found in the same partition might share partition resources. Such functions or tasks cannot execute concurrently, affecting performance.

Partitioning is widely used at the logic level, as well as on physical designs. In these cases, much more information is known about the design properties, and the interconnection structure has been determined. System partitioning is performed when information about the specific components' properties might be uncertain, and the interconnection structure undetermined. For these reasons, techniques used at lower levels must be modified to include predictions of design properties not yet known and prediction of the possible interconnection structure as a result of the partitioning.

The exact partitioning method used depends on the type of specification available. If detailed CDFG or HDL specifications are used, the partitioning method might be concerned with which register-transfer functions (e.g., add, multiply, shift) are found in each partition. If the specification primitives are tasks, as in a task-flow graph specification, then the tasks must be assigned to partitions. Generally, the more detailed the specification, the larger the size of the partitioning problem. Powerful partitioning methods can be applied to problems of small size ($n < 100$). Weaker methods such as incremental improvement must be used when the problem size is larger.

Partitioning methods can be based on constructive partitioning or iterative improvement. Constructive partitioning involves taking an unpartitioned design and assigning operations or tasks to partitions. Basic constructive partitioning methods include bin packing using a first-fit decreasing heuristic, clustering operations into partitions by assigning nearest neighbors to the same partition until the partition is full, random placement into partitions, and integer programming approaches.

Constructive Partitioning Techniques

Bin packing involves creating a number of bins equal in number to the number of partitions desired and equal in size to the size of partitions desired. Then, the tasks or operations are sorted by size. The largest task in the list is placed in the first bin, and then the next largest is placed in the first bin, if it will fit, or if it does not fit, into the second bin. Each task is placed into the first bin in which it will fit, until all tasks have been placed in bins. More bins are added if necessary. This simple heuristic is useful to create an initial set of partitions to be improved iteratively later.

Clustering is a more powerful method to create partitions. Here is a simple clustering heuristic. Each task is ranked by the extent of "connections" to other tasks either due to control flow, data flow, or physical position limitations. The most connected task is placed in the first partition, and then the tasks connected to it are placed in the same partition, in order of the strength of their connections to the first task. Once the partition is full, the task with the most total connections remaining outside a partition is placed in a new partition, and other tasks are placed there in order of their connections to the first task. This heuristic continues until all tasks are placed.

Random partitioning places tasks into partitions in a greedy fashion until the partitions are full. Some randomization of the choice of tasks is useful in producing a family of systems, of which each member is partitioned randomly. This family of systems can be used successfully in iterative improvement techniques for partitioning, as described later in this section.

The most powerful technique for constructive partitioning is mathematical programming. Integer and mixed integer-linear programming techniques have been used frequently in the past for partitioning. Such powerful techniques are computationally very expensive, and they are successful only when the number of objects to be partitioned is small. The basic idea behind integer programming used for

partitioning is the following: An integer, $TP(i,j)$, is used to represent the assignment of tasks to partitions. When $TP = 1$, task i is assigned to partition j. For each task in this problem, there would be an equation

$$\sum_{j=1}^{partition\ total} TP(i,j) = 1 \tag{74.1}$$

This equation more or less states that each task must be assigned to one and only one partition. There would be many constraints of this type in the integer program, some of which were inequalities. There would be one function representing cost, performance, or other design property, to be optimized. The simultaneous solution of all constraints, given some minimization or maximization goal, would yield the optimal partitioning.

Apart from the computational complexity of this technique, the formulation of the mathematical programming constraints is tedious and error prone if performed manually. The most important advantage of mathematical programming formulations is the discipline it imposes on the CAD programmer in formulating an exact definition of the CAD problem to be solved. Such problem formulations can prove useful when applied in a more practical environment, as described below in the next section, "Iterative Partitioning Techniques."

Iterative Partitioning Techniques

Of the many iterative partitioning techniques available, two have been applied most successfully at the system level. These techniques are min-cut partitioning, first proposed by Kernigan and Lin, and genetic algorithms.

Min-cut partitioning involves exchanging tasks or operations between partitions in order to minimize the total amount of "interconnections" cut. The interconnections can be computed as the sum of data flowing between partitions, or as the sum of an estimate of the actual interconnections that will be required in the system. The advantage of summing the data flowing is that it provides a quick computation, since the numbers are contained in the task flow graph. Better partitions can be obtained if the required physical interconnections are taken into account, since they are related more directly to cost and performance than to the amount of data flowing. If a partial structure exists for the design, predicting the unknown interconnections allows partitioning to be performed on a mixed design, one that contains existing parts as well as parts under design.

Genetic algorithms, highly popular for many engineering optimization problems, are especially suited to the partitioning problem. The problem formulation is similar in some ways to mathematical programming formulations. A simple genetic algorithm for partitioning is described here. In this example, a chromosome represents each partitioned system design, and each chromosome contains genes, representing information about the system. A particular gene, $TP(i,j)$, might represent the fact that task i is contained in partition j when it is equal to 1, and is set to 0 otherwise. A family of designs created by some constructive partitioning technique then undergoes mutation and crossover as new designs evolve. A fitness function is used to check the quality of the design, and the evolution is halted when the design is considered fit, or when no improvement has occurred after some time. In the case of partitioning, the fitness function might include the estimated volume of interconnections, the predicted cost or performance of the system, or other system properties.

The reader might note some similarity between the mathematical programming formulation of the partitioning problem presented here and the genetic algorithm formulation. This similarity allows the CAD developer to create a mathematical programming model of the problem to be solved, find optimal solutions to small problems, and create a genetic algorithm version. The genetic algorithm version can be checked against the optimal solutions found by the mathematical program. However, genetic

algorithms can take into account many more details than can mathematical program formulations, can handle non-linear relationships better, and can even handle stochastic parameters.[1]

Partitioning is most valuable when there is a mismatch between the sizes of system tasks and the capacities of system modules. When the system tasks and system modules are more closely matched, then the system design can proceed directly to scheduling and allocating tasks to processing modules.

74.4 Scheduling and Allocating Tasks to Processing Modules

Scheduling and allocating tasks to processing modules involve the determination of how many processing modules are required, which modules execute which tasks, and the order in which tasks are processed by the system. In the special case where only a single task is processed by each module, the scheduling becomes trivial. Otherwise, if the tasks share modules, the order in which the tasks are processed by the modules can affect system performance or cost. If the tasks are ordered inappropriately, some tasks might wait too long for input data, and performance might be affected. Or, in order to meet performance constraints, additional modules must be added to perform more tasks in parallel, increasing system cost.

A variety of modules might be available to carry out each task, with differing cost and performance parameters. As each task is allocated to a module, that module is selected from a set of modules available to execute the task. This is analogous to the task module selection, which occurs as part of high-level synthesis. For the system design problem considered here, the modules can be either general-purpose processors, special-purpose processors (e.g., signal processing processors), or special-purpose hardware. If all (or most) modules used are general-purpose, the systems synthesized are known as heterogeneous application-specific multiprocessors.

A variety of techniques can be used for the scheduling and allocation of system tasks to modules. Just as with partitioning, these techniques can be constructive or iterative. Constructive scheduling techniques for system tasks include greedy techniques such as ASAP (as soon as possible) and ALAP (as late as possible). In ASAP scheduling, the tasks are scheduled as early as possible on a free processing module. The tasks scheduled first are the ones with the longest paths from their outputs to final system outputs or system completion. Such techniques, with variations, can be used to provide starting populations of system designs to be further improved iteratively. The use of such greedy techniques for system synthesis differs from the conventional use in high-level synthesis, where the system is assumed to be synchronous, with tasks scheduled into time steps. System task scheduling assumes no central clock, and tasks take a wide range of times to complete. Some tasks could even complete stochastically, with completion time a random variable. Other tasks could complete basic calculations in a set time, but could perform a finer grain (more accurate) of computations if more time were available. A simple task-flow graph is shown in Fig. 74.2, along with a Gantt chart illustrating the ASAP scheduling of tasks onto two processors. Note that two lengthy tasks are performed in parallel with three shorter tasks, and that no two tasks take the same amount of time.

Similar to partitioning, scheduling and allocation, along with module selection, can be performed using mathematical programming. In this case, since the scheduling is asynchronous, time becomes a linear rather than integer quantity. Therefore, mixed integer-linear programming (MILP) is employed to model system-level scheduling and allocation. A typical MILP timing constraint is the following:

$$T_{OA}\left(i\right) + Cdelay \le T_{IR}\left(j\right) \tag{74.2}$$

[1]Stochastic parameters represent values that are uncertain. There is a finite probability of a parameter taking a specific value that varies with time, but that in general, probability is less than one.

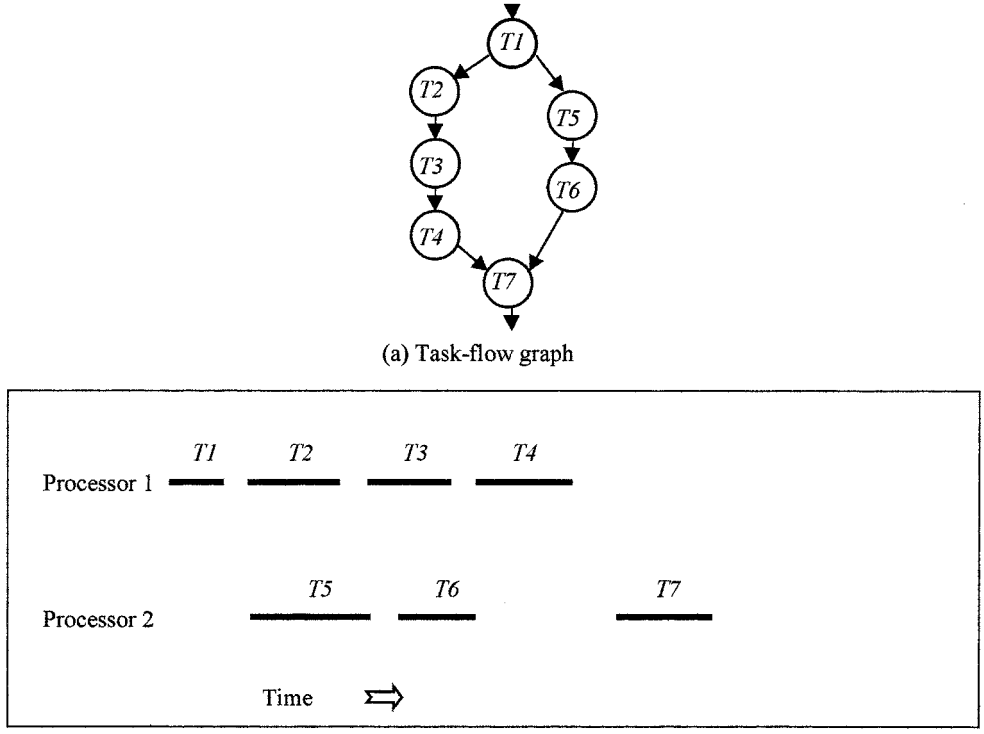

FIGURE 74.2 An example task-flow graph and schedule.

where $T_{OA}(i)$ is the time the output is available from task *i*, *Cdelay* is the communication delay, and $T_{IR}(j)$ is the time the input is required by task *j*. Unfortunately, the actual constraints used in scheduling and allocation are mostly more complex than this, because the design choices have yet to be made. Here is another example:

$$T_{OA}(i) \geq T_{IR}(i) + \sum_{k}\left[Pdelay(k) * M(i,k)\right] \tag{74.3}$$

This constraint states that the time an output from task *i* is available is greater than or equal to the time necessary inputs are received by task *i*, and a processing delay *Pdelay* has occurred. $M(i,k)$ indicates that task *i* is allocated to module *k*. *Pdelay* can take on a range of values, depending on which of k modules is being used to implement task *i*. The summation is actually a linearized select function that picks the value of *Pdelay* to use depending on which value of $M(i,k)$ is set to 1.

As with partitioning, mathematical programming for scheduling and allocation is computationally intensive and impractical for all but the smallest designs, but it does provide a baseline model of design that can be incorporated in other tools.

The most frequent technique used for iterative improvement in scheduling and allocation at the system level is a genetic algorithm. The genes can be used to represent task allocation and scheduling. In order to represent asynchronous scheduling accurately, time is generally represented as a linear quantity in such genes, rather than an integer quantity.

74.5 Allocating and Scheduling Storage Modules

In digital systems, all data requires some form of temporary or permanent storage. If the storage is shared by several data sets, the use of the storage by each data set must be scheduled. The importance of this task in system design has been overlooked in the past, but it has now become an important system-level task.

Modern digital systems usually contain some multimedia tasks and data. The storage requirements for multimedia tasks sometimes result in systems where processing costs are dwarfed by storage costs, particularly caching costs. For such systems, storage must be scheduled and allocated either during or after task scheduling and allocation. If storage is scheduled and allocated concurrently with task scheduling and allocation, the total system costs are easier to determine, and functional module sharing can be increased if necessary in order to control total costs. On the other hand, if storage allocation and scheduling are performed after task scheduling and allocation, then both programs are simpler, but the result may not be as close to optimal.

Techniques similar to those used for task scheduling and allocation can be used for storage scheduling and allocation.

74.6 Selecting Implementation and Packaging Styles for System Modules

Packaging styles can range from single-chip dual-in-line packages (DIPs) to multi-chip modules (MCMs), boards, racks, and cases. Implementation styles include general-purpose processor, special-purpose programmable processor (e.g., signal processor), COTS modules, Field Programmable Gate Arrays (FPGAs), gate array, standard cell, and custom integrated circuits. For many system designs, system cost, performance, power, and design time constraints determine selection of implementation and packaging styles. Tight performance constraints favor custom integrated circuits, packaged in multi-chip modules. Tight cost constraints favor off-the-shelf processors and gate array implementations, with small substrates and inexpensive packaging. Tight power constraints favor custom circuits. Tight design time constraints favor COTS modules and FPGAs. If a single design property has high priority, the designer can select the appropriate implementation style and packaging technology. If, however, design time is crucial, but the system to be designed must process video signals in real time, then tradeoffs in packaging and implementation style must be made. The optimality of system cost and power consumption might be sacrificed: The entire design might be built with FPGAs, with much parallel processing and at great cost and large size. Because time-to-market is so important, early market entry systems may sacrifice the optimality of many system parameters initially and then improve them in the next version of the product.

Selection of implementation styles and packaging can be accomplished by adding some design parameters to the scheduling and allocation program, if that program is not already computationally intensive. The parameters added would include

- a variable indicating that a particular functional module was assigned a certain implementation style;
- a variable indicating that a particular storage module was assigned a certain implementation style;
- a variable indicating that a particular functional module was assigned a certain packaging style; and
- a variable indicating that a particular storage module was assigned a certain packaging style.

Some economy of processing could be obtained if certain implementation styles precluded certain packaging styles.

74.7 The Interconnection Strategy

Modules in a digital system are usually interconnected in some carefully architected, consistent manner. If point-to-point interconnections are used, they are used throughout the system, or in a subsystem. In the

same manner, buses are not broken arbitrarily to insert point-to-point connections or rings. For this reason, digital system design programs usually assume an interconnection style and determine the system performance relative to that style. The most common interconnection styles are bus, point-to-point, and ring.

74.8 Word Length Determination

Functional specifications for system tasks are frequently detailed enough to contain the algorithm to be implemented. In order to determine the implementation costs of each system task, knowledge of the word widths to be used is important, as system cost varies almost quadratically with word width.

Tools to automatically select task word width are currently experimental, but the potential for future commercial tools exists.

In typical hardware implementations of an arithmetic-intensive algorithm, designers must determine the word lengths of resources such as adders, multipliers, and registers. In a recent publication,[6] Wadekar and Parker presented algorithm-level optimization techniques to select distinct word lengths for each computation which meet the desired accuracy and minimize the design cost for the given performance constraints. The cost reduction is possible by avoiding unnecessary bit-level computations that do not contribute significantly to the accuracy of the final results. At the algorithm level, determining the necessary and sufficient precision of an individual computation is a difficult task, since the precision of various predecessor/successor operations can be traded off to achieve the same desired precision in the final result. This is achieved using a mathematical model[7] and a genetic selection mechanism.[6] There is a distinct advantage to word-length optimization at the algorithmic level. The optimized operation word lengths can be used to guide high-level synthesis or designers to achieve an efficient utilization of resources of distinct word lengths and costs. Specifically, only a few resources of larger word lengths and high cost may be needed for operations requiring high precision to meet the final accuracy requirement. Other relatively low-precision operations may be executed by resources of smaller word lengths. If there is no timing conflict, a large word length resource can also execute a small word length operation, thus improving the overall resource utilization further. These high-level design decisions cannot be made without the knowledge of word lengths prior to synthesis.

74.9 Predicting System Characteristics

In system-level design, early prediction gives designers the freedom to make numerous high-level choices (such as die size, package type, and latency of the pipeline) with confidence that the final implementation will meet power and energy as well as cost and performance constraints. These predictions can guide power budgeting and subsequent synthesis of various system components, which is critical in synthesizing systems that have low power dissipation, or long battery life. The use by synthesis programs of performance and cost lower bounds allows smaller solution spaces to be searched, which leads to faster computation of the optimal solution.

System cost, performance, power consumption, and design time can be computed if the properties of each system module are known. System design using existing modules requires little prediction. However, if system design is performed prior to design of any of the contained system modules, their properties must be predicted or estimated. Due to the complexities of prediction techniques, describing these techniques is a subject worthy of an entire chapter. A brief survey of related readings is found in the next section.

The register-transfer and subsequent lower level power prediction techniques such as gate- and transistor-level techniques are essential for validation before fabricating the circuit. However, these techniques are less efficient for system-level design process, as a design must be generated before prediction can be done.

74.10 A Survey of Research in System Design

Many researchers have investigated the problem of system design, dating back to the early 1970s. This section highlights work that is distinctive, along with tutorial articles covering relevant topics. Much

good research is not referenced here, and the reader is reminded that the field is dynamic, with new techniques and tools appearing almost daily.

Issues in top-down vs. bottom-up design approaches were highlighted in the design experiment reported by Gupta et al.[8]

System Specification

System specification has received little attention historically except in the specific area of software specifications. Several researchers have proposed natural language interfaces capable of processing system specifications and creating internal representations of the systems that are considerably more structured. Of note is the work by Granacki[9] and Cyre.[10] One noteworthy approach is the Design Specification Language (D)SL, found in the Design Analysis and Synthesis Environment.[11] One of the few books on the subject concerns the design of embedded systems — systems with hardware and software designed for a particular application set.[12] In one particular effort, Petri nets were used to specify the interface requirements in a system of communicating modules, which were then synthesized.[13] The SIERA system designed by Srivastava, Richards, and Broderson[14] supports specification, simulation, and interactive design of systems.

Partitioning

Partitioning research covers a wide range of system design situations. Many early partitioning techniques dealt with assigning register-level operations to partitions. APARTY, a partitioner designed by Lagnese and Thomas, partitions CDFG designs for single-chip implementation in order to obtain efficient layouts.[15] Vahid[16] performed a detailed survey of techniques for assigning operations to partitions. CHOP assigns CDFG operations to partitions for multi-chip design of synchronous, common clocked systems.[17] Vahid and Gajski developed an early partitioner, SpecPart, which assigns processes to partitions.[18] Chen and Parker reported on a process-to-partition technique called ProPart.[19]

Non-pipelined Design

Although research on **system design** spans more than two decades, most of the earlier works focus on single aspects of design like task assignment, and not on the entire design problem. We cite some representative works here. These include graph theoretical approaches to task assignment,[20,21] analytical modeling approaches for task assignment,[22] and probabilistic modeling approaches for task partitioning,[23,24] scheduling,[25] and synthesis.[26] Two publications of note cover application of heuristics to system design.[27,28]

Other noteworthy publications include mathematical programming formulations for task partitioning[29] and communication channel assignment.[30] Early efforts include those done by soviet researchers since the beginning of the 1970s such as Linsky and Kornev[31] and others, where each model only included a subset of the entire synthesis problem. Chu et al.[32] published one of the first mixed integer-linear programming (MILP) models for a sub-problem of system-level design, scheduling. Recently the program SOS (Synthesis of Systems), including a compiler for MILP models[33,34] was developed, based on a comprehensive MILP model for system synthesis. SOS takes a description of a system described using a task-flow graph, a processor library and some cost and performance constraints, and generates an MILP model to be optimized by an MILP solver. The SOS tool generates MILP models for the design of non-periodic (non-pipelined) heterogeneous multiprocessors. The models share a common structure, which is an extension of the previous work by Hafer and Parker for high-level synthesis of digital systems.[35]

Performance bounds of solutions found by algorithms or heuristics for system-level design are proposed in many papers, including the landmark papers by Fernandez and Bussel[36] and Garey and Graham[37] and more recent publications.[38]

The recent work of Gupta et al.[8] reported the successful use of system-level design tools in the development of an application-specific heterogeneous multiprocessor for image processing. Gupta and Zorian[39] describe the design of systems using cores, silicon cells with at least 5000 gates. The same issue of Design and Test contains a number of useful articles on design of embedded core-based systems. Li and Wolf[40] report on a model of hierarchical memory and a multiprocessor synthesis algorithm which takes into account the hierarchical memory structure.

A major project, RASSP, is a rapid-prototyping approach whose development is funded by the U.S. Department of Defense.[41] RASSP addresses the integrated design of hardware and software for signal processing applications.

An early work on board-level design, MICON, is of particular interest.[42] Newer research results solving similar problems with more degrees of design freedom include the research by C-T Chen[43] and D-H Heo.[44] GARDEN, written by Heo, finds the design with the shortest estimated time to market, which meets cost and performance constraints.

All the MILP synthesis works cited to this point address only the nonperiodic case.

Synthesis of application-specific heterogeneous multiprocessors is a major activity in the general area of system synthesis. One of the most significant system-level design efforts is Lee's Ptolemy project at the University of California, Berkeley. Representative publications include papers by Lee and Bier describing a simulation environment for signal processing[45] and the paper by Kalavade et al.[46] Another prominant effort is the SpecSyn project[47] which is a system-level design methodology and framework.

Macro-pipelined Design

Macro-pipelined (periodic) multiprocessors execute tasks in a pipelined fashion, with tasks executing concurrently on different sets of data. Most research work on design of macro-pipelined multiprocessors has been restricted to homogeneous multiprocessors having negligible communication costs. This survey divides the past contributions according to the execution mode: preemptive or nonpreemptive.

Nonpreemptive Mode

The nonpreemptive mode of execution assumes that each task is executed without interruption. It is used quite often in low-cost implementations. Much research has been performed on system scheduling for the nonpreemptive mode. A method to compute the minimum possible value for the initiation interval for a task-flow graph given an unlimited number of processors and no communication costs was found by Renfors and Neuvo.[48]

Wang and Hu[49] use heuristics for the allocation and full static scheduling (meaning that each task is executed on the same processor for all iterations) of generalized perfect-rate task-flow graphs on homogeneous multiprocessors. Wang and Hu apply planning, an artificial intelligence method, to the task scheduling problem. The processor allocation problem is solved using a conflict-graph approach.

Gelabert and Barnwell[50] developed an optimal method to design macro-pipelined homogeneous multiprocessors using cyclic-static scheduling, where the task-to-processor mapping is not time-invariant as in the full static case, but is periodic, i.e., the tasks are successively executed by all processors. Gelabert and Barnwell assume that the delays for intra-processor and inter-processor communications are the same, which is an idealistic scenario. Their approach is able to find an optimal implementation (minimal iteration interval) in exponential time in the worst case.

In his doctoral thesis, Tirat-Gefen[51] extended the SOS MILP model to solve for optimal macro-pipelined, application-specific heterogeneous multiprocessors. He also proposed an integer-linear programming (ILP) model allowing simultaneous optimal retiming and processor/module selection in high and system-level synthesis.[52]

Verhaegh[53] addresses the problem of periodic multidimensional scheduling. His thesis uses an ILP model to handle the design of homogeneous multiprocessors without communication costs implementing data-flow programs with nested loops. His work evaluates the complexity of the scheduling and

allocation problems for the multidimensional case, which were both found to be NP-complete. Verhaegh proposes a set of heuristics to handle both problems.

Passos and Sha[54] evaluate the use of multi-dimensional retiming for synchronous data-flow graphs. However, their formalism can only be applied to homogeneous multiprocessors without communication costs.

The Preemptive Mode of Execution

Feng and Shin[55] address the optimal static allocation of periodic tasks with precedence constraints and preemption on a homogeneous multiprocessor. Their approach has an exponential time complexity. Ramamrithan[56] developed a heuristic method that has a more reasonable computational cost. Rate-monotonic scheduling (RMS) is a commonly used method for allocating periodic real-time tasks in distributed systems.[57] The same method can be used in homogeneous multiprocessors.

Genetic Algorithms

Genetic algorithms are becoming an important tool for solving the highly non-linear problems related to system-level synthesis. The use of genetic algorithms in optimization is well discussed by Michalewicz[58] where formulations for problems such as bin packing, processor scheduling, traveling salesman, and system partitioning are outlined.

Research works involving the use of genetic algorithms to system-level synthesis problems are starting to be published, for example, as are the results of the following:

- Hou et al.[59] — scheduling of tasks in a homogeneous multiprocessor without communication costs;
- Wang et al.[60] — scheduling of tasks in heterogeneous multiprocessors with communication costs but not allowing cost vs. performance tradeoff, i.e., all processors have the same cost;
- Ravikumar and Gupta[61] — mapping of tasks into a reconfigurable homogeneous array processor without communication costs;
- Tirat-Gefen and Parker[62] — a genetic algorithm for design of application-specific heterogeneous multiprocessors (ASHM) with nonnegligible communications costs specified by a nonperiodic task-flow graph representing both control and data flow; and
- Tirat-Gefen[51] — introduced a full-set of genetic algorithms for system-level design of ASHMs incorporating new design features such as imprecise computation and probabilistic design.

Imprecise Computation

The main results in imprecise computation theory are due to Liu et al.[63] who developed polynomial time algorithms for optimal scheduling of preemptive tasks on homogeneous multiprocessors without communications costs. Ho et al.[64] proposed an approach to minimize the total error, where the error of a task being imprecisely executed is proportional to the amount of time that its optional part was not allowed to execute, i.e., the time still needed for its full completion. Polynomial time-optimal algorithms were derived for some instances of the problem.[63]

Tirat-Gefen et al.[65] presented a new approach for application-specific, heterogeneous multiprocessor design that allows tradeoffs between cost, performance, and data-quality through incorporation of imprecise computation into the system-level design cycle.

Probabilistic Models and Stochastic Simulation

Many probabilistic models for solving different subproblems in digital design have been proposed recently. The problem of task and data-transfer scheduling on a multiprocessor when some tasks (data transfers) have nondeterministic execution times, (communication-times) can be modeled by PERT

networks, which were introduced by Malcolm et al.[66] along with the critical path method (CPM) analysis methodology.

A survey on PERT networks and their generalization to conditional PERT networks is done by Elmaghraby.[67] In system-level design, the completion time of a PERT network corresponds to the system latency, whose cumulative distribution is a nonlinear function of the probability density distributions of the computation times of the tasks and the communication times of the data transfers in the task-flow graph.

The exact computation of the cumulative probability distribution function (c.d.f.) of the completion time is computationally expensive for large PERT networks, therefore it is important to find approaches that approximate the value of the expected time of the completion time and its c.d.f. One of the first of these approaches was due to Fulkerson,[68] who derived an algorithm to find a tight estimate (lower bound) of the expected value of the completion time. Robillrad and Trahan[69] proposed a different method using the characteristic function of the completion time in approximating the c.d.f. of the completion time.

Mehrotra et al.[70] proposed a heuristic for estimating the moments of the probabilistic distribution of the system latency t_c. Kulkarni and Adlakha[71] developed an approach based on Markov processes for the same problem. Hagstrom[72] introduced an exact solution for the problem when the random variables modeling the computation and communication times are finite discrete random variables. Kamburowski[73] developed a tight upper bound on the expected completion time of a PERT network.

An approach using random graphs to model distributed computations was introduced by Indurka et al.,[23] whose theoretical results were improved by Nicol.[24] Purushotaman and Subrahmanyam[74] proposed formal methods applied to concurrent systems with a probabilistic behavior. An example of modeling using queueing networks instead of PERT networks is given by Thomasian and Bay.[75] Estimating errors due to the use of PERT assumptions in scheduling problems is discussed by Lukaszewicz.[76]

Tirat-Gefen developed a set of genetic algorithms using stratified stochastic sampling allowing simultaneous probabilistic optimization of the scheduling and allocation of tasks and communications on application-specific heterogeneous multiprocessor with nonnegligible communication costs.[51]

Performance Bounds Theory and Prediction

Sastry[77] developed a stochastic approach for estimation of wireability (routability) for gate arrays. Kurdahi[78] created a discrete probabilistic model for area estimation of VLSI chips designed according to a standard cell methodology. Küçükçakar[79] introduced a method for partitioning of behavioral specifications onto multiple VLSI chips using probabilistic area/performance predictors integrated into a package called BEST (Behavioral ESTimation). BEST provides a range of prediction techniques that can be applied at the algorithm level and includes references to prior research. These predictors provide information required by Tirat-Gefen's system-level probabilistic optimization methods.[51]

Lower bounds on the performance and execution time of task-flow graphs mapped to a set of available processors and communication links were developed by Liu and Liu[80] for the case of heterogeneous processors but no communication costs and by Hwang et al.[81] for homogeneous processors with communication costs. Tight lower bounds on the number of processors and execution time for the case of homogeneous processors in the presence of communication costs were developed by Al-Mouhamed.[82] Yen and Wolf[83] provide a technique for performance estimation for real-time distributed systems.

At the system and register-transfer level, estimating power consumption by the interconnect is important.[84] Wadekar et al.[85] reported "Freedom," a tool to estimate system energy and power that accounts for functional-resource, register, multiplexer, memory, input/output pads, and interconnect power. This tool employees a statistical estimation technique to associate low-level, technology-dependent, physical and electrical parameters with expected circuit resources and interconnection. At the system level, "Freedom" generates predictions with high accuracy by deriving an accurate model of the load capacitance for the given target technology — a task reported as critical in high level power prediction by Brand and Visweswariah.[86] Methods to estimate power consumption prior to high-level synthesis were also investigated by Mehra and Rabaey.[87] Liu and Svensson[88] reported a technique to estimate power consumption

in CMOS VLSI chips. The reader is referred to an example publication that reports power prediction and optimization techniques at the register transfer level.[89]

Word Length Selection

Many researchers studied word-length optimization techniques at the register-transfer level. A few example publications are cited here. These technique can be classified as statistical techniques applied to digital filters,[90] simulated annealing-based optimization of filters,[91] and simulation-based optimization of filters, digital communication, and signal processing systems.[92] Sung and Kum reported a simulation-based word-length optimization technique for fixed-point digital signal processing systems.[93] The objective of these particular architecture-level techniques is to minimize the number of bits in the design which is related to, but not the same as the overall hardware cost.

Synthesis at the Register Transfer Level and the Behavioral Level

J. Bhasker
Cadence Design Systems

75.1 Introduction

This chapter provides an overview of register transfer level synthesis and behavioral synthesis, contrasting the two with examples. Examples are written using VHDL and Verilog HDL, the two dominant hardware description languages (HDL) in the industry today.

The chapter intends to be more of a tutorial. It first describes the distinguishing characteristics of register transfer level (RTL) modeling as opposed to behavioral level modeling. It then uses both HDLs to illustrate how RTL models are mapped to hardware. Both combinational logic synthesis and sequential logic synthesis are presented. This includes how flip-flops, latches, and three-state gates are inferred from the RTL model. A finite state machine modeling example is also described. The later part of the chapter shows the behavioral synthesis methodology with examples to illustrate the flow of transformations that occur during the synthesis process. Many scheduling and resource allocation algorithms exist today. In this chapter, we illustrate the basic ideas behind the algorithms. Examples are used to show the architectural exploration that can be performed with behavioral synthesis, something that is not possible with register transfer level synthesis.

Synthesis is here! It has become an integral part of every design process. Once upon a time, all circuits were designed by hand and logic gates and their interconnections were entered into a system using a schematic capture tool. This is no longer the norm. More and more designers are resorting to synthesis because of the tremendous advantages that it provides, for example, describing the design at a higher level of abstraction. To this end, a language is needed to describe the design. This is where a hardware description language comes in. A hardware programming language is a formal language designed with the intent of describing hardware. Additionally, each language construct has a functional semantic

associated with it that can be used to verify a design described in HDL (a design described in a HDL is often called a "model"). The model also serves as a means of documenting the design.

75.2 The Two HDL's

The two dominant hardware description languages in use today are

i VHDL
ii Verilog HDL

VHDL originated from the Department of Defense through its VHSIC program and became a public domain standard in 1987, whereas Verilog HDL originated from a private company and became a public domain standard in 1995. Both languages are targeted at describing digital hardware. A design can be expressed structurally, in a dataflow style or in a sequential behavior style. The key difference between the two languages is that VHDL extends the modeling to higher levels of data abstraction, provides for strong type checking, and supports the delta delay mechanism.

An excellent introduction to both languages can be found in (Bhasker, 1995) and (Bhasker, 1997). The complete descriptions of languages can be found in their respective language reference manuals (LRMs), (IEEE, 1993) and (IEEE, 1995).

Here is an example of a simple arithmetic logic unit described using both languages. The design is described using a mixed style — it contains structural components, dataflow, and sequential behavior.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all, IEEE.NUMERIC_STD.all;
entity ALU is
  port (A, B: in UNSIGNED(3 downto 0);
        SEL: in STD_LOGIC_VECTOR(0 to 1);
        Z: out UNSIGNED(7 downto 0);
        ZComp: out BOOLEAN);
end;
architecture MIXED_STYLE of ALU is
  component MULTIPLIER
    port (PortA, PortB: in UNSIGNED (3 downto 0);
          PortC: out UNSIGNED (7 downto 0));
  end component;
  signal MulZ: UNSIGNED (7 downto 0);
begin
  ZComp <= A < B when SEL = "11" else FALSE;
  M1: MULTIPLIER port map (PortA => A, PortB => B,
                           PortC => MulZ);
  process (A, B, SEL, MulZ)
  begin
    Z <= (others => '0');
    case SEL is
      when "00" => Z(3 downto 0) <= A + B;
      when "01" => Z(3 downto 0) <= A – B;
      when "10" => Z < = MulZ;
      when others => Z <= (others => 'Z');
    end case;
  end process;
end;
```

```
//Verilog:
module ALU (A, B, SEL, Z, ZComp);
  input [3:0] A, B;
  input [0:1] SEL;
  output [7:0] Z;
  reg [7:0] Z;
  output ZComp;
  assign ZComp = (SEL == 2'b11) ? A < B: 'b0;
  MULTIPLIER M1 (.PortA(A), .PortB(B), .PortC(MulZ));
  always @(A or B or SEL)
  begin
    case (SEL)
      2'b00: Z = A + B;
      2'b01: Z = A – B;
      2'b10: Z = MulZ;
      default: Z = 'bz;
    endcase
  end
endmodule
```

In VHDL, the interface of the design (entity declaration) is separate from the description of the design (architecture body). Note that each signal is declared as a specific type (UNSIGNED). This type is declared in the package NUMERIC_STD, which in turn is included in the design using the context clauses (library and use clause). The structural part is described using a component instantiation statement — a component declaration is required to specify the interface for the component. The dataflow part is specified using a concurrent signal assignment. The sequential part is specified using a process statement; this contains a case statement that switches to an appropriate branch based on the value of the case expression.

In the Verilog model, each variable can have at most four values: 0, 1, x, and z. The model shows the two main data types in Verilog: net and register (a wire is a net data type, while a reg is a register data type). The structural part is described using a module instantiation statement. Notice that named association is used to specify the connection between the ports of the module and its external nets to which they are connected. Dataflow part is modeled using the continuous assignment statement, while the sequential part is represented using the always statement.

In this chapter, we shall use both of the languages to illustrate the examples when describing synthesis.

75.3 The Three Different Domains of Synthesis

There are three distinct domains in synthesis:

i logic synthesis
ii RTL synthesis
iii behavioral synthesis

But first, the definition (at least the author's) of synthesis: Synthesis is the process of transforming an HDL description of a design into logic gates. The synthesis process itself, starting from HDL, involves a number of tasks that need to be performed. These tasks may or may not be distinct in synthesis tools (Fig. 75.1).

Starting from an HDL description, synthesis generates a technology-independent RTL level netlist (RTL blocks interconnected by nets). Based on the target technology and design constraints, such as area and delay, the module builder generates a technology-specific gate level netlist. A logic optimizer further optimizes the logic to match the design constraints and goals such as area and delay. The synthesis process may bypass the module build phase and directly generate a gate level netlist if there are no RTL blocks in the design.

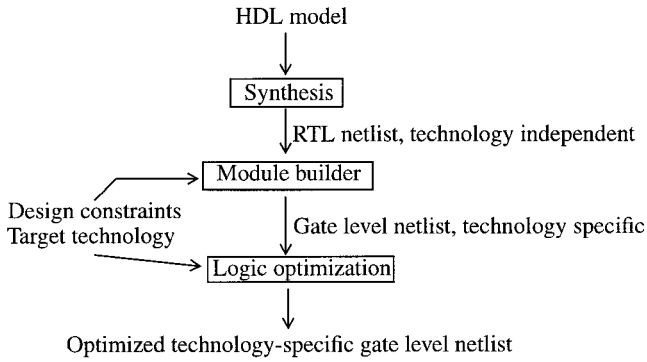

FIGURE 75.1 The tasks involved in synthesis process.

In this chapter, we will not discuss logic optimization and module building. One source that describes the algorithms behind logic optimization is (DeMicheli, 1994).

Coming back to the three different synthesis domains, let us briefly explore them. The level of abstraction increases as we go from the logic level to the behavioral level. Inversely, the structural inference reduces as we go from the logic level to the behavioral level (Fig. 75.2).

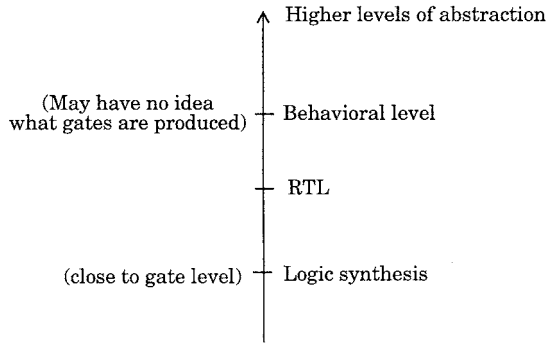

FIGURE 75.2 Varying levels of abstraction.

In the logic synthesis domain, a design is described in terms of Boolean equations. Components may be instantiated to describe hierarchy or may lower level primitives such as flip-flops. Here is a logic synthesis model for an incrementor whose output is latched.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
use IEEE.NUMERIC_STD.all;
entity INCREMENT is
  port (A: in UNSIGNED(0 to 2); CLOCK: in STD_LOGIC;
        Z: out UNSIGNED(0 to 2));
end;

architecture LOGIC_LEVEL of INCREMENT is
  component FD1S3AX
    port (DATA, CLK: in STD_LOGIC; Q: out STD_LOGIC);
  end component;
  signal DZ1, DZ2, DZ0, S429, A1BAR: STD_LOGIC;
```

```
begin
  DZ1 <= not ((A(1) or DZ2) and (A(2) or A1BAR));
  DZ2 <= not A(2);
  DZ0 <= not ((A(0) or DZ2) and (A1BAR or S429));
  A1BAR <= not A(1);
  S429 <= not ((DZ2 or A1BAR) and A(0));

  S0: FD1S3AX port map (DZ2, CLOCK, Z(2));
  S1: FD1S3AX port map (DZ1, CLOCK, Z(1));
  S2: FD1S3AX port map (DZ0, CLOCK, Z(0));
end;

//Verilog:
module INCREMENT (A, CLOCK, Z);
  input [0:2] A;
  input CLOCK;
  output [0:2] Z;

  wire A1BAR, S429, DZ0, DZ1, DZ2;

  assign DZ1 = ! ((A[1] || DZ2) && (A[2] || A1BAR));
  assign DZ2 = ! A[2];
  assign DZ0 = ! ((A[0] || DZ2) && (A1BAR || S429));
  assign A1BAR = ! A[1];
  assign S429 = ! ((DZ2 || A1BAR) && A[0]);

  FD1S3AX     S0 (DZ2, CLOCK, Z[2]),
              S1 (DZ1, CLOCK, Z[1]),
              S2 (DZ0, CLOCK, Z[0]);
endmodule
```

Notice that all operators are logical operators; these implicitly specify the structure of the synthesized netlist (Fig. 75.3). For example, the `and` operator produces an `and` gate, the `or` operator produces an `or` gate, and so on. The component instantiations (module instantiations in Verilog) instantiate three flip-flops.

In the register transfer level synthesis domain, the arithmetic operations are modeled using language operators and the behavior is described using the language behavioral constructs. The design is described in terms of data transfers between arithmetic logic units and registers, possibly at explicitly defined clock edges. Moreover, registers may be inferred implicitly from the design. In addition, hierarchy can be described by instantiating other RTL descriptions. RTL blocks, such as a custom-built multiplier, may be directly instantiated.

The key difference from logic synthesis is that in the register transfer level case, the behavior is described using higher level operators such as + and –, and constructs such as if and case, that are provided by the hardware description language. In addition, for sequential circuits, the behavior of the design at each clock edge is explicitly described. Here is the same example of the incrementor, this time at the register transfer level:

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
use IEEE.NUMERIC_STD.all;
entity INCREMENT is
  port (A: in UNSIGNED(0 to 2); CLOCK: in STD_LOGIC;
        Z: out UNSIGNED(0 to 2));
end INCREMENT;
```

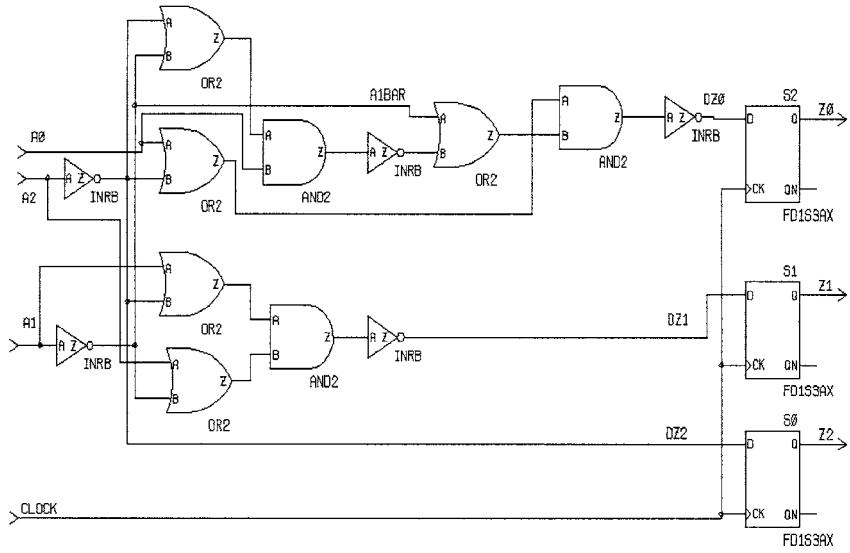

FIGURE 75.3 The synthesized netlist.

```
//The above entity declaration is identical to the
//logic level case.

architecture REGISTER_TRANSFER_LEVEL of INCREMENT is
  PZ: process
  begin
    wait until CLOCK = '1';
    Z <= A + 1;
  end process PZ;
end REGISTER_TRANSFER_LEVEL;

//Verilog:
module INCREMENT (A, CLOCK, Z);
  input [0:2] A;
  input CLOCK;
  output [0:2] Z;
  reg [0:2] Z;

    always @(posedge CLOCK)
    Z <= A + 1;
endmodule
```

Notice that flip-flops are not explicitly instantiated but are inferred. Inference rules are used to infer flip-flops. One such rule is that if any variable or signal (a reg in Verilog HDL) is assigned a value under the control of a clock edge (as shown using a wait on a clock edge in a process statement for VHDL and using a posedge event in an always statement for Verilog), then the variable or signal is inferred as a flip-flop. Also note that in the RTL description, the behavior of the design at every clock edge is explicitly specified. In the behavioral synthesis domain, this is one level above register transfer level synthesis, no clocking information is specified in the model (this is not completely true as we will see later when we talk about partially scheduled and fully scheduled models). Inference rules are not used to infer registers. The behavior of the design is described as a sequential program, and the synthesis tool's job is to figure

out which operations are to be done in which clock cycle based on the design constraints that are specified. Any variable whose value needs to be saved between clock cycles will have to be stored in a register.

Here is a simple example used to illustrate behavioral synthesis:

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all, IEEE.NUMERIC_STD.all;
entity SIMPLE_TREE is
  port (InData: in UNSIGNED(0 to 3);
        OutData: out UNSIGNED(0 to 3));
end SIMPLE_TREE;

architecture ONLY_TO_EXPLAIN of SIMPLE_TREE is
begin
  P1: process (InData)
    variable Tree: UNSIGNED (0 to 3);
  begin
    Tree: = InData + 1;
    Tree: = Tree + 1;
    OutData <= Tree + 1;
  end process P1;
end ONLY_TO_EXPLAIN;

//Verilog:
module SIMPLE_TREE (InData, OutData);
  input [0:3] InData;
  output [0:3] OutData;
  reg [0:3] OutData;
  reg [0:3] Tree;

  always @(InData)
  begin
    Tree = InData + 1;
    Tree = Tree + 1;
    OutData <= Tree + 1;
  end
endmodule
```

Notice that no clocking information, such as clock edges, is explicitly present in the model. Now if we assume that an adder (the addition operator) takes 5 ns to compute and assume a clock period of 6 ns, we can see that it will take three clock cycles to completely execute the behavior. In addition, all the three "+" operators can be shared using only one adder. Also, only one register *Tree* is required to save the intermediate values (the value between clock cycles). Figure 75.4 shows one architecture (RTL netlist) generated under the given assumptions. The controller sequencing is shown in Fig. 75.5.

If a clock period of 11 ns is specified, then only two clock cycles are required to complete execution. See Fig. 75.6 for the controller sequencing. This time two adders are required. Figure 75.7 shows the new architecture.

By changing the constraints, different architectures for the same behavior are produced — this is called "architectural exploration." Such generation of different architectures is not possible with RTL synthesis, since the architecture of the design is explicitly specified in the RTL model.

We describe register transfer level synthesis and behavioral synthesis in further detail in the next two sections.

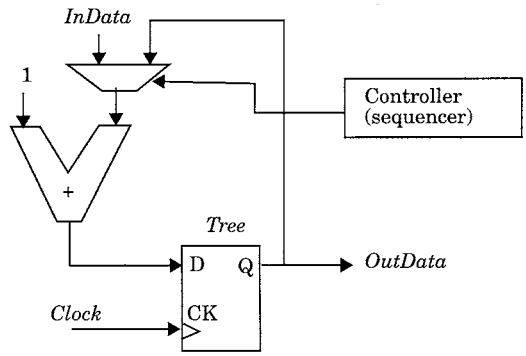

FIGURE 75.4 One architecture with a clock cycle of 6 ns.

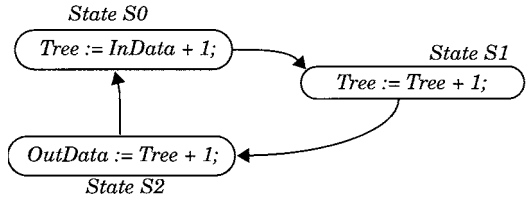

FIGURE 75.5 Controller sequencing.

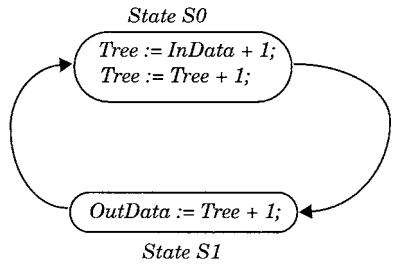

FIGURE 75.6 Controller sequencing with new specification.

75.4 RTL Synthesis

In describing an RTL model, different design styles are used for modeling combinational logic and for modeling sequential logic.

Combinational Logic

Combinational logic can be described using

i concurrent signal assignment (Continuous assignment in Verilog)
ii process statement with no clock edges (always statement with no edge event in event list for Verilog).

Language operators such as + and –, and behavioral constructs such as if, case, and loop statements, may be used to model the design. Here is an example of a BCD to seven-segment decoder:

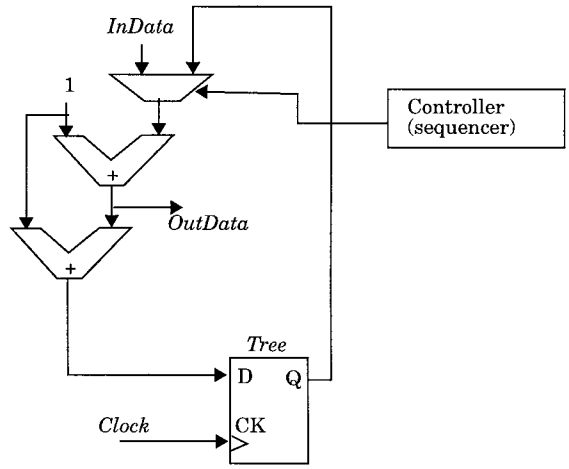

FIGURE 75.7 Another architecture with a clock period of 11 ns.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
entity BCD_TO_7 is
  port (D: in STD_LOGIC_VECTOR(0 to 3);
        Q: out STD_LOGIC_VECTOR(0 to 6));
end BCD_TO_7;

architecture RTL_MODEL of BCD_TO_7 is
begin
  P1: process (D)
  begin
    case D is
      when "0000" => Q <= "1111110";
      when "0001" => Q <= "00011000";
      when "0010" => Q <= "10110111";
      when "0011" => Q <= "00111111";
      when "0100" => Q <= "01011101";
      when "0101" => Q <= "01101111";
      when "0110" => Q <= "11001111";
      when "0111" => Q <= "00111100";
      when "1000" => Q <= "11111111";
      when "1001" => Q <= "01111101";
      when others => Q <= "--------";
    end case;
  end process P1;
end RTL_MODEL;

//Verilog:
module BCD_TO_7 (D, Q);
  input [0:3] D;
  output [0:6] Q;
  reg [0:6] Q;
```

```
  always @(D)
    case (D)
      4'd0: Q = 7'b1111110;
      4'd1: Q = 7'b00011000;
      4'd2: Q = 7'b10110111;
      4'd3: Q = 7'b00111111;
      4'd4: Q = 7'b01011101;
      4'd5: Q = 7'b01101111;
      4'd6: Q = 7'b11001111;
      4'd7: Q = 7'b00111100;
      4'd8: Q = 7'b11111111;
      4'd9: Q = 7'b01111101;
      default: Q = 7'bx;
    endcase
endmodule
```

It is required that all signals (variables in Verilog) read within the process statement (always statement) must appear in the sensitivity list (event list for Verilog), or else there may be a possibility for a functional mismatch between the RTL model and its synthesized netlist. Some synthesis tools issue a warning about such missing signals.

Sequential Logic

Edge-sensitive storage elements (flip-flops) are modeled differently from level-sensitive storage elements (latches). First, let us take a look at how level-sensitive storage devices are modeled.

Modeling a Level-Sensitive Storage Element

When a variable or a signal is not explicitly assigned a value in every iteration of a process statement (or an always statement in Verilog), a level-sensitive storage element is inferred. For example, this can happen if a variable is not assigned a value in all branches of an if statement.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
entity LSSE is
  port (D, Clock: in STD_LOGIC; Q: out STD_LOGIC);
end LSSE;

architecture LATCH_INFERENCE of LSSE is
begin
  process (Clock, D)
  begin
    if (Clock = '1') then
      Q <= D;
    end if;
  end process;
end LATCH_INFERENCE;

//Verilog:
module LSSE (D, Clock, Q);
  input D, Clock;
  output Q;
  reg Q;
```

```
  always @(D or Clock)
    if (Clock)
      Q = D;
endmodule
```

Based on the language semantics, *Q* needs to retain its value during the period when *Clock* is 0. This is achieved by implementing a level-sensitive storage element for *Q*. This is shown in Fig. 75.8, which shows the synthesized netlist (FD1S1A is a latch).

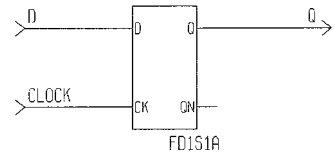

FIGURE 75.8 Synthesizing a level-sensitive storage element.

Modeling an Edge-Sensitive Storage Element

A signal or a variable assigned a value under the control of a clock edge is inferred as a flip-flop.

In VHDL: Here is a template of a process statement that has to be used to infer edge-sensitive storage elements.

```
process
  declarations, if any
begin
  wait until <clock_edge>
  <sequential_statements>
end process;
-- <clock_edge> can be either of:
--  Signal = '1' for a rising edge
--  Signal = '0' for a falling edge.
```

In Verilog: Here is a template of the always statement.

```
always @(<edge_event>)
  <statement>
//<edge_event> is:
//  "posedge VariableName" for positive edge,
//  "negedge VariableName" for negative edge.
```

Here is an example.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all, IEEE.NUMERIC_STD.all;
entity ESSE is
  port (Clk: in STD_LOGIC; D: in UNSIGNED (0 to 2);
        Q: out UNSIGNED(0 to 2));
end ESSE;

architecture FF_INFERENCE of ESSE is
begin
  process
  begin
    wait until Clk = '0';
    Q <= D + 1;
  end process;
end FF_INFERENCE;

//Verilog:
module ESSE (Clk, D, Q);
```

```
  input Clk;
  input [0:2] D;
  output [0:2] Q;
  reg [0:2] Q;

  always @(negedge Clk)
    Q <= D + 1;
endmodule
```

Since *Q* is assigned a value under the control of a clock edge, an edge-sensitive storage element is inferred for *Q*. This is shown in the synthesized netlist (Fig. 75.9).

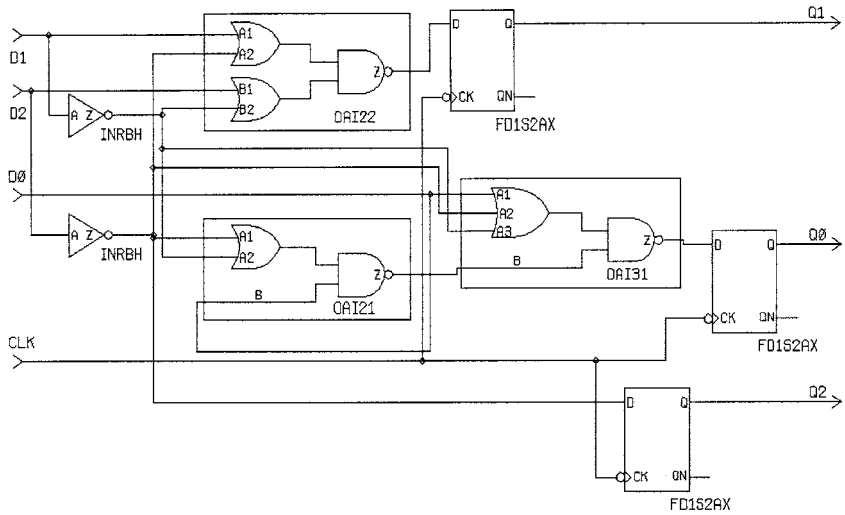

FIGURE 75.9 Inferring a flip-flop.

75.5 Modeling a Three-State Gate

A three-state gate is modeled at the register transfer level by assigning the high-impedance value to a signal or variable under the control of a condition.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
entity THREE_STATE is
  generic (NBITS: POSITIVE:= 3);
  port (Enable: in STD_LOGIC;
        MemDataReg: in STD_LOGIC_VECTOR(1 to NBITS);
        ReadBus: out STD_LOGIC_VECTOR (1 to NBITS));
end THREE_STATE;

architecture INFERENCE of THREE_STATE is
begin
  process (Enable, MemDataReg)
  begin
    if (Enable = '0') then
      ReadBus <= (others => 'Z');
    else
      ReadBus <= MemDataReg;
```

```
    end if;
  end process;
end INFERENCE;

//Verilog:
module THREE_STATE (Enable, MemDataReg, ReadBus);
  parameter NBITS = 3;
  input Enable;
  input [1:NBITS] MemDataReg;
  output [1:NBITS] ReadBus;
  reg [1:NBITS] ReadBus;

  always @(Enable or MemDataReg)
    if (! Enable)
      ReadBus = 'bz;
    else
      ReadBus = MemDataReg;
endmodule
```

The target *ReadBus* is assigned the high impedance value under the control of the condition "*Enable* = 0". The synthesized netlist contains three three-state gates with the condition "*Enable* = 0" controlling the three-state behavior of the gate and *MemDataReg* as the input to the three-state gate (see Fig. 75.10 for the synthesized netlist).

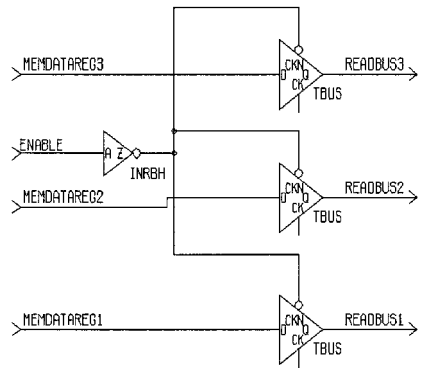

FIGURE 75.10 Synthesizing a three-state gate.

75.6 An Example

Here is an example of a synthesis model. There exists a mango juice dispenser that dispenses mango juice cartons for 25¢ each. The machine accepts only coins (quarters, dimes, and nickels), and appropriate change is to be returned. All state transitions are synchronized to the positive edge of a clock. The state transition diagram is shown as shown in Fig. 75.11.

```
-- VHDL:
entity MANGO_JUICE is
  port (CoinIn: in POSITIVE; Clock, Reset: in BIT;
        DispenseJuice: out BOOLEAN;
        NickelOut, DimeOut: out NATURAL);
end MANGO_JUICE;
```

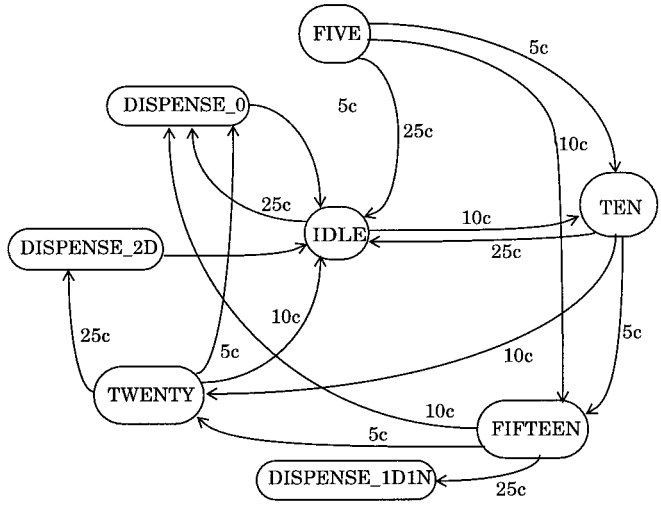

FIGURE 75.11 State transition for mango juice dispensing machine.

```
architecture DISPENSER of MANGO_JUICE is
  type STATES is (IDLE, FIVE, TEN, FIFTEEN, TWENTY);
  signal NextState, CurrentState: STATES;
begin
  process (Clock, Reset, NextState)
  begin
    if Reset = '0' then
      CurrentState <= IDLE;
    elsif (Clock = '0' and Clock'EVENT) then
      CurrentState <= NextState;
    end if;
  end process;

  process (CoinIn, CurrentState)
  begin
    NextState <= CurrentState;
    DispenseJuice <= FALSE;
    NickelOut <= 0;
    DimeOut <= 0;

    case CurrentState is
      when IDLE =>
        case CoinIn is
          when 5 => NextState <= FIVE;
          when 10 => NextState <= TEN;
          when 25 =>
            NextState <= IDLE;
            DispenseJuice <= TRUE;
          when others => NextState  <= IDLE;
        end case;
      when FIVE =>
        case CoinIn is
          when 5 => NextState <= TEN;
```

```
            when 10 => NextState <= FIFTEEN;
            when 25 =>
              NextState <= IDLE;
              DispenseJuice <= TRUE;
              NickelOut <= 1;
            when others => NextState <= IDLE;
          end case;
        when TEN =>
          case CoinIn is
            when 5 => NextState <= FIFTEEN;
            when 10 => NextState <= TWENTY;
            when 25 =>
              NextState <= IDLE;
              DispenseJuice <= TRUE;
              DimeOut <= 2;
            when others => NextState <= IDLE;
          end case;
        when FIFTEEN =>

                end
              25:
                begin
                  DispenseJuice = TRUE;
                  DimeOut = 2;
                end
              default:;
            endcase
          end
        default: NextState = IDLE;
      endcase
    end
  endmodule
```

The finite state machine is modeled using two processes (two always statements in Verilog). The first process is used to model the sequential logic, while the second process models the combinational logic. A case statement switches between the different states based on *CurrentState* and goes to the next state, depending on the value of the coin read in. Three asynchronous, clear flip-flops are synthesized from this model: these flip-flops hold the state of the mango juice dispenser.

For further reading on these topics of register transfer level synthesis, see (Bhasker, 1998). Since the modeling style enforces certain restrictions on what features of the language can be used, an IEEE standard for such a register transfer level synthesis subset is just evolving. The one for VHDL synthesis, IEEE PAR 1076.6, will be an IEEE standard by the end of this year, while the one for Verilog synthesis, IEEE PAR 1364.1, is expected to be an IEEE standard by the end of 1999. The VHDL synthesis subset standard is being developed by the VHDL synthesis interoperability working group, whereas the Verilog standard is being developed by the Verilog synthesis interoperability working group. The author is the chair for both working groups.

75.7 Behavioral Synthesis

As mentioned in an earlier section, behavioral synthesis differs from register transfer level synthesis due to the fact that clocking information may not exist in the model, that is, the behavior of the design at every clock edge is not explicitly described in the model. This is the task of the behavioral synthesis tool to determine.

Behavioral synthesis is often referred to as "high-level synthesis." In its basic form, an input to such a program is a sequential program, that is, a program that contains a sequence of statements that describes the behavior. This program is analyzed by a behavioral synthesis tool that then performs three major tasks:

- Scheduling — this is the task of determining the clock boundaries or assigning operations to clock cycles.
- ALU allocation — this is the task of determining which types of ALUs and how many ALUs are required.
- Register allocation — this task is to determine the required registers.

These tasks may be performed in any order by a behavioral synthesis tool. The fact is that these three problems need to be addressed. We shall explore each of these tasks in greater detail using the algorithm of a differential equation solver (see (Paulin, 1986)).

```
//Solve the differential equation:
//y'' + 5 x y' + 3y = 0

-- VHDL:
entity DIFF_EQ is
  port (A, DX: in INTEGER; X, U, Y: inout INTEGER);
end DIFF_EQ;

architecture HIGH_LEVEL of DIFF_EQ is
begin
  process
  begin
    while X < A loop
      X < = X + DX;
      U < = U – 5 * U * X * DX – 3 * Y * DX;
      Y < = Y + U * DX;
      wait for 0 ns;//Just so signal values settle.
    end loop;
  end process;
end HIGH_LEVEL;

//Verilog:
module DIFF_EQ (A, DX, X, U, Y);
  input [0:31] A, DX;
  output [0:31] X, U, Y;
  reg [0:31] X, U, Y;

  always @ (A or DX or X or U or )
    while (X < A)
    begin
      X < = X + DX;
      U < = U – 5 * U * X * DX – 3 * Y * DX;
      Y < = Y + U * DX;
```

```
        #0;
    end
endmodule
```

As you can see from the model, there is no mention of a clock, just the behavior of the differential equation solver is described. To ease the explanation of the following tasks that occur in a behavioral synthesis tool, we will use just one of the assignments (the second assignment) to explain the techniques and issues behind these tasks. The line is:

```
U <= U - 5 * U * X * DX - 3 * Y * DX;
```

Quite often, it is useful to construct a data flow graph (DeMicheli, 1994) of such a behavior. This is shown in Fig. 75.12. There are five multipliers and two subtractors. The arrows show the flow of data from one operation to another.

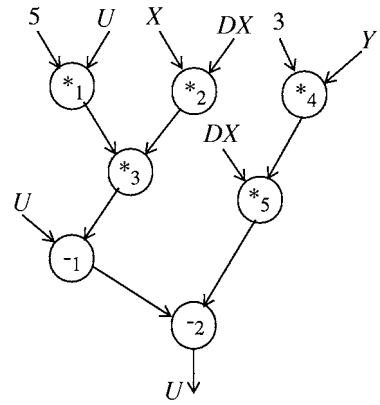

FIGURE 75.12 Data flow graph of assignment statement.

Scheduling

Given the previous model, we can see that there is no information about what operations are to be done in which clock cycle. The behavior would be performed in a number of clock cycles. Note that each clock cycle represents one state of the behavior. More or less, the behavior is broken up into a number of clock cycles based on the clock period. To determine the scheduling, additional data needs to be provided. In the previous case, the path delay of the subtractor and the multiplication operator needs to be known. This information can be derived from a technology library. In this instance, let us assume that a subtractor has a delay of 5 ns and a multiplier has a delay of 12 ns.

The number of operations that can be done in one control step is dependent on the clock period — this also needs to be known. Let us say, a clock period of 14 ns is specified. In such a case, Fig. 75.13 and Fig. 75.14 shows two possible ways of scheduling the operations. In the first schedule, operations $*_1$, $*_2$, $*_3$ are performed in the first clock cycle, operations $*_3$, $*_5$ are performed in the second clock cycle, operation $-_1$ is performed in the third clock cycle, and the operation $-_2$ is performed in the fourth clock cycle. With this schedule, the behavior takes four clock cycles to complete execution. In the second schedule, operators $*_1$ is performed in the first clock cycle, $*_2$ and $*_4$ are performed in the second clock cycle, $*_3$ is done in the third clock cycle, $-_1$ and $*_5$ in the fourth, and $-_2$ in the fifth. Which schedule is better depends on how the other tasks (ALU allocation and register allocation) perform in achieving the user constraints (typically area and speed).

If the clock period is changed to 25 ns, a different set of schedules can occur. One such example is shown in Fig. 75.15. Notice that the clock period is large enough to support two or more operations that are performed in sequence to be done in a single clock cycle. With this schedule, it takes only three clock cycles to complete execution.

Another constraint that could have been provided is the number of clock cycles.

Thus, by controlling the clock period and the number of clock cycles, different schedules (and different architectures) for the same behavior can be produced. This is called "exploration of architectural design space." The output of a scheduling task is typically an equivalent RTL model. An RTL model for the last schedule is shown next.

```
-- VHDL:
architecture RTL of EXAMPLE is
  type STATES is (CLOCK_CYCLE_1, CLOCK_CYCLE_2,
                  CLOCK_CYCLE_3);
```

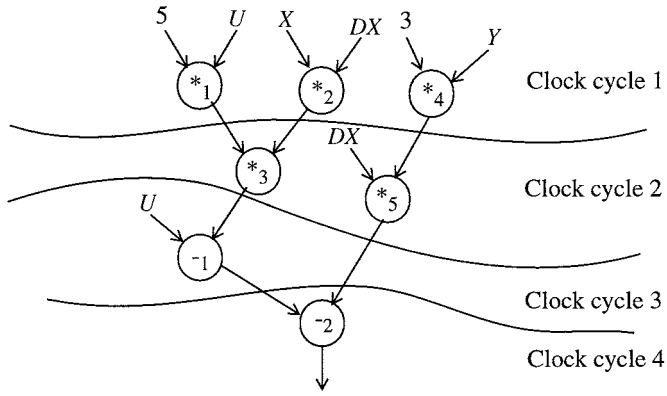

FIGURE 75.13 One possible schedule.

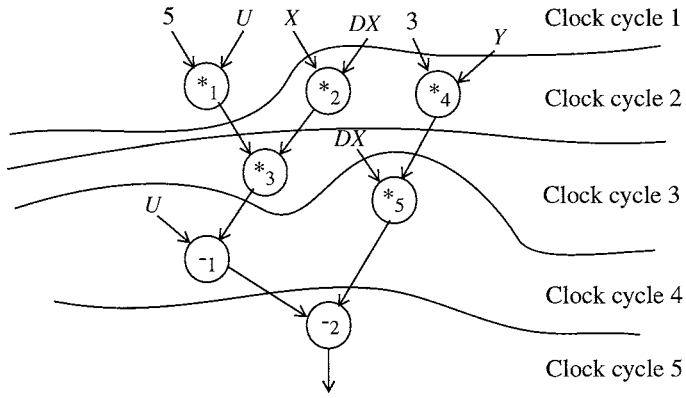

FIGURE 75.14 Another possible schedule.

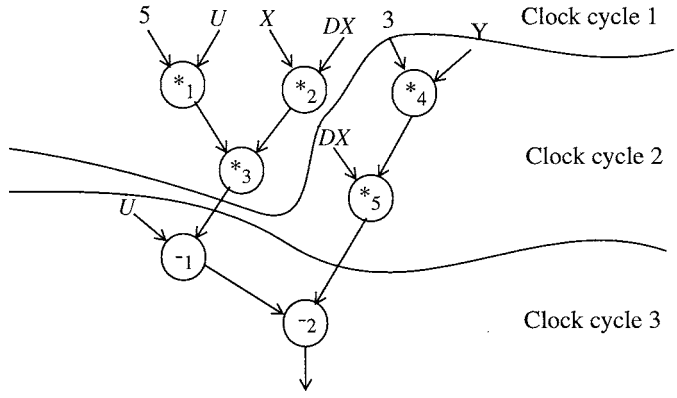

FIGURE 75.15 A schedule when the clock period is 25 ns.

```
  signal STATE: STATES;
  signal SAVE_1, SAVE_2: INTEGER;
begin
  process
    variable T1, T2: INTEGER;
  begin
    wait until CLOCK = '1';
    case STATE is
      when CLOCK_CYCLE_1 =>
        T1:= 5 * U;                          -- *1
        T2:= X * DX;                         -- *2
        SAVE_1 <= T1 * T2;                   -- *3
        STATE <= CLOCK_CYCLE_2;
      when CLOCK_CYCLE_2 =>
        T1:= 3 * Y;                          -- *4
        SAVE_2 <= T1 * DX;                   -- *5
        STATE <= CLOCK_CYCLE_3;
      when CLOCK_CYCLE_3 =>
        T1:= U - SAVE_1;                     -- -1
        U <= T1 - SAVE_2;                    -- -2
        STATE <= CLOCK_CYCLE_1; - Go back and repeat.
      when others:
        STATE <= CLOCK_CYCLE_1;
    end case;
  end process;
end RTL;

//Verilog:
parameter CLOCK_CYCLE_1 = 1, CLOCK_CYCLE_2 = 2,
          CLOCK_CYCLE_3 = 3;
reg [0:1] STATE;
integer T1, T2, SAVE_1, SAVE_2;

always @(posedge CLOCK)
  case (STATE)
    CLOCK_CYCLE_1:
      T1 = 5 * U;                        //*1
      T2 = X * DX;                       //*2
      SAVE_1 <= T1 * T2;                 //*3
      STATE <= CLOCK_CYCLE_2;
    CLOCK_CYCLE_2:
      T1 = 3 * Y;                        //*4
      SAVE_2 <= T1 * DX;                 //*5
      STATE <= CLOCK_CYCLE_3;
    CLOCK_CYCLE_3:
      T1 = U - SAVE_1;                   //-1
      U <= T1 - SAVE_2;                  //-2
      STATE <= CLOCK_CYCLE_1;
    default:
      STATE <= CLOCK_CYCLE_1;
  endcase
```

ALU Allocation

Once a schedule is known, the knowledge about which operations are mutually exclusive is also known. Two operations that are mutually exclusive, that is, are not used in the same clock cycle, may be shared using just one ALU. For example, in the schedule of Fig. 75.15, operations $*_2$ and $*_4$ are mutually exclusive; therefore, these two operations can be performed using a single multiplier (ALU that just does multiplication): in clock cycle 1, the multiplier performs the $*_2$ operation while in clock cycle 2, the multiplier performs the $*_4$ operation. However, sharing has a cost. Extra multiplexers may be needed at the input of the multiplier to multiplex the inputs in. This introduces extra delay and could be in the critical path of the circuit. So, a behavioral synthesis tool has to make a judicious choice when sharing.

Here are the various possibilities that can occur when sharing an ALU:

i Same operator, same operands: definitely must share. Example: $A + B$, $A + B$
ii Same operator, one different operand: tradeoff, since one multiplexer is introduced. Example: $A + B$, $A + C$
iii Same operator, different operands: tradeoff, since two multiplexers are introduced. Example: $A + B$, $C + D$
iv Different operators, same operands: useful to share. Example: $A + B$, $A - B$
v Different operators, one different operand: tradeoff, since one multiplexer is introduced. Example: $A + B$, $A - C$
vi Different operators, different operands: tradeoff, since two multiplexers are introduced. Example: $A + B$, $C - D$

Possibility i is the best case to share followed by iv, ii, v, iii, and vi.

Consider the schedule in Fig. 75.13. Sharing to its maximum, to reduce area, yields us just one subtractor and three multipliers. One possible way to share is:

- Operation $*_1$, $*_3$: ALU1 (multiplier)
- Operation $*_4$, $*_5$: ALU2 (multiplier)
- Operation $*_2$: ALU3 (multiplier)
- Operation $-_1$, $-_2$: ALU4 (subtractor)

The block diagram of the architecture is shown in Fig. 75.16. Notice that there are values that need to be saved in registers; these are shown as circles in the figure; more on this is in the next section.

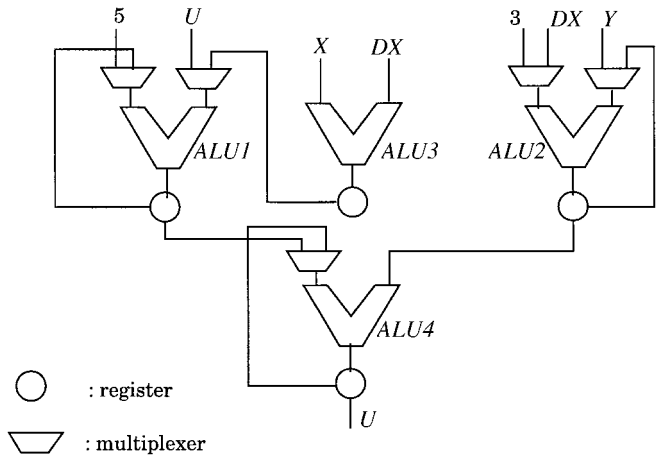

FIGURE 75.16 The ALU architecture of the first schedule.

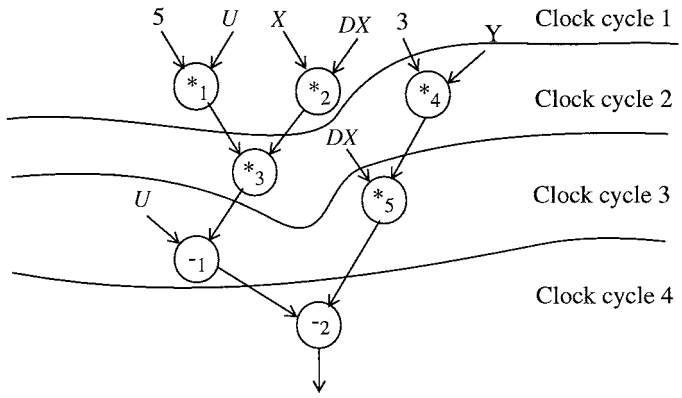

FIGURE 75.17 A schedule subject to resource constraints.

If a different kind of constraint, called resource constraints, is placed on the behavioral synthesis tool, for example, only two multipliers and one subtractor are available, then a different schedule and different sharing will occur. Figure 75.17 shows a possible schedule. Notice that in each clock cycle, two multiplications at most and one subtraction at most are performed. A possible sharing strategy is

- $*_1$, $*_3$: ALU1 (multiplier)
- $*_2$, $*_4$, $*_5$: ALU2 (multiplier)
- $-_1$, $-_2$: ALU3 (subtractor)

The architecture produced with this sharing is shown in Fig. 75.18. Another possible sharing strategy is

- $*_1$, $*_4$, $*_5$: ALU1 (multiplier)
- $*_2$, $*_3$: ALU2 (multiplier)
- $-_1$, $-_2$: ALU3 (subtractor)

Notice that even within the same schedule, different kinds of sharing can produce architectures that have different total area and speed.

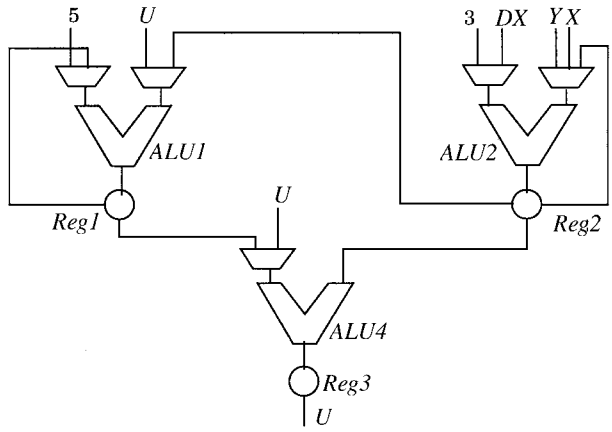

FIGURE 75.18 Architecture with resource constraints specified.

Register Allocation

The input to a behavioral synthesis tool is a behavioral model in which no registers are explicitly specified. But once a schedule has been determined, registers can be identified. A register is needed for any variable whose value has to be saved from one clock cycle to the next. For example, in Fig. 75.17, the output of $*_1$ has to be saved, since its value is defined in clock cycle 1 and used by $*_3$ in clock cycle 2. Similarly, the output of $*_4$ has to be saved as a register, since it is defined in clock cycle 2 and the value used in clock cycle 3.

The problem of register allocation is minimizing the number of such registers. If we do not apply any minimization, from the schedule shown in Fig. 75.17, we see that we will need six registers:

- R1: output of $*_1$
- R2: output of $*_2$
- R3: output of $*_3$
- R4: output of $*_4$
- R5: output of $*_5$
- R6: output of $-_1$

By optimizing the number of registers, this number can be reduced significantly. Such an analysis is performed by looking at the lifetimes of the potential registers. A lifetime is defined as the period from the clock cycle;it is defined to the clock cycle in which its value ceases to be not required. For example, here are the lifetimes of the above identified registers:

- R1: clock cycle 1 to 2
- R2: clock cycle 1 to 2
- R3: clock cycle 2 to 3
- R4: clock cycle 2 to 3
- R5: clock cycle 3 to 4
- R6: clock cycle 3 to 4

Two or more registers whose lifetimes are nonoverlapping can share the same register — basically once a register use is over, another register can reuse the same register for its lifetime, after which another register can use the register and so on. A possible register allocation may produce the following:

- Reg1: R1, R3
- Reg2: R2, R4, R5
- Reg3: R6

This allocation is shown in Fig. 75.18.

A different register allocation scheme may produce the following:

- Reg1: R1, R3, R6
- Reg2: R2, R4, R5

Notice that sharing of registers may also introduce multiplexers at the inputs of registers, as in the previous specified register allocation scheme. This is shown in Fig. 75.19. Selecting an appropriate register allocation is once again based on user-specified constraints such as area and speed.

There are other variations that are possible with the input HDL model:

i Zero scheduled
ii Partially scheduled
iii Fully scheduled

The example we have seen so far follows the “zero scheduled” model, since no explicit clock boundaries were defined. In a “fully scheduled” model, all the scheduling information is explicitly specified by the user. In a “partially scheduled” model, some points in the model are explicitly demarcated as clock

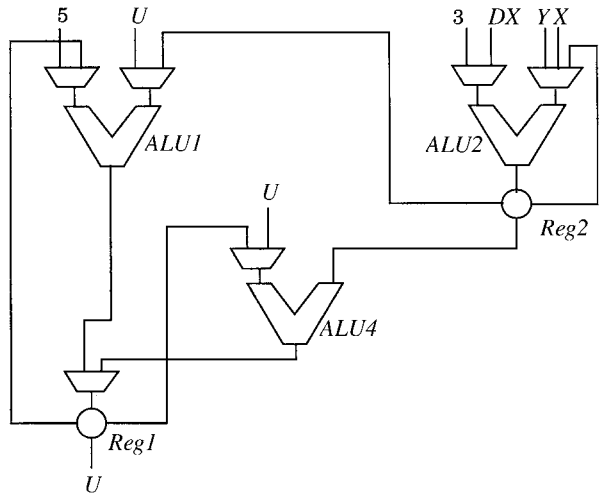

FIGURE 75.19 A register allocation may introduce extra multiplexers.

boundaries — for example, when a user knows exactly where a clock boundary must be but the behavioral synthesis tool is free to schedule the remaining parts of the behavior. We will break up our assignment statement that we have been using as an example to illustrate the various scheduling options.

```
-- Zero scheduled:
T1:= 5 * U;                -- *1
T2:= X̄ * DX;               -- *2
T3:= T1 * T2;              -- *3
T4:= 3 * Y;                -- *4
T5:= DX * T4;              -- *5
T6:= U – T3;               -- -1
U <= T6 – T5;              -- -2

-- Partially scheduled:
T1:= 5 * U;                -- *1
T2:= X * DX;               -- *2
T3 = T1 * T2;              -- *3
T4:= 3 * Y;                -- *4
wait until CLOCK = '1';
T5:= DX * T4;              -- *5
T6:= U – T3;               -- -1
U <= T6 – T5;              -- -2

-- Fully scheduled:
T1 = 5 * U;                -- *1
T2:= X * DX;               -- *2
wait until CLOCK = '1';
T3:= T1 * T2;              -- *3
T4:= 3 * Y;                -- *4
wait until CLOCK = '1';
T5:= DX * T4;              -- *5
T6:= U – T3;               -- -1
wait until CLOCK = '1';
U <= T6 – T5;              -- -2
```

Scheduling information is explicitly specified in the model by placing the clock edges — the demarcation points are "**wait until** *CLOCK* = '1';". In Verilog HDL, "@(**posedge** *CLOCK*);" can be used. In the partially scheduled and fully scheduled cases, architectural exploration is limited but still can be achieved by controlling the ALU sharing and register sharing.

An additional factor that may be considered in behavioral synthesis is scheduling with a clock period less than the maximum delay of an operator, for example, if a multiplier has a delay of 12 ns, then having a clock period of 5 ns.

Due to lack of space, we have skipped talking about controller synthesis which is an important aspect of behavioral synthesis. A good starting point on this topic is the reference (Nagle, 1982).

Verification of a behavioral synthesis model is a little more tricky than verification of an RTL model. This is due to lack of clocking information in the behavioral model. (See (Bhasker, 1991) for further details of an example of how verification can be performed.)

Two references for reading on the topic of logic synthesis are (Devadas, 1994) and (DeMicheli, 1994). Detailed algorithms are also described in these references. Further readings on behavioral synthesis can be found in (DeMicheli, 1994), (Camposano, 1991), and (Gajski, 1992).

For behavioral synthesis, it is usually not possible to support the entire set of language constructs supported by Verilog HDL and VHDL. However, at present, there is no publicly available standard subset.

75.8 Conclusion

The purpose of this chapter was to give an overview of synthesis in the register transfer level domain and the behavioral synthesis domain and to elaborate on the differences between the two. VHDL and Verilog HDL examples were used to illustrate these differences.

Behavioral synthesis is still a well-studied research topic. If you are interested in learning more about the latest state-of-the-art advances in this technology, a good starting point would be the Design Automation Conference proceedings, which usually contain a good one or two full sessions devoted to the topic of behavioral (high-level) synthesis.

76.1 Introduction

It has been noted by the digital design community that the greatest potential for additional cost and iteration cycle time savings is through improvements in tools and techniques that support the early stages of the design process.[1] As shown in Fig. 76.1, decisions made during the initial phases of a product's development cycle determine up to 80% of its total cost. The result is that accurate, fast analysis tools must be available to the designer at the early stages of the design process to help make these decisions. Design alternatives must be effectively evaluated at this level with respect to multiple metrics, such as performance, dependability, and testability. This analysis capability will allow a larger portion of the design space to be explored yielding higher quality as well as lower cost designs.

There are a number of current tools and techniques that support analysis of these metrics at the system level to varying degrees. A major problem with these tools is that they are not integrated into the engineering design environment in which the system will ultimately be implemented. This problem leads to a major disconnection in the design process. Once the system-level model is developed and analyzed, the resulting high-level design is specified on paper and thrown "over the wall" for implementation by the engineering design team, as illustrated in Fig. 76.2. As a result, the engineering design team has to often interpret this specification in order to implement the system, which often leads to design errors. It also has to develop their own initial "high-level" model from which to begin the design process in a top-down manner. Additionally, there is no automated mechanism by which feedback on design assumptions and estimations can be provided to the system design team by the engineering design team.

For systems that contain significant portions of both application-specific hardware and software executing on embedded processors, design alternatives for competing system architectures and hardware/software (HW/SW) partitioning strategies must be effectively and efficiently evaluated using high-level performance models. Additionally, the selected hardware and software system architecture must be

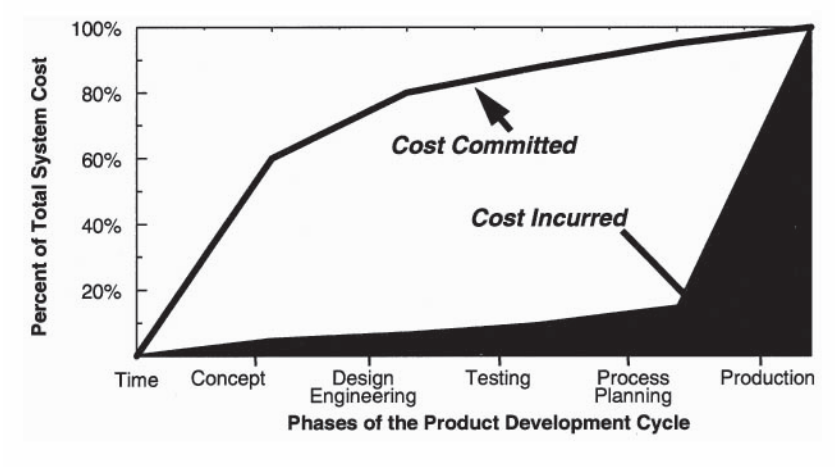

FIGURE 76.1 Product costs over the development cycle.

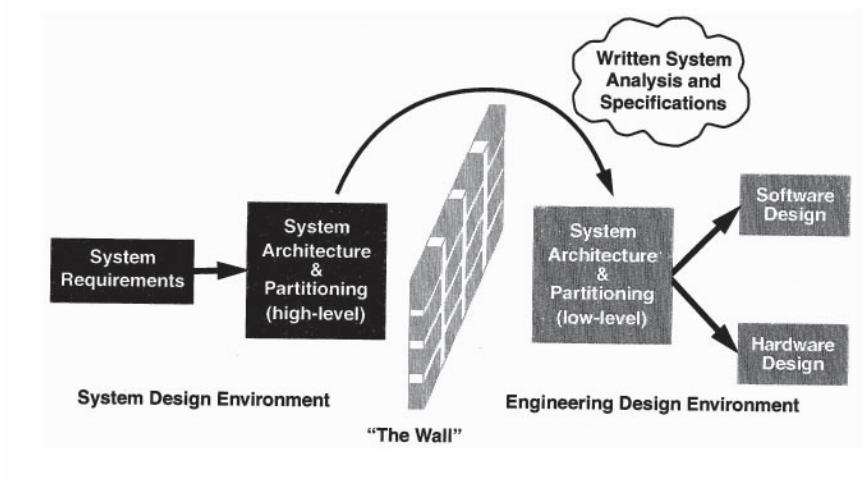

FIGURE 76.2 The disconnection between system-level design environments and engineering design environments.

refined in an integrated manner from the high-level models to an actual implementation in order to avoid implementation mistakes and the associated high redesign costs. Unfortunately, most existing design environments lack the ability to model and design a system's hardware and software in the same environment. A similar wall to that between the system design environment and the engineering design environment exists between the hardware design environment and the software design environment. This results in a design path as shown Fig. 76.3, where the hardware and software design process begins

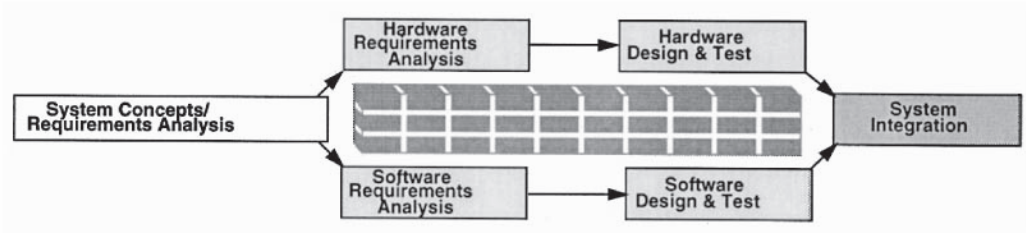

FIGURE 76.3 Current hardware/software system development methodology.

with a common system requirement and specification but proceeds through a separate and isolated design process until final system integration. At this point, assumptions on both sides may prove to be drastically wrong, resulting in incorrect system function and poor system performance.

A unified, cooperative approach in which the hardware and software options can be considered together is required to increase the quality and decrease the design time for complex hardware/software (HW/SW) systems. This approach is called hardware/software codesign, or simply codesign.[2-4] Codesign leads to more efficient implementations and improves overall system performance, reliability, and cost-effectiveness.[4] Also, because decisions regarding the implementation of functionality in software can impact hardware design (and vice versa), problems can be detected and changes made earlier in the development process.[5]

Codesign can especially benefit the design of embedded systems,[6] systems which contain hardware and software tailored for a particular application. As the complexity of these systems increases, the issue of providing design approaches that scale up to more complicated systems becomes of greater concern. A detailed description of a system can approach the complexity of the system itself,[7] and the amount of detail present can make analysis intractable. Therefore, decomposition techniques and abstractions are necessary to manage this complexity.

What is needed is a design environment in which the capability for performance modeling of HW/SW systems at a high-level of abstraction is fully integrated into the engineering design environment. In order to completely eliminate the "over the wall" problem and the resulting model discontinuity, this environment must support the incremental refinement of the abstract system level performance model into an implementation level model. Using this environment, a design methodology based on incremental refinement can be developed.

The design methodology illustrated in Fig. 76.4 was proposed by Lockheed Martin Advanced Technology Laboratory as a new way to design systems.[8] This methodology uses the level of the risk of not meeting the design specifications as the metric for driving the design process. In this spiral-based design methodology, there are two iteration cycles. The major cycles (or spirals), denoted as CYCLE 1, CYCLE 2, …, CYCLE N, on the figure correspond to the design iterations where major architectural changes are made in response to some specification metric(s) and/or the system as a whole is refined and more design detail is added to the model. Consistent with the new paradigm of system design, these iterations will actually produce virtual or simulation-based prototypes. A virtual prototype is simply a simulatable model of the system with stimuli described at a given level of design detail or design abstraction that describes the system's operation. Novel to this approach are the mini spirals. The mini spiral cycles, denoted by the levels on the figure labled SYSTEMS, ARCHITECTURE, and DETAILED DESIGN, correspond to the refinement of only those portion(s) of the design that are deemed to be "high risk." High risk is obviously defined by the designer but is most often the situation where if one or more of

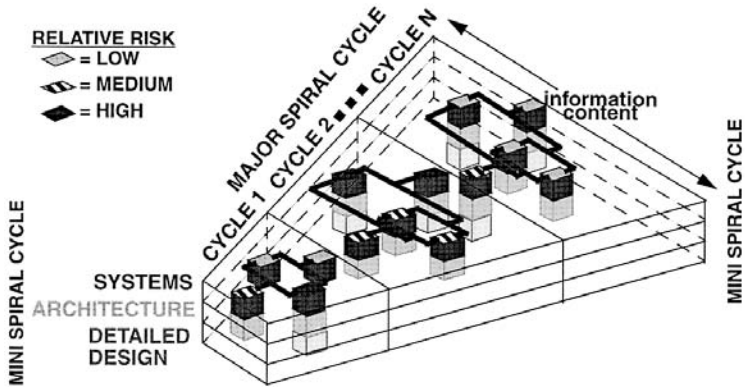

FIGURE 76.4 Risk-driven expanding information model (RDEIM).

these components fail to meet their individual specifications, the system will fail to meet its specifications. The way to minimize the risk is to refine these components to possibly an implementation so that the actual performance is known. Unlike the major cycles where the entire design is refined, the key to the mini spirals is the fact that only the critical portions of design are refined. For obvious reasons, the resulting models have been denoted as risk-driven expanding information models (RDEIMs).

The key to being able to implement this design approach is to be able to evaluate the overall design with portions of the system having been refined to a detailed level while the rest of the system model remains at the abstract level. For example, in the first major cycle of Fig. 76.4, the element with the highest relative risk is fully implemented (detailed design level) while the other elements are described at more abstract levels (system level or architectural level). If the simulation of the model shown in the first major cycle detects that the overall system will not meet its performance requirements, then the "high risk" processing element could be replaced by two similar elements operating in parallel. This result is shown in the second major cycle, and at this point another element of the system may become the new "bottleneck", i.e., the highest relative risk, and it will be refined in a similar manner.

Implied in the RDEIM approach is a solution to the "over the wall" problem, including HW/SW codesign. The proposed solution is to fully integrate performance modeling into the design process.

Obviously, one of the major capabilities necessary to implement a top-down design methodology like the RDEIM is the ability to co-simulate system models which contain some components that are modeled at an abstract performance level (uninterpreted models) and some that are modeled at a detailed behavioral level (interpreted models). This ability to model and co-simulate uninterpreted models and interpreted models is called mixed-level modeling (sometimes referred to as hybrid modeling). Mixed-level modeling requires the development of interfaces that can resolve the differences between uninterpreted models that, by design, do not contain a representation of all of the data or timing information of the final implementation, and interpreted models which require most, or possibly all, data values and timing relationships to be specified. Techniques for systematic development of these mixed-level modeling interfaces and resolution of these differences in abstraction is the focus of the latest work in mixed-level modeling.

A unified end-to-end design environment has been developed at the University of Virginia that attempts to achieve this goal. This environment supports the development of system-level models of digital systems that can be analyzed for multiple metrics, like performance and dependability, and can then be used as a starting point for the actual implementation. A tool called ADEPT (Advanced Design Environment Prototype Tool) has been developed to implement this environment. ADEPT actually supports both system-level performance and dependability analysis in a common design environment using a collection of predefined library elements. ADEPT also includes the ability to simulate both system level and implementation-level (behavioral) models in a common simulation environment. This capability allows the stepwise refinement of system-level models into implementation-level models.

Multi-Level Modeling

The need for multi-level modeling was recognized almost three decades ago. Multi-level modeling implies that representations at different levels of detail coexist within a model.[7,9,10] Until the early 1990s, the term multi-level modeling was used for integrating behavioral or functional models with lower level models. The objective was to provide a continuous design path from functional models down to implementation. This objective was achieved, and the VLSI industry utilizes it today. An example is the tool called Droid, developed by Texas Instruments.[11]

The mixed-level modeling approach, as described in this chapter, is a specific type of multi-level modeling which integrates performance and behavioral models. Thus, only related research on multi-level modeling systems that spans both the performance and the functional/behavioral domains will be described.

Although behavioral or functional modeling is typically well-understood by the design community, performance modeling is a foreign topic to most designers. Performance modeling, also called uninterpreted modeling, is utilized in the very early stages of the design process in evaluating such metrics as

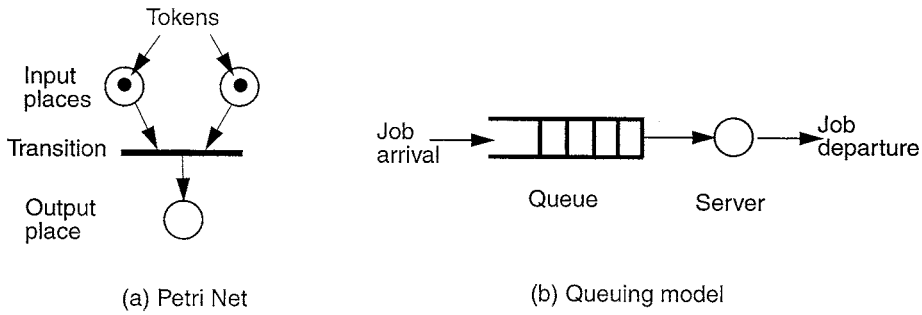

FIGURE 76.5 Petri Net and queuing model.

throughput and utilization. Performance models are also used to identify bottlenecks within a system and are often associated with the job of a system engineer. The term "uninterpreted modeling" reflects the view that performance models lack value-oriented data and functional (input/output) transformations. However, in some instances, this information is necessary to allow adequate analysis to be performed.

A variety of techniques have been employed for performance modeling. The most common techniques are Petri Nets[12-14] and queuing models.[15,16] A combination of these techniques, such as a mixture of Petri Nets and queuing models,[17] has been utilized to provide more powerful modeling capabilities. All of these models have mathematical foundations. However, models of complex systems constructed using these approaches can quickly become unwieldy and difficult to analyze.

Examples of a Petri Net and a queuing model are shown in Fig. 76.5. A queuing model consists of queues and servers. Jobs (or customers) arrive at a specific arrival rate and are placed in a queue for service. These jobs are removed from the queue to be processed by a server at a particular service rate. Typically, the arrival and service rates are expressed using probability distributions. There is a queuing discipline, such as first-come-first-serve, which determines the order in which jobs are to be serviced. Once they are serviced, the jobs depart and arrive at another queue or simply leave the system. The number of jobs in the queues represents the model's state. Queueing models have been used successfully for modeling many complex systems. However, one of the major disadvantages of queuing models is their inability to model synchronization between processes.

As a system modeling paradigm, Petri Nets overcome this disadvantage of queuing models. Petri Nets consist of places, transitions, arcs, and a marking. The places are equivalent to conditions and hold tokens which represent information. Thus, the presence of a token in the place of a Petri Net corresponds to a particular condition being true. Transitions are associated with events, and the "firing" of a transition indicates that some event has occurred. A marking consists of a particular placement of tokens within the places of a Petri Net and represents the state of the net. When a transition fires, tokens are removed from the input places and are added to the output places, changing the marking (the state) of the net and allowing the dynamic behavior of a Petri Net to be modeled.

Petri Nets can be used for performance analysis by associating a time with the transitions. Timed and stochastic Petri Nets contain deterministic and probabilistic delays, respectively. Normally, these Petri Nets are uninterpreted, since no interpretation (values or value transformations) are associated with the tokens or transitions. However, values or value tranformations can be associated with the various elements of Petri Net models as described below.

Petri Nets that have values associated with tokens are known as colored Petri Nets (CPNs). In the colored Petri Nets, each token has an attached color, indicating the identity of the token. The net is similar to the basic definition of the Petri Net except that a functional dependency is specified between the color of the token and the transition firing action. In addition, the color of the token produced by a transition may be different from the color of the token(s) on the input place(s). CPNs have an increased

ability to efficiently model real systems with small nets which are equivalent to much larger plain Petri Nets due to their increased descriptive powers.

Numerous multi-level modeling systems exist based on these two performance modeling techniques. ADAS (Architecture Design and Assessment System) is a set of tools specifically targeted for high-level design.[18] ADAS models both hardware and software using directed graphs based on timed Petri Nets. The flow of information is quantified by identifying discrete units of information called tokens. ADAS supports two levels of modeling. The more abstract level is a dataflow description and is used for performance estimation. The less abstract level is defined as a behavioral level but still uses tokens which carry data structures with them. The functionality is embedded into the models using C or Ada programs. The capability of generating high-level VHDL models from the C or Ada models is provided. These high-level VHDL models can be further refined and developed in a VHDL environment, but the refined models cannot be integrated back into the ADAS performance model. The flow of information in these high-level VHDL models is still represented by tokens. Therefore, implementation-level components cannot be integrated into an ADAS performance model. Another limitation is that all input values to the behavioral node must be contained within the token data structure.

SES/Workbench (Scientific and Engineering Software) is a design specification, modeling and simulation tool.[19] It is used to construct and evaluate proposed system designs and to analyze their performance. A graphical interface is used to create a structural model which is then converted into a specific simulatable description (SES/sim). SES/Workbench enables the transition across domains of interpretation by using a user node, in which C-language and SES/sim statements can be executed. Therefore, SES/Workbench has similar limitations to ADAS; the inability to simulate a multi-level model when input values of behavioral nodes are not fully specified and the inadequacy of simulating components described as implementation-level HDLs (the capability of integrating VHDL models will be introduced later in the next paragraph). In addition, multiple simulation languages (both SES/sim and C) are required for multi-level models.

The Reveal Interactor is a tool developed by Redwood Design Automation.[20] A model constructed in Reveal is aimed at the functional verification of RTL-level VHDL and Verilog descriptions and, therefore, does not include a separate transaction-based performance modeling capability. However, Reveal can work in conjunction with SES/Workbench. By mixing models created in Reveal and SES/Workbench, a multi-level modeling capability exists. Again, these multi-level models are very limited due to the fact that all the required information at the lower level part of the model must be available within the higher level model.

IDAS (Integrated Design Automation System) is a multi-level design environment which allows for rapid prototyping of systems.[21] Although the behavioral specifications need to be expressed as Ada, C, or Fortran programs, IDAS provides the capability of automatically translating VHDL description to Ada. However, the user cannot create abstract models in which certain behavior is unspecified. Also, it does not support classical performance models (such as queuing models and Petri Nets) and forces the user to specify a behavioral description very early in the design process.

Transcend claims to integrate multi-level descriptions into a single environment.[22,23] In the more abstract level, T-flow models are used, in which tokens are used to represent flow of data. The capability of integrating VHDL sub-models into a T-flow model is provided. However, interfacing between the two models requires a "C++ like" language, which maps variables to/from VHDL signals, resulting in a heterogeneous simulation environment. Although its approach is geared toward the same objective as mixed-level modeling, the T-flow model must also include all the necessary data to activate the VHDL sub-models. Therefore, the upper level model cannot be "too abstract" and must include lower level details.

MIDAS (Methodology for Integrated Design and Simulation) supports the design of distributed systems via iterative refinement of PIPS (Partially Implemented Performance Specification) models.[24] A PIPS model is a partially implemented design where some components exist as simulation models and others as operational subsystems (i.e., implemented components). Although the term "hybrid model" is used in this context, it refers to a different type of modeling. MIDAS is an "integrated approach to

software design."[24] It supports the performance evaluation of software being executed on a given machine. It does not allow the integration of components expressed in an HDL into the model.

The Ptolemy project is an academic research effort being conducted at the University of California at Berkeley.[25,26] Ptolemy, a comprehensive system prototyping tool, is actually constructed of multiple domains. Most domains are geared toward functional verification and have no notion of time. Each domain is used for modeling a different type of system. The domains also vary in the modeling level (level of abstraction). Ptolemy provides limited capability of mixing domains within one design. The execution of a transition across domains is accomplished with a "wormhole." A wormhole is the mechanism for supporting the simulation of heterogeneous models. Thus, a multi-level modeling and analysis capability is provided. There are two major limitations to this approach compared with the mixed-level modeling approach being described. The first one is the heterogeneity — several description languages. Therefore, translation between simulators is required. The second limitation is that the interface between domains only translates data. Therefore, all the information required by the receiving domain must be generated by the transmitting domain.

Honeywell Technology Center (HTC) currently has a research effort that is specifically addressing the mixed-level modeling problem.[27] This research has its basis in the UVa mixed-level modeling effort. The investigators at HTC have developed a Performance Modeling Library (PML)[28,29] and are currently working on adding a mixed-level modeling capability to this environment. The PML is used for performance models at a relatively low level of abstraction. Therefore, it assumes that all the information required by the interpreted element is provided by the performance model. In addition, their interface between uninterpreted and interpreted domains allows for bidirectional data flow.

To summarize, numerous multi-level modeling efforts exist. However, they are being developed not addressing the issue of lack of information at the transition between levels of abstraction. A solution to this problem is essential for true stepwise refinement of the performance models to behavioral models. In addition, integration of performance modeling level and behavioral modeling level was mostly performed by mixing different simulation environments, which results in heterogeneous modeling approach.

76.2 The ADEPT Design Environment

Two approaches to creating a unified design environment are possible. An evolutionary solution is to provide an environment that translates data from different models at various points in the design process and creates interfaces for the noncommunicating software tools used to develop these models. With this approach, users must be familiar with several modeling languages and tools. Also, analysis of design alternatives is difficult and is likely to be limited by design time constraints.

A revolutionary approach, the one being developed in ADEPT, is to use a single modeling language and mathematical foundation. This approach uses a common modeling language and simulation environment, which decreases the need for translators and multiple models, reducing inconsistencies and the probability of errors in translation. Finally, the existence of a mathematical foundation provides an environment for complex system analysis using analytical approaches.

Simulators for hardware description languages accurately and conveniently represent the physical implementation of digital systems at the circuit, logic, register-transfer, and algorithmic levels. By adding a system-level modeling capability based on extended Petri Nets and queuing models to the hardware description language, a single design environment can be used from concept to implementation. The environment would also allow for the mixed simulation of both uninterpreted (performance) models and interpreted (behavioral) models due to the use of a common modeling language. Although it would be possible to develop the high-level performance model and the detailed behavioral model in two different modeling languages and then develop some sort of translator or foreign language interface to hook them together, a better approach is to use a single modeling language for both models. A single modeling language that spans numerous design phases is much easier to use, encouraging more design analysis and consequently better designs.

ADEPT implements an end-to-end unified design environment based on the use of the VHSIC Hardware Description Language (VHDL).[30] VHDL is a natural choice for this single modeling language in that it has high-level language constructs, but unlike other programming languages, it has a built-in timing and concurrency model. VHDL does have some disadvantages in terms of simulation execution time, but techniques have been developed to help address this problem.[31]

ADEPT supports the integrated performance and dependability analysis of system-level models and includes the ability to simulate both uninterpreted and interpreted models through mixed-level modeling. ADEPT also has a mathematical basis in Petri Nets, thus providing the capability for analysis through simulation or analytical approaches.[32]

In the ADEPT environment, a system model is constructed by interconnecting a collection of predefined elements called ADEPT modules. The modules model the information flow, both data and control, through a system. Each ADEPT module has a VHDL behavioral description and a corresponding mathematical description in the form of a CPN based on Jensen's CPN model.[33] The modules communicate by exchanging tokens, which represent the presence of information, using a fully interlocked, four-state handshaking protocol.[34] The basic ADEPT modules are intended to be building blocks from which useful modeling functionality can be constructed. In addition, custom modules can be developed by the user if required and incorporated into a system model as long as the handshaking protocol is adhered to. Finally, some libraries of application-specific, high-level modeling modules such a Multiprocessor Communications Network Modeling Library[35] have been developed and included in ADEPT.

The following sections discuss the VHDL implementation of the token data type and transfer mechanism used in ADEPT and the modules provided in the standard ADEPT modeling library.

Token Implementation

The modules defined in this chapter have been implemented in VHDL and use a modified version of the token passing mechanism defined by Hady.[34] Signals used to transport tokens must be of the type token, which has been defined as a record with two fields. The first field, labeled STATUS, is used to implement the token passing mechanism. The second field, labeled COLOR, is an array or integers that is used to hold user-defined color information in the model. The ADEPT tools allow the user to select from a predefined number of color field options. The tools then automatically link in the proper VHDL design library so that the VHDL descriptions of the primitive modules operate on the defined color field. The default structure of the data-type token used in the examples discussed in this document is shown in Fig. 76.6.

There are two types of outputs and two types of inputs in the basic ADEPT modules. Independent outputs are connected to control inputs, and the resulting connection is referred to as a control-type signal. Dependent outputs are connected to data inputs, and the resulting connection is referred to as a data-type signal. To make the descriptions more intuitive, outputs are often referred to as the "source side" of a signal, and inputs are referred to as the "sink side" of a signal.

Tokens on independent outputs may be written over by the next token, so the "writing" process is independent of the previous value on the signal. On the other hand, new tokens may not be placed on dependent outputs until the previous token has been removed, so the "writing" process is dependent on the previous value on the signal. Data-type signals use the four-step handshaking process to ensure that tokens do not get overwritten, but no handshaking occurs on control-type signals.

The STATUS field of a token signal can take on four values. Signals connecting independent outputs to control inputs (control-type signals) make use of only two of the four values. Independent outputs place a value PRESENT on the status field to indicate that a token is present. Since control inputs only copy the token but do not remove it, the independent output only needs to change the value of the status field to RELEASED to indicate that the token is no longer present on the signal, and the control input can no longer consider the signal to contain valid information. The signals connecting dependent outputs to data inputs (data-type signals) need all four values (representing a fully interlocked handshaking scheme) to ensure that a dependent output does not overwrite a token before the data input to which it

```
type handshake is (removed, acked, released, present);
type token_fields is (status,
                      tag1, tag2, tag3, tag4, tag5,
                      tag6, tag7, tag8, tag9, tag10,
                      tag11, tag12, tag13, tag14, tag15,
                      boole1, boole2, boole3,
                      fault, module_info,
                      index,act_time,color);

type color_type is array (token_fields range tag1 to act_time) of integer;

type token is
      record
         status    : handshake;
         color     : color_type;
     end record;

type op_fields is (add, sub, mul, div);
type cmp_fields is (lt, le, gt, ge, eq, ne);
type tkf_array is array (1 to 25) of token_fields;-- used in file_read

type token_vector is array (integer range <>) of token;

--  resolution function for token
function protocol (input : token_vector) return token;
subtype token_res is protocol token;
```

FIGURE 76.6 Token type definition.

is connected has read and removed it. This distinction is important, since a token on control-type signals represents the presence or absence of a condition in the network while tokens on data-type signals, on the other hand, represent information or data that cannot be lost or overwritten. In addition, fan-out is not permitted on dependent outputs and is permitted on independent outputs.

The signals used in the implementation are of type token. The token passing mechanism for data-type signals is implemented by defining a VHDL bus resolution function. This function is called each time a signal associated with a dependent output and a data input changes value. The function essentially looks at the value of the STATUS field at the ports associated with the signal and decides the final value of the signal. At the beginning of simulation, the STATUS field is initialized to REMOVED. This value on a signal corresponds to an idle link in the nets defined by Dennis.[36] This state of a signal indicates that a signal is free and a request token may be placed on it. Upon seeing the REMOVED value, the requesting module may set the value of the signal to PRESENT. This operation corresponds to the ready signal in Dennis' definition. The requested module acknowledges a ready signal (PRESENT) by setting the signal value to ACKED, after the requested operation has been completed. Upon sensing the value of ACKED on the signal, the requesting module sets the value of the signal to RELEASED, which in turn causes the requested module to place the value of REMOVED on the signal. This action concludes one request/acknowledge cycle, and the next request/acknowledge cycle may begin.

In terms of Petri Nets, the models described here can be described as one-safe Petri Nets, since at any given time, no place in the net can contain more than one token. The correspondence between the signal values and transitions in a Petri Net may be defined in general in the following manner:

1. PRESENT: A token arrives at the input place of a transition.
2. ACKED: The output place of a transition is empty.
3. RELEASED: The transition has fired.
4. REMOVED: The token has been transferred from the input place to the output place.

FIGURE 76.7 Wye module ADEPT symbol, its behavioral VHDL description, and its CPN representation.

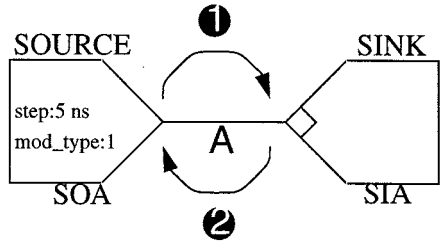
The modules to be described in this chapter may be defined in terms of Petri Nets. As an example, a Petri Net description of the Wye module is shown in Fig. 76.7.

The function of the Wye module is to copy the input token to both outputs. The input token is not acknowledged until both output tokens have been acknowledged. In the Petri Net of Fig. 76.7, the "R" and "A" labels correspond to "ready" and "acknowledge", respectively. When a token arrives at the place labeled "0r", the top transition is enabled and a token is placed in the "1r", "2r", and center places. The first two places correspond to a token being placed on the module outputs. Once the output tokens are acknowledged (corresponding to tokens arriving at the "1a" and "2a" places, the lower transition is enabled and a token is placed in "0a", corresponding to the input token being acknowledged. The module is then ready for the next input token. Note that since this module does not manipulate the color fields, no color notation appears on the net.

The specific CPN description used is based on the work of Jensen.[33] The complete CPN descriptions of each of the ADEPT building blocks can be found in the work of Swaminathan et al.[37]

ADEPT Handshaking and Token Passing Mechanism

Recall that the ADEPT standard token has a status field which can take on four values: PRESENT, ACKED, RELEASED, and REMOVED. These values reflect which stage of the token passing protocol is currently in progress. Several examples will now be presented to show how the handshaking and token passing



Time between new tokens on A = step + path delay = 5 ns

Table A: Simplified Event Sequence

Event	Time	Description
1	0 ns	Source module places token on signal A.
2	0 ns	Sink module acknowledges token on A.
1	5 ns	Source module places next token on signal A.

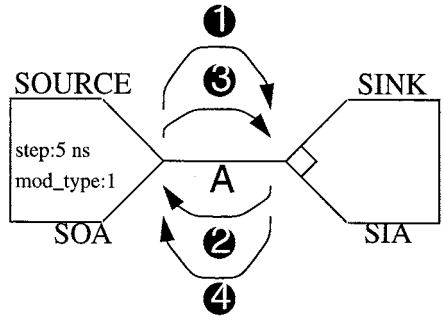


Table B: Detailed Event Sequence

Event	Time	Delta	Description	Resolved Signal A
1	0 ns	1	Source module places token on A	present
2	0 ns	2	Sink module acknowledges token on A	acked
3	0 ns	3	Source module releases token on A	released
4	0 ns	4	Sink module removes token on A	removed
1	5 ns	1	Source module places token on A	present

FIGURE 76.8 Two-module handshaking example.

occurs between ADEPT modules. Figure 76.8 illustrates the handshaking process between a source module connected to a Sink module.

Figure 76.8A describes the simplified event sequence. Here, we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. Thinking of the handshaking in this simplified manner, Table A in Fig. 76.8 shows the simplified event sequence and times. At time 0 ns, the source module places a token on A, corresponding to Event 1. The token is immediately acknowledged by the sink module, corresponding to Event 2. Since the source module has a step generic of 5 ns and there is no other delay along the path to the sink, the next token will be output by the source module at time 5 ns.

Figure 76.8B details the entire handshaking process. Table B in Fig. 76.8 lists the detailed event sequence for this example. Since handshaking occurs in zero simulation time, the events are listed by delta cycles within each simulation time. The function of delta cycles in VHDL is to provide a means for ordering and synchronizing events (such as handshaking) which occur in zero time. The actual event sequence for this example consists of four steps, as shown in Fig. 76.8B. Event 1 is repeated at time 5 ns, which starts the handshaking process over again.

A Three-Module Example

To illustrate how tokens are passed through intermediate modules, a three-module example will now be examined. Consider the case where a fixed delay module is placed between a source and sink. This situation is illustrated in Fig. 76.9.

Figure 76.9A shows the simplified event sequence, where we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. Table A in Fig. 76.9A lists this simplified event sequence. Notice that since now there is a path delay from the source to the sink, the time between new tokens from the source is *step* + *path_delay* = 5 ns + 5 ns = 10 ns. At time 0 ns, the source module places the first token on Signal A (Event 1). This token is read by the delay module and placed on signal B after a delay of 5 ns (Event 2). The sink module then immediately acknowledges the token on signal B (Event 3). The delay module then passes this acknowledgment back through to signal A (Event 4). At time 10 ns, the source module places the next token on Signal A, starting the process over again.

Figure 76.9B shows the detailed event sequence for this example. Since there are two signals, there are a total of eight detailed events. Table B in Fig. 76.9 lists the detailed event sequence for this example. Again, since the handshaking occurs in zero simulation time, the events are listed by delta cycles within each simulation time. Table B lists the resolved values on both signal A and signal B, where a value of "----" indicates no change in value. Notice that the sequence of events on each signal proceeds in this order: place the token (present) by the source side, acknowledge the token (acked) by the sink side, release the token (released) by the source side, and finally remove the token (removed) by the sink side. The important concept to note in this example is the ordering of events. Notice that the delay module releases the token on its output (Event 4) before it acknowledges the token on its input (Event 5), even though the two events occur in the same simulation time. These actions trigger the sink module to then remove the token on signal B (Event 6) and the source module to release the token on signal A (Event 7), both in the next delta cycle. Thus signal B is ready for another token (removed) a full delta cycle before signal A is ready.

Token Passing Example

To illustrate how tokens propagate in a larger system, consider the model shown in Fig. 76.10. This figure shows the simplified event sequence, where again we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. In this system, the source module provides tokens to the sequence A (SA) module (Event 1), who first passes them to the sequence B (SB) module (Event 2). The SB module first passes the token to the fixed delay A (FDA) module (Event 3), who passes it to the sink A (SIA) module after a delay of 5 ns (Event 4). The SIA module then immediately acknowledges the token (Event 5), which causes the FDA module to pass the acknowledgment back to the SB module (Event 6). At this point, the SB module places a copy of the token on its second output (Event 7), where it is passed through the Union A and onto its output (Event 8). The read color A module then places the token on its out_1 output (Event 9) and simultaneously places the token on its independent output. The sink B module then acknowledges the token on signal H (Event 10). Upon seeing this acknowledgment, the read color A module releases the token on its independent output, since the read color module has no "memory" (the *release?* generic equals true). The acknowledgment is then propagated back to the SB module (Events 11 and 12). At this point, the SB module acknowledges its input token (Event 13), freeing the SA module to place a token on its second output (Event 14). This token is then passed through the union A, read color A, and sink module (Events

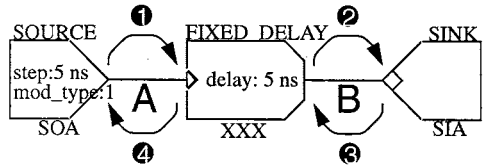

Table A: Simplified Event Sequence

Event	Time	Description
1	0 ns	Source module places token on signal A.
2	5 ns	Delay module places token on signal B.
3	5 ns	Sink module acknowledges token on signal B.
4	5 ns	Delay module acknowledges token on signal A.
1	10 ns	Source module places next token on signal A.

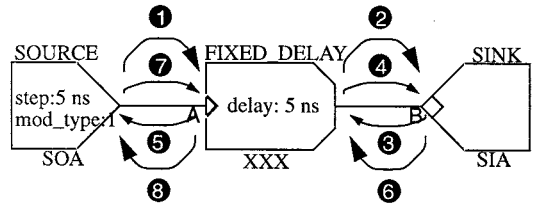

Table B: Detailed Event Sequence

Event	Time	Delta	Description	Resolved Signal A	Resolved Signal B
1	0 ns	1	Source module places token on A	present	removed
2	5 ns	1	Delay module places token on B	--	present
3	5 ns	2	Sink module acknowledges token on B	--	acked
4	5 ns	3	Delay module releases token on B	--	released
5			Delay module acknowledges token on A	acked	--
6	5 ns	4	Sink module removes token on B	--	removed
7			Source module releases token on A	released	--
8	5 ns	5	Delay module removes token on A	removed	--
1	10 ns	1	Source module places token on A	present	--

FIGURE 76.9 Three module handshaking example.

15, 16) and the acknowledgment is returned (Events 17, 18, and 19). The SA module can then acknowledge the token on its input (Event 20), allowing the source module to generate the next token 5 ns (step) later.

If we examine the activity on Signal I (the independent output of the read color A module), we see that it goes present after Event 8, released after Event 10, present after Event 15, and released again after Event 17. Consider the operation of the terminator module attached to this signal. Since the Terminator module halts simulation after the number of active events specified by the *stop_after* generic, if we were to simulate this example, the simulation would halt after Event 15 (the second active event).

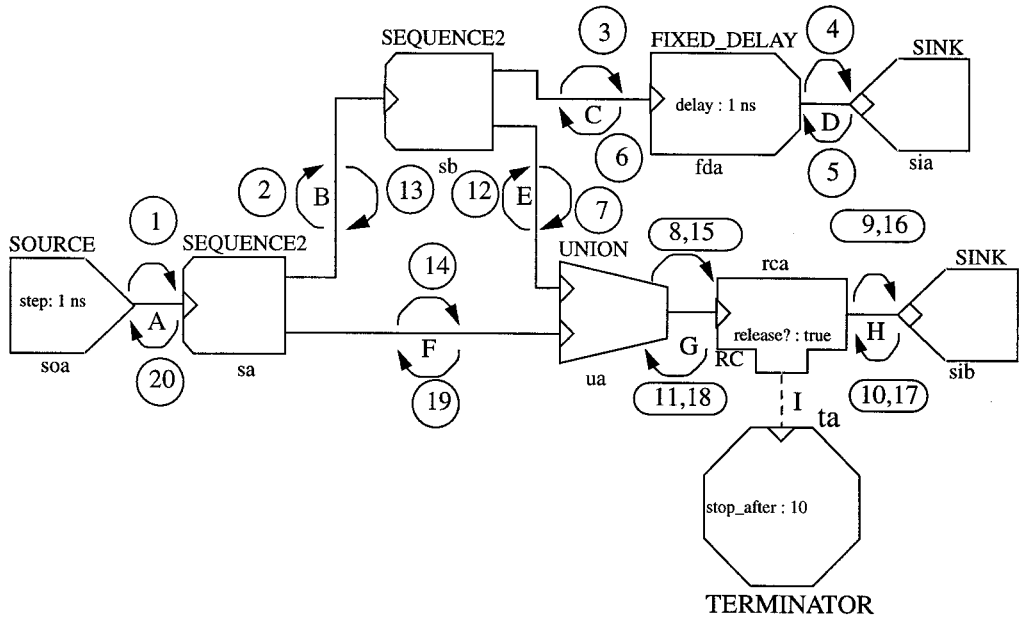

FIGURE 76.10 Token passing example showing simplified event sequence.

Module Categories

The ADEPT primitive modules may be divided into six categories: control modules, color modules, delay modules, fault modules, miscellaneous parts modules, and mixed-level modules. The control modules, except the Switch, Queue and logical modules, have been adapted from Dennis.[36] The color and delay categories of primitive modules have been defined to enable the manipulation of the coloring of tokens and to introduce the element of time into model descriptions, respectively. The fault modules are used to model the presence of faults and errors in a system model. The miscellaneous parts category contains some modules that are used for statistical data-collection with the ADEPT system. The mixed-level modules were created to aid in mixed-level modeling. The functionality of each primitive module is defined and the generics associated with each of the modules is described in the *ADEPT Library Reference Manual.*[38] The standard ADEPT module symbol convention is also explained in more detail in the *ADEPT Library Reference Manual.*

In addition to the primitive modules, there are libraries of more complex modules included in ADEPT. In general, these libraries contain modules for modeling systems in a specific applications area. These libraries are also discussed in more detail in the *ADEPT Library Reference Manual.*

Control Modules

The ADEPT representations of the 20 control modules are shown in Fig. 76.11. For each module in the figure, the XXX label represents a user-defined unique name that is assigned to each module in the system model. Further, some of the modules have generic parameters that need to be set when the module is instantiated.

The control modules operate only on the STATUS field of a signal and do not alter the color of a token on a signal. Further, no elapsed simulation time results from the activation of the control modules, since they do not have any delay associated with them.

The modules whose names end in a numeral, such as "union2", are part of a family of modules that have the same function, but differ in the number of inputs or outputs that they possess. For example, there are eight "union" modules, "union2," "union3," "union4,"… "union8."

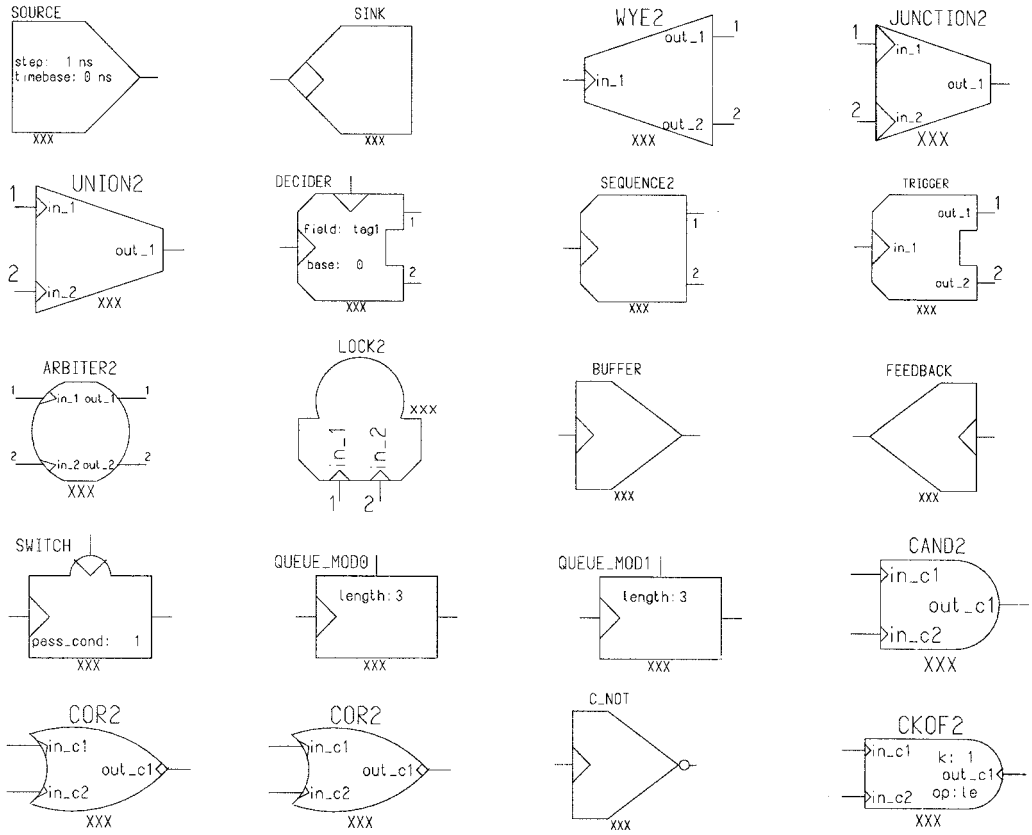

FIGURE 76.11 ADEPT control modules.

Color Modules

As noted when describing Petri Nets, using tokens that can be distinguished significantly increases the modeling capability and understanding of a given net. Therefore, ADEPT supports the ability to encapsulate pertinent system state (values) in a portion of the token called the color field. Such state information might include a memory address or an instruction opcode for a performance model of a computer system. The Control modules described in the previous section process colored tokens but do not alter the color fields of the tokens passing through them. Manipulation of the color field of a token is reserved to color modules. These color modules permit various operations on the color fields such as allowing the user to read and write the color fields of the tokens. The color modules also permit the user to compare the color information carried by the tokens and to control the flow of the tokens based on the result of the comparisons.

The ADEPT representations of the ten color modules are shown in Fig. 76.12. The use of these modules enables high-level modeling of systems at different levels of detail. These modules permit the designer to add more detail or information to the model by placing and manipulating information placed on the color fields of tokens flowing through the model. The color fields of these tokens can be set and read by these modules to represent such things as destination or source node addresses, data length, data type ("digital" or "analog," for example), or any type of such information that the designer feels is important to the design.

Delay Modules

The delay modules facilitate the description of data path delays at the conceptual or block level of a design. The ADEPT representation of the six delay modules is shown in Fig. 76.13. The fixed delay (FD) module, may be used in conjunction with the control modules to model the delay in the control structure

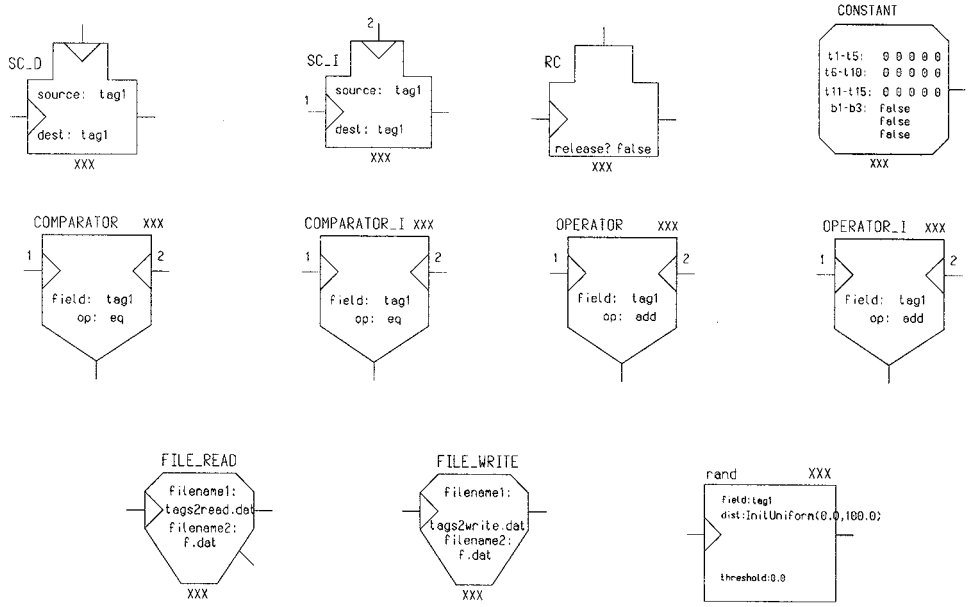

FIGURE 76.12 ADEPT color modules.

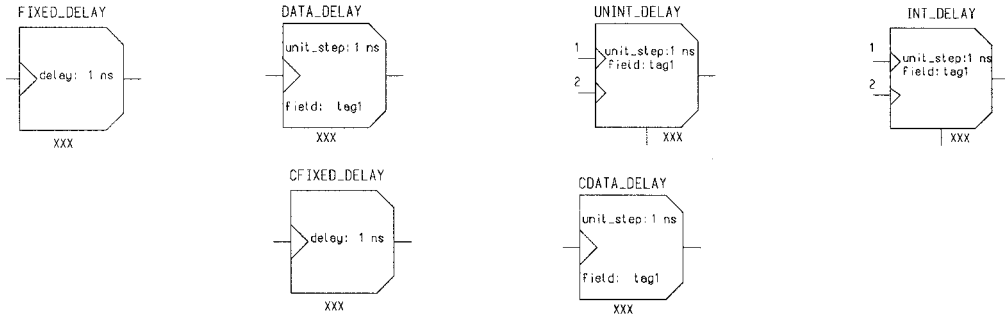

FIGURE 76.13 ADEPT delay modules.

of a design. The data-dependent delay module may be used to model processes in which the time to complete a particular operation is dependent on the data being processed. The uninterruptible data-dependent delay (UD) module and the interruptible data-dependent delay module (ID) may be used to model both hardware and software processes at the uninterpreted level. The control fixed delay (CFD) and control data-dependent delay (CDD) modules are used to add delay to independent paths in an ADEPT model that models real control processes.

Fault Modules

The fault modules are used to represent the presence of faults and errors in a system model. The modules allow the user to model fault injection, fault/error detection, and error correction processes. The ADEPT representation of the 13 Fault modules is shown in Fig. 76.14.

Miscellaneous Parts Modules

The Miscellaneous Parts category contains six modules that perform convenience functions in ADEPT. The ADEPT representation of three these modules is shown in Fig. 76.15. The collector module is used to write input activation times to a file, and the terminator module is used to halt simulation after a

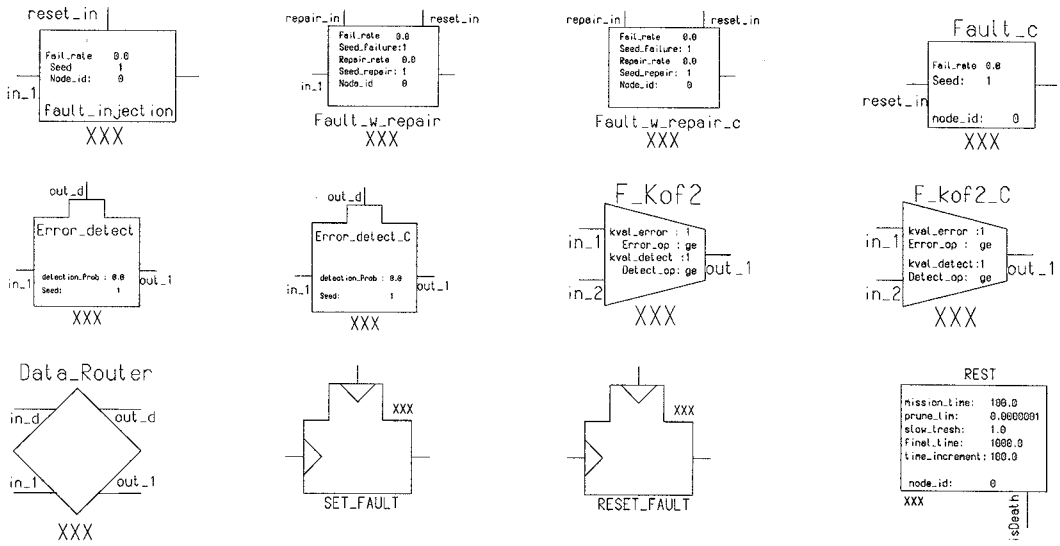

FIGURE 76.14 ADEPT fault modules.

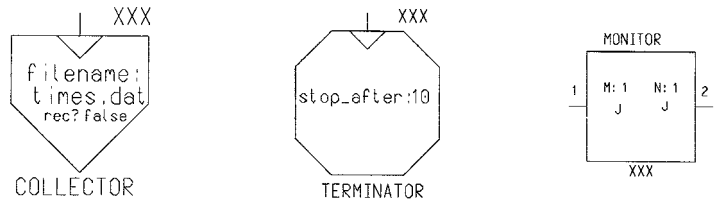

FIGURE 76.15 ADEPT miscellaneous parts modules.

specified number of events has occurred. The monitor module is a data-collection device that can be connected across other modules to gather statistical information during a VHDL simulation. This category also contains three additional modules (not shown in the figure) which are used to collect statistical information during simulation. These modules have no symbolic representation and are inserted automatically into the VHDL representation by the ADEPT tools.

Mixed-Level Modeling Modules

In order to support mixed-level modeling in the ADEPT environment, a category of building blocks called mixed-level modules was created which are used to define the interfaces around the interpreted and uninterpreted components in a system model. The functions of these modules and their use in creating mixed-level models is described in more detail in Section 76.4.

ADEPT Tools

The ADEPT system is currently available on Sun platforms using Mentor Graphics' *Design Architect* as the front-end schematic capture system, or on Windows PCs using OrCAD's *Capture* as the front-end schematic capture system. The overall architecture of the ADEPT system is shown in Fig. 76.16.

The schematic front-end is used to graphically construct the system model from a library of ADEPT module symbols. Once the schematic of the model has been constructed, the schematic capture system's netlist generation capability is used to generate an EDIF (Electronic Design Interchange Format) 2.0.0 netlist of the model. Once the EDIF netlist of the model is generated, the ADEPT software is used to

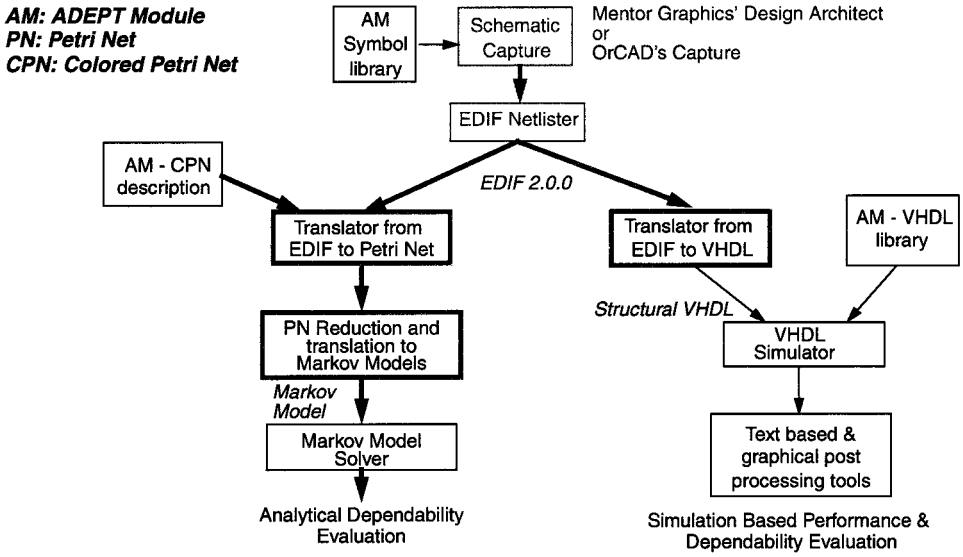

FIGURE 76.16 ADEPT design flow.

translate the model into a structural VHDL description consisting of interconnections of ADEPT modules. The user can then simulate the structural VHDL that is generated using the compiled VHDL behavioral descriptions of the ADEPT modules to obtain performance and dependability measures.

In addition to VHDL simulation, a path exists that allows the CPN description of the system model to be constructed from the CPN descriptions of the ADEPT modules. This CPN description can then be translated into a Markov model using well-known techniques and then solved using commercial tools to obtain reliability, availability, and safety information.

Figure 76.17 is an illustration of the construction of a schematic of an ADEPT model using *Design Architect*. The schematic shown is that of an ADEPT model of a simple three-computer system used in the ADEPT tutorial. Most of the elements in this top-level schematic are hierarchical, with separate schematics describing each component. The most primitive elements of the hierarchy are the ADEPT modules.

76.3 A Simple Example of an ADEPT Performance Model

This section presents a simple example of the usage of the primitive building blocks for performance modeling. The example is a three-computer system wherein the three computers share a common bus. The example also presents simulation results and system performance evaluations.

A Three-Computer System

This section discusses a simple example to illustrate how the modules discussed previously may be interconnected to model and evaluate the performance of a complete system. The system to be modeled consists of three computers communicating over a common bus, as shown in Fig. 76.18. Each block representing a computer can be thought to contain its own processor, memory and peripheral devices. The actual ADEPT schematic for the three-computer system is shown in Fig. 76.19.

Computer C1 contains some sensors and preprocessing capabilities. It collects data from the environment, converts it into a more compact form, and sends it to computer C2 via the bus. The computer C2 further processes the data and passes it to computer C3 where the data is appropriately utilized. It is assumed that data is transferred in packets and each packet of data is of varying length. In the example described here, computers C1 and C2 receive packets whose sizes are uniformly distributed between 0

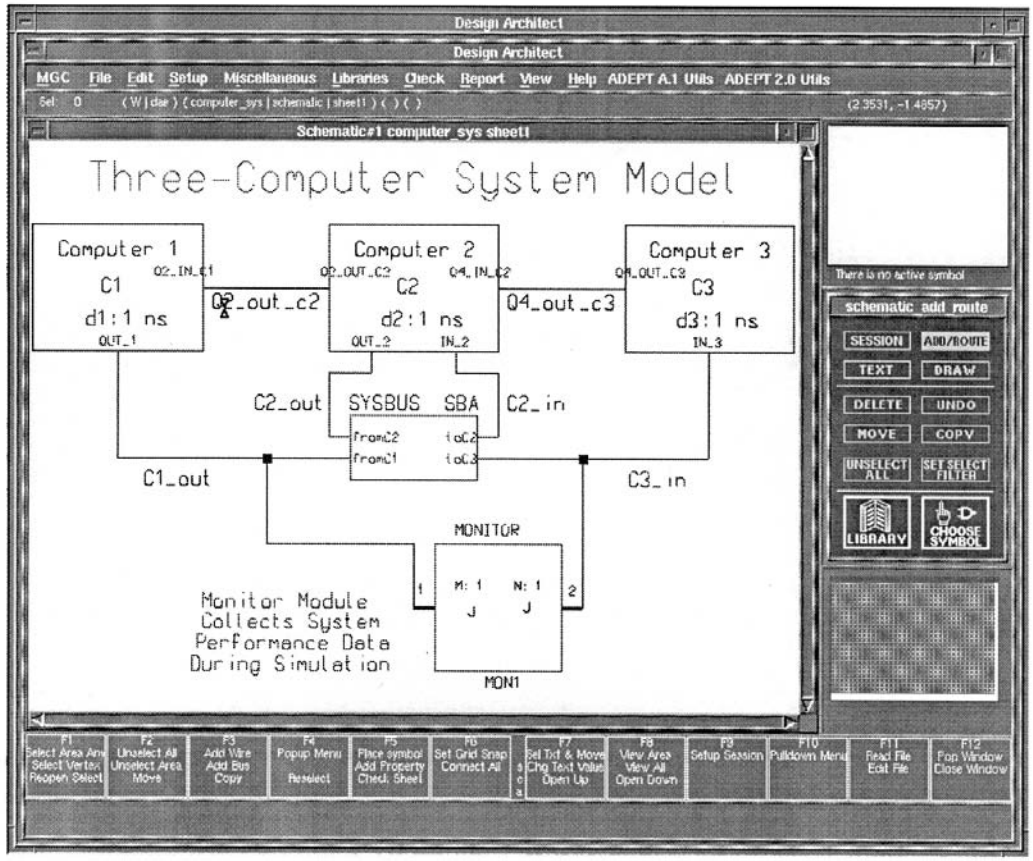

FIGURE 76.17 Sample ADEPT schematic (*Design Architect*).

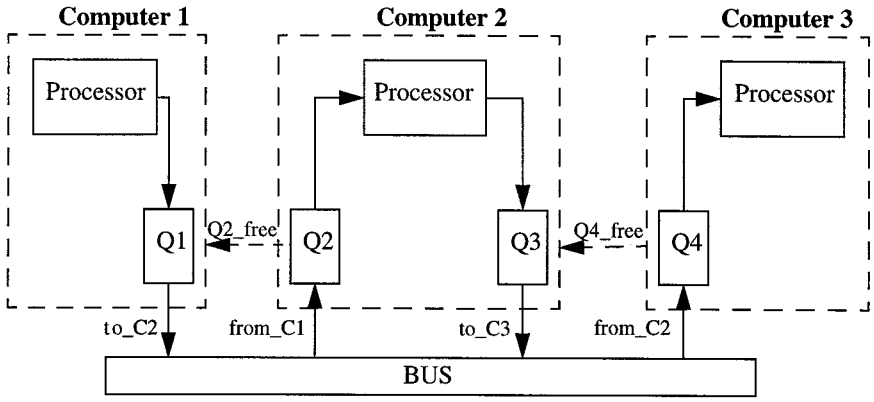

FIGURE 76.18 A three-computer system.

and 100. The packet size of computer C3 is uniformly distributed between 0 and 500. The external environment in this example is modeled by a Source module in C1 and a sink module in C3.

C1 has an output queue, C2 has both an input queue and an output queue, while C3 has one input queue. All queues in this example are assumed to be of length 8. If the input queues of C2 or C3 are full, the corresponding Q_free signal is released (value = RELEASED). This interconnection prevents the

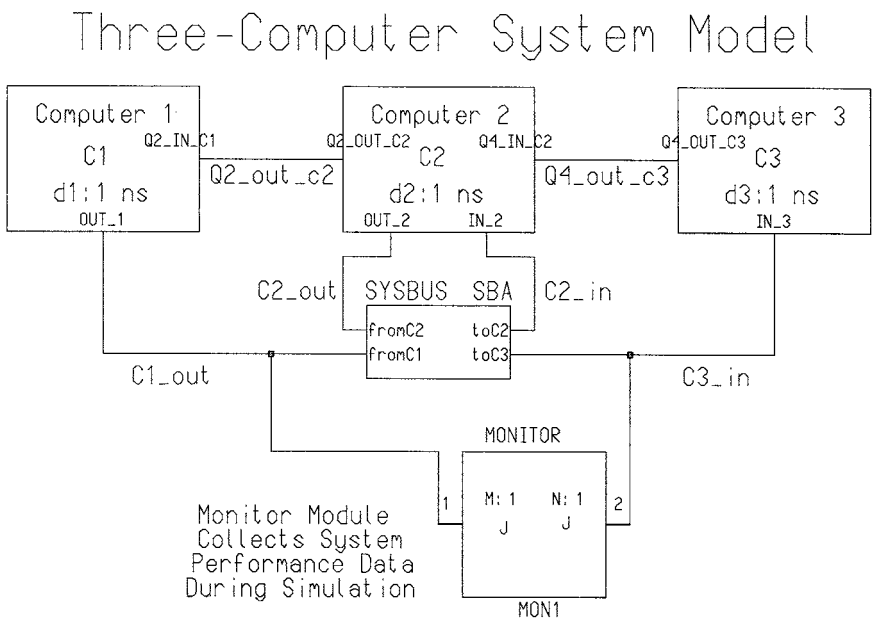

FIGURE 76.19 A three-computer system ADEPT schematic.

computer writing into the corresponding queue from placing data on the bus when the queue is full. This technique not only prevents the bus from being unnecessarily held up but also eliminates the possibility of a deadlock.

The ADEPT model of Computer 1 (C1) is shown in Fig. 76.20. The Source A (SOA) module along with the SA, Set_Color A (SCA), and random A (RA) modules generate tokens whose *tag1* field is set according to a distribution which is representative of the varying data sizes that C1 receives. The data-dependent delay A (DDA) models the processing time of C1 which is directly proportional to the packet size. The *unit_step* delay for the DDA module is passed down as a generic *d1**1ns. As soon as a token, representing one packet of data, appears at the output of the DDA module, the SB, Set_Color B (SCB), and random B (RB) modules together set the *tag1* field of the token to represent the packet size after processing. The constant A (COA) and Set_Color C (SCC) modules set the *tag2* field of the token to 2. This coloring indicates to the bus arbitration unit that the token is to be transferred to C2. The token is then placed in the output queue (Q1) of C1 and the token is acknowledged. This acknowledge signal is passed back to the source A module, which then produces the next token. The fixed delay (FDA & FDB) modules represent the read and write times associated with the queue. The switch A (SWA) element is controlled by the Q_free signal from C2 and prevents a token from the output queue of C1 from being placed on the bus if the incoming Q_Free signal is inactive.

Figure 76.21 shows the ADEPT model of Computer 2 (C2). When a token arrives at the *data* input of C2, the token is placed at the input of the queue (Q2). The *control* output of the queue becomes the Q2_Free output of C2. The remaining modules perform the same function as in C1 except that the tag2 field of the tokens output by C2 is set to 3, which indicates to the bus arbitration unit that the token is to be sent to C3. The DDA module represents the relative processing speed of Computer C2. The *unit_step* delay for the DDA module is passed down as a generic *d2**1ns.

The modules defining Computer 3 (C3) are shown in Fig. 76.22. A token arriving at the input is placed in the queue. The DDA element reads one token at a time and provides the delay associated with the processing time of C3 before the Sink A (SIA) module removes the token. The *unit_step* delay for the DDA module is passed down as a generic *d3**1ns.

The bus is shown in Fig. 76.23. Arbitration is provided to ensure that both C1 and C2 do not write onto the bus at the same time. The arbiter A (AA) element provides the required arbitration. Since the

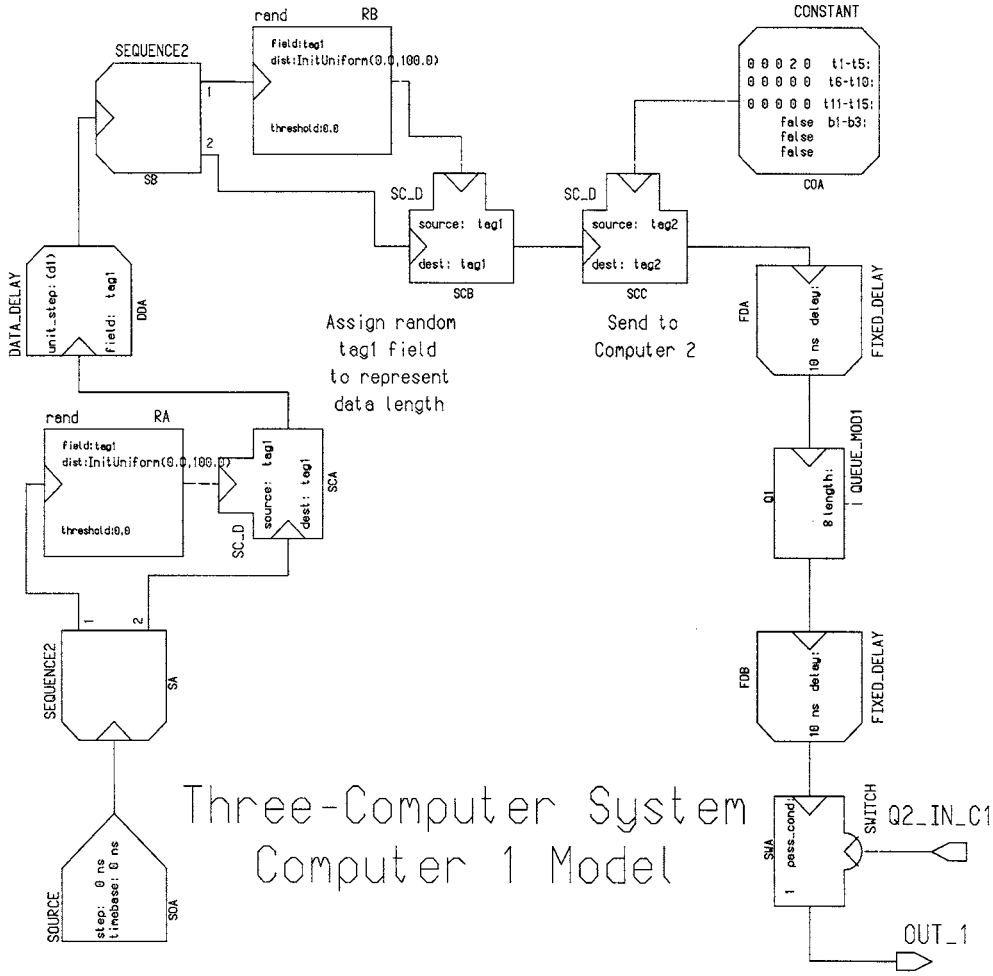

FIGURE 76.20 ADEPT model of computer 1.

output of C2 is connected to the IN_1(1) input of the AA element, it has a higher priority over C1. The union A (UA) element passes a token present at either of its inputs to its output. The output of the UA element is connected to the DDA element, which models the packet transfer delay associated with moving packets over the bus. The delay through the bus is dependent on the size of the packet of information being transferred (size stored on the *tag1* field). Note that in this analysis, the bus delay was set to zero. The independent output of the Read_Color A(RCA) element is connected to the control input of the Decider A (DA) module. The base of the DA element is set to 2. Since the *tag2* field of the token is set to 2 or 3 depending on whether it originated from C1 or C2, the first output of the DA module is connected to C2 and the second output is connected to C3. This technique ensures that the tokens are passed on to the correct destination, C2 or C3.

Simulation Results

This section presents simulation results that illustrate the queuing model capabilities of the ADEPT system. The model enables the study of the overall speed of the system in terms of the number of packets of information transferred in a given time. It also allows the study of the average number of tokens present in each queue during simulation, and the effect of varying system parameters on the number of items in the queues and overall throughput of the system. The generic unit_step delay of the DD elements

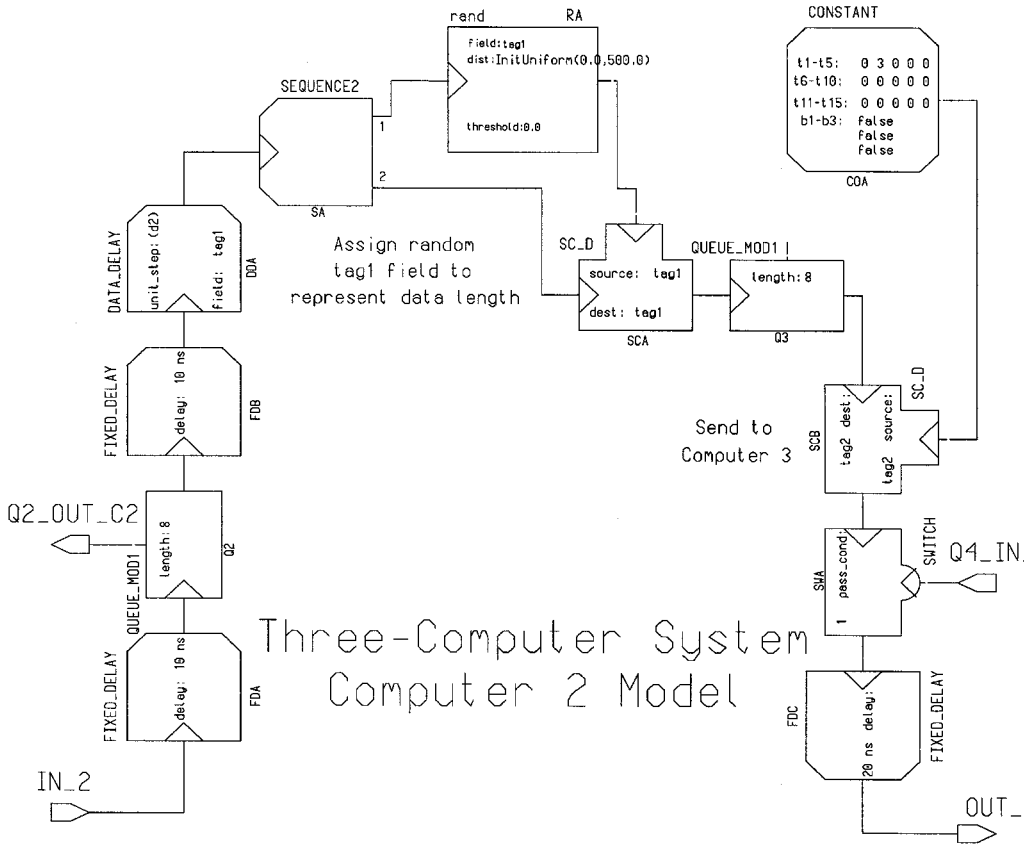

FIGURE 76.21 ADEPT model of computer 2.

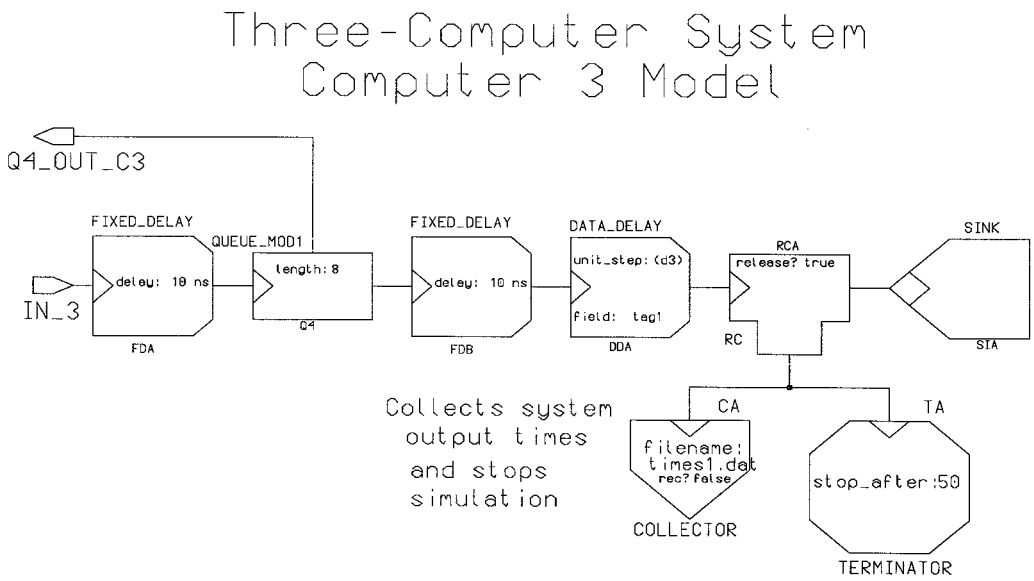

FIGURE 76.22 ADEPT model of computer 3.

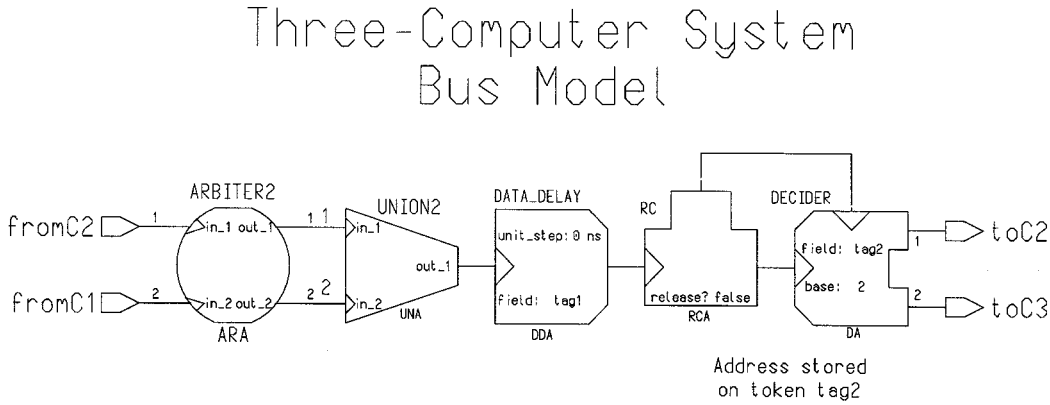

FIGURE 76.23 ADEPT model of system bus.

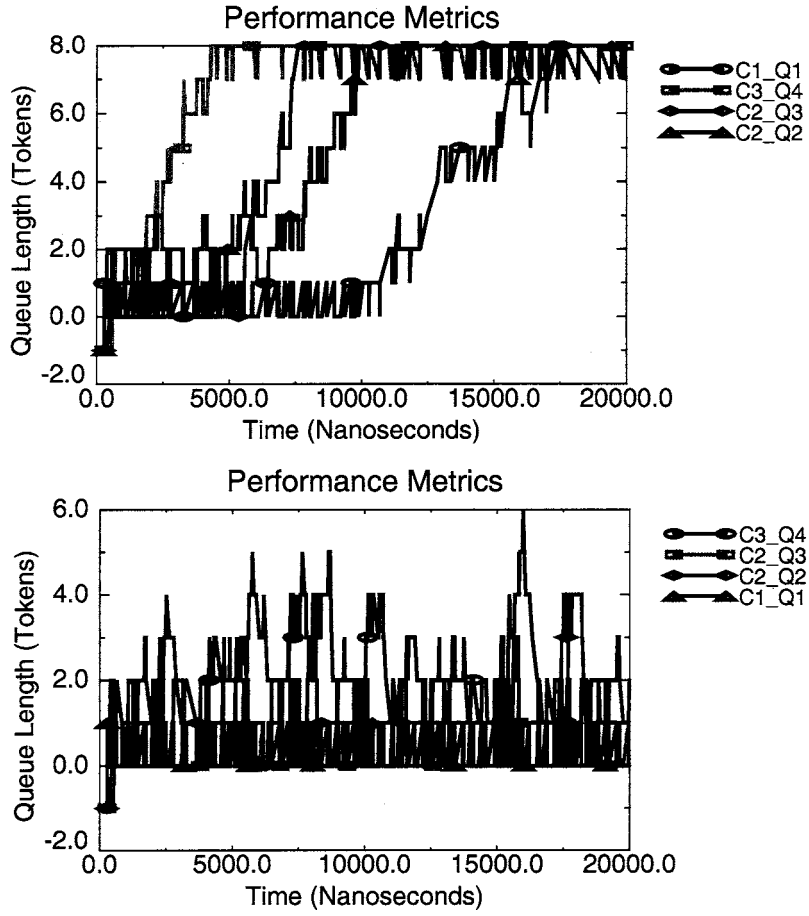

FIGURE 76.24 Queue lengths vs. simulation time for various processing delay times.

(*d1*, *d2*, and *d3*) associated with the three computers is representative of the processing speed of the computers. The optimal relative speeds of the computers may also be deduced by simulation of this model. Figure 76.24 shows graphs of the number of items in each queue versus simulation time. These graphs were generated using the BAARS postsimulation analysis tool. The upper graph shows the queue

lengths when *d1*, *d2*, *d3* was set to 5 ns, 5 ns, and 2 ns. The lower graph shows the queue lengths when *d1*, *d2*, *d3* was set to 5 ns, 4 ns, and 1 ns. In the first case, because the processing time of Computer 3 was so much longer than Computers 1 or 2, the queue in Computer 3 became full at approximately 4000 ns of simulation time. The filling of the queue in Computer 3 delayed items coming out of Computers 1 and 2, thus causing their queues to also become full. In the second case, the processing time ratios were such that Computer 3 could keep up with the incoming tokens and the queues never got completely full.

Table 76.1 summarizes the effect of relative speeds of the computers on the number of packets transferred. Since the size of the packets received by C3 is uniformly distributed between 0 and 500 while the size of the packets received by C1 and C2 is uniformly distributed between 0 and 100, it is intuitively obvious that the overall throughput of the system is largely determined by the speed of computer C3. The results do indicate this behavior. For example, when the relative instruction execution times for C1, C2, and C3 are 5, 5, and 2, respectively, a total of 197 packets are transferred. By increasing the instruction execution time of C2 by one time unit and decreasing the instruction execution time of C3 by one time unit, it is seen that a total of 321 packets are transferred, an increase of slightly over 60%.

TABLE 76.1 System Throughput vs. Computer Delay Times

C1 delay (ns)	C2 delay (ns)	C3 delay (ns)	Packets per 100000 time units (ns)
8	8	3	131
9	10	2	194
5	5	2	197
3	5	2	197
2	2	2	197
5	6	1	321
5	4	1	322
4	3	1	384
3	2	1	385
2	2	1	386

This example has illustrated the use of the various ADEPT modules to model a complete system. Note how the interconnections between modules describing a component of the system are similar to a flow chart describing the behavior of the component. This example also demonstrated that complex systems at varying levels of abstraction and interpretation can easily be modeled using the VHDL-based ADEPT tools.

76.4 Mixed-Level Modeling

As described earlier, performance (uninterpreted) modeling has been previously used primarily by systems engineers when performing design analysis at the early stages of the design process. Although most of the design detail is not included in these models, since this detail does not yet exist, techniques such as token coloring can be used to include that design detail that is necessary for an accurate model. However, most of the detail, especially very low-level information such as word widths and bit encoding, are not present. In fact, many additional design decisions must be made before an actual implementation could ever be constructed. In performance models constructed in ADEPT, abstract tokens are used to represent this information (data and control) and its flow in the system. An illustration of such a performance model with its analysis was given the three-computer system described in Section 76.3. On the other hand, behavioral (interpreted) models can be thought of as including much more design detail often to the point that an implementation could be constructed. Therefore, data values and system timing are available and variables typically take on integer, real, or bit values. For example, a synthesizable model of a carry-lookahead adder would be one extreme of a behavioral model.

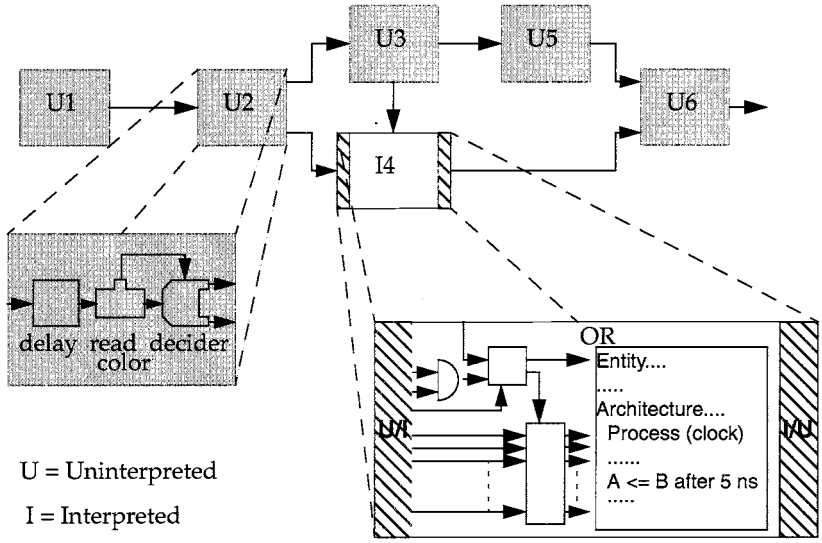

FIGURE 76.25 General structure of a mixed-level model.

It should be obvious that the two examples described above are extremes of the two types of models. Extensive design detail can be housed in the tokens of a performance model and information in a behavioral model can be encapsulated in a very abstract type. However, there is always a difference in the abstraction level of the two modeling types. Therefore, in order to develop a model that can include both performance and behavioral models, interfaces between the different levels of design abstraction, called mixed-level interfaces, must be included in the overall model to resolve differences between these two modeling domains.

The mixed-level interface is divided into two primary parts which function together: the part that handles the transition from the uninterpreted domain to the interpreted domain (U/I) and the part that handles the transition from the interpreted domain to the uninterpreted domain (I/U). The general structure of a mixed-level model is shown in Fig. 76.25.

In addition to the tokens-to-values (U/I) and values-to-tokens (I/U) conversion processes, the mixed-level interface must resolve the differences in design detail that naturally exist at the interface between uninterpreted and interpreted elements. These differences in detail appear as differences in data and timing abstraction across the interface. The differences in timing abstraction across the interface arise because the components at different levels model timing events at different granularities. For example, the passing of a token that represents a packet of data being transferred across a network in a performance model may correspond to hundreds or thousands of bus cycles for a model at the behavioral level.

The differences in data abstraction across the interface are due to the fact that typically performance models do not include full functional details, whereas behavioral models require full functional data (in terms of values on their inputs) to be present before they will execute correctly. For example, a performance level modeling token arriving at the inputs to the mixed-level interface for a behavioral floating point coprocessor model may contain information about the operation the token represents, but it may not contain the data on which the operation is to take place. In this case, the mixed-level interface must generate the data required by the behavioral model and do it in a way that a meaningful performance metric, such as best or worst case delays, is obtained.

Mixed-Level Modeling Taxonomy

The functions that the mixed-level interface must perform and the most efficient structure of the interface is affected by several attributes of the system being modeled and the model itself. In order to partition

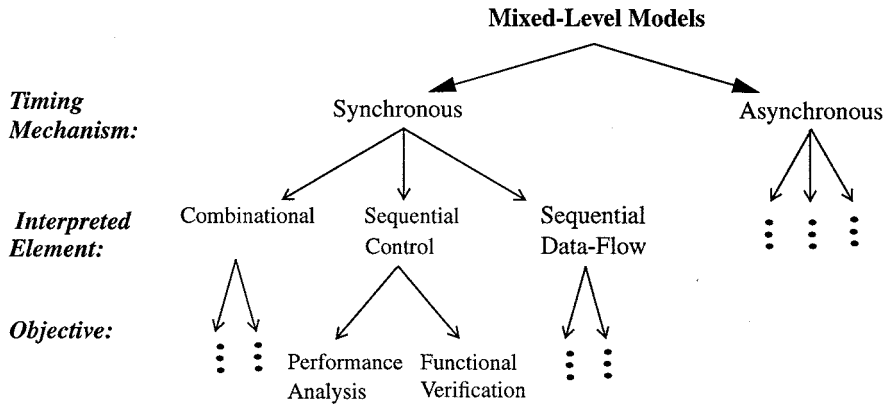

FIGURE 76.26 Mixed-level modeling categories.

the mixed-level modeling space and better define the specific solutions, a taxonomy of mixed-level model classes has been developed.[39] The classes of mixed-level modeling are defined by those model attributes which fundamentally alter the development and the implementation of the mixed-level interface. The mixed-level modeling space is partitioned according to three major characteristics:

1. The evaluation objective of the mixed-level model,
2. The timing mechanism of the uninterpreted model, and
3. The nature of the interpreted element.

For a given mixed-level model, these three characteristics can be viewed as attributes of the mixed-level model and the analysis effort. Figure 76.26 summarizes the taxonomy of mixed-level models.

Mixed-Level Modeling Objectives

The structure and the functionality of the mixed-level interface are strongly influenced by the objective that the analysis of the mixed-level model will be targeted toward. For the purposes of this work, these objectives were broken down into two major categories:

1. *Performance analysis* and *timing verification*: To analyze the performance of the system (as defined previously) and verify that the specific component(s) under consideration meet system timing constraints. Note that other metrics, such as power consumption, could be analyzed using mixed-level models, but these were outside the scope of this classification.
2. *Functional verification*: To verify that the function (input-to-output value transformation) of the interpreted component is correct within the context of the system model.

Timing Mechanisms

Typically, performance (uninterpreted) models are asynchronous in nature, and the flow of tokens depends on the handshaking protocol. However, in modeling a system that is globally synchronous (all elements are synchronized to a global clock) a mechanism to synchronize the flow of tokens across the model can be introduced. This synchronization of the performance model will require different mixed-level modeling approaches. Thus, the two types of system models that affect the mixed-level interface are

1. *Asynchronous models*: Tokens on independent signal paths within the system model move asynchronously with respect to each other and arrive at the interface at different times.
2. *Synchronous models*: The flow of tokens in the system model is synchronized by some global mechanism, and they arrive at the interface at the same time according to that mechanism.

Interpreted Component

The mixed-level modeling technique strongly depends on the type of the interpreted component that is introduced into the performance model. It is natural to partition interpreted models into those that model combinational elements and those that model sequential elements. Techniques for constructing mixed-level interfaces for models of combinational interpreted elements have been developed previously.[40] In the combinational element case, the techniques for resolving the timing across the interface were more straightforward because of the asynchronous nature of the combinational elements, and the data abstraction problem was solved using a methodology similar to the one presented here. However, using sequential interpreted elements in mixed-level models requires more complex interfaces to solve the synchronization problem and different specific techniques for solving the data abstraction problem. Further research into the problem of mixed-level modeling with sequential elements suggested that interpreted components be broken down into three classifications as described below:

1. *Combinational Elements*: Unclocked (with no states) elements.
2. *Sequential Control Elements* (SCE): Clocked elements (with states) that are used for controlling data flow, e.g., a control unit or a controller
3. *Sequential Dataflow Elements* (SDE): Elements that include datapath elements and clocked elements that control the data flow, e.g., control unit and datapath.

The major reason for partitioning the sequential elements into sequential dataflow and sequential control elements is based on the timing attributes of these elements. In a SCE, control input values are read every cycle and control output values (that control a datapath) are generated every cycle. On the other hand, SDEs have data inputs and may have some control inputs, but the output data is usually generated several clock cycles later. This difference in the timing attributes will dictate a different technique for mixed-level modeling. Because the solution for the timing and data abstraction problem for SDE elements is more complex and the solution for SCE elements can be derived from the solution for SDE elements, developing a solution for SDE elements was the focus of this work.

An Interface for Mixed-Level Modeling with FSMD Components

This section describes the interface structure and operation for sequential interpreted elements that can be described as Finite State Machines with a Datapath (FSMDs).[41] They consist of a Finite State Machine (FSM) used as a control unit, and a datapath, as shown in Fig. 76.27. System models are quite often

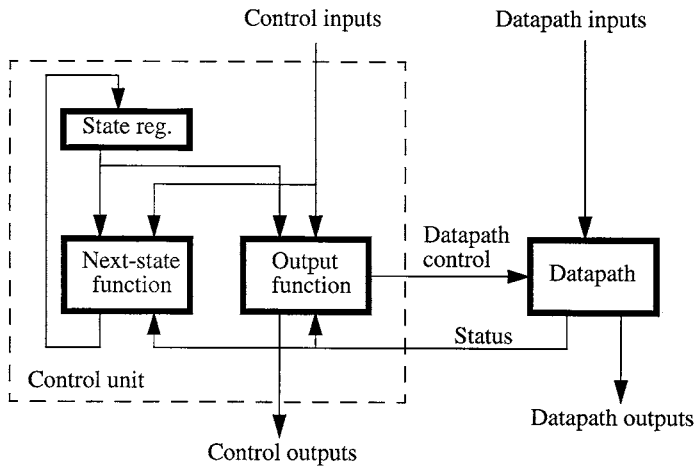

FIGURE 76.27 Generic FSMD block diagram.

naturally partitioned to blocks which adhere to the FSMD structure. Each FSMD processes the data and has some processing delays associated with it. These FSMDs indicate the completion of a processing task to the rest of the system either by asserting a set of control outputs or by the appearance of valid data on their outputs. This characteristic of being able to determine when the data processing task of the FSMD is completed is a key property in the methodology of constructing mixed-level models with FSMD interpreted components.

The functions performed by the U/I operator include placing the proper values on the inputs to the FSMD interpreted model and generating a clock signal for the FSMD interpreted model. The required values to be placed on the inputs to the FSMD interpreted model are contained on the incoming token's information, or "color" fields, are supplied by the modeler via some outside source, or are derived using the techniques described in the next section. The clock signal is either generated locally if the system-level model is globally asynchronous or converted from the global clock into the proper format if the system-level model is globally synchronous. The functions performed by the I/U operator include releasing the tokens back into the performance model at the appropriate time and, if required, coloring them with new values according to the output signals of the interpreted element. The structure of these two parts of the mixed-level interface is shown in Fig. 76.28. The U/I operator is composed of the following blocks: a driver, an activator, and a clock_generator. The I/U operator is composed of an Output_Condition_Detector, a Colorer, and a Sequential_Releaser.

In the U/I operator, the activator is used to detect the arrival of a new token (packet of data) to the interpreted element, inform the driver of a new token arrival, and drive control inputs of the interpreted element. The activator's output is also connected to the I/U operator for use in gathering information on the delay through the interpreted element. The driver reads information from the token's color fields and drives the proper input signals to the interpreted element according to predefined assignment properties. The Clock_Generator generates the clock signal according to the overall type of system-level model, either synchronous or asynchronous.

In the I/U operator, the Output_Condition_Detector detects the completion of the interpreted element data processing operation, as discussed earlier, by comparing the element's outputs with predefined properties. The colorer samples the datapath outputs and maps them to color fields according to predefined binding properties. The Sequential_Releaser, which "holds" the original token, releases it back to the uninterpreted model on receiving the signal from the Output_Condition_Detector. The information carried by the token is then updated by the colorer, and the token flows back to the uninterpreted part of the model.

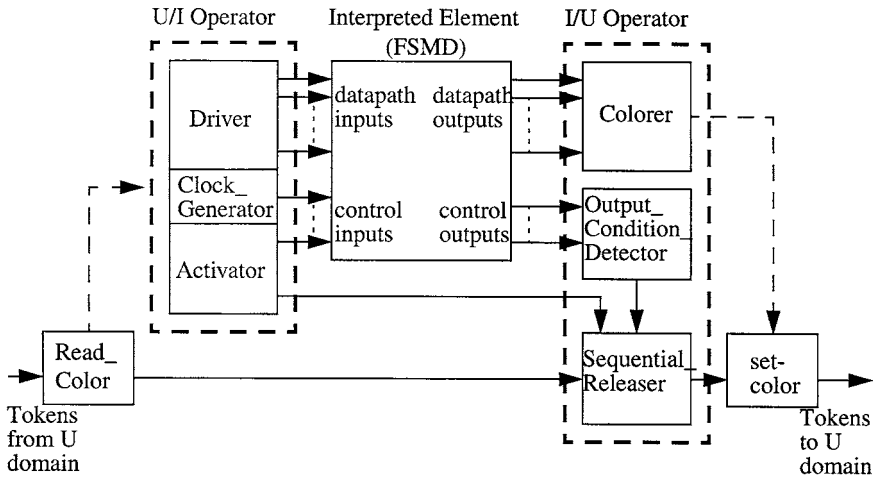

FIGURE 76.28 The mixed-level element structure.

Given this structure, the operation of the mixed-level model can be described using the general example in Fig. 76.28. Upon arrival of a new token to the mixed-level interface (U/I operator), the Read_color module triggers the activator component and passes the token to the Sequential_Releaser where it is stored until the interpreted component is finished with its operation. Once triggered by the Read_Color module, the activator notifies the driver to start the data conversion operation on a new packet of data. In the case of a globally asynchronous system-level model, the activator will notify the Clock_Generator to start generating a clock signal. Since the interpreted element is a sequential machine, the driver may need to drive sequences of values onto the inputs of the interpreted element. This sequence of values is supplied to the interpreted element, while the original token is held by the Sequential_Releaser. This token is released back to the uninterpreted model only when the Output_Condition_Detector indicates the completion of the interpreted element operation. The Output_Condition_Detector is parameterized to recognize the completion of data processing by the particular FSMD interpreted component. Once the Output_Condition_Detector recognizes the completion of data processing, it signals the Sequential_Releaser to release the token into the performance model. Once the token is released, it passes through the colorer, which maps the output data of the interpreted element onto color fields of the token. The new color information on the token may be used by the uninterpreted model for such things as delays through other parts of the model or for routing decisions.

Finding Values for the "Unknown Inputs" in an FSMD-Based Mixed-Level Model

As described previously, because of the abstract nature of a performance model, it may not be possible to derive values for all of the inputs to the interpreted component from the data present in the performance model. Typically, the more abstract the performance model (i.e., the earlier in the design cycle), the higher the percentage of input values that will be unknown. In some cases, particularly during the very early stages of the design process, it is possible that the abstract performance model will not provide any information to the interpreted element, other than the fact that new data has arrived. In this case, the data abstraction gap will be large. This section describes an analytical technique developed to determine values for these "unknown inputs" such that a meaningful performance metric — best or worst case delay — can be derived from the mixed-level model.

If some (or all) inputs are not known from the performance model, some criteria for deriving the values on the unknown inputs must be made. Choosing a criterion is based on the objective of the mixed-level model. For the objective of timing verification, delays (number of clock cycles) through the interpreted element are of interest. The most common criterion in such cases is the worst-case processing delay. In some cases, best-case delay may be desired. If the number of unknown inputs is small, an exhaustive search for worst/best case may be practical. Therefore, it is desirable to minimize the number of unknown inputs that can affect the delay through the interpreted element. The methods for achieving this objective are described conceptually in the next section. By utilizing these methods, the number of unknown inputs is likely to be reduced, but unknown inputs will not be eliminated completely. In this case, the performance metrics of best- and worst-case delay can be provided by a "traversal" of the state graph of the SDE component. The next section describes the traversal method developed for determining the delays through a sequential element.

Note that in the algorithms subsequently described, the function of the SDE component is represented by the State Transition Graph (STG) or State Table. These two representations are essentially equivalent and are easily generated from a behavioral VHDL description of the SDE, either by hand, or using some of the automated techniques that have been developed for formal verification.

Reducing the Number of Unknown Inputs

Although it is not essential, reducing the number of unknown inputs can simplify the simulation of a mixed-level model significantly. Since the FSMD elements being considered have output signals that can be monitored to determine the completion of data processing as discussed previously, other outputs may not be significant for performance analysis. Therefore, the "nonsignificant" (insignificant) outputs can

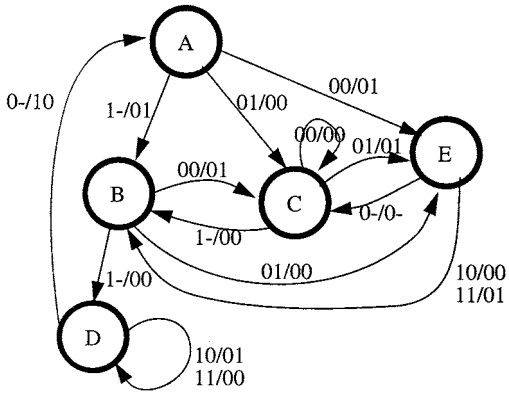

FIGURE 76.29 STG of a 2-inputs, 2-outputs state machine.

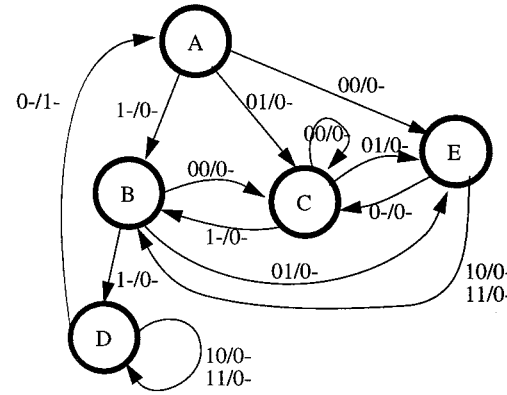

FIGURE 76.30 STG with "significant" output values only.

be considered as "don't-cares." By determining which inputs do not affect the values on the significant outputs, it is possible to minimize the number of unknown delay affecting inputs (DAIs).

The major steps in the DAI detection algorithm are

Step 1: Select the "insignificant" outputs (in terms of temporal performance).
Step 2: In the STG of the machine, replace all values for these outputs with a don't-care to generate the modified state machine.
Step 3: Minimize the modified state machine and generate the corresponding state table.
Step 4: Find the inputs which do NOT alter the flow in the modified state machine by detecting identical columns in the State Table and combining them by implicit input enumeration.

This method is best illustrated by an example. Consider the state machine which is represented by the state transition graph shown in Fig. 76.29. This simple example is a state machine with two inputs, X_1 and X_2, and two outputs, Y_1 and Y_2. This machine cannot be reduced, i.e., it is a minimal state machine. Assume that this machine is the control unit of an FSMD block and that the control output Y_1 is the output which indicates the completion of the "data processing" when its value is 1. Thus, output Y_2 is an "insignificant output" in terms of delay in accordance with Step 1. Therefore, a don't-care value is assigned to Y_2 as per Step 2. The modified STG is shown in Fig. 76.30. As per Step 3, the modified STG is then reduced. In this example, states A, C, and E are equivalent (can be replaced by a single state, K) and the minimal machine consists of three states, K, B, and D. This minimal machine is described by the State Table shown in Table 76.2.

TABLE 76.2 Next-State and Output Y_1 of the Minimal Machine

P.S.\X_1X_2	00	01	10	11
K = (ACE)	K, 0	K, 0	B, 0	B, 0
B	K, 0	K, 0	D, 0	D, 0
D	K, 1	K, 1	D, 0	D, 0

All possible input combinations appear explicitly in Table 76.2. However, it can be seen that the first two columns of the table are identical (i.e., the same next state and output value for all possible present states). Similarly, the last two columns of the table are identical. Therefore, in accordance with Step 4, these columns can be combined yielding the reduced State Table shown in Table 76.3.

TABLE 76.3 The Minimal Machine with Implicit Input Enumeration

P.S. \ X1X2	0-	1-
K = (ACE)	K, 0	B, 0
B	K, 0	D, 0
D	K, 1	D, 0

The reduced state table reveals that the minimal machine does not depend on the value of input X_2. Therefore, the conclusion is that input X_2 is not a DAI. This result implies that by knowing only the value of input X_1, the number of clock cycles (transitions in the original STG) required to reach the condition that output $Y_1 = 1$ can be determined regardless of the values of X_2. This is the case for any given initial state. It is important to emphasize that the paths in the original STG and their lengths are those which must be considered

during the traversal process and that the modified state machine is used only for the purpose of detecting non-DAIs. The machine which is actually being traversed during the mixed-level simulation is the original state machine with all its functionality.

To demonstrate the meaning of an input which is not a DAI, consider the original state machine represented by the graph in Fig. 76.29 and assume that the initial state is A. Consider, for example, one possible sequence of values on input X_1 to be 0, 1, 0, 0, 1, 1, 0. By applying this input sequence, the sequence of values on output Y_1 is 0, 0, 0, 0, 0, 0, 1, regardless of the values applied to input X_2. Therefore, two input sequences which differ only in the values of the non-DAI input X_2 will produce the same sequence of values on the "significant" output Y_1. For example, the sequence X_1X_2 = 00, 10, 00, 01, 10, 10, 01 will drive the machine from state A to E, B, C, E, B, D, and back to A, and the sequence of values on output Y_1 will be as above. Another input sequence, X_1X_2 = 01, 11, 01, 00, 11, 11, 00, in which the values of X_1 are identical to the pervious sequence, will drive the machine from state A to C, B, E, C, B, D, and back to A, while the sequence of values on output Y_1 is identical to the previous case. Therefore, the two input sequences will drive the machine via different states but will produce an identical sequence of values on the "significant" output (which also implies that the two paths in the STG have an equal length).

Traversing the STG for Best and Worst Delay

After extracting all possibilities for minimizing the number of unknown inputs, a method for determining values for those unknown inputs which are DAIs is required. The method developed for mixed-level modeling is based on the traversal of the original STG of the sequential interpreted element. As explained earlier, some combination of output values may signify the completion of processing the data. The search algorithm will look for a minimum or maximum number of state transitions (clock cycles) between the starting state of the machine and the state (Moore machine) or transition (state and input combination — Mealy machine), which generates the output values which signify the completion of data processing. Once this path is found, the input values for the unknown DAIs that will cause the SDE to follow this state transition path will be read from the STG and applied to the interpreted component in the simulation to generate the required best- or worst-case delay. Since the state machine is represented by the STG, this search is equivalent to finding the longest or shortest path between two nodes in a directed graph (digraph).

The search for the shortest-path utilizes a well-known algorithm. Search algorithms exist for both single-source shortest-path and all-pairs shortest-path. One of the first and most commonly used algorithm is Dijkstra's algorithm,[42] which finds the shortest-path from a specified node to any other node in the graph. The search for all-pairs shortest-path is also a well-investigated problem. One such algorithm by Floyd[43] is based on work by Warshall.[44] Its computation complexity is $O(n^3)$ when n is the number of nodes in the graph, which makes it quite practical for moderate-sized graphs. The implementation of this algorithm is based on Boolean matrix multiplication, and the actual realization of all-pairs shortest-paths can be stored in an $n \times n$ matrix. Utilizing this algorithm required some enhancements in order to make it applicable to mixed-level modeling. For example, if some of the inputs to the interpreted element are known (from the performance model), then the path should include transitions that include these known input values.

On the other hand, the search for the longest path is a more complex task. It is an NP-complete problem that has not attracted significant attention. Since most digraphs contain cycles, the cycles need to be handled during the search in order to prevent a path from containing an infinite number of cycles. One possible restriction that makes sense for many state machines that might be used in mixed-level modeling is to construct a path that will not include a node more than once. Given a digraph $G(V,E)$ which consists of a set of vertices (or nodes) $V = (v_1, v_2, \ldots\}$ and a set of edges (or arcs) $E = \{e_1, e_2, \ldots)$, a simple-path between two vertices v_{init} and v_{fin} is a sequence of alternating vertices and edges $P = v_{init}$, e_n, v_m, e_{n+1}, v_{m+1}, e_{n+2}, …, v_{fin} in which each vertex does not appear more than once. Although an arbitrary choice was made to implement the search allowing each vertex to appear in the path only once, the same algorithm could be easily modified to allow the appearance of each vertex a maximum of N times.

Given an initial node and a final node, the search algorithm developed for this application starts from the initial node and adds nodes to the path in a depth-first-search (DFS) fashion until the final node is reached. At this point, the algorithm backtracks and continues looking for a longer path. However, since the digraph may be cyclic, the algorithm must avoid the possibility of increasing the path due to a repeated cycle, which may produce an infinite path.

The underlying approach for avoiding repeated cycles in the algorithm dynamically eliminates the cycles while searching for the longest-simple-path. Let u be the node that the algorithm just added to the path. All the in-arcs to node u can be eliminated from the digraph at this stage of the path construction. The justification for this dynamic modification of the graph is that, while continuing in this path, the simple-path cannot include u again. While searching forward, more nodes are being added to the path and more arcs can be removed temporarily from the graph. At this stage, two things may happen: (1) either the last node being added to the path is the final node, or (2) the last node has no out-arcs in the dynamically modified graph. These two cases are treated in the same way except that in the first case the new path is checked to see if it is longer than the longest one found so far. If it is, the longest path is updated. However, in both cases the algorithm needs to backtrack.

Backtracking is performed by removing the last node from the path, hence decreasing the path length by one. During the process of backtracking, the in-arcs to a node being removed from the path must be returned to the current set of arcs. This process will enable the algorithm to add this node when constructing a new path. At the same time, whenever a node is removed from the path, the arc that was used in order to reach that node is marked in the dynamic graph. This process will eliminate the possibility that the algorithm repeats a path that was already traversed. Therefore, by dynamically eliminating and returning arcs from/to the graph, a cyclic digraph can be treated as if it does not contain cycles. The process of reconnecting nodes, i.e., arcs being returned to the dynamic graph, requires that the original graph be maintained. A more detailed description of this search algorithm can be found in Ref. 45.

In some mixed-level modeling cases, more realistic restriction on the longest-path than that it must not include any node more than once is that it not include any transition (arc) more than once. A longest-path with no repeated arcs may include a node multiple times as long as it is reached via different arcs. In the case of more than one transition that meets the condition on the output combination, a search for the longest-path should check all paths between the initial state and all of these transitions. However, such a path should include any of these transitions only once, and it should be the last one in the path.

Performing a search with the restriction that no arc is contained in the path more than once requires maintaining information on arcs being added or removed from the path. Maintaining this information during the search makes the algorithm and its implementation much more complicated relative to the search for the longest path with no repeated nodes. Therefore, a novel approach to this problem was developed. The approach used is to map the problem to the problem of searching for the longest path with no repeated nodes. This mapping can be accomplished by transforming the digraph to a new digraph, to be referred to as the transformed-digraph (or Tdigraph). Given a digraph, $G(V, E)$, which consists of a set of nodes $V = (v_1, v_2, \ldots, v_k)$ and a set of arcs $E = (e_1, e_2, \ldots, e_l)$ the transformation τ maps $G(V, E)$ into a Tdigraph $TG(N, A)$, where N is its set of nodes and A is its set of arcs. The transformation is defined as $\tau(G(V, E)) = TG(N, A)$ and contains the following steps:

Step 1: $\forall\ (e_i \in E)$ generate a node $n_i \in N$
Step 2: $\forall\ (v \in V)$ and $\forall\ (e_p \in d_{in}{}^v, e_q \in d_{out}{}^v)$ generate an arc $a \in A$ such that A: $n_p \rightarrow n_q$.

The first step is used to create a node in the Tdigraph for each arc in the original digraph. This one-to-one mapping defines the set of nodes in the Tdigraph to be $N = \{n_1, n_2, \ldots, n_l\}$ which has the same number of elements found in the set E.

The second step creates the set of arcs, $A = \{a_1, a_2, \ldots, a_u\}$, in the Tdigraph. For each node in the original digraph and for each combination of in-arcs and out-arcs to/from this node, an arc in the Tdigraph is created. For example, given a node v with one in-arc e_i and one out-arc e_j, e_i is mapped to a node n_i, e_j is mapped to a node n_j, and an arc from n_i to n_j is created. In Step 2 of the transformation

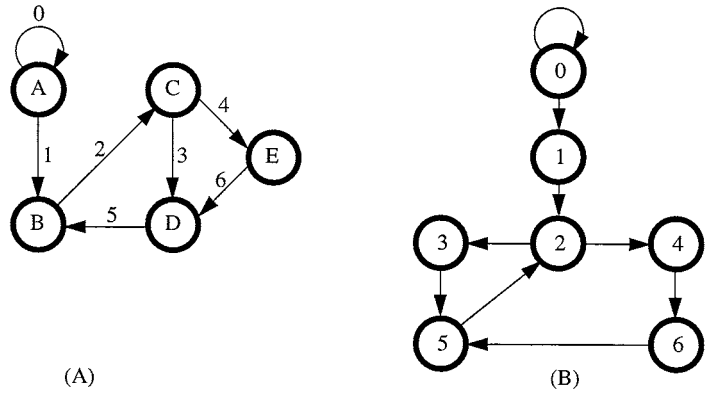

FIGURE 76.31 Transformation of a digraph.

process, it is guaranteed that all possible connections in the original digraph are preserved as transitions between nodes in the Tdigraph. As a result of this transformation, the restriction on not visiting an arc more than once in the original digraph is equivalent to not visiting a node more than once in the Tdigraph. Therefore, by using this transformation, the problem of searching for the longest path with no repeated arcs in the original digraph is mapped to a search for the longest path with no repeated nodes in the Tdigraph. The algorithm described above can then be used to search the Tdigraph.

This transformation is best illustrated by a simple example. Consider the digraph shown in Fig. 76.31(A). The arcs in this digraph are labeled by numbers 0 to 6. The first step of the transformation is to create a node for each arc in the original digraph. Therefore, there will be seven nodes, labeled 0 to 6, in the Tdigraph as shown in Fig. 76.31(B). The next step is to create the arcs in the Tdigraph. As an illustration of this step, consider node C in the original digraph. Arc "2" is an in-arc to node C, while arcs "3" and "4" are out-arcs from node C. Applying Step 2 results in an arc from node "2" to node "3" and a second arc from node "2" to node "4" in the Tdigraph. Considering node B in the original digraph, the Tdigraph will include an arc from node "1" to node "2" and an arc from node "5" to node "2". This process is repeated for all the nodes in the original digraph until the Tdigraph, as shown in Fig. 76.31(B), is formed. A search algorithm can now be executed to find the longest path with no repeated nodes.

A mixed-level modeling methodology, which is composed of all the methods described previously, has been integrated into the ADEPT environment. The steps for minimizing the unknown inputs can be performed prior to simulating the mixed-level model. On the other hand, the search for longest/shortest possible delay must be performed during the simulation itself. This requirement arises because each token may carry different information, which may alter the known input values and, therefore, alter the search of the STG. The STG traversal process has been integrated into the ADEPT modeling environment using the following steps: (1) when a token arrives to the mixed-level interface, the simulation is halted and the search for minimum/maximum number of transitions is performed; and (2) on completion of the search, the simulation continues while applying the sequence of inputs found in the search operation. The transfer of information between the VHDL simulator and the search program, which is implemented in C, is done by using the simulator's VHDL/C interface. A component called the Stream_Generator has been created that implements the STG search process via this interface.

Since mixed-level models are part of the design process and are constructed by refining a performance model, it is likely that many tokens will carry identical relevant information. This information may be used for selective application of the STG search algorithm, hence increasing the efficiency of the mixed-level model simulation. For example, if several tokens carry exactly the same information (and assuming the same initial state of the FSM), the search is performed only once, and the results can be used for the following identical tokens.

An Example of Mixed-Level Modeling with an FSMD Component

This section presents an example of the construction of a mixed-level model with an FSMD interpreted component. The example is based on the performance model of an execution unit of a particular processor. This execution unit is composed of an Integer Unit (IU), a Floating-Point Unit (FPU), and a Load-Store Unit (LSU). These units operate independently, although they receive instructions from the same queue (buffer of instructions). If the FPU is busy processing one instruction and the following instruction requires the FPU, it is buffered, waiting for the FPU to be free again. Meanwhile, instructions which require the IU can be consumed and processed by IU at an independent rate. Both the FPU and the IU have the capability of buffering only one instruction. Therefore, if two or more consecutive instructions are waiting for the same unit, the other units cannot receive new instructions (since the second instruction is held in the main queue). One practical performance metric that can be obtained from this model is the time required for the execution unit to process a given sequence of instructions.

Because the Floating-Point Unit was identified as the most complex and time critical portion of the design, a behavioral description of a potential implementation of it was developed. At this point, a mixed-level model, in which the behavioral description of the FPU is introduced into the performance model, was constructed using the interface described above. The mixed-level model is shown in Fig. 76.32. The mixed-level interface is constructed around the interpreted block which is the behavioral description of the FPU. This FPU is an FSMD type of element, and the interpreted model consists of a clock cycle accurate VHDL behavioral description of this component. The inputs to the FPU include the operation to be performed (Add, Sub, Comp, Mul, MulAdd, and Div), the precision of the operation (single or double) and some additional control information. The number of clock cycles required to complete any instruction depends on these inputs.

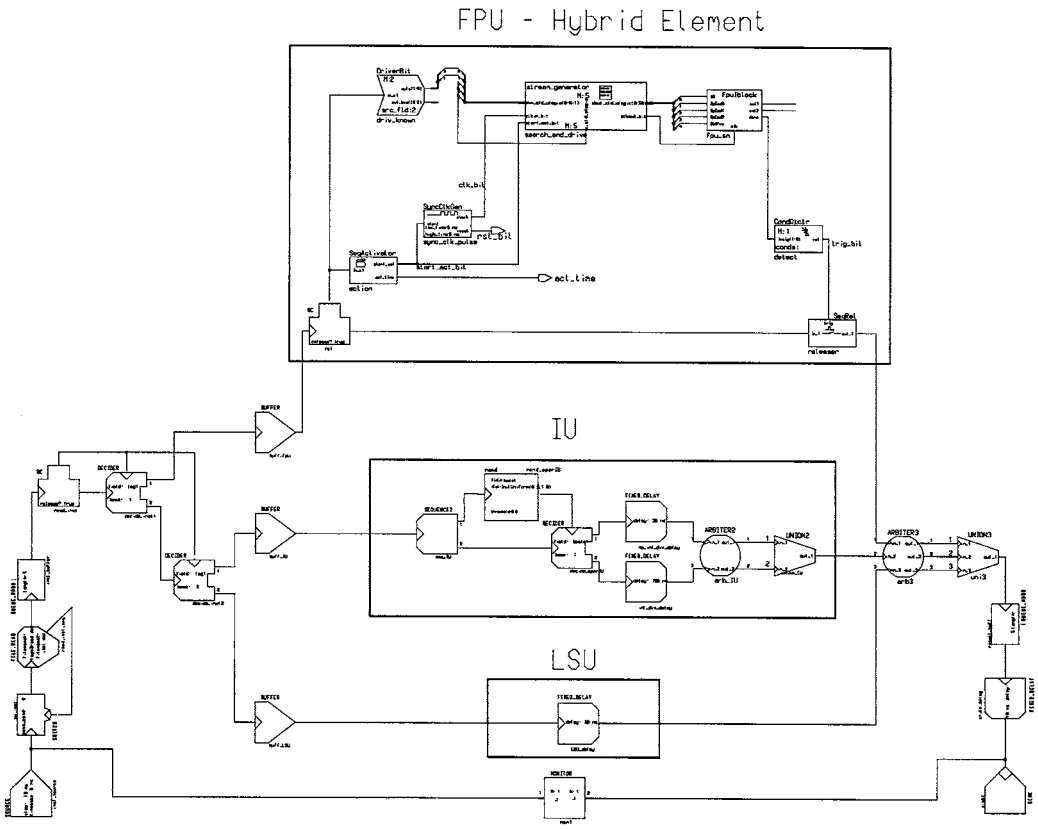

FIGURE 76.32 Mixed-level model with the FPU behavioral description.

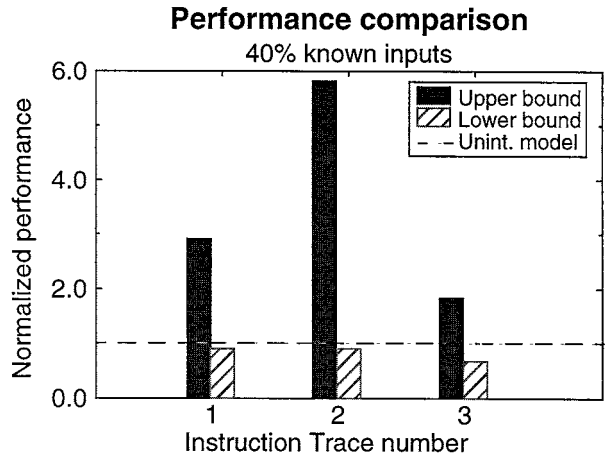

FIGURE 76.33 Performance comparison of the execution unit for three instruction traces.

Figure 76.33 shows the execution unit performance derived from the mixed-level model for three different instruction traces. In this case, only 40% of the inputs have values that are supplied by the abstract performance model; the remainder of the values for the inputs are derived using the techniques described in the section "Finding Values for the "Unknown Inputs" in an FSMD Based Mixed-Level Model." The performance value is normalized by defining unity to be the amount of time required to process a trace according to the initial uninterpreted performance model. In this example, the benefit of the simulation results of the mixed-level model is clear. It provides performance bounds in terms of best- and worst-case delays for the given implementation of the FPU.

An Interface for Mixed-Level Modeling with Complex Sequential Components

A methodology and components for constructing a mixed-level interface involving general sequential interpreted components that can be described as FSMDs was detailed in the previous section. However, many useful mixed-level models can be constructed that include sequential interpreted components that are too complex to be represented as FSMDs, such as microprocessors, complex coprocessors, network interfaces, etc. In these cases, a more "programmable" mixed-level interface that is able to deal with the additional complexity in the timing abstraction problem was needed. This section describes the "watch-and-react" interface that was created to be a generalized, flexible interface between these complex sequential interpreted components and performance models.

The two main elements in the watch-and-react interface are the trigger and the driver. Figure 76.34 illustrates how the trigger and driver are used in a mixed-level interface. Both elements have ports that can connect to signals in the interpreted components of a model. Collectively, these ports are referred to as the probe. The primary job of the trigger is to detect events on the signals attached to its probe, while the primary job of the driver is to force values onto the signals attached to its probe. The driver decodes information carried in tokens to determine what values to force onto signals in the interpreted model (the U/I interface), and the trigger encodes information about events in the interpreted model onto tokens in the performance model (the I/U interface).

The trigger and driver were designed to be as generic as possible. A command language was designed that specifies how the trigger and driver should behave to allow users to easily customize the behavior of the trigger and driver elements without having to modify their VHDL implementation. This command language is interpreted by the trigger and driver during simulation. Because the language is interpreted, changes can be made to the trigger and driver programs without having to recompile the model, thus minimizing the time required to make changes to the mixed-level model.

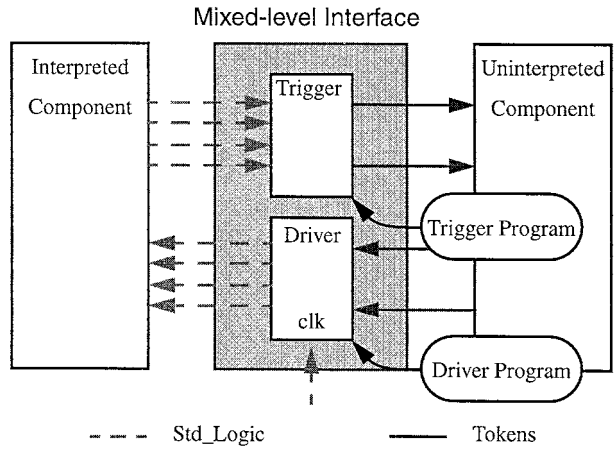

FIGURE 76.34 The watch-and-react mixed-level interface.

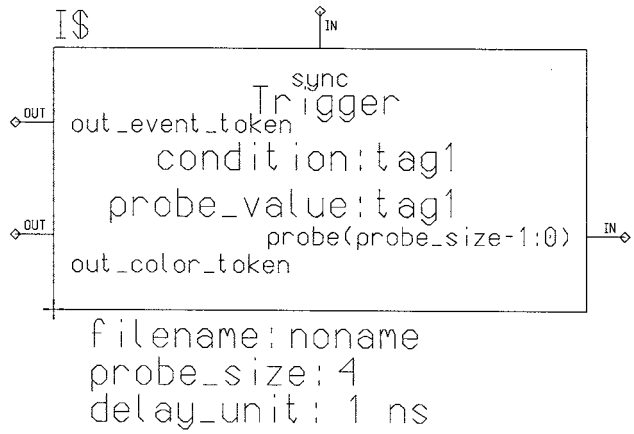

FIGURE 76.35 Schematic symbol for the trigger.

The schematic symbol for the trigger is shown in Fig. 76.35. The primary job of the trigger is to detect events in the interpreted model. The probe on the trigger is a bus of std_logic signals `probe_size` bits wide, where `probe_size` is a generic on the symbol. There is one token output called `out_event_token` and one token output called `out_color_token`. Tokens generated by the trigger when events are detected are placed on the `out_event_token` port. The condition number (an integer) of the event that caused the token to be generated is placed on the `condition` tag field, which is specified as a generic on the symbol. Also, each time a signal changes on the probe, the color of the token on the `out_color_token` port changes appropriately regardless of whether an event was detected or not. The probe value is placed on the `probe_value` tag field of the `out_color_token` port. The `sync` port is used to synchronize the actions of the trigger element with the driver element as explained below.

The name of the file containing the trigger's program is specified by the `filename` generic on the symbol. The `delay_unit` generic on the symbol is a multiple that is used to resolve the actual length of an arbitrary number of delay units specified by some of the interface language statements.

The schematic symbol for the driver element is shown in Fig. 76.36. The primary job of the driver is to create events in the interpreted model by driving values on its probe. These values come from either the command program, or from the values of tag fields on the input tokens to the driver. The probe on the driver is a bus of std_logic signals `probe_size` bits wide, where the `probe_size` is a generic on

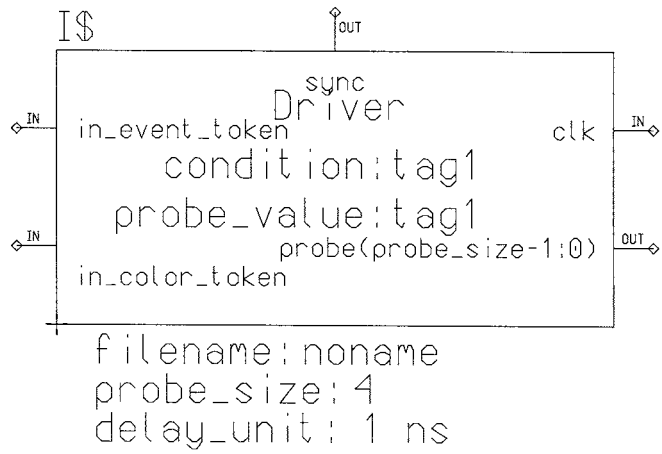

FIGURE 76.36 Schematic symbol for the driver.

the symbol. There is one token input called `in_event_token`, one token input called `in_color_token`, and a special input for a std_logic type clock signal called `clk`. The `clk` input allows driver to synchronize its actions with an external interpreted clock source. The `sync` port is used to synchronize the actions of the driver element with the trigger element. The `filename` and `delay_unit` generic on the symbol function the same as for the trigger.

As discussed previously, a command language was developed to allow the user to program the actions of the trigger and driver. This command language is read by the trigger and driver at the beginning of the simulation. Constructs are available within the command language to allow waiting on events of various signals and driving values or series of values on various signals, either asynchronously or synchronously, with a specified clock signal. In addition, several looping and go-to constructs are available to implement complex behaviors more easily. A summary of the syntax of the command language constructs is shown in Table 76.4.

Example of Mixed-Level Modeling with a Complex Sequential Element

This section presents an example which demonstrates how the trigger and driver elements can be used to interface an interpreted model of a complex sequential component with an uninterpreted model. In this example, the interpreted model is a microprocessor-based controller and the uninterpreted model is that of a motor control system that includes a motor controller and a motor. The motor controller periodically asserts the microcontroller's interrupt line. The microcontroller reacts by reading the motor's current speed from a sensor register on the motor controller, calculating the new control information, and writing the control information to the motor controller.

The microcontroller system consists of interpreted models of eight-bit, RISC-like microprocessors; RAM; memory controller; I/O controller; and clock. The memory controller handles read and write requests issued by the processor to the RAM, while the I/O controller handles read and write request issued by the processor to an I/O device. In the system model, the I/O device is the uninterpreted model of a motor controller. A schematic of the model is shown in Fig. 76.37.

Three triggers and two drivers are used to construct the mixed-level interface for the control system model. One of the triggers is used to detect when the I/O controller is doing a read or write. The other two triggers are used to collect auxiliary information about the operation, such as the address on the address bus and data on the data bus. One of the drivers is used to create a microcontroller interrupt, and the other driver is used to force data onto the data bus when the processor reads from the speed sensor register on the motor controller.

The interrupt driver's program is listed in Fig. 76.38. The program begins by forcing the interrupt line to 'Z' and then waiting for a token from the uninterpreted model of the motor controller to arrive. Once

TABLE 76.4 Trigger and Driver Command Programming Language Constructs

Command	Element	Meaning
--<comment>	both	comment — no action
alert_user	both	print message in simulation window
delay_for <T>	both	delay for <T> time units where the time unit is specified as a generic on the module's symbol
end	both	end the command program
for <N> <loop body> **next**	both	iterate N times over the sequence of statement in the loop body
goto <L>	both	go to line <L> in the command program
output_sync	both	generate a token on the sync output of the module
wait_on_sync	both	wait for an occurrence of a token on the sync port of the module
case_probe_is **when** <STD_LOGIC_VAL> <sequence of statements> **when**… **end_case**	trigger	conditionally execute some sequence of statements depending on the STD_LOGIC value of the probe signal
output <INTEGER_VAL> **after** <T>	trigger	generate a token on the trigger's output with the value of <INTEGER_VAL> on the tag field specified by the generic on the symbol after <T> time units
trigger	trigger	must appear as the first statement in the trigger's command program
wait_on <STD_LOGIC_VAL>	trigger	wait until the probe signal takes on the specified STD_LOGIC value
wait_on_probe	trigger	wait until there is ANY event on the probe signal
case_token_is **when** <INTEGER_VAL> <sequence of statements> **when**… **end_case**	driver	conditionally execute some sequence of statements depending on the integer value of the input token's tag field specified by the generic on the symbol
driver	driver	must appear as the first statement in the driver's command program
dynamic_output_after <T>	driver	force the value from the specified tag field of the input token onto the probe after <T> time units
output <STD_LOGIC_VAL> **after** <T>	driver	force the specified STD_LOGIC value onto the probe signal after <T> time units
wait_on <INTEGER_VAL>	driver	wait until a token with the given integer value on the tag field specified by the generic on the symbol arrives on the in_event_token signal
wait_on_fclk	driver	wait until the falling edge of the clock occurs
wait_on_rclk	driver	wait until the rising edge of the clock occurs
wait_on_token	driver	wait until a token arrives on the in_event_token signal

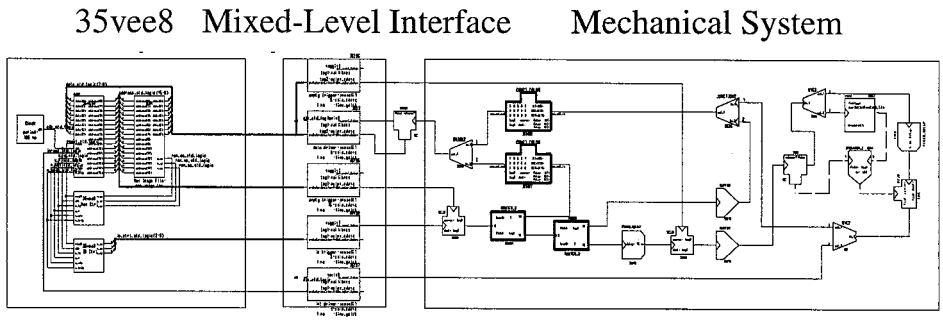

FIGURE 76.37 Schematic of control system model.

a token arrives, the program forces the interrupt line high for ten clock cycles. This condition is accomplished by using a `for-next` statement with a `wait_on_rclk` as the loop body. After ten clock cycles, the program jumps to line 10 where the cycle begins again.

The data driver's program is listed in Fig. 76.39. The program begins by also waiting for a token from the uninterpreted model of the motor controller to arrive. If the value on the condition tag field of the token is 1, then "ZZZZZZZZ" is forced onto the data bus. If the condition tag field value is 3, then the value on the `probe_value` tag field of the `in_color_token` input is forced on the data bus. This process is repeated for every token that arrives.

The I/O trigger's program is listed in Fig. 76.40. This trigger waits until there is a change on the probe. Once there is a change, the program checks to see if the I/O device is being unselected, written to, or read from. If one of the `when` statements matches the probe value, then its corresponding `output` statement is executed. An output of 1 corresponds to the I/O device not being selected. An output of 2 corresponds to the processor writing control information to the motor controller. An output of 3 corresponds to the processor reading the motor's speed from the sensor register on the motor controller.

```
driver
10 output Z after 0
20 wait_on_token
30 output 1 after 0
40 for 10
50    wait_on_rclk
60 next
70 goto 10
80 end
```

FIGURE 76.38 The interrupt driver's program for the control system.

Figure 76.41 shows the results from the mixed-level model as a plot of the sensor output and the processor's control response. Some random error was introduced to the sensor's output to reflect variations in the motor's load as well as sensor noise. The target speed for the system was 63 ticks per sample time (a measure of the motor's RPM). The system oscillates slightly around the target value because of the randomness introduced into the system.

```

76.5 Conclusions

Integration of performance modeling into the design process such that it can actually drive the refinement of the design into an implementation has clear advantages in terms of design time and quality. The ability to cosimulate detailed behavioral models and abstract system-level models is vital to the development of a design environment that fully integrates performance modeling into the design process. One methodology and implementation for cosimulating behavioral models of individual components with an abstract performance model of the entire system was presented. This environment results in models that can provide estimates of the performance bounds of a system that converge as the refinement of the overall model increases.

This chapter has only scratched the surface on the possible improvements that performance or system-level modeling can have on the rapid design of complex VLSI systems. As more and more functionality can be incorporated into the embedded VLSI systems and these systems find their way into safety-critical applications, measures of dependability such as reliability and safety at the system-level are becoming of great interest. Tools and techniques are being developed that can use the performance model from which to derive the desired dependability measures. In addition, behavioral fault simulation and testability analysis are finding their way into the early phases of the design process. In summary, the more attributes of the final implementation that can be determine from the early and often incomplete model, the better the resulting design and the shorter the design cycle.

Embedded Computing Systems and Hardware/Software Co-Design

Wayne Wolf
Princeton University

77.1 Introduction

This chapter describes embedded computing systems that make use of microprocessors to implement part of the system's function. It also describes hardware/software co-design, which is the process of designing embedded systems while simultaneously considering the design of its hardware and software elements.

77.2 Uses of Microprocessors

An embedded computing system (or more simply an embedded system) is any system which uses a programmable processor but itself is not a general purpose computer. Thus, a personal computer is not an embedded computing system (though PCs are often used as platforms for building embedded systems), but a telephone or automobile which includes a CPU is an embedded system. Embedded systems may offer some amount of user programmability — 3Com's PalmPilot, for example, allows users to write and download programs even though it is not a general-purpose computer — but embedded systems generally run limited sets of programs. The fact that we know the software that we will run on the hardware allows us to optimize both the software and hardware in ways that are not possible in general-purpose computing systems.

Microprocessors are generally categorized by their word size, since word size is associated both with maximum program size and data resolution. Commercial microprocessors come in many sizes; the term microcontroller is used to denote a microprocessor which comes with some basic on-chip peripheral devices, such as serial input/output (I/O) ports. Four-bit microcontrollers are extremely simple but capable of some basic functions. Eight-bit microcontrollers are workhorse low-end microprocessors. Sixteen- and 32-bit microprocessors provide significantly more functionality. A 16/32-bit microprocessor

may be in the same architectural family as the CPUs used in computer workstations, but microprocessors destined for embedded computing often do not provide memory management hardware. A digital signal processor (DSP) is a microprocessor tuned for signal processing applications. DSPs are often Harvard architectures, meaning that they provide separate data and program memories; Harvard architectures provide higher performance for DSP applications. DSPs may provide integer or floating-point arithmetic.

Microprocessors are used in an incredible variety of products. Furthermore, many products contain multiple microprocessors. Four- and eight-bit microprocessors are often used in appliances: for example, a thermostat may use a microcontroller to provide timed control of room temperature. Automatic cameras often use several eight-bit microprocessors, each responsible for a different aspect of the camera's functionality: exposure, shutter control, etc. High-end microprocessors are used in laser and ink-jet printers to control the rendering of the page. Many printers use two or three microprocessors to handle generation of pixels, control of the print engine, and so forth. Modern automobiles may use close to 100 microprocessors, and even inexpensive automobiles generally contain several. High-end microprocessors are used to control the engine's ignition system — automobiles use sophisticated control algorithms to simultaneously achieve low emissions, high fuel economy, and good performance. Low-end microcontrollers are used in a number of places in the automobile to increase functionality: for example, four-bit microcontrollers are often used to sense whether seat belts are fastened and turn on the seat belt light when necessary.

Microprocessors may replace analog components to provide similar functions, or they may add totally new functionality to a system. They are used in several different ways in embedded systems. One broad application category is signal conditioning, in which the microprocessor or DSP performs some filtering or control function on a digitized input. The conditioned signal may be sent to some other microprocessor for final use. Signal conditioning allows systems to use less-expensive sensors with the application of a relatively inexpensive microprocessor. Beyond signal conditioning, microprocessors may be used for more sophisticated control applications. For example, microprocessors are often used in telephone systems to control signaling functions, such as determining what action to take based on the reception of dial tones, etc. Microprocessors may implement user interfaces; this requires sensing when buttons, knobs, etc. are used, taking appropriate actions, and updating displays. Finally, microprocessors may perform data processing, such as managing the calendar in a personal digital assistant.

There are several reasons why microprocessors make good design components in such a wide variety of application areas. First, digital systems often provide more complex functionality than can be created using analog components. A good example is the user interface of a home audio/video system, which provides more information and is easier use than older, non-microprocessor-controlled systems. Microprocessors also allow related products much more cost-effectively. An entire product family, including models at various price and feature points, can be built around a single microprocessor-based platform. The platform includes both hardware components common to all the family members and software running on the microprocessor to provide functionality. Software elements can easily be turned on or off in various family members. Economies of scale often mean that it is cheaper to put the same hardware in both expensive and cheap models and to turn off features in the inexpensive models rather than to try to optimize the hardware and software configurations of each model separately. Microprocessors also allow design changes to be made much more quickly. Many changes may be possible simply by reprogramming; other features may be made possible by adding memory or other simple hardware changes along with some additional programming. Finally, microprocessors aid in concurrent engineering. After some initial design decisions have been made, hardware and software can be designed in parallel, reducing total design time.

While embedded computing systems traditionally have been fabricated at the board level out of multiple chips, embedded computing systems will play an increasing role in integrated circuit design as well. As VLSI technology moves toward the ability to fabricate chips with billions of transistors, integrated circuits will increasingly incorporate one or several microprocessors executing embedded software. Using microprocessors as components in integrated circuits increases design productivity, since CPUs can be used as large components which implement a significant part of the system functionality. Single-chip

embedded systems can provide much higher performance than board-level equivalents, since chip-to-chip delays are eliminated.

77.3 Embedded System Architectures

Although embedded computing spans a wide range of application areas, from automotive to medical, there are some common principles of design for embedded systems. The application-specific embedded software runs on a hardware platform. An example hardware platform is shown in Fig. 77.1. It contains a microprocessor, memory, and I/O devices. When designing on a general-purpose system such as a PC, the hardware platform would be predetermined, but in hardware/software co-design the software and hardware can be designed together to better meet cost and performance requirements.

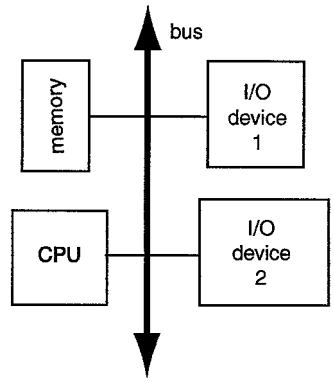

FIGURE 77.1 Hardware structure of a microprocessor system.

Depending on the application, various combinations of criteria may be important goals for the system design. Two typical criteria are speed and manufacturing cost. The speed at which computations are made often contributes to the general usability of the system, just as in general-purpose computing. However, performance is also often associated with the satisfaction of deadlines — times at which computations must be completed to ensure the proper operation of the system. If failure to meet a deadline causes a major error, it is termed a hard deadline. And missed deadlines, which result in tolerable but unsatisfactory degradations are called soft deadlines. Hard deadlines are often (though not always) associated with safety-critical systems. Designing for deadlines is one of the most challenging tasks in embedded system design. Manufacturing cost is often an important criteria for embedded systems. Although the hardware components ultimately determine manufacturing cost, software plays an important role as well. First, the size of the program determines the amount of memory required, and memory is often a significant component of the total component cost. Furthermore, the improper design of software can cause one to require higher-performance, more-expensive hardware components than are really necessary. Efficient utilization of hardware resources requires careful software design. Power consumption is becoming an increasingly important design metric. Power is certainly important in battery-operated devices, but it can be important in wall socket-powered systems as well — lower power consumption means smaller, less-expensive power supplies and cooling and may result in environmental ratings that are advantageous in the marketplace. Once again, power consumption is ultimately determined by the hardware, but software plays a significant role in power characteristics. For example, more efficient use of on-chip caches can reduce the need for off-chip memory access, which consumes much more power than on-chip cache references

Figure 77.1 shows the hardware architecture of a basic microprocessor system. The system includes the CPU, memory, and some I/O devices, all connected by a bus. This system may consist of multiple chips for high-end microprocessors or a single-chip microcontroller. Typical I/O devices include analog/digital (ADC) and digital/analog (DAC) converters, serial and parallel communication devices, network and bus interfaces, buttons and switches, and various types of display devices. This configuration is a complete, basic, embedded computing hardware platform on which application software can execute.

The embedded application software includes components for managing I/O devices and for performing the core computational tasks. The basic software techniques for communicating with I/O devices are polling and interrupt-driven. In a polled system, the program checks each device's status register to determine if it is ready to perform I/O. Polling allows the CPU to determine the order in which I/O operations are completed, which may be important for ensuring that certain device requests are satisfied at the proper rate. However, polling also means that a device may not be serviced in time if the CPU's program does not check it frequently enough. Interrupt-driven I/O allows a device to change the flow

of control on the CPU and call a device driver to handle the pending I/O operation. An interrupt system may provide both prioritized interrupts to allow some devices to take precedence over others and vectored interrupts to allow devices to specify which driver should handle their request.

Device drivers, whether polled or interrupt-driven, will typically perform basic device-specific functions and hand-off data to the core routines for processing. Those routines may perform relatively simple tasks, such as transducing data from one device to another, or may perform more sophisticated algorithms such as control. Those core routines often will initiate output operations based on their computations on the input operations.

Input and output may occur either periodically or aperiodically. Sampled data is a common example of periodic I/O, while user interfaces provide a common source of aperiodic I/O events. The nature of the I/ O transactions affects both the device drivers and the core computational code. Code which operates on periodic data is generally driven by a timer which initiates the code at the start of the period. Periodic operations are often characterized by their periods and the deadline for each period. Aperiodic I/O may be detected either by an interrupt or by polling the devices. Aperiodic operations may have deadlines, which are generally measured from the initiating I/O event. Periodic operations can often be thought of as being executed within an infinite loop. Aperiodic operations tend to use more event-driven code, in which various sections of the program are exercised by different aperiodic events, since there is often more than one aperiodic event which can occur.

Embedded computing systems exhibit a great deal of parallelism which can be used to speed up computation. As a result, they often use multiple microprocessors which communicate with each other to perform the required function. In addition to microprocessors, application-specific ICs (ASICs) may be added to accelerate certain critical functions. CPUs and ASICs in general are called processing elements (PEs). An example multiprocessor system built from several PEs along with I/O devices and memory is shown in Fig. 77.2.

The choice of several small microprocessors or ASICs rather than one large CPU is primarily determined by cost. Microprocessor cost is a nonlinear function of performance, even within a microprocessor family. Vendors generally supply several versions of a microprocessor which run at different clock rates; chips which run at varying speeds are a natural consequence of the variations in the VLSI manufacturing process. The slowest microprocessors are significantly less expensive than the fastest ones, and the cost increment is larger at the high end of the speed range than at the low end. As a result, it is often cheaper to use several smaller microprocessors to implement a function.

When several microprocessors work together in a system, they may communicate with each other in several different ways. If slow data rates are sufficient, serial data links are commonly used for their low hardware cost. The I^2C bus is a well-known example of a serial bus used to build multi-microprocessor embedded systems; the CAN bus is widely used in automobiles. High-speed serial links can achieve

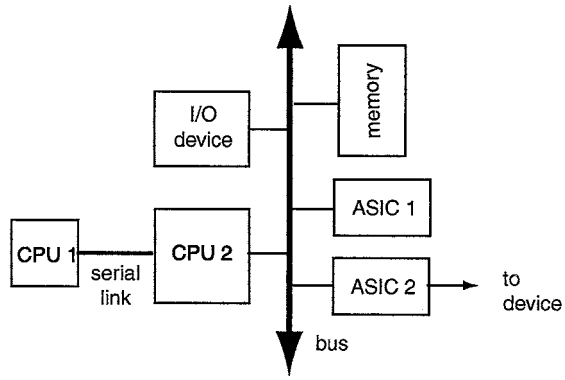

FIGURE 77.2 A heterogeneous embedded multiprocessor.

moderately high performance and are often used to link multiple DSPs in high-speed signal processing systems. Parallel data links provide the highest performance thanks to their sheer data width. High-speed busses such as PCI can be used to link several processors.

The software for an embedded multiprocessing system is often built around processes. A process, as in a general-purpose computing system, is an instantiation of a program with its own state. Since problems complex enough to require multiprocessors often run sophisticated algorithms and I/O systems, dividing the system into processes helps manage design complexity. A real-time operating system (RTOS) is an operating system specifically designed for embedded, and specifically real-time applications. The RTOS manages the processes and device drivers in the system, determining when each executes on the CPU. This function is termed scheduling. The partitioning of the software between application code which executes core algorithms and an RTOS which schedules the times to which those core algorithms are executed is a fundamental design principle in computing systems in general and is especially important for real-time operation.

There are a number of techniques which can be used to schedule processes in an embedded system — that is, to determine which process runs next on a particular CPU. Most RTOSs use process priorities in some form to determine the schedule. A process may be in any one of three states: currently executing (there can obviously be only one executing process on each CPU); ready to execute; or waiting. A process may not be able to execute until, for example, its data has arrived. Once its data arrives, it moves from waiting to ready. The scheduler chooses among the ready processes to determine which process runs next. In general, the RTOS's scheduler chooses the highest-priority ready process to run next; variations between scheduling methods depend in large part on the ways in which priorities are determined. Unlike general-purpose operating systems, RTOSs generally allow a process to run until it is preempted by a higher-priority process. General-purpose operating systems often perform time-slicing operations to maintain fair access of all the users on the system, but time-slicing does not allow the control required for meeting deadlines.

A fundamental result in real-time scheduling is known as rate-monotonic scheduling. This technique schedules a set of processes which run independently on a single CPU. Each process has its own period, with the deadline happening at the end of each period. There can be arbitrary relationships between the periods of the processes. It is assumed that data does not in general arrive at the beginning of the period, so there are no assumptions about when a process goes from waiting to ready within a period. This scheduling policy uses static priorities — the priorities for the processes are assigned before execution begins and do not change. It can be shown that the optimal priority assignment is based on period — the shorter the period, the higher the priority. This priority assignment ensures that all processes will meet their deadlines on every period. It can also be shown that at most, 69% of the CPU is used by this scheduling policy. The remaining cycles are spent waiting for activities to happen — since data arrival times are not known, it is not possible to utilize 100% of the CPU cycles.

Another well-known, real-time scheduling technique is earliest deadline first (EDF). This is a dynamic priority scheme — process priorities change during execution. EDF sets priorities based on the impending deadlines, with the process whose deadline is closest in the future having the highest priority. Clearly, the rate of change of process priorities depends on the periods and deadlines. EDF can be shown to be able to utilize 100% of the CPU, but it does not guarantee that all deadlines will be met. Since priorities are dynamic, it is not possible in general to analyze whether the system will be overloaded at some point.

Processes may be specified with data dependencies, as shown in Fig. 77.3, to create a task graph. An arc in the data dependency graph specifies that one process feeds data to another. The sink process cannot become ready until all the source processes have delivered their data. Processes which have no data dependency path between them are in separate tasks. Each task can run at its own rate. Data dependencies allow schedulers to make more efficient use of CPU resources. Since the source and sink processes of a data dependency cannot execute simultaneously, we can use that information to eliminate some combinations of processes which may want to run at the same time. Narrowing the scope of process conflicts allows us to more accurately predict how the CPU will be used.

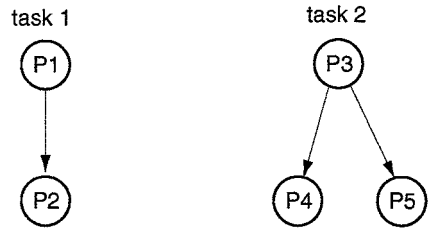

FIGURE 77.3 A task graph with two tasks and data dependencies between processes.

A real-time operating system is often designed to have a small memory footprint, since embedded systems are more cost-sensitive than general-purpose computers. RTOSs are also designed to be more responsive in two different ways. First, they allow greater control over the order of execution of processes, which is critical for ensuring that deadlines are met. Second, they are designed to have lower context-switching overhead, since that overhead eats into the time available for meeting deadlines. The kernel of an RTOS is the basic set of functions that is always resident in memory. A basic RTOS may have an extremely small kernel of only a few hundred instructions. Such microkernels often provide only basic context-switching and scheduling facilities. More complex RTOSs may provide high-end operating system functions such as file systems and network support; many high-end RTOSs are POSIX (a Unix standard) compliant. While running such a high-end operating system requires more hardware resources, the extra features are useful in a number of situations. For example, a controller for a machine on a manufacturing line may use a network interface to talk to other machines on the factory floor or the factory coordination unit; it may also use the file system to access a database for the manufacturing process.

77.4 Hardware/Software Co-Design

Hardware/software co-design refers to any methodology which takes into account both hardware and software during the design of an embedded computing system. When the hardware and software are designed together, the designer has more opportunities to optimize the system by making tradeoffs between the hardware and software components. Good system designers intuitively perform co-design, but co-design methods are increasingly being embodied in computer-aided design (CAD) tools. We will discuss several aspects of co-design and co-design tools, including models of the design, co-simulation, performance analysis, and various methods for architectural co-synthesis. We will conclude with a look at design methodologies that make use of these phases of co-design.

Models

In designing embedded computing systems, we make use of several different types of models at different points in the design process. We need to model basic functionality. We must also capture nonfunctional requirements: speed, weight, power consumption, manufacturing cost, etc.

In the earliest stages of design, the task graph is an important modeling tool. The task graph does not capture all aspects of functionality, but it does describe the various rates at which computations must be performed and the expected degrees of parallelism available. This level of detail is often enough to make some important architectural decisions. A useful adjunct to the task graph are the technology description tables, which describe how processes can be implemented on the available components. One of the technology description tables describes basic properties of the processing elements, such as cost and basic power dissipation. A separate table describes how the processes may be implemented on the components, giving execution time (and perhaps other function-specific parameters like precise power consumption) on a processing element of that type. The technology description is more complex when ASICs can be used as processing elements, since many different ASICs at differing price/performance points can be designed for a given functionality, but the basic data still applies.

A more detailed description is given by either high-level language code (C, etc.) for software or hardware description language code (VHDL, Verilog, etc.) for software components. These should not be viewed as specifications — they are, in fact, quite detailed implementations. However, they do provide a level of abstraction above assembly language and gates and so can be valuable for analyzing performance, size, etc. The control-data flow graph (CDFG) is a typical representation of a high-level language: a flowchart-like structure describes the program's control, while data flow graphs describe the behavior within expressions and basic blocks.

Co-simulation

Simulation is an important tool for design verification. The simulation of a complete embedded system entails modeling both the underlying hardware platform and the software executing on the CPUs. Some of the hardware must be simulated at a very fine level of detail — for example, buses and I/O devices may require gate-level simulation. On the other hand, the software can and should be executed at a higher level of abstraction. While it would be possible to simulate software execution by running a gate-level simulation of the CPU and modeling the program as residing in the memory of the simulated CPU, this would be unacceptably slow.

We can gain significant performance advantages by running different parts of the simulation at different levels of detail: elements of the hardware can be simulated in great detail, while software execution can be modeled much more directly. Basic functionality aspects of a high-level language program can be simulated by compiling the software on the computer on which the simulation executes, allowing those parts of the program to run at the native computer speed. Aspects of the program which deal with the hardware platform must interface to the section of the simulator which deals with the hardware. Those sections of the program are replaced by stubs which interface to the simulator. This style of simulation is a multi-rate simulation system, since the hardware and software simulation sections run at different rates: a single instruction in the software simulation will correspond to several clock cycles in the hardware simulation. The main jobs of the simulator are to keep the various sections of the simulation synchronized and to manage communication between the hardware and software components of the simulation.

Performance Analysis

Since performance is an important design goal in most embedded systems, both for overall throughput and for meeting deadlines, the analysis of the system to determine its speed of operation is an important element of any co-design methodology. System performance — the time it takes to execute a particular aspect of the system's functionality — clearly depends both on the software being executed and the underlying hardware platform. While simulation is an important tool for performance analysis, it is not sufficient, since simulation does not determine the worst-case delays. Since the execution times of most programs are data-dependent, it is necessary to give the simulation of the program the proper set of inputs to observe worst-case delay. The number of possible input combinations makes it unlikely that one will find those worst-case inputs without the sort of analysis that is at the heart of performance analysis.

In general, performance analysis must be done at several different levels of abstraction. Given a single program, one can place an upper bound on the worst-case execution time of the program. However, since many embedded systems consist of multiple processes and device drivers, it is necessary to analyze how these programs interact with each other, a phase which makes use of the results of single-program performance analysis.

Determining the worst-case execution time of a single program can be broken into two subproblems: determining the longest execution path through the program and determining the execution time of that program. Since there is at least a rough correlation between the number of operations and the actual execution time, we can determine the longest execution path without detailed knowledge of the instructions being executed — the longest path depends primarily on the structure of conditionals and loops. One way to find the longest path through the program is to model the program as a control-flow graph and use network flow algorithms to solve the resulting system.

Once the longest path has been found, we need to look at the instructions executed along that path to determine the actual execution time. A simple model of the processor would assume that each instruction has a fixed execution time, independent of other factors such as the data values being operated on, surrounding instructions, or the path of execution. In fact, such simple models do not give adequate results for modern high-speed microprocessors. One problem is that in pipelined processors, the execution time of an instruction may depend on the sequence of instructions executed before it. An even greater cause of performance variations is caching, since the same instruction sequence can have variable execution times, depending on whether the code is in the cache. Since cache miss penalties are often 5X or 10X, the cost of mischaracterizing cache performance is significant. Assuming that the cache is never present gives a conservative estimate of worst-case execution time, but one that is so over-conservative that it distorts the entire design. Since the performance penalty for ignoring the cache is so large, it results in using a much faster, more expensive processor than is really necessary. The effects of caching can be taken into account during the path analysis of the program — path analysis can determine bound how often an instruction present in the cache.

There are two major effects which must be taken into account when analyzing multiple-process systems. The first is the effect of scheduling multiple processes and device drivers on a single CPU. This analysis is performed by a scheduling algorithm, which determines bounds on when programs can execute. Ratemonotonic analysis is the simplest form of scheduling analysis — the utilization factor given by ratemonotonic analysis tells one an upper limit on the amount of active CPU time. However, if data dependencies between processes are known, or some knowledge of the arrival times of data is known, then a more accurate performance estimate can be computed. If the system includes multiple processing elements, more sophisticated scheduling algorithms must be used, since the data arrival time for a process on one processing element may be determined by the time at which that datum is computed on another processing element.

The second effect which must be taken into account is interactions between processes in the cache. When several programs on a CPU share a cache, or when several processing elements share a second-level cache, the cache state depends on the behavior of all the programs. For example, when one process is suspended by the operating system and another process starts running, that process may knock the first program out of the cache. When the first process resumes execution, it will initially run more slowly, an effect which cannot be taken into account by analyzing the programs independently. This analysis clearly depends in part on the system schedule, since the interactions between processes depends on the order in which the processes execute. But the system scheduling analysis must also keep track of the cache state — which parts of which programs are in the cache at the start of execution of each process. Good accuracy can be obtained with a simple model which assumes that a program is either in the cache or out of it, without considering individual instructions; higher accuracy comes from breaking a process into several sub-processes for analysis, each of which can have its own cache state.

Hardware/Software Co-Synthesis

Hardware/software co-synthesis tries to simultaneously design the hardware and software for an embedded computing system, given design requirements such as performance as well as a description of the functionality. Co-synthesis generally concentrates on architectural design rather than detailed component design — it concentrates on determining such major factors as the number and types of processing elements required and the ways in which software processes interact.

The most basic style of co-synthesis is known as hardware/software partitioning. As shown in Fig. 77.4, this algorithm maps the given functionality onto a template architecture consisting of a CPU and one or more ASICs communicating via the microprocessor bus. The functionality is usually specified as a single program. The partitioning algorithm breaks that program into pieces and allocates pieces either to the CPU or ASICs for execution. Hardware/software partitioning assumes that total system performance is dominated by a relatively small part of the application, so that implementing a small fraction of the application in the ASIC leads to large performance gains. Less performance-critical sections of the application are relegated to the CPU.

The first problem to be solved is how to break the application program into pieces; common techniques include determining where I/O operations occur and concentrating on the basic blocks of inner loops. Once the application code is partitioned, various allocations of those components must be evaluated. Given an allocation of program components to the CPU or ASICs, performance analysis techniques can be used to determine the total system performance; performance analysis should take into account the time required to transfer necessary data into the ASIC and to extract the results of the computation from the ASIC. Since the total number of allocations is large, heuristics must be used to search the design space. In addition, the cost of the implementation must be determined. Since the CPU's cost is known in advance, that cost is determined by the ASIC cost, which varies as to the amount of hardware required to implement the desired function. High-level synthesis can be used to estimate both the performance and hardware cost of an ASIC which will be synthesized from a portion of the application program.

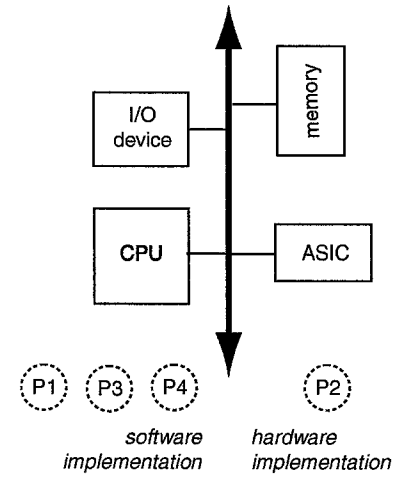

FIGURE 77.4 Hardware/software partitioning.

Basic, co-synthesis heuristics start from extreme initial solutions: We can either put all program components into the CPU, creating an implementation which is minimal cost but probably does not meet performance requirements, or put all program elements in the ASIC, which gives a maximal-performance, maximal-expense implementation. Given this initial solution, heuristics select which program component to move to the other side of the partition to either reduce hardware cost or increase performance, as desired. More sophisticated heuristics try to construct a solution by estimating how critical a component will be to overall system performance and choosing a CPU or ASIC implementation accordingly. Iterative improvement strategies may move components across the partition boundary to improve the design.

However, many embedded systems do not strictly follow the one CPU, one bus, n ASIC architectural template. These more general architectures are known as distributed embedded systems. Techniques for designing distributed embedded systems rest on the foundations of hardware/software partitioning, but they are generally more complicated, since there are more free variables. For example, since the number and types of CPUs is not known in advance, the co-synthesis algorithm must select them. If the number of busses or other communication links is not known in advance, those must be selected as well. Unfortunately, these decisions are all closely related. For example, the number of CPUs and ASICs required depends on the system schedule. The system schedule, in turn, depends on the execution time of each of the components on the available hardware elements. But those execution times depend on the processing elements available, which is what we are trying to determine in the first place. Co-synthesis algorithms generally try to fix several designs and vary only one or a few, then check the results of a design decision on the other parameters. For example, the algorithm may fix the hardware architecture and try to move processes to other processing elements to make more efficient use of the available hardware. Given that new configuration of processes, it may then try to reduce the cost of the hardware by eliminating unused processing elements or replacing a faster, more expensive processing element with a slower, cheaper one.

Since the memory hierarchy is a significant contributor to overall system performance, the design of the caching system is an important aspect of distributed system co-synthesis. In a board-level system with existing microprocessors, the sizes of second-level caches is under designer control, even if the first-level cache is incorporated on the microprocessor and therefore fixed in size. In a single-chip embedded system, the designer has control over the sizes of all the caches. Co-synthesis can determine hardware elements such as the placement of caches in the hardware architecture and the size of each cache. It can

also determine software attributes such as the placement of each program in the cache. The placement of a program in the cache is determined by the addresses used by the program — by relocating the program, the cache behavior of the program can be changed. Memory system design requires calculating the cache state when constructing the system schedule and using the cache state as one of the factors to determine how to modify the design.

Design Methodologies

A co-design methodology tries to take into account aspects of hardware and software during all phases of design. At some point in the design process, the hardware and software components are well-specified and can be designed relatively independently. But it is important to consider the characteristics of both the hardware and software components early in design. It is also important to properly test the system once the hardware and software components are assembled into a complete system.

Co-synthesis can be used as a design planning tool, even if it is not used to generate a complete system architectural design. Because co-synthesis can evaluate a large number of designs very quickly, it can determine the feasibility of a proposed system much faster than a human designer. This allows the designer to experiment with what-if scenarios, such as adding new features or speculating on the effects of lower component costs in the future. Many co-synthesis algorithms can be applied without having a complete program to use as a specification. If the system can be specified to the level of processes with some estimate of the computation time required for each process, then useful information about architectural feasibility can be generated by co-synthesis.

Co-simulation plays a major role once subsystem designs are available. It does not have to wait until all components are complete, since stubs may be created to provide minimal functionality for incomplete components. The ability to simulate the software before completing the hardware is a major boon to software development and can substantially reduce development time.

Design Automation Technology Roadmap

Donald Cottrell
Silicon Integration Initiative, Inc.

78.1 Introduction

No invention in the modern age has been as pervasive as the semiconductor, and nothing has been more important to its technological advancement than Electronic Design Automation (EDA). EDA was born in the 1960s both for the electronic computer and because of it. It was the advent of the computer that allowed for the development of specialized programs that perform the complex management, design, and analysis operations associated with semiconductors and electronic systems. At the same time, it was the design, management, and manufacture of the thousands (now tens of millions) of devices that make up a single electronic assembly that made EDA an absolute requirement to fuel the semiconductor progression. Today, EDA programs are used on electronic packages for all business markets from computers to games, telephones to aerospace guidance systems, toasters to automobiles. Across these markets, EDA supports many different package types, such as integrated circuit (IC) chips, multi-chip modules (MCM), printed circuit boards (PCB), and entire electronic assemblies of several different packages.

- No electronic circuit package is as challenging to those EDA as the integrated circuit. The growth in complexity in ICs has placed tremendous demands on EDA. Mainstream EDA applications such as simulation, layout, and test generation have had to improve their speed and capacity characteristics with this ever-increasing growth in the number of circuits to be processed. New types of design and analysis applications, new methodologies, and new design rules have been necessary to keep pace. Yet, even with the technological breakthroughs that have been made in EDA across the past three decades, it is still having difficulty keeping up with the breakthroughs being made in the electronic technologies that it supports. The increase in the chip's die size, coupled with the decrease in the size of features on the chip, is causing the number of design elements per IC to increase at a tremendous rate. The decrease in feature size and spacing coupled with the increase in operating frequency is causing additional levels of complexity to be approximated in the models used by design and analysis programs.

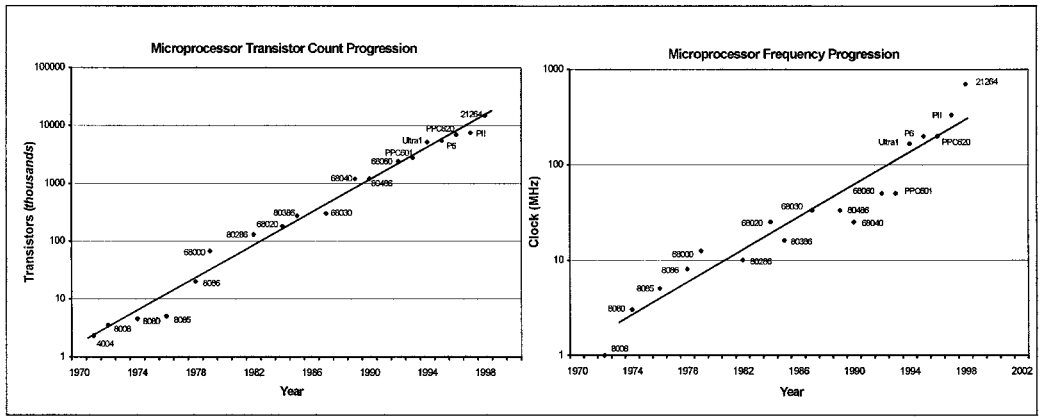

FIGURE 78.1 Microprocessor development.

In the period from 1970 to the present, the following semiconductor advances occurred:

- IC integration has grown from tens of transistors on a chip to over ten million.
- The feature size on ICs has shrunk from 10 microns to 0.18 microns.
- On-chip clock frequency has increased from a few MHz to over 600 MHz.
- Die sizes have increased from less than 20 mm^2 to over 400 mm^2.

Playing an essential part in the advancement of EDA have been advances in computer architectures that run the EDA applications. These advances have included the following:

- Computer CPU speed: from less than a million instructions per second (MIPS) of shared mainframe to hundreds of MIPS on a dedicated workstation.
- Computer memory: from fewer than 32 kilobytes to over 500 gigabytes.
- Data archive: from voluminous reels of (rather) slow speed tape to virtually limitless amounts of high-speed electronic storage devices.

Nevertheless, these major improvements in computing power alone would not have been sufficient to meet the EDA needs of the even more significant advances in semiconductors. Major advances also had to be made in fundamental algorithms used by EDA programs, and entirely new design techniques and design paradigms had to be invented and established for the technology advances to be supportable. This chapter will trace the more notable advancements made in EDA across the past three decades. From there, it will go on to discuss the technology trends predicted across the next decade along with the impact they will have on EDA of the future. It is important to understand these trends and projections, because if the EDA systems cannot keep pace with the semiconductor projections, then these projections will never be realized. Although it may be possible to build manufacturing processes that can produce ultra-deep submicron and find the billions of dollars of capital required, without the necessary EDA support these factories will never be fully utilized. SEMATECH reports that chip design productivity has increased at a compounded rate of 21%, while Moore's Law predicts the number of transistors on a chip to increase at a compound rate of 56%. This means that at some time building manufacturing plants that can produce smaller, denser chips will reach a point of diminishing returns, because the ability to design chips with that many transistors will not be possible.

78.2 Design Automation — An Historical Perspective

The 1960s — The Beginnings of Design Automation

Early entries into design automation were made in the areas of design records, PCB wiring, and manufacturing test generation. A commercial EDA industry did not exist, and developments were made within

companies with the need, such as IBM[1] and Bell Labs, on mainframe computers such as the IBM 7090. The 7090 had addressable 36-bit words and a limit of 32,000 words of main storage (magnetic cores). By today's standard, this would be equivalent to the storage in a small electronic address book, far less than the typical 32 megabytes of RAM on the average notebook PC and certainly no match for a high-function RISC workstation with 512 megabytes of main store. Computer limitations continue to be the curse of EDA development, particularly when the EDA support is targeted for design of the next generation computer. However, the limitations of the computers of the 1960s was particularly acute.

In retrospect, the limit of computers in the 1960s was a blessing for the development of design automation. Because of these limitations, design automation developers were forced to invent highly creative algorithms that operated on very compact data structures. Many of the algorithms developed during this decade are still in use within commercial EDA systems today, with only minor differences in fundamental concepts. Notable advances during this period were

- The fundamental "stuck-at" model for manufacturing test and a formal algebra for the generation of tests and diagnosis of faults
- Parallel fault simulation, which provided simulation of many fault conditions in parallel with the good-machine (nonfaulty circuit) to reduce fault-simulation run-times
- A three-valued algebra for simulation which yields accurate results using simple delay models, even in the presence of race conditions within the design
- Development of fundamental algorithms for the placement and wiring of components.

Moreover, there was development of fundamental heuristics for placement and wire routing, and for divide and conquer concepts. One such concept was the hierarchical division of a wiring image into cells, globally routing between cells and then performing detailed routing within cells, possibly subdividing them further. Many of these fundamental concepts are still applied today, although the complexities of physical design of today's LSI is vastly more complex.

The 1960s represented the awakening of design automation and provided the proof of its value and need for electronic design. It would not be until the end of this decade when the explosion of the number of circuits designed on a chip would occur and the term LSI (large-scale integration) would by coined. EDA development in the 1960s was primarily focused on printed circuit assemblies, but the fundamental concepts developed for design entry, test generation, and physical design provided the basics for EDA in the LSI era.

Design Entry

Before the use of computers in electronic design, the design schematic was a drawing. This drawing was a draftsman's rendering of the notes and sketches provided by the designer. The drawings provided the basis for manufacturing or repair operations in the field. As automation developed, it became desirable to store these drawings on media usable by computers so that the creation of input to the automated processes could itself be automated. So, the need to record the design of electronic products and assemblies in computers was recognized in the late 1950s and early 1960s. In the early days of design automation, the electronic designer would develop the design using paper and pencil and then transcribe it to a form suitable for keyed entry to a computer. Once keyed into the computer, the design could be rendered in a number of different formats to support the manufacturing and field support processes. It recognized further that these computerized representations of the circuit design drawing could also drive design processes, such as the routing of printed circuit traces or the generation of manufacturing test patterns. From there, it was but a short step to the use of computers to generate data in the form required to drive automated manufacturing and test equipment.

Early design entry methods involved the keying of the design into transcription records that were read into the computer and saved on a persistent storage device. This became known as the design's database, and it is the start of the design automation system. From the database, schematic diagrams and logic diagrams were rendered for use in engineering, manufacturing, and field support. This was typically a two-step process, whereby the designer drew the schematic by hand and then submitted it to another

for conversion to the transcription records, keypunch, and submission to the computer. Once in the computer, the formal automated drawings were generated, printed, and returned to the designer. Although this process seems archaic by today's standards, it did result in a permanent record of the design in computer readable format. This could be used for many forms of records management, engineering change history, and as input to design, analysis, and manufacturing automation that would soon follow.

With the introduction of the alphanumeric terminal, the keypunch was replaced as the window into the computer. With this, new design description languages were developed and the role of the transcription operator dissolved. Although these description languages still represented the design at the device or gate level, they were free-format and keyword-oriented and engineers were willing to use them. The design engineer now had the tools to enter design descriptions directly into the computer, thus eliminating the inherent inefficiencies of the "middle-man." Thus, a paradigm shift began to evolve in the method by which design was entered to the EDA system. Introduction of the direct access storage devices (disks) in the late 1960s also improved the entry process as well as the entire design system by providing on-line, high-speed direct access to the entire design or any portion of it. This was also important to the acceptance of design entry by the designer, as the task was still viewed as a necessary overhead rather than a natural part of the design task. It was necessary to get access to the other evolving design automation tools, but typically, the real design thought process took place with pencil and paper techniques. Therefore, any changes that made the entry process faster and easier were eagerly accepted.

With the evolution of design tools, new design description languages began to be introduced that were capable of representing the functional design intent, but without the implementation details. The design engineer was now able to represent his design ideas at a more abstract level with less detail. Register Transfer Level (RTL) design languages were introduced, and with new simulators capable of simulation directly from these, the designer was able to verify design intent much earlier in the design cycle.

The next shift occurred in the later part of the 1970s with the introduction of graphics terminals. With these, the designer could enter a design into the database in schematic form. This form of design entry was a novelty, but not a clear performance improvement. In fact, until the introduction of the workstation and dedicated graphics support, graphic entry was detrimental to design productivity in many cases. Negative effects such as less-than-effective transaction speed and time lost in making the schematic aesthetically pleasing, and the low level of detail all added to less-than-obvious advances. On the other hand, use of the graphics display to view the design and make design change proved extremely effective and was a great improvement over the red-lined prints, and for this reason alone, graphics represent a major advance. However, even with the negative virtues of graphic schematic entry, this style took off with the introduction of the workstation in the 1980s. In fact, the graphic editor glitz and capability often was a major decision point in the purchase of one commercial EDA system over another, and to be considered a commercially viable system, graphics entry was required. Nevertheless, as the density of ICs grew and grew, graphics entry of schematics would begin to yield to the advantages of alphanumeric entry languages. As EDA design and analysis tool technology advanced, entry of design at the RTL level would become commonplace. Today, design entry using RTL descriptions is the generally accepted approach for original design of standard cell design, although schematic entry is the accepted method for PCB design and many elements of custom ICs.

There is no doubt that the introduction of graphics into the design automation system represents a major advance and a major paradigm shift. Use of graphics to visualize design details, wiring congestion, timing diagrams, etc. is of major importance. Use of the graphics to perform certain edit functions is standard operating procedure. Large system design often entails control circuitry, dataflow, and functional modules. Classically, these systems span across several chips and boards and employ several styles of entry for the different physical packages. These may include

- Schematics — graphic
- RTL and behavorial level languages — alphanumeric
- Timing diagrams — graphic

- State diagrams — alphanumeric
- Flowcharts — graphic

Today, these entry techniques can be found in different EDA tools, and each is particularly effective for different types of design problems. Schematics are effective for the design of "glue" logic that interconnects functional design elements, such as modules on a PCB. Behavorial languages are useful for all design, but particularly effective for dataflow behavior. Timing diagrams lend themselves well to describe the functional operations of "black-box" components at their I/Os without needing to describe their internal circuitry. State diagrams are a convenient way to express the logical operation of combinational circuits. Flowcharts are effective for describing the operations of control logic, much like use of flowcharts for specification of software program flow. With technology advances, the IC is engulfing more and more of the entire system, and all of these forms of design are prevalent on a single chip. It is even expected that the design of "black-box" functions will be available from multiple sources to be embedded onto the chip similar to the use of modules on a PCB. Thus, it is likely that future EDA systems will support a mixture of design description forms to allow the designer to represent sections of the design in a manner most effective to each. After all, design is described in many forms by the designer outside the design system.

Test Generation

Testing of manufactured electronic subassemblies entails the use of special test hardware that can provide stimulus (test signals) to selected [input] pins of the part under test and measure for specified responses on selected [output] pins. If the measured response matches the specified response, then the part under test passed that test successfully. If some other response is measured, then the part failed that test and the presence of a defect is indicated. Manufacturing testing is the successive application of test patterns that causes some measurable point on the part under test to be sensitized to the presence of a manufacturing defect. That is, some measurable point on the part under test will result in a value if the fault is present that is different from what it would be if the fault were not present. The collection of test patterns cause all (or almost all) possible manufacturing failures to render a different output response than would the non-defective part. For static dc testers, each stimulus is applied, and after the part under test settles to steady state, the specified outputs are measured and compared with the expected results for a nondefective part.

To bound the test generation problem, a model was developed to represent possible defects at the abstract gate level. This model characterizes the effects of defects as a stuck-at value. This model is fundamental to most of the development in test generation and is still in use today. It characterizes defects as causing either a stuck-at-one or a stuck-at-zero condition at pins on a gate. Additionally, it assumes that a fault is persistent and that only one fault occurs at a time. Thus, this model became known as the single stuck-at fault model. Stuck-at fault testing assumes that the symptom of any manufacturing defect can be characterized by the presence of a stuck-at fault some place within the circuit. By testing for the presence of all possible stuck-at faults that can occur, all possible manufacturing defects can thus be tested.

The stuck-fault models for NAND and NOR gates are shown in Fig. 78.2. For the NAND gate, the presence of an input stuck-at-one defect can be sensitized (made detectable) at the gate's output pin by setting the good-machine state for that input to zero and setting the other input values to 1. If a 0-state is observed at the gate's output node, then the fault is detected. A stuck-at-zero condition on any specific input to the NAND gate is not distinguishable from a stuck-at-zero on any other input to the gate, thus is not part of the model. However, a stuck-at-one is modeled at the gate's output to account for such a fault or a defect on the gate's output circuitry.

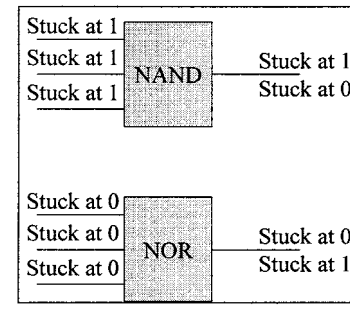

FIGURE 78.2 Stuck fault models.

The fault model for the NOR gate is similar except that here the input condition is stuck-at-zero only, as the stuck-at-one defect cannot be isolated to a particular input.

Later in time, additional development would attack defects not detectable with this stuck-at fault model. For example, bridging faults where nodes are shorted together, and delay faults where the output response does not occur within the required time. The stuck-at fault model cannot detect these fault types, and they became important as the development of CMOS progressed. Significant work was performed in both of these areas beginning in the 1970s, but it did not have the impact on test generation development that the stuck-at fault model did.

The creation of the fault model was very important to test generation, as it established a realistic set of objectives to be met by the test generator that could be achieved in a realistic amount of compute time. A formal algebra was developed by Roth,[2] called the D-ALG, that formalized an approach to test generation and fault diagnosis.

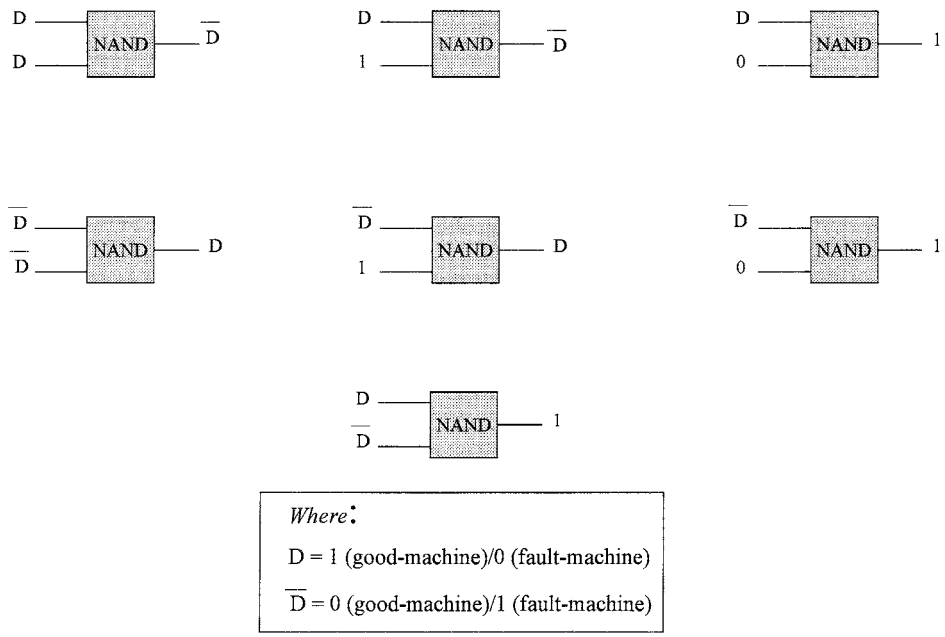

FIGURE 78.3 D-ALG calculus.

The test generation programs could choose a fault based on the instances of gates within the design and the fault models for the gates. It could then trace back from that fault to the input pins of the design and, using the D-ALG calculus, find a set of input states that would sensitize the fault. Then, it could trace forward from that fault to the design's output pins, sensitizing the path (cause the good-machine value to be the opposite from the stuck-at-fault value along that path) to at least one observable pin.

Use of functional patterns as the test patterns in lieu of heuristic test generation was another approach for manufacturing testing. However, this required an extreme number of tests to be applied and worse, depended on the experience and skill of the designer to create quality tests. The use of fault models and automatic test generation produced a minimum set of tests and greatly reduced manually intensive labor.

The exhaustive method to assure coverage of all possibly detectable defects would be to apply all possible input states to the design under test and compare the measured output states with the simulated good-machine states. For a design with n input pins, however, it requires the simulation of 2^n input patterns for combinatorial logic and at least 2^{n+m} for sequential logic (where m is the number of independent storage elements). For even a relatively small number of input pins, this amount of simulation

would not be possible even on today's computers, and the time to apply this number of patterns at the tester would be grossly prohibitive.

The amount of time that a part resides on the tester is critical in the semiconductor business, as it impacts the number of parts that can be produced in a given amount of time and the capital cost for testers. This implies that the number of test patterns that need to be applied at the tester should be keep to a minimum. Early work in test generation attacked this problem in two ways. First, when a test pattern was generated for a specific fault, it was simulated against all possible faults. In many cases, the application of a test pattern that is targeted for a specific fault will also detect several other faults at the same time. The test for the specific fault may be detectable on one output pin, for example, but additional faults may be observable at other output pins. The use of fault simulation detected these cases and provided a mechanism to mark as tested those faults that were "accidentally" covered. This meant that the test-generation algorithm did not have to generate a specific test for those faults. Second, schemes were developed to merge input patterns together into a smaller number of test vectors to minimize the number of patterns that need to be applied at the tester. This is possible when two adjacent test patterns require the application of specific stimulus values at different input pins, each allowing all other input pins to be at the don't-care state. In these cases, the patterns can be merged into a single test vector. With successive analysis in this way, all pairs of test patterns (pattern n with $n + 1$, or the merger of m and $m + 1$ with pattern $m + 2$) are analyzed and merged into a reduced set of patterns.

Sequential design elements severely complicate test generation, as they require the analysis of previous states and the application of sequences of patterns. Early work in test generation broke feedback nets, inserted a lumped delay on them, and analyzed the design using a Huffman model. Later work attempted to identify the memory elements within the design using sophisticated topological analysis and then used a Huffman model to analyze each. State tables for each sequential element were generated and saved for later use as lookup tables in the test generation process. Use of three-value simulation within the analysis both reduced the analysis time and guaranteed that the results were always accurate. Huffman analysis required 2^x simulations (where x is the number of feedback nets) to determine if critical hazards existed in the sequential elements. Using three-valued simulation[3] (all value transitions go through an X state), this was reduced to a maximum of $2x$ simulations.

This lumped delay model did not account for the distribution of delays in the actual design, thus it often caused pessimistic results. Often simulated results yielded don't-know (X-state) conditions when a more accurate model could yield a known state. This made it difficult to generate patterns that would detect all faults in the model. As the level of integration increased, the problems associated with automatic test generation for arbitrary sequential circuits became unwieldy. This necessitated that the designer be called back into the problem of test generation most often to develop tests that would detect those missed by the test generation program. New approaches were developed that ranged from random pattern generation to advanced algorithms and heuristics which used sequences of different approaches. However, by the mid-70s the need to design-for-test was becoming evident to many companies.

During the mid-70s, the use of scan-design was developed.[4] Scan design provides external control and observability to points within a design that might otherwise be inaccessible. This is accomplished inserting special scan registers into the design at the points to be controlled and observed. These registers are connected into a shift register chain that has each of its data input and its data output connected to an accessible pin. Under normal conditions, signals from the design are passed through individual registers. Under test conditions, test vectors can be scanned in from the input pin of the scan register and applied to the appropriate points within the design. Similarly, values on points within the design are captured in individual registers and scanned out to the output pin of the scan register.

The development of scan design was important for two reasons. First, level-sensitive scan design (LSSD) allowed for external control and observability of sequential elements within the design. With specific design-for-test rules, this reduced the problem of test generation by allowing the design to be analyzed as a combinational circuit. In LSSD, rigid design rules such as the following were developed, and checking programs or scan generation algorithms were implemented to assure they were adhered to before entering test generation:

- all internal storage elements implemented in hazard-free polarity-hold latches
- absence of any global feedback loops
- latches may not be controlled by the same clock as latches feeding them
- externally controllable clocks to shift register latches

Second, scan design allowed for external control and observability at otherwise nonprobable points between modules on an MCM or PCB. During the 1980s, an industry standard for this was developed called Boundary Scan (IEEE 1149.1 Joint Test Action Group).[5] Use of a standard technique and shift register latches greatly improved the transfer of complex modules into a random design by simplifying the test problem. Each of these uses of scan techniques to provide additional control and observability have a price. They require additional real estate in the IC design and have a level of performance overhead. However, with the achievable transistor density levels on today's ICs and the test benefits accrued, these penalties are easily justified in all but the most performance critical designs. In fact, with today's IC densities and speeds, the use of circuitry on-chip is often used to generate test vectors.

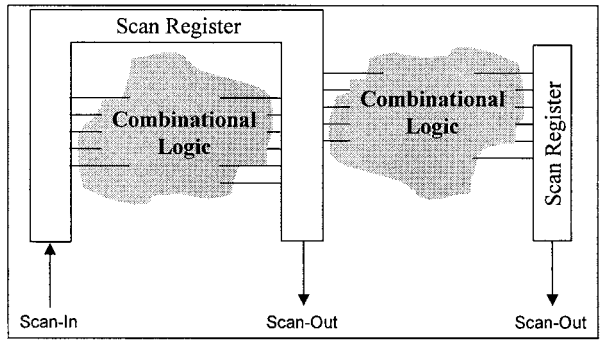

FIGURE 78.4 Scan design.

During the 1980s, IC density allowed for the design of built-in self-test (BIST) circuitry on the chip itself. Operating at hardware speed, it became feasible to generate complete exhaustive tests and large numbers of random tests never before possible with software and stored program testers. BIST tests are generated on the tester by the device under test, reducing the management of data transfer from design to manufacturing. Use of a binary-counter or linear feedback shift-registers (LFSR) generate the patterns for exhaustive or random tests, respectively. In the latter case, a pseudo-random bit sequence is formed by the exclusive-OR of the bits on the LFSR, and this result is then fed back into the LFSR input. Thus, a pseudo-random bit sequence can be generated whose sequence length is based on the number of LFSR stages and the initial LFSR state. The design can be simulated to determine the state conditions for the generated test patterns, and these simulated results compared with the actual device-under-test results are observed at the tester.

Today, BIST techniques are becoming common for the test of on-chip RAM and ROS. BIST is also used for logic sections of chips either with fault-simulated, weighted random test patterns or good machine simulated exhaustive patters. In the latter case, logic is partitioned into electrically isolated regions with a smaller number of inputs in order to reduce the number of test patterns. Partitioning of the design reduces the number of exhaustive tests from 2^n (where n is the total number of inputs) to

$$\sum_{i=1}^{m} 2^{n^i}$$

where m is the number of partitions and n^i ($n^i < n$) is the number of inputs on each logic partition.

Since the use of BIST implies extremely large numbers of tests, the simulated data transfer and test measurement time is reduced greatly by the use of a compressed signature to represent the expected and actual test results. Thus, only a comparison of the simulated signatures for each BIST region needs to be made with the signatures derived by the on-chip hardware, rather than the results of each individual test pattern. This is accomplished by feeding the output bit sequence to a single input serial input LFSR after exclusive-OR with the pseudo-random pattern generated by that LFSR. In this way, a unique pattern can be observed for a sequence of test results, which is a function of the good-machine response and a pseudo-random number.

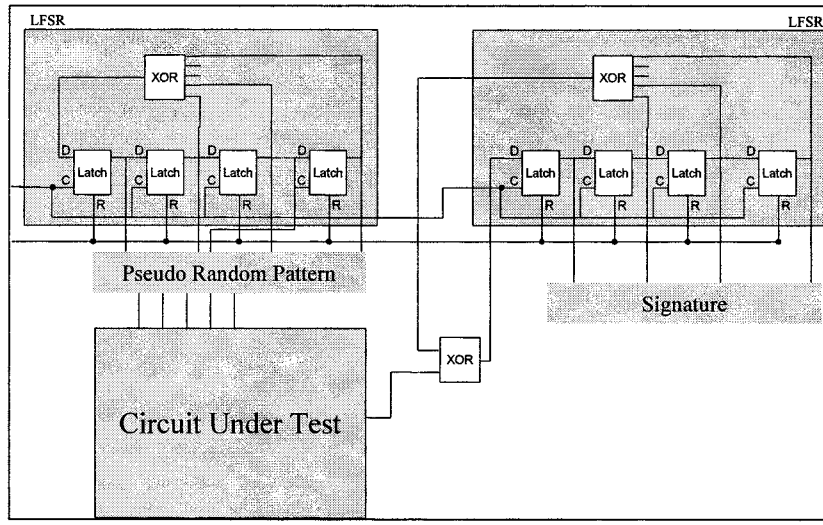

FIGURE 78.5 BIST logic.

Today, testing of ICs typically consists of combinations of different test strategies. These may include stored program stuck fault tests, BIST tests, dc and delay tests (which test for signal arrival times in addition to state), and I_{DDQ} tests (direct drain quiescent current testing checks for CMOS defects that cause current leakage). These latter two test techniques are used to detect defect conditions not identified by stuck-at fault tests such as shorts (bridging faults) between signal nets or gate oxide defects which cause incorrect device operation. The progression of inventions in stuck-fault modeling and scan design, that have taken place over the last 30 years have been key to the success in this field. Moreover, as will be seen later in this chapter, these techniques will continue to be essential ingredients for IC testing in the future.

Fault Simulation

Fault simulation is used to predict the state of a design at observable points in the presence of a defect. This is used in manufacturing testing to detect faulty parts and for field diagnostics of entire assemblies. Early work in fault simulation relied on the stuck-fault model and performed successive simulations of the design with each single fault independent of any other fault; thus a single stuck-at-fault model was assumed. Because even these early designs consisted of thousands of faults, it was too time-consuming to simulate each fault serially, and it was necessary to create high-speed simulation algorithms.

For manufacturing testing, fault simulation took advantage of three-valued zero-delay simulation. The simulation model of the design was levelized and compiled into an executable program. Levelization assured that driver-gates were simulated before the gates receiving the signals, thus allowing a state resolution in a single simulation pass. Feedback loops were cut and the X-transition of three-valued simulation resolved race conditions. The inherent instruction set of the host computer (such as AND, OR, XOR, etc.) allowed the use of a minimum set of instructions to simulate a gate's function.

The parallel-fault simulation algorithm was developed during the 1960s, which allowed many faults to be simulated in parallel. Using the 32-bit word length of the IBM 7090 computer architecture, for example, simulation of 31 faults in a single pass (using the last bit for the good-machine) was possible. For each gate in the design, two host machine words were assigned to represent its good-machine state and the state for 31 single stuck-at faults. A bit position in the first word was set to one or zero to represent the state of the node represented for the good or faulty machine, which that bit position represented. The corresponding bit position in the second word was set to zero if it was a known state and one if it was an X-state. The entire fault list was divided into n partitions of 31 faults, and each partition was then simulated against all input patterns. In this way, the run-time for simulation is a function of

$$\sum_{i=1}^{n=F/31} Patterns$$

where, F is the total number of single stuck-at faults in the design. Specific faults are injected within the word representing their location within the design by the insertion of a mask that is AND'd or OR'd at the appropriate word. For stuck-at-one conditions, the mask contains a 1-bit in the position representing the fault (and 0-bits at others) and it is OR'd to the gate's memory location. For stuck-at-zero faults, the mask contains a 0-bit at the positions representing the fault (and 1-bits at others) and it is AND'd with the gate's memory location.

As the level of integration increased, however, so did the number of faults. The simulation speed improvement realized from parallel-fault simulation is limited to the number of faults simulated in parallel and because of the algorithm overhead, it was typically less than that factor. Also, during the 1970s the challenges to testing became those of the IC, which was major because of the rapidly increasing circuit density. However, the IC also allowed relaxed goals in test.

When manufacturing testing is performed on PCB packages, it is desirable to not only detect the presence of a fault, but also to isolate it to the faulty module, which can then be replaced. With IC's the notion of fixing faulty parts is not realistic. To isolate faults to a particular replaceable unit, it is necessary to simulate all generated tests against all faults exhaustively. When fault detection is the only goal, a fault-machine need only be simulated up to the point where it is detectable at an observable pin and need not be simulated against any other patterns. Parallel-fault simulation did not lend itself to be able to drop out simulation of detected faults because even when individual faults within a word were detected, others were not, thus, simulation of the entire set had to continue. Only when all faults in the word were detected could simulation of that parallel set cease. This, coupled with the limiting factor of a speedup of the number of parallel faults, led to the development of event-based fault simulation and improved algorithms.

Deductive-fault simulation was developed early in the 1970s and required only one simulation pass per test pattern. This is accomplished by simulating only the good-machine behavior and using deductive techniques to determine each fault that is detectable along the simulated paths. Because lists of faults detectable at every point along the simulated path need to be kept, this algorithm requires extensive memory, far more than the parallel algorithm. However, with increasing memory on host computers and the inherent increase in fault simulation speed, this technique won the favor of many fault simulators.

Concurrent-fault simulation refined the deductive algorithm by recognizing the fact that paths in the design quickly become insensitive to the presence of most faults, particularly after some initial set of test patterns is simulated. [An observation made in the 1970s was that a high percentage of faults is detected in a low percentage of the initial test patterns, even if these patterns are randomly generated.] The concurrent-fault simulation algorithm simulates the good-machine and "concurrently" simulates a number of fault-machines. Once it is determined that a particular fault-machine state is the same as the good-machine state, simulation for that fault ceases. Since in logic paths most faults will become insensitive rather close to the point where the fault is located, the amount of simulation for these fault machines was kept small. This algorithm required even more memory, particularly for the early test patterns; however, host machine architectures of the late 1970s were supporting what then appeared as massive amounts of addressable memory.

With the use of scan-design, all sequential elements are controllable from the tester. Therefore, the design can be simulated as a combinational circuit and its state is deterministic based on any single test pattern — and not dependent of previous patterns or states. Parallel-Pattern fault simulation was developed in the late 1970s to take advantage of this and simulate multiple test patterns in parallel against a single fault. A performance advantage is achieved because compiled simulation could again be utilized as opposed to the more general event-based approach. In addition, because faults not detected by the initial test patterns are typically detectable by only a few patterns, simulation of many sets of patterns does not require a complete pass across the design. In most cases, the required sensitized path to detect these faults disappears within a close proximity to the fault. Adjustment of the number of patterns to simulate in parallel, therefore, could effect the required simulation time.

Because of the increasing number of devices on chips, the test generation and fault simulation problem continued to face severe challenges. During the 1980s, BIST began to evolve as a method for manufacturing testing. Use of circuitry on the IC itself to generate test vectors meant that exhaustive tests could be generated and exercised at the tester. With exhaustive tests, and no need to provide fault isolation diagnostics, fault simulation can be eliminated. With BIST approaches to testing, only the good machine behavior needs to be simulated and compared with the actual results at the tester. To decrease the amount of data passed from the simulation to the tester and the time on the tester, special hardware is designed on the chip to capture the results and compress them into a single value (signature). This signature is compared with the simulated signature only at the end of a sequence of tests, thus minimizing the number of comparisons required.

Physical Design

As with test generation, physical design has evolved from early work on PCBs. Physical design (PD) automation programs generate the physical routing (wiring) for the interconnections of the logical nets in a design. To accomplish this, the suite PD programs must be capable of assigning physical package pins (pin assignment) to nets, placing logic functions (placement) on the package, and performing myriad electrical and topographical checks to assure the quality of the solution. The challenge for PD has become ever greater since the early days. It started with PCBs, where the goal was simply to route all the nets, typically with the shortest paths. Any nets that were not auto-routed were routed (embedded) manually, or with discrete wires as a last resort. As the problem moved to ICs, the ability to use discrete wires to finish routing was no more. For nets that could not be auto-routed, manual routing (embedding) was required. Now, wiring congestion in areas on the IC had to be considered by PD programs. Too much congestion in an area could block the passage of more wires through that area and complicate or negate a possible solution, and less than a 100% solution is unacceptable. As the IC densities increased, so did the number of nets. This necessitated the invention of smarter wiring programs and heuristics, for even a small number of incomplete (overflow) routes became too complex of a task for manual solutions.

Later, as IC device sizes shrank and the gate delays decreased, the delay caused by interconnect wiring became an important factor. No longer was any wiring solution that connected the nodes on the nets necessarily a correct solution. Now, the wiring problem was complicated by the need to find wiring solutions that fall within acceptable timing limits. Thus, the wiring lengths and thickness need to be considered. As IC features become packed closer together, cross-coupled capacitance (crosstalk) effects between them is now an important consideration as well. For advanced ICs even today, effects of cross coupling have expanded into a three-dimensional space.

As if this challenge were not enough, the decrease in power supply (V_{dd}) voltage levels with smaller, more closely spaced features has introduced a new problem with which physical design must contend. This is called noise, the unwanted introduction of voltage on a signal. Noise can cause both increases in signal delays and incorrect logical behavior. Noise is a function of both the physical layout of the design and the signal switching characteristics. It results from design factors such as signal termination, simultaneous switching of circuits, and crosstalk between adjacent lines. These conditions result from characteristics such as spacing between signal lines, switching frequency, rise times, cross-sectional area of wires, etc. Design tools for PCBs and multi-chip modules have had to contend with noise for some time.

However, it is now becoming a significant factor in the design of ICs. Future PD solutions must consider these complex factors and still achieve a 100% solution that meets the designer specified timing for IC designs that contain millions of nets.

Because of these increasing demands on PD, major paradigm changes have taken place in design methodology. In the early days, there was a clear separation of logic design and physical design. The logic designer was responsible to create a netlist that correctly represented the logic behavior desired. Timing was a function of the drive capability of the driving circuit and the number of receivers. Different power levels for drivers could be chosen by the logic designer to match the timing requirements, based on the driven circuits. The delay imposed by the time-of-flight along interconnects and due to the parasitics on the interconnect was insignificant. Therefore, the logic designer could hand-off the physical design to another, more adept at using the PD programs and manually embedding overflow wires. As the semiconductor technology progressed, however, there needed to be more interactions between the logic designer and the physical designer, as the interconnect delays became a more dominant factor across signal paths. The logic designer had to give certain timing constraints to the physical designer, and if these could not be met, the design was often passed back to the logic designer. The logic designer, in turn, had to choose different driver gates or a different logical architecture to meet his design specification. In many cases, the pair had to become a team or there was a merger of the two previously distinct operations into one "IC designer."

This same progression of merging logic design and physical design into one operational responsibility has also begun at the EDA system architecture level. In the 1960s and 1970s, front-end (design) programs were separate from back-end (physical) programs. Most often they were developed by different EDA development teams, and designs were transferred between them by means of data files. Beginning in the 1980s and into today, the data transferred between front-end programs and back-end included specific design constraints that must be met by the PD programs — the most common being a specific amount of allowed delay across an interconnect or signal path. As the number of constraints that must be met by the PD programs increases, however, the likelihood that a 100% solution can be found is less and less. This results in additional design cycles between front-end and back-end programs coupled with longer processing times within any cycle. This will result in another necessary paradigm shift in the architecture and design of physical design systems and algorithms, which will be discussed in more detail later in this chapter.

Ignoring the complexities of checking and electrical constraints that modern-day physical design programs have to deal with, however, many of the fundamental wiring heuristics and algorithms spawned from work done in the 1960s for PCBs.

Before global routing is performed, placement of the modules, cells, or gates is performed. Early placement algorithms were developed to minimize the total length of the interconnect wiring using Steiner Trees and Manhattan wiring graphs. In addition, during these early years, algorithms were developed to analyze wiring congestion that would occur as a result of placement choices and minimize it to give routing a chance to succeed. Later work in the 1960s led to algorithms that performed a hierarchical division of the wiring image and performed global wiring between these subdivisions (then called cells) before routing within the cells.[6] This divide and conquer approach simplified the problem and led to quicker and more complete results. Min-cut placement algorithms often used today are a derivative of this divide and conquer approach. The image is divided into partitions and placement of these partitions are swapped to minimize interconnect length and congestion. Then, placement is performed within the partitions using the same objectives. Many current placement algorithms are based on these early techniques although they need to consider more constraints, such as crosstalk, timing requirements, and power dissipation.

Development of efficient maze routing algorithms also began in the 1960s, and many of today's routers use enhanced derivatives of these early techniques. The Lee algorithm[7] finds a solution by emitting a "wave" out from both the source and target points to be wired. This wave is actually a ordered identification of available channel positions — where the available positions adjacent to the source or destination are numbered 1, and the available positions adjacent to them are numbered 2, etc. Successive moves and

sequential identification is made (out in all directions as would a wave) until the source and destination moves meet (the waves collide). Then a backtrace is performed from the intersecting position in reverse sequential order along the numbered track positions back to the source and destination. At points where a choice is available (that is, there are two adjacent points with the same order number), the one which does not require a change in direction is chosen.

Other techniques, such as the Hightower Line-Probe technique,[8] were developed during this period and speeded up maze routing by use of emanating lines rather than waves. This algorithm emanated a line out from both the source and destination points toward each other. When either line encounters an obstacle, then another line is emanated from a point just missing the edge of the obstacle on the original line at a right angle to the original line, and toward the target or source. Thus, the process is much like walking blindly in an orthogonal line toward the target and changing direction only after bumping into a wall. This process continues until the lines intersect at which time the path is complete.

In today's ICs, the challenge of completed wiring that meets all constraints is of crucial importance. Unlike test generation, which can be considered successful when a very high percentage of the faults are detected by the test patterns, 100% of the nets must be wired. Further 100% of the wires must fall within the required electrical and physical design constraints; nothing less than 100% is acceptable. Today these constraints include timing, power consumption, noise, and electromigration, and this list will become more complex as IC feature sizes and spacing are reduced further.

The 1970s — The Awaking of Verification

Before the introduction of LSI components it was common practice to build prototype hardware and then verify the design correctness. PCB packages containing small-scale integrated modules allowed for engineering rework of real hardware within the verification cycle. Prototype PCBs were built, and engineering used drivers and oscilloscopes to determine whether the correct output conditions resulted from input stimuli. As design errors were detected, they were repaired on the PCB prototype, validated, and recorded for later engineering change (EC) into the production version of the design. Use of the wrong logic function within the design could easily be repaired by replacing the low cost component(s) in error with the correct one(s). Incorrect connections could easily be repaired by cutting a printed circuit and replacing it with a discrete wire (as opposed to a printed circuit). Using wire-wrap tools, these discrete wires could easily connect the desired pins of the modules on the PCB. Thus, design verification was a sort of trial and error process and the final rework of a PCB could contain hundreds of these wires.

The introduction of LSI drastically changed the design verification (DV) paradigm. Although use of software simulation to verify design correctness began during the 1960s, it was not until the advent of LSI that this concept became widely accepted. With LSI, it became impossible to accurately model the design with a populated PCB, and it was not possible to rework gates and wires on the chip. Thus, the 1970s are best represented as a quantum leap into software design verification and verification before manufacture. This represented a major paradigm shift in electronic design, and it was a difficult change for some to accept. Design verification on hardware prototypes resulted in a tangible result that could be touched and held. It was a convenient tangible, which could be shown to management to represent real progress. Completed design verification against a software model did not produce the same level of touch and feel. Further, since the use of computer models was a relatively new concept, it met with the distrust of many. However, the introduction of LSI demanded this change and today, software design verification is commonly accepted practice for all levels of electronic components, subassemblies, and systems.

Early DV simulators simulated gate-level models of the design with two-valued simulation. Since gates had nearly equal delays and the interconnect delay was insignificant by comparison, use of a unit delay value of each gate was common. Later simulators exploited the use of three-valued simulation to resolve race conditions and identify oscillations within the design more quickly. With the emergence of LSI, however, these simple models had to become more complex, and simulators had to become more flexible and faster much faster. In the first half of the 1970s, important advances were made to design verification simulators that included

- Use of abstract (with respect to the gate-level) models to improve simulation performance and allow for verification throughout the design cycle (not just at the end)
- More accurate representations of gate and interconnect delays to enhance the simulated accuracy

In the latter half of the decade, significant contributions began as a result of design constraints such as scan design, which reduced the problem to combinational circuits. During this period work began on separating functional characteristics from timing, and more formal approaches verification. However, the fundamental DV tool is simulation, and the challenge to make simulators faster and more flexible continues even today.

Simulation

Although some early DV simulators used compiled models, these quickly gave way to interpretative event-driven approaches. Compiled simulators have the advantage of higher-speed simulation of individual gates because host machine instructions are compiled in-line and are directly executed with minimum simulator overhead. Event-based simulators require more overhead to manage the simulation operations, but they provide a level of flexibility and generality not possible with the compiled model. This flexibility was necessary to provide for simulation of timing characteristics as well as function, and to handle general sequential designs. Therefore, this approach was generally adopted for DV simulators over the compiled approach used by early fault simulators. There are four main concepts to an event-based simulator:

- The Netlist, which provides the list of blocks (gates at first, but any complex function later), connections between blocks, and delay characteristics of the blocks.
- Event time queues, which are lists of events that need to be executed (blocks that need to be simulated) at specific points in [simulation] time. Event queues contain two types of events — update and calculate. Update events change the specified node to the specified value, then schedule calculate-events for the blocks driven from that node. Calculate events call the simulation behavior of the specified block and, on return from the behavior routine, schedule update events to change the states on the output nodes to the new values.
- Block simulation behavior (the instructions that, when passed the block's input states will compute its output states — possibly also scheduling some portion of itself to be simulated at a later time).
- Value list — the current state of each node in the design.

Simulation begins with the stimulus generator, which schedules update events in the time-zero queue. After all update events are stored for all time-zero stimuli, the time-zero event queue is traversed and, one-by-one, each update event in the queue is executed. Update events update the node in the value list and, if the new value is different from the current value, schedule calculate events for blocks driven from the updated node. These calculate events may be placed back in the time-zero queue or in other time queues based on delay specifications (which will be discussed later). After all update events are executed and removed from the queue, the simulator traverses the queue, selects the next calculate event, interprets its function, and passes control to the appropriate block simulation behavior for calculation. Thus, event-based simulation is interpretative as opposed to the compiled simulator, which is ignorant of the function because it is compiled in-line with host instructions.

Execution of a calculate event causes simulation of a block to take place. This is accomplished by passing control to the simulation behavior of the block with pointers to the current state-values on its inputs (in the value list). When complete, the simulation routine of the block will pass control back to the simulator with the new state condition for its output(s). The simulator then schedules the block output(s) value update by placing an update event for it in the appropriate time queue. The decision of which time queue the update events are scheduled within is based on what the delay value is for the block.

Once all calculate events are executed and removed from the queue, the cycle begins again, but first the stimulus generator is again called. The stimulus generator may store new update-events in the next time queue or (if required) insert a new time queue for a time between the present and that of the next existing queue. Then the process of executing update events followed by calculate events for the current time queue repeats. This cycle repeats until there are no more events or until some specified maximum

simulation time. To keep update events separated from calculate events within the linked-list queues, it is common to add update events at the top of the linked-list and calculate events at the bottom, updating the chain-links accordingly.

Because it is not possible to predetermine how many events will reside in a queue at any time, it is common to create these as linked lists of dynamically allocated memory. Additionally, time queues are linked, since the required number of time queues cannot be determined in advance and similar to events. New time queues can be inserted into that chained list as required.

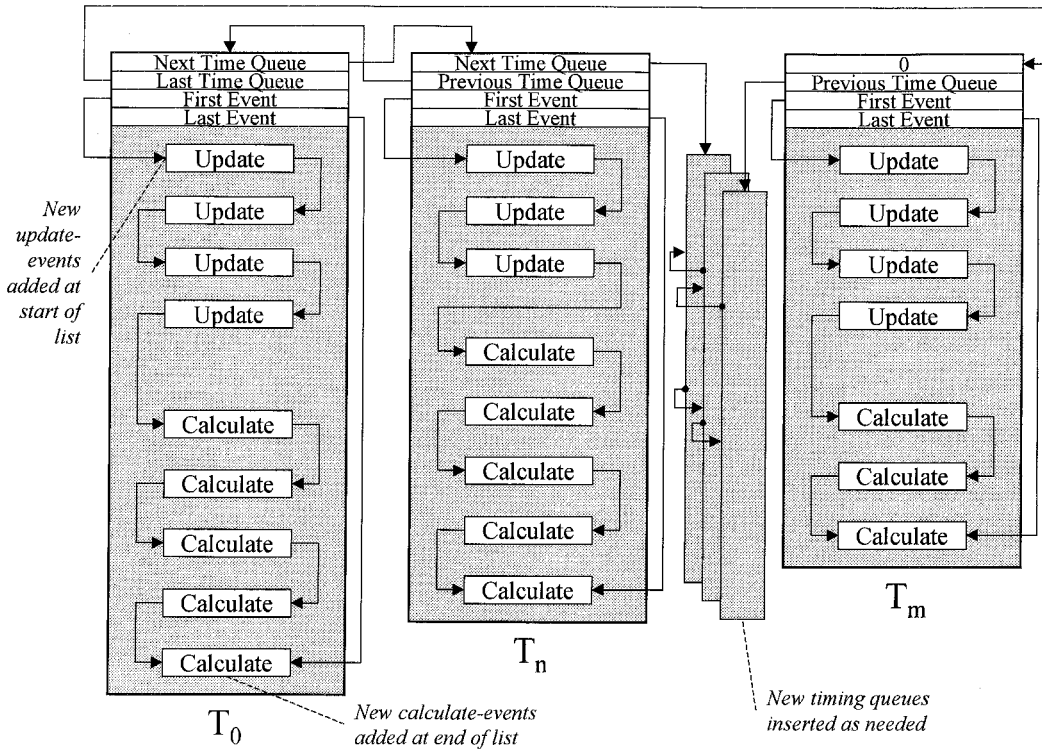

FIGURE 78.6 Event queues.

A number of techniques have been developed to make queue management fast and efficient, as it is the heart of the simulator, and because of its generality, the event-based algorithm was the clear choice for DV. One advantage of event-based simulation over the compiled approach is that it easily supports the simulation of delay. Delays can be assigned to blocks, and they are simulated by choosing the appropriate time queue(s) in which to schedule the update event(s) for the block output(s) change. Delays can be assigned to nets, and they are simulated by choosing the appropriate time queues in which to schedule calculate events for the fan-out nodes. (Note that this allows different delays to be associated with each path in the net as receiver block calculation events can be scheduled in different time queues.) Therefore, even early simulators typically supported a very complete delay model, even before sophisticated delay calculators were available to take advantage of it.

The delay model included

- Intrinsic block delay (T_{block}) — the time required for the block output to change state relative to the time that a controlling input to that block changed state.
- Interconnect delay (T_{int}) — the time required for a specific receiver pin in a net to change state relative to the time that the driver pin changed state.
- Input-output delay (T_{io}) — the time required for a specific block output to change state relative to the time the state changed on a specific input to that block.

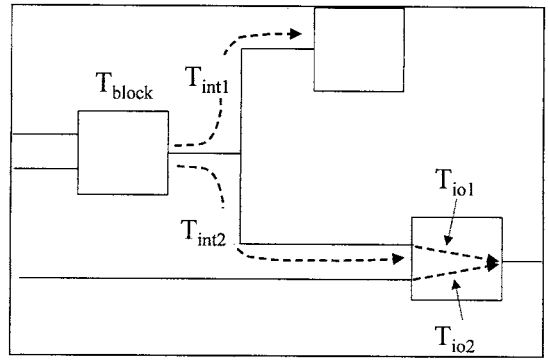

FIGURE 78.7 Simulation delay types.

Treatment of delay has had to evolve and expand since the beginnings of software DV. Unit delay was the first model used — where each gate in the design is assigned one unit of delay and interconnect delays are zero. This was a crude approximation but allowed for high-speed simulations because of the simplifying assumptions and it worked reasonably well. As the integrated circuit evolved, however, the unit delay model was replaced by a lumped delay model in which each gate could be assigned a unique value for delay — actually, a rise-delay and a fall-delay. This was assigned by the technologist based on some average load assumed. At this time, also, the beginnings of development of delay calculators began. These early calculators used simple equations, adding the number of gates driven by the gate being calculated and then adding the additional delay to the intrinsic delay values of that gate. As interconnect wiring became a factor in the timing of the circuit, the pin-to-pin delay came into use. At first, delay calculation for the interconnect contribution to delay was crude, associating a fixed value for pin-to-pin delay for very long interconnects. Today's ICs, however, require delay calculation based on very accurate, distributed RC-models for interconnects, as these delays have become more significant with respect to gate delays. Tomorrow's ICs will require even more precise modeling for delays, as will be discussed later in this chapter, and consider inductance (L) in addition to the RC parasitics. Additionally, transmission line models will be necessary for the analysis of certain critical global interconnects. However, the delay model defined in the early years of DV and the capabilities of the event-based simulation algorithm stand ready to meet this challenge.

Another significant advantage of the event-based simulation algorithm commonly used today evolved from development that began in the early 1970s. This is the mixed-level simulation model. Recall that one of the fundamental components of event simulation is the Block Simulation Behavior. A calculation-event for a block passes control to the sub-routine that simulates the behavior along with the block's input states. For gate-level simulation, these behavior subroutines are quite simple: AND, OR, NOR, etc. However, since the behavior is actually a program sub-routine, it can be arbitrarily complex as well. Realizing this, early work took place to generalize the interface between the simulator control program and the Block Simulation Behavior. A small number of functional-level commands were formalized to access input states, schedule execution at a specific entry to the behavior for a later time, and update the block output states. Thus, a Block Simulation Behavior might look like the following:

```
FUNCTION (CNOR);
/* Complimentary output NOR function with 3 inputs. Input delay  = 2,
   intrinsic delay for true output = 10, intrinsic delay for complement
   output = 12*/
INPUT (a,b,c);/*Declare for inputs a, b, c*/
OUTPUT (x,y);
DECLARE input1, input2, input3;/*Declare storage for inputs*/
DECLARE out, cout;/*Declare storage for outputs*/
GET a,input1, b,input2, c,input3;
```

```
DELAY 2, Entry1;
Entry1: out = input1|input2|input3;
cout = ¬out;
DELAY 10,(x = out);/*Schedule this update-event for 10 time units later */
DELAY 12 (y = cout);/*Schedule this update-event for 12 time units later */
END Entry1;
ENDCNOR;
```

Sophisticated use of these behavorial commands supported the direct representation not only for simple gates, but also for complex functions such as registers, MUXs, RAM, ROS, etc. In doing so, simulation performance was improved because what before was treated as a complex interconnection of gates could now be simulated as a single block.

By generalizing the simulator system, block simulation routines could be loaded at simulation run-time if required (by the use of a block with that function in the netlist) and dynamically linked with the simulator control program. This meant that the block simulation behaviors could be developed by anyone, compiled independently of the simulator, stored in a library of simulation behavioral models, and used as needed in simulation. This is common practice in DV simulators today, but this concept in the early 1970s represented a significant breakthrough and supported a major paradigm shift in design — namely, the concept of top-down-design and verification.

With top-down-design, the designer no longer had to design the gate-level netlist before verification could take place. Now, high-level models could be written to represent the behavior of sections of the design not yet complete, and they could be used in conjunction with gate-level descriptions of the completed parts to perform full system verification. Now, simulation performance could be improved by swapping in the use of gate-level models or behavior models for system elements based on what the verification goals were. Now, concurrent design and verification could take place across design teams. And now there was a formal method to support design reuse of system elements without the need to expose internal design details for reusable elements. In the extreme case, the system designer could write a single functional model for the entire system and verify it with simulation. The design could then be partitioned into sub-system elements, and each could be described with a behavorial model before being handed off for detailed design. During the detailed design phase, individual designers could verify their sub-system in the full system context even before the other sub-systems were completed. This was particularly valuable for generation of the functional patterns to be simulated, as they could now be generated by the simulation of the other system components. Thus, verification of the design no longer had to wait until the end; it could now be a continuous process throughout the design.

Throughout the period, improvements were made to DV simulators to improve performance in the formulation and capability of behavorial description languages. In addition, designers found more and more novel ways to use behavorial models to describe non-digital system elements such as card readers, and analog assemblies. For analog devices, the digital-to-analog interface was modeled on entry to the behavior and the analog-to-digital interface when returning to the simulator, as well as the analog behavior within the modeled element. Punch-card reader behavior could be modeled with software that would access stored memory containing the data on the simulated cards and return the bit patterns back to the simulator — on the proper nodes and at the proper simulation times. Late in the 1970s and across the 1980s, this was formalized into:

- VHDL[9] (VHSIC [Very High speed Integrated Circuit] High-Level Description Language), sponsored by DARPA, and
- Verilog,[10] a commercially developed RTL-level description language.

These two languages are now both industry-accepted standard hardware-description languages. Simulator performance improved by means of creative queue algorithms and the use of compiled representations of standard functions, etc. Additionally, methodologies and tools were developed to compare simulated results of simulations against the high-level models with those of the detail-level designs at

selected outputs, and top-down-design verification using event-based simulation became common practice. This was a natural evolution for large system designers. It was, however, the introduction of synthesis and the commercial ASIC that evolved in the 1980s that made its use the norm today.

With the advent of structured scan design, such as LSSD, the use of compiled simulation returned for verification of the combinational sections of the design between scan latches. A simulation technique, called cycle-simulation, was developed that yielded a major performance advantage over event-based simulation. Cycle-simulation treats the combinational sections of a scan-based design as compiled zero-delay models. The simulator executes each section at each simulated cycle by passing control to the compiled routine for it along with its input states. The resulting state values at the outputs of these sections are assumed to be correctly captured into their respective latch positions. That is, the clock circuitry and path delays are assumed correct and are not simulated during this phase of verification. The (latched) output values are used as the input states to the sections they drive at the next cycle, and the process repeats for the each simulated cycle. Each simulation pass across the compiled models represents one cycle of the design's system clock, starting with an input state and resulting in an output state. To assure only one pass is required, the gates or RTL-level statements for the combinational sections are levelized before compilation into the host-machine instructions. This assures that value updates occur before calculations, and only one pass across a section of the model is required to achieve the correct state response at the outputs.

Simulation performance was greatly improved with cycle-simulation because of the compiled model and because the clock circuitry did not have to be simulated repeatedly with each simulated-machine cycle. Early cycle-simulators were developed on mixed-level event simulators and by unique implementations. For cycle-simulation on top of event simulators, the design model consisted of a netlist containing an interconnected set of the combinational sections. Each of the combinational sections was described in an RTL-level language and treated as a general compiled behavioral model by the simulator. The event simulator operated as normal, except that the control program precluded simulated state changes at the outputs of simulated models were not propagated to the inputs of the driven sections until the start of the next simulated clock cycle. Later implementations used look-up table models[11] in place of compiled in-line host instructions, which provided additional speed improvements, as they did not require the execution of compiled host-instructions for every element within a combinational logic section for each cycle.

Cycle-simulation did not completely replace event simulation, as the clock circuitry needs to be verified. Its use, however, was effective for control logic of synchronous computer designs. Cycle-simulation is less useful of dataflow circuitry and not useful for unstructured asynchronous designs. It requires use of structured design constraints so the design can be viewed as combinational. Thus, its use was limited to a few companies with designs large enough to justify the perceived overhead of the design constraints. However, early use of cycle-simulation was very effective for many large systems and these early developments provided the foundations for modern cycle-simulators that are now beginning to gain acceptance for complex ICs.

Simulation has a couple of severe inherent problems. First, unlike test generation or physical design, there is no precise measure of completeness. Test generation has the stuck-fault model, and physical design has a finite list of nets that must be routed. However there was no equivalent metrics to determine when verification of the design is complete, or when enough simulation is done. During the 1970s, research began to develop a metric for verification completeness, but to this day none has been generally accepted. Use is made of minimum criteria, such as all nets must switch in both directions, and statistical models using random patterns. Recent work in formal verification is applying algorithmic approaches to validate coverage of paths and branches within the model. However, the generally accepted goal is to "do more." Second, it is a hard and time-consuming task to create effective simulation vectors to verify a complex design. DV simulators typically support a rich high-level language for the stimulus generator, but it still requires the thought, experience, and ingenuity of the design verification engineer to develop and debug these programs. Therefore, it is desirous to simulate the portion of the design being verified in as much of the total system environment as possible and have the simulation create functional stimulus for the portion to be verified. Likewise, it is hard to validate the simulated results for correctness, making it desirable to use them in the

full system environment where it is easier to validate them. Ideally, the owner of an ASIC chip being designed for a computer could simulate that chip within a model of all of the computer's hardware, the microcode, and the operating system, and use example software programs as the ultimate simulation experiment. To even approach this goal, however, the simulators have to become faster and faster.

During the 1980s, research and development took place on custom hardware simulators and accelerators. Special purpose hardware-simulators use massively parallel instruction processors with much customized instruction sets to simulate gates. These provide simulation speeds that are orders of magnitude faster than software simulation on general-purpose computers. However, they are expensive to build, lack the flexibility of software simulators, and the hardware technology they are built in soon becomes outdated (although general parallel architectures may allow the incremental addition of additional processors). Hardware accelerators use custom hardware to simulate portions of design in conjunction with the software simulator. These are more flexible, but they still have the inherent problems that their big brothers have. Nonetheless, use of custom hardware to tackle the simulation performance demands has gained acceptance in many companies and they are commercially available today using both gate-level and HDL design descriptions.

Timing Analysis

The practice of divide and conquer in design verification started in the 1970s with the introduction of the behavorial model. Another divide-and-conquer style born in the 1970s, that has become generally popular in the 1990s, is to separate verification of the design's function from its timing. With the invention of scan design, it became possible to verify logic as a combinational circuit using high-speed compiled cycle-simulators. Development of path tracing algorithms to verify timing resulted in a technique to verify timing without simulation, thus providing a complete solution rather than an experimental one. This became known as static timing analysis. Static timing analysis (TA) is used to analyze signal paths from primary inputs to latches, latches to latches, latches to primary outputs, and primary inputs to primary outputs. At each gate, the TA program computes the min-max time that gate will change in state based on the min-max arrival times of its input signals. TA tools do not simulate the gate function; they add only its contribution to the path delay, although the choice of using rise or fall times for the gate is based on whether it has a complimentary output, or not. Because the circuitry between the latches is combinational, only one pass needs to be made across the design. The addition can be based on the minimum rise or fall delay for gates or both, providing a min-max analysis. The designer specifies the required arrival times for paths at the latches or primary outputs, and the TA program compares these with the actual arrival times. The difference between the required arrival and the actual arrival is defined as slack. The TA tool computes the slack at the termination of each path, sorts them numerically, and provides a report. The designer then verifies the design correctness by analysis of all negative slacks.

Engineering judgment is applied during the analysis, including the elimination of false-path conditions. A false-path is a signal transition that will never occur in the real operation of the design. Since the TA tool does not simulate the behavior of the circuit, it cannot automatically eliminate all false paths. Through knowledge of the signal polarity, TA can eliminate false paths caused by the fan-out and reconvergence of certain signals. However, other forms of false-paths are only identifiable by the designer.

Formal Verification

Development of a formal method to verify the equivalence of two different representations of a design began during the 1970s. Boolean verification analyzes a circuit against a known good reference and provides a mathematical proof of equivalence. An RTL model, for example, of the reference circuit is verified using standard simulation techniques. The Boolean verification program then compiles the known-good reference design into a canonical NAND-NOR equivalent circuit. This equivalent circuit is compared with the gate-level hardware design using sophisticated theorem provers to determine equivalence. User controls map the logically corresponding design signals in the RTL to their equivalent node in the gate-level model. To reduce processing times, formal verification pre-processes the two circuits to create an overlapping set of smaller logic cones to be analyzed. These cones are simply the set of logic

traversed by backtracing across the circuit from an output node (latch positions or primary outputs) to the controlling input nodes (latch positions or primary inputs). User controls specify the nodes that are supposed to be logically equivalent between the two circuits.

Early work in this field explored the use of test generation algorithms to prove equivalence. Two cones to be compared can be represented as $F_{cone1} = f$(a,b,c,X,Y,Z..) and $F_{cone2} = f$(d,e,f,.,X′,Y′,Z′..). F_{cone1} and F_{cone2} are user defined output nodes to be compared for equivalence. The terms a,b,c and d,e,f represent the set of input nodes for the function, and X,Y,Z are the computational sub-functions. User input defines the equivalence between a,b,c and d,e,f. If F_{cone1} and F_{cone2} are functionally equivalent, then the value at of G must be 0 for all possible input states. If the two cones are equivalent, then use of D-ALG test generation techniques for G = F_{cone1} XOR F_{cone2} will be unable to derive a test for the stuck-at-zero fault on the output of G. Similarly, the use of random pattern generation and simulation can be applied to prove equivalence between cones by observing the value on G for all input states.

Research across the 1980s provided improvements in Boolean equivalence checking techniques and models (such as binary decision diagrams), and modern Boolean equivalence checking programs may employ a number of mathematical and simulation algorithms to optimize the overall processing. However, Boolean equivalence checking methods require the existence of a reference design against which equivalence is proved. This implies there must be a complete validation of the reference design against the design specification. Validating the reference design has typically been a job for simulation. However, this leads to the problems of assuring coverage and completeness of the simulation experiment. Consequently, formal methods to validate the correctness of functional-level models have become an important topic in EDA. Modern design validation tools use a combination of techniques to validate the correctness of a design model. These typically include techniques used if software development to measure completeness of simulation test cases, such as

- checking for coverage of all instructions [in the model]
- checking to assure all possible branch conditions [in the model] were exercized.

They may also provide more formal approaches to validation, such as

- checking [the model] against designer asserted conditions (or constraints) that must be met
- techniques that construct a proof that the intended functions are realized by the design.

These concepts and techniques continue to be the subject of research and will gain more importance as the size of IC designs stretch the limits of simulation based techniques.

Verification Methodologies

With the use of structured design techniques, the design to be verified can be treated as a set of combinational designs. With the arsenal of verification concepts that began to emerge during this period, the user had many verification advantages not previously available. Without structured design, delay simulation of the entire design was required. Use of functional models intermixed with gate-level descriptions of subsections of the design provided major improvements, but it was still very costly and time-consuming. Further, to be safe, the practical designer would always attempt to delay simulate the entire design at the gate-level.

With structured design techniques, the designer could do the massive simulations at the RTL level, focusing on the logic function only, without regards for timing. Cycle-simulation improved the simulation performance by one to two orders of magnitude by eliminating repetitive simulations of the clock circuitry and use of compiled (or table look-up) simulation. For some, the use of massively parallel hardware-simulators offered even greater simulation speeds — the equivalent of hundreds of millions events per second. Verification of the logic function of the gate-level design could be accomplished by formally proofing its equivalence with the simulated RTL-level model instead of additional simulation. Static timing analysis provided the basis to verify the timing of all data paths in a rigorous and methodical manner. Functional and timing verification of the clock circuitry could be accomplished with the standard delay-simulation techniques using the event simulator. Collectively, these tools and techniques provided

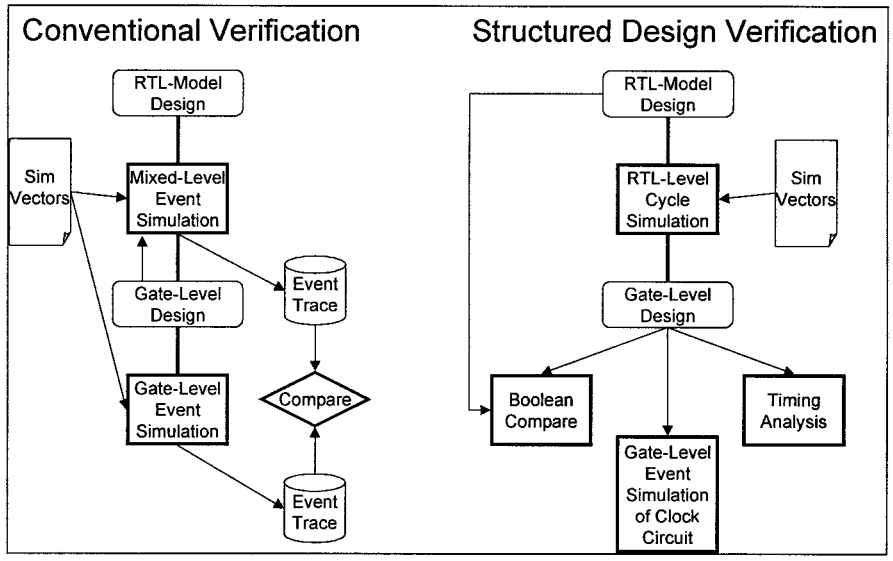

FIGURE 78.8 Verification methodology.

major design productivity improvements. However, the IC area and performance overhead required for these structured design approaches limited the number of designs taking advantage of them. Across the 1980s, as the commercial EDA business developed, these new verification tools and techniques remained as in-house tools in a few companies. Commercial availability did not emerge until the 1990s when the densities and complexities of ICs began to demand the change.

The 1980s — Birth of the Industry

Up to the 1980s design automation was, for the most part, developed in-house by a small number of large companies for their own proprietary use. Almost all EDA tools operated against large mainframe computers using company-specific interfaces. High-level modeling languages were unique and most often proprietary, technology rules formats were proprietary, and user interfaces were unique. As semiconductor foundries made their manufacturing lines available for customer-specific chip designs, however, the need for access to EDA tools grew. With the expansion of the application specific integrated circuit (ASIC), the need for commercially available EDA tools exploded. Suddenly, a number of commercial EDA companies began to emerge and electronic design companies had the choice of developing tools in-house or purchasing them from a variety of vendors. The EDA challenge now often became one of integrating tools from multiple suppliers into a homogeneous system. Therefore, one major paradigm shift of the 1980s was the beginnings of EDA standards to provide the means to transfer designs from one EDA design system to another or from a design system to manufacturing. VHDL and Verilog matured and became the industry-standard hardware description languages (HDL). EDIF[12] (Electronic Data Interchange Format) was developed as an industry standard for the exchange of netlist, and GDSII became a standard interface for shapes data to manufacturing. This was only the start of a necessary change, however. As time progressed, the need for standard interfaces between EDA tools would become evident in order to provide efficient design flows containing EDA tools from a number of different vendors.

A second paradigm shift of the 1980s was the introduction of the interactive workstation as the platform for EDA tools and systems. Although some may view it as a step backwards, the "arcade" graphics capabilities of this new hardware caught the attention of enough designers to make it a clear choice over the mainframe wherever possible. For a time, it appeared that many of the advances made in alphanumeric HDLs were about to yield to pizzazz of graphical schematic editors. Nevertheless, although the graphics pizzazz may have dictated the purchase of one solution over another, the dedicated processing, and the

ability to incrementally add compute power made the move from the mainframe to the workstation inevitable. Early commercial EDA entries such as those from Daisy (Logician) and Valid (SCALD) were developed on custom hardware using commercial microprocessors from Intel and Motorola. This soon gave way, however, to commercially available workstations using RISC-based microprocessors, and Unix became the defacto operating system standard. During the period, there was a rush of redevelopment of many of the fundamental algorithms for EDA to the workstation. However, as commercial products with the new power of high-function graphics, these applications were vastly improved along the way. Experience and new learning streamlined many of the fundamental algorithms. The high-function graphic display provided the basis for enhanced user interfaces to the applications. The commercial ASIC business provided focus on the need for technology libraries from multiple manufacturers. Finally, there was significant exploration into custom EDA hardware such as hardware simulators and accelerators and parallel processing techniques.

From an IC design perspective, however, the major paradigm shift of the 1980s was synthesis. With the introduction of synthesis, automation could be used to reduce a HDL description of the design to the final hardware representation. This provided major productivity improvements for ASIC design, as chip designers could work at the HDL level and use automation to create the details. Also, there was a much higher probability that the synthesis-generated design would be correct than for manually created schematics. The transgression from the early days of integrated circuit design to the 1980s is similar to what occurred earlier in software. Early computer programming was done at the machine language level. This could provide optimum program performance and efficiency, but at the maximum labor cost. Programming in machine instructions proved too inefficient for the vast majority of software programs, thus the advent of assembly languages. Assembly language programming offers a productivity advantage over machine instructions because the assembler abstracts up several of the complexities of machine language. Thus, the software designer works with less complexity, using the assembler to add the necessary details and build the final machine instructions. However, assembly language programming is still at a low level of abstraction. Introduction of functional level program languages and compilers provided even more productivity improvements by providing a set of programming statements that each provided function that would otherwise require many machine instructions to implement. Thus the level at which the programmer could now work was even higher, allowing him to construct programs with far fewer statements. The analog in IC design is the progression of transistor-level design (machine level), to gate level design (assembler level), to HDL-based design. Synthesis provided the basis for HDL-based design, its inherent productivity improvements, and major changes to the IC design methodology.

Synthesis

Fundamentally, synthesis is a three-step process:

- Compile a HDL description of a design into an equivalent NAND-NOR description.
- Optimize the NAND-NOR description based on design targets.
- Map the resulting NAND-NOR description to the building blocks supported for the final package.

Although work on synthesis techniques has occurred on and off since the beginnings of design automation and back to TTL-based designs, it was not until gate array style ICs reached a significant density threshold that it found production use. In the late 1970s and 1980s, considerable research and development in industry and universities took place on high-speed algorithms and heuristics for synthesis. In the early 1980s, IBM exploited the use of synthesis on ICs used in the 3090 and AS400 computers. These computers used chips that were designed from qualified sets of pre-designed functions interconnected by personalized wiring. These functions (now called cells) represented the basic building blocks for each specific IC family. The computers used a high number of uniquely personalized chip designs, so it was advantageous to design at the HDL level and use automation to compile to the equivalent cell-level detail. The result was significant improvements to overall design productivity. Today, synthesis is a fundamental cornerstone of the design methodology for ASICs (both gate-array and standard-cell) supporting both VHDL and Verilog as the standard input.

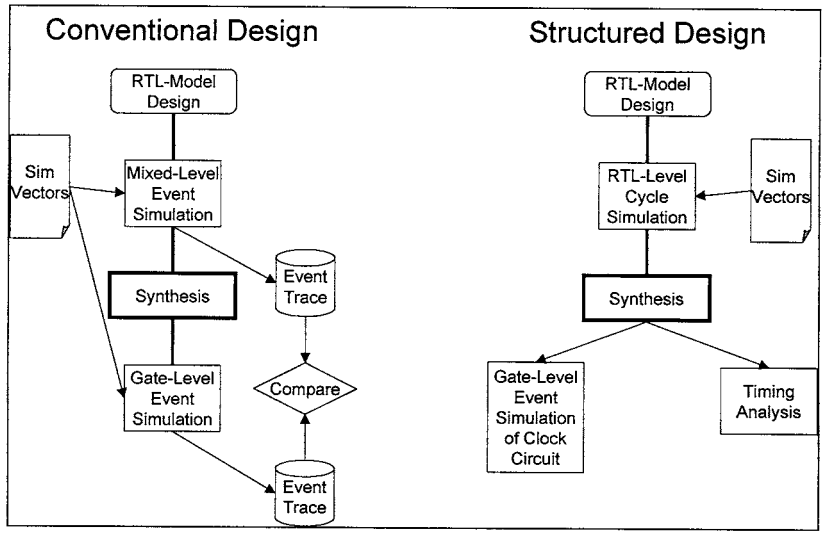

FIGURE 78.9 Synthesis methodology.

As the complexities of IC design have increased, so have the challenges for synthesis. Early synthesis had relatively few constraints to be observed in its optimization phase. Based on user controls, the design was optimized for minimum area, minimum fan-out (minimum power), or maximum fan-out (maximum performance), etc. This was accomplished by applying a series of logic reduction algorithms (transforms) that provide different types of reduction and refinement.[13] Cell behavior could also be represented in primitive-logic equivalent form, and a topological analysis could find matches between the design gates and equivalent cell patterns. The mapping phase would then select the appropriate cells based on function and simple electrical and physical parameters for each cell in the library, such as drive strength, area, etc. Early on, synthesis was not overly concerned with signal delays in the generated design or other electrical constraints that the design may be required to meet. As IC feature sizes decrease, however, these constraints are getting more demanding and automation is required to achieve them. Thus, synthesis is now required to make intelligent choices not only based on the HDL function and simple controls, but also on a number of constraints that must be met by its result.

The design input to modern synthesis tools is not the functional HDL design alone, but now includes constraints such as the maximum allowed delay along a path between two points in the design. This complicates the synthesis decision process, as it must now generate a solution that meets the required function with a set of cells and interconnections that will fall within the required timing constraints. Therefore, additional tradeoffs must be made between the optimization and mapping phases, and the effects of interconnection penalty need to be considered. Additionally, synthesis must now have additional technology characteristics available to it such as delay for cells and wiring. To determine this delay, it is necessary to understand the total load seen by a driver cell as a result of the input capacitance of the cells it drives and the RC parasitics on the interconnect wiring. However, the actual wiring of the completed IC is not yet available (since routing has not taken place) and estimates for interconnect parasitics must be made. These are often based on wire load models that are created from empirical analysis of other chip designs in the technology. These wire load models are tables that provide an estimate of interconnect length and parasitic values based on the fan-out and net density.

As interconnect delay became a more dominant portion of path delay, it became necessary to refine the wire load estimations based on more than total net count for the chip. More and more passes through the synthesis-layout design loop became necessary to find a final solution that achieved the required path delays. The need for a new design tool in the flow became apparent as this estimation of interconnect delay was too coarse. The reason is that different regions on a typical chip have different levels of real

estate (net) congestion. This means that wire load estimates differ across different regions on the chip because the average amount of wiring length for a net with a given pin count is different by region. Conversely, the actual placement of cells on the chip effect the congestion and therefore the resulting wire load models. Consequently, a new tool, called floor planning, was inserted in the flow between synthesis and layout.

Floorplanning

The purpose of floorplanning is to provide a high-level plan for the placement of functions on the chip, which is used to both refine the synthesis delay estimations and direct the final layout. In effect, it inserts the designer into the synthesis-layout loop by providing a number of automation and analysis functions used to effectively partition and place functional elements on the chip. As time progressed, the number of functions integrated into the floorplanner grew to a point where today; it is more generally thought of as design planning.[14] The initial purpose of the floorplanner was to provide the ability to partition the chip design functions and develop a placement of these partitions that optimized the wiring between them. Optimization of the partitioning and placement may be based on factors such as minimum wiring or minimum timing across a signal path. A typical scenario for the use a design planner is as follows:

- Run synthesis on the RTL description and map to the cell level
- Run the design planner against the cell-level design with constraints such as path delays and net priorities:
  - partition and floorplan the design, either automatically or manually, with the design planner
  - create wire load models based on the congestion within the physical partitions and empirical data
- Rerun synthesis to optimize the design at the cell level using the partitioning, global route, and wire load model data.

User-directed graphics and placement-wiring software algorithms are used to place the partitions and route the inter-partition (global) nets. One key to the planner is the tight coupling of partitioning and routing capability with electrical analysis tools, such as power analysis, delay calculation, and timing analysis. Checking of the validity of a design change (such as placement) can be made immediately on that portion of the design that changed. Another is that it needs to be reasonably tightly connected to synthesis, as it is typical to pass through the synthesis-planner-synthesis loop a number of times before reaching a successful plan for the final layout tools.

After a pass in the floorplanner, more knowledge is available to synthesis. With this new knowledge, the optimization and mapping phases can be rerun against the previous results to produce a refined solution. The important piece of knowledge now available is the gate density within different functions in the design (or regions on the chip). With this, the synthesis tool can be selective about which wire load table to use and develop a more accurate estimate of the delay resulting from a specific solution choice.

Floorplanning has been a significant enhancement to the design process and is widely used today. In addition to floorplanning, modern design planners include support for clock tree, design power bus design, I/O assignment, and a wealth of electrical analysis tools. As will be discussed later, semiconductor technology trends will place even more importance on the design planner and dictate an ever-tightening integration between it with both synthesis and layout. Today, synthesis, design planning, and layout are three discrete steps in the typical design flow. Communication between these steps is accomplished by file-based interchange of the design data and constraints. As designs become more dense and with the growing complexities of electrical analysis required, it will become necessary to integrate these three steps into one tight process as are the functions within the modern design planners.

The 1990s — The Age of Integration

Before EDA tools were commercially available, software architecture standards could be established to assure smooth integration of the tools into complex EDA systems supporting the entire design flow.

Choice of languages, database and file exchange formats, host hardware and operating systems, and user interface conventions could be made solely by the developing company. Moreover, the need for comprehensive EDA systems supporting the entire flow through design and manufacturing release in a managed process is paramount. Design of ICs with hundreds of thousands of gates (growing to the millions) across a design team requires gigabytes of data contained within thousands of files. All of this data must be managed and controlled to assure its correctness and consistency with other design components. Design steps must be carried out and completed in a methodical manner to assure correctness of the design before release to manufacturing. The EDA system that encompasses all of this must be efficient, effective, and manageable. This was always a challenge for EDA system integrators, but the use of EDA tools from external vendors compounded the problem. EDA vendors may develop their tools to different user interfaces, database and file formats, computer hardware, and operating systems. In turn, it is the EDA system integrator who must find a way to connect them in a homogeneous flow that is manageable, yet provides the necessary design efficiency across the tools. By the late 1980s, it was said that the cost to integrate an EDA tool into the in-house environment was often over twice that of the tool itself. Consequently, the CAD framework initiative (CFI) was formed whose charter was to establish software standards for critical interfaces necessary for EDA tool integration. Thus began the era of the EDA Framework.

The EDA framework[15] is a layer of software function between the EDA tool and the operating system, database, or user. CFI defined a set of functional elements for this software layer each of which had a standard interface and provided a unique function in support of communication between different tools. The goal was to provide EDA system integrators the ability to choose EDA tools from different vendors and be able to plug them into a homogeneous system to provide an effective system operation across the entire design flow. The framework components included

- Design information access — a formal description of design elements and a standard set of software functions to access each, called an API (application program interface)
- Design data management — a model and API to provide applications the means to manage concurrent access and configuration of design data
- Inter-tool communication — an API to communicate control information between applications and a standard set of controls (called messages)
- Tool encapsulation — a standard for specifying the necessary information elements required to integrate a tool into a system such as, input files, output files, etc.
- Extension language — specification of a high-level language that can be used external to the EDA tools to access information about the design and perform operations on it.
- Session management — a standard interface used by EDA tools to initiate and terminate their operation and report errata, etc.
- Methodology management — APIs used by tools so that they could be integrated into software systems to aid the design methodology management
- User interface — a set of APIs to provide consistency in the graphical user interface (GUI) across tools.

Each of these functional areas needs to be considered for integration of EDA tools and provide interoperability between them. In its first release, CFI published specifications for design representation and access (DR), intertool communication (ITC), tool encapsulation (TES), and extension language (EL). Additionally, the use of MOTIF and X-Windows were specified as the GUI tool kit. However, for many practical, business, and human nature reasons, these standards did not achieve widespread adoption across the commercial EDA industry beyond the use of MOTIF and X-Windows. Offerings for DR, ITC, and EL became available in products such as CDB (Mentor Graphics' DR based product), ToolTalk (Sun Microsystems' ITC product), and SCHEME (the CFI EL standard). Because, however, use of these required EDA tools to modify their internal structures to interact directly with the committee-derived APIs, their use across the industry was less than desired and the "Plug-and-Play" motto of CFI was not realized. However, the work at CFI did serve to formalize the science of integration and communication, and a number of the information models developed for the necessary components are used today but often are slightly modified and within a proprietary interface.

As it was learned, not only was it costly to change EDA tools to use a different internal interface (API), but it was not considered good business to allow tools to be integrated into commercial system offerings from competitors. For a period, several framework offerings became available, but these quickly became the end product rather than a means to an end. These products were marketed as a means to bring outside EDA tools into the environment, but few vendors modified their tools to support this by adopting the CFI APIs. Instead, to meet the need for tool integration, the commercial industry focused on data flow only and chose an approach that provides communication between tools by file generation and translation. Consequently, today's EDA systems are typically a disparate set of heterogeneous tools stitched together by the creation of data files. These files are created from one tool and translated by another tool [within the design flow] to its internal data structures. Many of these formats evolved from proprietary formats developed within commercial companies that were later transferred or licensed for use across the industry. Common EDA file formats in use today are

- Electronic data interchange format (EDIF) — netlist exchange (EIA→IEC)
- Physical data exchange format (PDEF) — floorplan exchange (Synopsys →IEEE)
- Standard delay file (SDF) — delay data exchange (Cadence Design Systems→IEEE)
- Extended standard parasitic file (ESPF) — parasitic data exchange (Cadence Design Systems→IEEE)
- Library exchange file (LEF) — physical charactistics information for a circuit family (Cadence)
- Data exchange format (DEF) — physical data exchange (Cadence)
- Library data format (.LIB) — ASIC cell characterization (Synopsys)
- ASIC library format (ALF) — ASIC cell characterization (Open Verilog International)
- VISIC high level design language (VHDL) — behavorial design description language (IEEE)
- Verilog — RTL-level design description language (Cadence Design Systems→IEEE)

These "standard" formats have provided the desired engineering and business autonomy necessary to get adoption and their use across the industry has improved the ability to integrate tools into systems drastically compared with the 1980s. It has proved to be an effective method for the design of today's commodity ICs above .25 micron. However, the inherent ambiguities, translation requirements, rapidly increasing file sizes (due to increasing IC density), and the fundamental nonincremental sequential nature of design flows based on them will soon give way to IC technology advances.

78.3 The Future

It may be said that the semiconductor industry is the most predictable industry on earth. Whether it was an astute prediction or the cause, the prediction of Gordon Moore (now known as Moore's Law) has held steadily across the past two decades. Every 18 months, the number of transistors or bits on an IC doubles. To accomplish this, feature sizes are shrinking, spacing between features is shrinking, and chip die sizes are increasing. In addition, the fundamental physics that govern the electrical properties of these devices and between them has been documented in electrical engineering textbooks for some time. However, there are points within this progression where paradigm shifts occur in the elemental assumptions and models required to characterize these circuits, and where fundamental EDA design and analysis must change. Earlier we discussed paradigm shifts in design verification because of inability to repair. We also discussed shifts resulting from the number of elements in a design versus the necessary tool performance and designer productivity. Across the past three decades, we have seen shifts in test, verification, design abstraction, and design methodologies. Now, as semiconductor technology crosses the .25 micron barrier, another paradigm shift is required. Feature packing, decreased rise times, increased clock frequencies, increased die sizes, and the explosion of the number of switching transistors are all interacting to place new demands of models, tools, and EDA systems. Thus, the next decade will require new work in design tools, rules, systems, and schools for problematic areas of delay, signal integrity, power, test, and mixed technology.

SIA National Technology Roadmap for Semiconductors

The semiconductor industry association and SEMATECH periodically publish a report called the "National Technology Roadmap for Semiconductors"[16] (NTRS). This report characterizes planned semiconductor directions and advances across the next decade and the necessary technology advancements in all support areas including

- Design and test
- Process integration devices and structures
- Front-end [manufacturing] processes
- Lithography
- Interconnect
- Factory integration
- Assembly and packaging
- Environment, safety, and health
- Defect reduction
- Metrology
- Modeling and simulation

It provides a wealth of information on the semiconductor future, as well as the problematic areas that will arise and the inventions that will be required. Semiconductor advancements for high-function microprocessors that are documented in the NTRS that will impact the next-generation EDA tools and systems are shown in Table 78.1. The reader is encouraged to study the technology characteristics in the NTRS, as it details the roadmap across all intermediate years for high-volume ASICs as well. For simplicity, only the years 1997 and 2012 are given in Table 78.1, as these trends lead and represent the design points required. However, ASIC advancements do not lag far behind in time.

TABLE 78.1 NTRS Microprocessor Roadmap

Characteristic	1997	2001	2006	2012
Transistor Gate Length	.20 μm	.12 μm	.07 μm	.035 μm
Feature Size Scale Factor ($S_{feature}$)	1	.6	.35	.175
Die Size	300 mm^2	385 mm^2	520 mm^2	750 mm^2
Chip Size Scale Factor (S_{die})	1	1.13	1.32	1.58
Transistors per Chip	11×10^6	40×10^6	200×10^6	1.4×10^9
Gate Scale Factor (S_{gates})	1	3.6	18	127
Local Net Clock Frequency	750 MHz	1500 MHz	3500 MHz	10000 MHz
Local Cycle Scale Factor (S_{freq})	1	.5	.21	.075
Global Net Clock Frequency	750 MHz	1400 MHz	2000 MHz	3000 MHz
Global Cycle Scale Factor (S_{freq})	1	.54	.38	.25
Supply Voltage (V_{dd})	1.8 Volts	1.2 Volts	0.9 Volts	0.5 Volts
Maximum Power	70 Watts	110 Watts	160 Watts	175 Watts
Current Scale Factor ($S_{current}$)	1	2.3	4.6	9

In order to understand the implications of the NTRS data, it is convenient to review the effects of scaling on a number of electrical parameters.[17]

Delay is typically specified as the time from when the switching input to a driver gate reaches 50% of its voltage to the time the input to a receiver gate reaches its 50% value. It may be viewed as the driver gate delay plus the interconnect delay. Unloaded gate delay is a function of the gate capacitance and transistor resistance. The gate capacitance is a function of the gate width and length, and the gate-oxide thickness (T_{gox}). Decreasing the size or transistors by a factor of $S_{feature}$ decreases the capacitance by the same scale, since

$$C_{gate} = \varepsilon_{ox}\left(W_{gate}L_{gate}\right)/T_{gox} \alpha \left(S_{feature}S_{feature}\right)/S_{feature} = S_{feature}$$

The transistor on-resistance (R_{tr}) is proportional to supply voltage and current which both scale down proportionally, so the resistance is constant. The intrinsic gate delay, decreases by a factor of $S_{feature}$, since

$$T_{gate} \alpha R_{transistor}C_{gate} \alpha 1S_{feature} = S_{feature}$$

Thus, unloaded gate delays decrease in direct proportion with feature size ($S_{feature}$). Loading imposed on a driving gate effects this delay, however. And for cases where the interconnect resistance $R_{int} < R_{tr}$, this load is the sum of the capacitances of the receiver gates. As R_{int} gets larger, however, the actual delay of a driving gate must take into account the interconnect resistance and capacitance as well.

Interconnect delay is a function of the RC-time constant, which is a result of resistance and distributed capacitance of the interconnect. As feature sizes decrease by a factor of $S_{feature}$, the local interconnects are likewise scaled down in cross-sectional area, thus the width and height of the interconnect metal are each scaled down by a factor of $S_{feature}$. Additionally, the interconnection insulator layer (t_{ox}) is assumed to scale with feature size.

Interconnect resistance is proportional to the length and inversely proportional to the cross-sectional area of the interconnect

$$R_{int} \alpha L_{int}/\left(W_{int}H_{int}\right) \alpha L_{int}/S_{feature}S_{feature} = L_{int}/S_{feature}^{2}$$

where L_{int}, H_{int}, and W_{int} are the length, width, and height of the interconnect, respectively.

Capacitance is a function of the plate area and the spacing between the plates. The self-capacitance to ground of the interconnect is proportional to length and the width of the conductor and inversely proportional to t_{ox}:

$$C_{self} = \varepsilon_{ox}L_{int}\, W_{int}/t_{ox} \alpha L_{int}S_{feature}/S_{feature} = L_{int}$$

The resulting interconnect RC constant, therefore, scales by

$$RC_{int} \alpha \left(L_{int}/S_{feature}^{2}\right)\left(L_{int}\right) = L_{int}^{2}/S_{feature}^{2}$$

Scaling down of transistor sizes is accompanied by closer spacing. For local nets, the interconnect length (L_{int}) is scaled down by a factor of $S_{feature}$, thus the RC constant remains constant:

$$RC_{local} \alpha \left(L_{int}S_{feature}\right)^{2}/S_{feature}^{2} \alpha S_{feature}^{2}/S_{feature}^{2} = 1$$

Therefore, the delay along local interconnects is constant. However, as seen above, the gate delay is reduced by a factor of $S_{feature}$, so the relative impact of interconnect delay with respect to gate delay on the overall timing across a signal path is increasing. Below 1 μm, this became a significant factor. And around .35 μm, the delay of local nets approaches that of the gate. As feature sizes scale down further, the local interconnect delays will exceed the gate delays.

For global nets, the interconnect length does not scale down with the feature sizes. As the chip die size increases, the global net length increases. For these, the resulting RC constant scales like

$$RC_{global} = L_{int}^{2} / S_{feature}^{2} \alpha S_{die}^{2} / S_{feature}^{2}$$

Thus, the RC delay for global nets increases proportional to the square of the die size and inversely proportional to the square of the feature size decrease.

Applying simple RC approximation for delay against the NTRS data indicates that interconnect delay has become an important factor in the overall delay characterization of digital circuits (see Table 78.2). Thus, the need for accurate models for interconnect delay will continue to increase in importance. In practice, this type of uniform scaling across all interconnects (particularly global interconnects) is not applied; however, the importance of accurately modeling interconnect delay is evident in any case.

TABLE 78.2 Interconnect Delay Scaling

Characteristic	1997	2001	2006	2012
Feature size scale factor ($S_{feature)}$)	1	.6	.35	.175
Chip (die) size scale factor (S_{die})	1	1.13	1.32	1.58
T_{int}/T_{gate} local nets	1	1.7	2.8	5.7
T_{int}/T_{gate} global nets	1	5.9	40	466

Plate capacitance to ground is not the only consideration in today's ICs. Capacitance results whenever two conducting bodies are charged to different electric potentials and may be viewed as the reluctance of voltage to build or decay quickly in response to injected power. To reduce the interconnect resistive effects of decreasing metal cross-sectional area, the height of signal lines has not decreased at the same proportion. Thus, the plate areas effecting mutual capacitance do not scale down proportionally. This combined with the closer spacing between signal lines leads to an increased amount of mutual capacitance relative to self-capacitance. As a result, effects of mutual capacitance between signal lines is now as important in the overall design of ICs as is the self-capacitance of these lines. To get an accurate measure of the total capacitance along any interconnect wire, it is necessary to consider all conducting bodies within a sufficiently close proximity. This includes not only the ground plane, but also adjacent signal wires, as there is a mutual capacitance between these.

Figure 78.10 depicts three interconnect wires on a signal plane. An approximate formula for the capacitance[18] of the center wire is

C = Self Capacitance + Mutual Capacitance = $C_{int\text{-}ground} + 2\ C_m$. The mutual capacitance is a function of the plate area along the sides of the interconnects and the spacing between them and may be simply approximated as

$$C_m = \varepsilon_{ox} L_{int} H_{int} / S_{int}$$

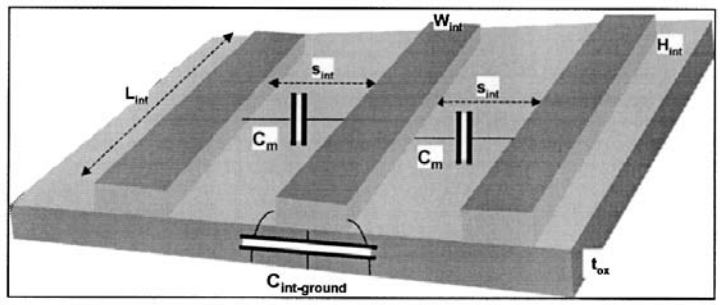

FIGURE 78.10 Mutual capacitance.

More accurate approximations for capacitance must take into account fringing effects, and the referenced literature gives the more accurate expression for capacitance as

$$C_{int-ground} = \left[\varepsilon_{ox}\left(1.15\left(W_{int}/t_{ox}\right)+2.8\left(H_{int}/t_{ox}\right)^{0.222}\right)\right]L_{int}$$

$$C_{m} = \left[\varepsilon_{ox}\left(0.03\left(W_{int}/t_{ox}\right)+0.83\left(H_{int}/t_{ox}\right)-0.07\left(H_{int}/t_{ox}\right)^{0.222}\right)\left(t_{ox}/s_{int}\right)^{1.34}\right]L_{int}$$

This mutual capacitance increases the RC delay for the interconnect. However, these simplifying equations assume the capacitive effect between the plates and ground. The actual effect of mutual capacitance is a function of the voltage potential between the conductors (Miller effect) and, therefore, a complex function of the signals on each line.

Noise is the introduction of unwanted voltage onto a signal line and is proportional to mutual capacitance and mutual inductance and inversely proportional to signal rise times. Mutual capacitance injects current into adjacent (victim) signal lines proportional to the rate of change in voltage along the exciting (aggressor) signal line. The amount of induced current can be approximated by the following equation:[19]

$$I_{mC} = C_{m}\left(dV_{aggressor}/dt\right)$$

Therefore, it can be shown that the voltage introduced (crosstalk noise) into a victim net by a switching aggressor is proportional to the mutual capacitance and inversely proportional to the rise time (τ_r) of the aggressor waveform:

$$V_{mC} = I_{m}Z_{victim} = C_{m}\left(\Delta V_{aggressor}/\tau_{r}\right)R_{victim}$$

This induced voltage can increase or even decrease[20] delays along victim nets, depending on the relative switching activities between the aggressor and victim. Further, if the crosstalk noise is of sufficient magnitude, it can give rise to faulty operation in the design. Accurate models to approximate the total effect of this crosstalk between signals for high-speed EDA processing is a current topic of much research.

Mutual inductance can also be the cause of noise. Using approximations and analysis similar to the used for noise induced by mutual capacitance yields the following relationships for mutual inductance:

$$V_{mL} = L_{m}\left(dI_{aggressor}/dt\right) = L_{m}\left(\Delta I/\Delta t\right)$$

Thus, rapidly changing current on an aggressor signal can also cause noise on a victim. These effects have classically not been of great importance on ICs, but as switching frequencies along wide lines increase, this noise must also be considered as well. This is particularly true for the power bus. As the number of transistors on the IC scales up, the amount of current required by switching transistors increases and rise times decrease.

$$V_{mL} = L_{m}\left(I_{total}/\tau_{r}\right)\alpha\left(S_{gates}/S_{features}\right)$$

Thus, the amount of induced noise resulting from mutual inductance becomes more significant as ICs scale down.

TABLE 78.3 Noise Scaling

Characteristic	1997	2001	2006	2012
Gate Scale Factor (S_{gates})	1	3.6	18	127
Feature Size Scale Factor ($S_{feature)}$)	1	.6	.35	.175
Relative Rise Time (τ_r) α $S_{feature}$	1	.6	.35	.175
Relative I_{total} α $S_{gates}S_{feature}$	1	2.16	6.3	22.2
Relative I_{tot} (NTRS)	1	2.3	4.6	9
Relative V_{mL}	1	3.8	13	51.4

EDA Impact

The references point to a number of texts that discuss the complexities of interacting electrical effects resulting from decreasing IC feature sizes and increased die sizes. These give rise to new design rules that design and analysis applications must deal with. The importance of crosstalk effects gives rise to the need for accurate parasitic extractors that can work in 2-D and 3-D space. Mutual capacitance gives rise to the need for more exacting delay calculators, and noise gives rise for new analysis tools that need to be aware of the switching activity of the IC in order to perform complete analysis. Switching activity is particularly important to power and clock bus design analysis and may be required on critical signal paths. Noise, crosstalk, Delta-I, reflection, and electromigration are well-defined properties, but their introduction into the CMOS IC design space is just beginning. Further, while the design complexities due to electrical effects are increasing, the number of circuits on the IC continues to increase. More required analysis on many more circuit elements is the fundamental challenge for EDA to meet.

EDA System Integration

With the design size increases that are projected, it will be necessary for the next-generation EDA systems to formalize the use all of the techniques that have been learned over the past three decades. It is not conceivable that current loosely coupled EDA system flows, which support only sequential design and analysis steps on a full design, will yield the required cycle times. Thus, it will be necessary to integrate EDA systems in a way that provides major decreases in cycle times and provides the increased accuracy and scope of electrical analysis to assure designs that meet specifications. Beyond the extensions to the application algorithms and development of new algorithms, the exploitation of hierarchy, abstraction, shared access, incremental analysis, and concurrent processing across design flows will become essential.

Hierarchy is the term used to describe the logical top-down organization of the design as a set of elements that can be designed and verified with minimum regards to other elements. Different levels within the hierarchy represent different levels of abstraction for the design, where each successively lower level in the hierarchy provides additional design detail. This hierarchy allows decomposition of the design into individual elements, sets of elements at different levels of abstraction, or sets of elements at the same level of abstraction. This allows for large teams of designers to work on different elements in parallel and reduces the overall processing times required individual EDA tools ($2^n > n2^m$ as discussed earlier). However, hierarchy preserves the integrity of the overall design and provides a system-level view when necessary.

Many steps in the design process can operate on an individual element without the specifics of other elements. Still, others may require an abstract representation or model of other elements within the hierarchy but not the complete design detail. And others will depend on the details of the portion of the design they are analyzing as well as for other hierarchical nodes and require an expanded occurrence-level description of the design. For example, functional-level design of a hierarchical element can be performed in a large part without the details of other elements. On the other hand, early delay calculation needs a representation of the actual loading imposed by elements connected to outputs of the element being analyzed. Yet detailed parasitic extraction requires the detailed wiring on all elements in the design

hierarchy. Design systems will need to recognize and support each of these levels of representation for the applications they serve.

Abstraction is used to describe the representation of a design at a less detailed (higher) level. Through abstraction, analysis tools deal with fewer elements, thus improving performance and memory requirements. The support for abstraction also provides the basis for a continuum of design analysis across the entire design-cycle. This top-down approach to design is common within simulation, but it will need to be expanded up and out in future EDA systems. Expanding formal design support up will provide the designer formal support in the very early stages of systems design where design algorithms, instruction set analysis, global timing, hardware-software tradeoffs, design reuse, and functional partitioning are evaluated. Thus, there will be necessary movement to higher-level (with respect to Verilog and VHDL) system design languages and analysis tools. Today, the use of simulation and synthesis at the RTL abstracted level is considered commonplace. Support at an even more abstract behavorial level will provide an additional level of efficiency. Expansion out provides for more design and analysis tools operating off abstractions of the physical IC. Accurate abstract models for physical design elements may be key to providing necessary efficiencies in physical design and analysis.

Shared relates to the architectural principle that the design tools operate off a common representation and a single shared instance of the design. That is to say, there is one common definition of the design elements, and physical store of design data is nonredundant. Today's EDA system architectures communicate data between different design tools via file transfers. These files typically represent design information already existing in the permanent storage of other files or databases in the system. Because there is no common information model for these design elements, there are many different definitions used across these different files. With the increasing number of design elements on an IC, an explosion in the number of bytes of permanent storage and run times required by applications to read and translate the data will occur. Use of standard file formats (such as EDIF, SDF, ESPF, LEF, DEF, etc.) to transfer different types of design information is becoming stressed to the limit even today. Many large designs require gigabytes of storage for these individual files and often hours of processing time to translate them into the form required by individual design applications. Across the next decade, the number of transistors will scale up by two orders of magnitude, and these interchange files can be expected to expand at the same rate. Further, more and more design tools will need to access additional types of design data to analyze increasing important electrical effects of delay and noise, making it more difficult to compartmentalize data elements into independent files. Thus, the need for a more data-centric view in design systems will need to replace today's tool-centric architectures.

Incremental means simply that only the effected portion of the design needs to be processed to analyze a change. The goal of this is to make the analysis time required for a design change proportional to the size of that change and not the size of the entire circuit. With the increase in design elements, it will be too time-consuming to re-analyze the entire IC, or even a hierarchical node within it, for every design change. Analysis applications will need enhanced algorithims to support analysis of changed portions of the design, and EDA systems will need methods to keep efficient records of design changes. This implies the tagging of records within the design database that have changed since some reference point in time. Using this information, applications can then determine what portions of the design to process (or reprocess). Strictly speaking, however, it is not necessary to keep these change tags directly with the data records. Change history can be kept and managed external to the design data either as change flags or design change orders to be processed on demand.

Structuring design algorithms to perform incrementally is no longer a simple goal. Historically, for example, a wire router could reroute a net by knowing only the open channels. It would not require detailed information about logical nets and physical wires occupying blocked channels—only that they are blocked. Now, because of the interaction of electrical effects between features on the IC, the router needs details about wire in occupied channels to correctly predict delay and noise. Further, just re-routing the changed net may not be sufficient. It is possible that the rerouted net produces a mutual capacitance with a previously correctly routed net that results in signal timing of the path that net is within beyond the critical threshold. Similar effects occur in other long-running applications, such as parasitic extraction. Here, not only does

the changed net need to be re-extracted, but so may the nets within its sphere of influence. For applications such as this, a conceptual region of influence around the change needs to be defined and other elements within that region need to be considered. Of course, in the case of the router, this region of influence could grow as additional rework is performed to correctly route the original changed net.

Concurrent is the term used to describe a closer coupling (tighter integration) between design and analysis. Typical EDA system flows of today are highly sequential in nature. That is, a set of design changes is made and this is followed by a set of analysis applications to verify their validity within the design environment. Typically, in today's systems, individual tools are integrated by file-based data exchange, and each analysis tool needs to be started, parse the design changes, perform the analysis, and terminate before another type of analysis is performed. As design size scales up, cycle times across design and analysis will scale accordingly. Furthermore, as the complexities of achieving an accurate design increase, the number of design-analyze cycles may increase, thus compounding the overall design time increase. Future EDA design systems will need to provide analysis engines that can be called dynamically, on demand, by design programs to provide incremental analysis of changes (conceptually) concurrent with the change. Development and use of a common set of these sub-routines (engines) working off of the same design model, will not only streamline the design cycle time, but will also provide better convergence in the cycle. Using common analysis engines throughout the flow will assure that different applications will predict the same results for complex computations that are key to accurate prediction of the hardware. Common engines for delay calculation, noise prediction, extraction, design rule checking, etc. will greatly improve the design cycle by yielding the same answer independent of the design application calling them.

To summarize, future EDA systems will be required to take a data-centric view of the design process as opposed to the tool-centric view common today. There will necessarily be a tighter linkage between design planning and synthesis and design planning and layout. Links will not be to entire tools as we think of them today, but rather, to functional modules within those tools. For example, a design planner may realize that a floorplan cannot be derived to meet the required design points or constraints given the current netlist. Therefore, it may call up a synthesis transform to re-optimize the troublesome sub-section of the design. Global routing of nets between partitions may require the design planner to call on extraction and delay calculation engines, and local simulation to predict noise spikes in adjacent routes in order to find a correct result. Final layout will require tight concurrent integration with all forms of analysis engines as the end design becomes more dependent on complex inter-relationships between netlist, interconnect properties, feature spacing, frequency, and signal transition. A tightly integrated model that uses a common view of the design data and common engines will be more than just a productivity enhancement, it may be essential to converge all the constraints, rules, and physics to a valid result.

This issue is recognized today, and the movement toward data-centric EDA system architectures has begun in several major EDA system companies. Additionally, SEMATECH has launched a program to develop an industrywide model and access API, enabling all of the above architectural features across design-analysis functions. An additional goal of the SEMATECH chip hierarchical design system technical data (CHDStd) program is that the design model and API be open and available for use across the EDA industry. In this way, design flows can be developed using tools and engines from different suppliers and integrated into a homogeneous system. This is in contrast to the proprietary architectural solutions now being developed by the commercial EDA system companies which prevent the necessary level of integration with competing tools.

Delay

Simplifying assumptions and models for delay have provided the foundation for high-speed event-driven delay simulation since its initial use in the 1970s. More accurate waveform simulation such as that provided by SPICE implementations has played a crucial role in the characterization of IC devices across over three decades and continues to do so. SPICE-level simulations are important for characterization and qualification of ASIC cells and custom macros of all levels of complexity. However, the run times required for this level of device modeling are too large to support its use across entire ICs. SPICE is often used to analyze the most critical signal paths, but SPICE-level simulation on circuits with millions of

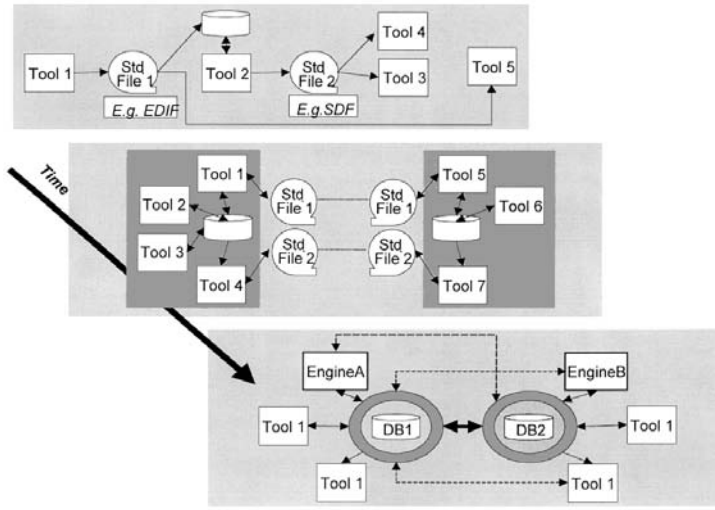

FIGURE 78.11 EDA system architecture progression.

transistors is not practical. Consequently, event-based simulation at the abstracted gate-level, or higher, is essential for IC verification. However, simplifying models used to characterize delay for discrete-event simulation and other timing analysis algorithms have had to improve and become more complex as feature sizes on ICs have shrunk and the importance of interconnect resistance and crosstalk have increased. In the future, these models will need to improve even more.

When ICs were well above 1 μm, gate delay was the predominant factor in determination of timing. Very early simulation of TTL logic used a simple model which assigned a fixed unit of delay to each gate and assumed no delay across the interconnects. Timing was based only on the number of gates through which a signal traversed along its path. As LSI advanced, this was refined to a lumped-capacitance model. With this model, gate delay was based on a foundry specified intrinsic value (actually a rise delay and a fall delay) that was adjusted up based on the capacitive load of the gates it fanned out to (receiver gates). At integration levels above 1 μm, the load seen by a gate was dominated by the capacitance of its receivers, so this delay model was sufficiently accurate. As feature sizes crossed below 1 μm, however, the parasitic wire resistance and capacitance became a significant factor. More precise modeling of the total load effect on gate delay and interconnect delay had to be taken into account. By .5 μm the delay attributed to global nets about equaled that of gates, and by .35 μm the delay attributed to short nets equaled the gate delay.

Today, a number of models are used to represent the distributed parasitics along interconnects using lumped-form equations. The well-known π-model, for example, is a popular method to model these distributed RCs. Different degrees of accuracy can be obtained by adding more sections to the equivalent lumped RC model for interconnect.

Delay calculators are developed to analyze the circuit topology, in particular, the length of interconnect wires and gate loads and compute delay across circuit elements based on the characterization model used. Calculated delay for gates and interconnects are used by design tools such as synthesis, floorplanning, and routing to constrain design choices, and analysis tools such as simulators and STV for circuit verification.

As the importance of timing-based design tools grows, integration of multiple-sourced design tools into an EDA flow becomes problematic. As more EDA vendors use built-in models for gate and interconnect delays, these different delay models often result in different calculated delays for the same circuit. This results in difficult and time-consuming analysis on the designers' part to correlate the different results. In mid-1994, an industry effort began to develop a common delay-calculation engine.[21] The goal

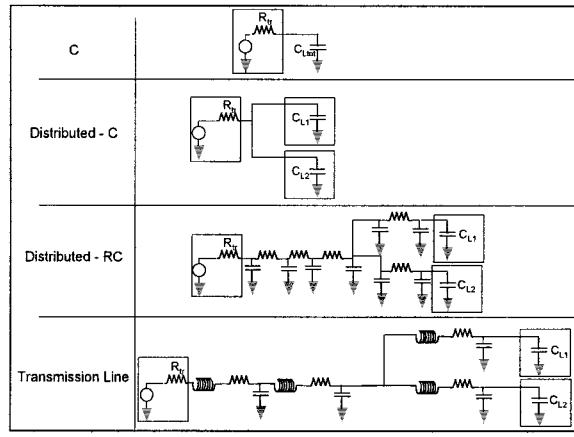

FIGURE 78.12 Delay models.

of this effort was to provide a standard language usable by ASIC suppliers to specify the delay calculation models and equations (or table look-ups) for their technology families. In this way, the complexities of deciding appropriate models to be used to characterize circuit delay and the resulting calculation expressions could be placed in the hands of the technology supplier rather than across the EDA vendors. These calculation models and expressions were to be rendered into a form that could be directly used by any EDA application requiring delay calculation and in a way that would protect the intellectual property these specifications represent. By providing a single source for the calculation of delay, all applications in the design flow could provide consistency in the computed results. The delay calculation language (DCL) technology developed by IBM was contributed to industry as the basis for this. Today, DCL has been extended to cover power calculation in addition to delay, and it has been released to IEEE as an open industry standard (delay and power calculation system — DPCS, IEEE 1481).

DPCS is an example of an industrywide available computational engine as described in the previous section. DCL language statements that specify the characterizing models for delay and power are compiled into an executable program that can be used by any EDA tool. The power of the DCL language leads the technologist to a means to characterize the delay model and calculation algorithms. Once compiled, the DCL program becomes a calculation engine for a particular technology family that can be called on demand by any EDA application adhering to the DPCS API. Compilation protects the intellectual property of the semiconductor company while providing a common executable subroutine. With DPCS, the EDA application provides the design details, and the calculation engine returns the calculated delays. The DPCS-API specifies the interface between the compiled engine and the EDA application. EDA applications may call the DPCS engine to compute delay for cells and interconnects individually or traverse across the entire design. Use of the DPCS engine across a broad scope of EDA tools provides the necessary accuracy and consistency in the computed delays resulting in shorter design times.

By .25 μm, mutual capacitance between signal lines begins to have a significant effect on interconnect delay. In this technology generation, it is necessary to consider wire size, length, and the proximity of adjacent wires. When features are significantly close so that mutual capacitance between them becomes sufficient, determination of the RC parasitics along an interconnect is no longer a simple multiplication of RC parasitics per unit length times interconnect length. Now, sophisticated tools must additionally analyze the proximity of features (including wires, vias, pads, etc.) and electrical characteristics of dielectrics between them in order to extract the parasitics from the design. Parasitic Extraction tools derive the total circuit parasitics, including the mutual capacitance in a 2-dimensional space and as ICs shrink further a 3-dimensional space.

Extraction tools are now in the commercial EDA market. They are available as stand-alone products and as part of complete system offerings. Unfortunately, similar to what occurred with delay calculation,

different extractors from different suppliers may yield different results because of different simplifying models used. Also, because of the large of processing time required to perform full extraction, it is becoming desirous to have the capability to mix and match extractors within a design flow. On nets where timing is critical, exacting parasitic models are needed, while for less critical nets, less accuracy is acceptable in favor of shorter run-times. Further, there is a growing need to call up extraction within a design tool to test the validity of a design choice. For these reasons, it is apparent that the industry need for incremental extraction engines will become as important as did the delay calculation engine.

Distributed RC models used to characterize delay are very accurate approximations so long as the rise-time (t_r) of the signals is much larger than the time-of-flight (t_{of}) across the wire. As die size scales up, so does the length of global wires and the resultant t_{of}. As transistor size scales down, so do the signal rise times. As t_{of} approaches t_r, then lossy-transmission line analysis is necessary to model delay. When $t_r > t_{of}$, lumped model approximation is accurate. Between these points is a grey area where transmission line analysis may be necessary depending on the criticality of the timing across a particular path. Published papers[22,23] address the question of where this level of analysis is important and design rules to be considered for time-critical global lines. For future EDA systems, however, it means more complexities in the design and analysis of circuits. Extraction tools will now need to derive inductance for interconnects so that the effects of the magnetic fields surrounding these lines can be factored into the delay calculations. Effects of mutual inductance also become important, particularly along the power lines which will drive large amounts of current in very short times ($e = L di/dt$). Design planners and routers will need to be aware of these effects when designing global nets and power bus structures. Design rules will need to be developed and checked by EDA tools to assure final designs that meet the expected timing. This again gives rise to the need for use of calculation and checking engines within design tools, which are developed with appropriate models and rules for these calculations by those best understanding the particular IC technology.

In summary, although the use of standard files such as SDF and the ESPF to communicate delays and parasitics between tools provides a great advantage to multi-vendor tool flows, it is problematic in the long term. As ICs shrink below .25 μm, the amount of data generated for millions of gates and their interconnects is huge, thus causing large performance overhead due to the read and translation times. Files exceeding 2-gigabytes are common for circuits of less than 1 million gates and will scale up with technology. Additionally, the practice of regenerating the entire set of delays or parasitics each time a design change is made becomes impractical, as the required processing times are too large. Therefore, future IC tools will need the ability to incrementally extract parasitics, calculate delay, and analyze the effects of electrically interacting IC features. However, different models and methods for these complex calculations can yield different conclusions across the design flow and result in design inefficiency. Thus, there will be a growing need for industry-standard calculation engines that are characterized by technologists who best understand their device technology and are made available for EDA tools independent of their source.

Signal Integrity

Beyond delay, the IC roadmap indicates the growing importance of a number of electrical analysis checks. Many of these checks have been necessary for high-performance MCMs and PCBs, but their importance for CMOS ICs is just beginning. The combined effect of decreased feature spacing, signal rise times, and voltage levels will soon reach a point where these new checks are of critical importance to all IC design. Of most importance is the effect of signal noise, which can result from mutual capacitance and mutual inductance between signal lines, and signal reflections. Noise can affect the integrity of signals and result in unacceptable delay or logic failures, and it is a function of the design's topology and functional operation. Therefore, analysis of noise is a complex and time-consuming process. However, because noise analysis is becoming more necessary across the entire design process, new analysis techniques, models, and design rules will become critical in next-generation design systems. Furthermore, its effects are increasing the need for enhanced support for design and analysis of power and clock distribution.

Signal integrity is the term used in relationship to whether or not injected noise will cause a logical fault. As discussed earlier, noise (unwanted voltage) can be introduced onto a signal line as the result of high-speed switching of an adjacent line. This is a result of mutual capacitance and mutual inductance.

If this noise is of sufficient magnitude, it can cause, for example, a latch to be set to an incorrect state. Therefore, design tools must now begin to make decisions based not only on the logical intent, the physical package constraints, and timing, but noise as well. As is the case for delay, design rules will be developed as a first order of defense and for the quick decisions for many design phases. New constraints, such as the maximum noise tolerated on a signal line, will become design rules that must be adhered to. However, this means that design tools, such as routers may need to call on noise calculation engines to determine if a decision falls within the tolerable limits. Unfortunately, for critical nets these (relatively) quick approximations and checks may be overly pessimistic. For these interconnects, it will be necessary to perform more exhaustive analysis of the effects of the noise. Unfortunately, to determine whether or not a signal has integrity requires knowledge of the functional operation in addition to the topological and electrical characteristics of the design and the properties of the materials. Therefore, a new type of EDA analysis is becoming more necessary in the design flows. This is signal integrity verification.

Precise signal integrity verification requires functional patterns to exercise signal paths, in addition to the electrical characteristics of those paths for accurate analysis. Induced noise on a signal may or may not represent a problem, depending on whether that condition can exist in the real machine operation (If a tree falls in the woods and no one is there to hear it, does it make noise?) and whether the path is sensitive to the state of the noisy net. Therefore, simulation of functional patterns is necessary to completely determine if a noise spike causes a fault. This, however, takes on the same problems as functional design verification — pattern generation and completeness analysis. Current and future research in this field must develop formal solutions and more algorithmic solutions to pattern generation — similar to those employed by test generation.

Test

Manufacturing test of ICs today is becoming a heuristic process involving a number of different strategies in combination to assure coverage and maximize generation costs and throughput at the tester. Today, an IC test employs the use of one or more of the following approaches:

- Static stuck-fault test using stored program testers

  The test patterns may be derived algorithmically or from random patterns, and the test is based on final steady state conditions independent of arrival times. The goal of stuck-fault test is to achieve 100% detection of all stuck-at faults (except for redundancies and certain un-testable design situations that can result from the design). Algorithmic test generation for all faults in general sequential circuits is often not possible, but test generation for combinational circuits is. Therefore, the use of design-for-test strategies (such as LSSD) is becoming more accepted.

- Delay test using stored program testers

  Delay test patterns may be algorithmically generated or functional patterns derived from design verification. The tester measures output pins for the logic state at the specified time after the test pattern is applied.

- Built-in self test (BIST)

  BIST tests are generated at the tester by the device under test, and output values are captured in scan latches for comparison with simulated good-machine responses. BIST tests may be exhaustive or random patterns, and the expected responses are determined by simulation. BIST requires special circuitry on the device-under-test (linear feedback shift registers and scan-latches) for pattern generation and results capture. To improve tester times, output responses are typically compressed into a signature and comparison of captured results and simulated results is made only at the end of sequences of tests.

- Quiescent current test (I_{DDQ})

  I_{DDQ} measures quiescent current draw (current required to keep transistors at their present state) on the power bus. This form of testing can detect faults not observable by stuck-fault tests (such a bridging faults), which may cause incorrect system operation.

Complicating semiconductor trends that will affect manufacturing test in the future are the speed at which these future chips operate and the quiescent current required for the large density of transistors on the IC. In order to perform delay test, the tester must operate at speeds faster than the device-under-test. That is, if a signal is to be measured at a time *n* after the application of the test pattern, then the tester must be able to cycle in less than *n* units of time. It is possible that the hardware costs required to build testers that operate at frequencies above future IC trends will be prohibitive. I_{DDQ} tests are very effective means to quickly identify faulty chips, as only a small number of patterns are required. Furthermore, these tests find faults not otherwise detected by stuck-fault test. Electric current measurement techniques are far more precise that voltage measurements. However, the amount of quiescent current draw required for the millions of transistors on future ICs may make it impossible to detect the small amount of excess current resulting from small numbers of faulty transistors. Obviously, new inventions and techniques may be introduced into the test menu. However, at present it appears that in the future manufacturing test must rely on static stuck-fault tests and BIST. Therefore, it is expected that more and more application of scan-design will be prevalent in future ICs. This will be have a second-order benefit for many EDA tools, as the design and analysis of combinational circuits and divide and conquer approaches can be utilized.

Design Productivity

The NTRS points out that future ICs will contain hundreds of million of transistors. Even with the application of the aforementioned architectural features, faster tools, and support for architectural design, it is unclear that design productivity (number of good-circuits designed per person-year) will achieve the necessary level. Designing and managing anything containing over 100,000,000 sub-elements is almost unthinkable. Doing it right and within the typical 18-month product cycles of today seems impossible. Yet, if this is not accomplished, semiconductor fabs may run at less than full production, and the ability to see returns the exorbitant capital expenditures required for new fabs will be at risk. Ultimately, this could negate the predictions in the NTRS.

Over the history of IC design, a number of paradigm shifts have enhanced designer productivity, the most notable being high-level design languages and synthesis. Use of design rules, such as LSSD, to constrain the problem has also represented productivity advances. Algorithm advances will continue to play a crucial role as well, as the design cycle-time is a function of computer resources required. Many of the EDA application algorithms, however, are not linear with respect to design size, and processing times can increase as an exponential function of transistors. Therefore, exploitation of hierarchy, abstraction, shared, incremental, and concurrent EDA system architectures will play an important role to overall productivity. However, even with all of this there is a major concern that industry will not be able to design enough good circuits fast enough. Consequently, there is a major push in the semiconductor industry toward design reuse. There is a major activity in the EDA industry (Virtual Sockets Interface Alliance — VSIA) to define the necessary standards, formats and, test rules to make design reuse real on ICs.

Design reuse is not new to electronic design or EDA. Early TTL modules were an example of reuse, standard cell ASICs, and PCB-level MSI modules. With each, the design of the component is done once, then qualified, then reused repeatedly in application specific designs. Reuse is also common within design teams. A logical function may be designed, verified, then reused in many other sections of the system's design. However, the ability to embed semiconductor designs from one process into chips manufactured on another process, or from one company to another, is just in its beginnings.

The VSIA has defined three different types of reusable property for ICs:

1. Hard macros — these functions have been designed and verified, and have completed layout. They are characterized by being a technology-fixed design and a mapping of manufacturing processes is required to retarget them to another fabrication line. The most likely business example for hard macros is that they will be available from the semiconductor vendor for use in application-specific designs being committed to that supplier's fabrication line. In other words, hard macros will most

likely not be generally portable across fabs except in cases where special business partnerships are established. The complexities of plugging a mask-level design for one process into another process line are a gating factor for further exploitation at present.
2. Firm macros — can be characterized as reusable parts that have designed down to the cell level and through partitioning and floorplanning. These are more flexible than hard macros, since they are not process-dependent and can be retargeted to other technology families for manufacture.
3. Soft macros — these are truly portable design descriptions but are only completed down through the logical design level. No technology mapping or physical design is available.

In order to achieve reuse at the IC level, it will be necessary to define or otherwise establish a number of standard interfaces for design data. The reason for this is that it will be necessary to fit design data from other sources into the design system being used to develop the IC. Therefore, VSIA has been established to determine where standard interfaces or data formats are necessary and to elect what the standard is to be. For soft-macros, these interfaces will need to include behavorial descriptions, simulation models, timing models, etc. For firm macros, the scope will additionally include cell libraries, floorplan information, and global wiring information. For hard macros, GDSII may be supplied.

In order to reuse designs that were developed elsewhere (hereafter called intellectual property blocks, or IP blocks), the first essential requirement is that the functional and electrical characteristics of the available IP blocks be available. Since internal construction of firm and hard IP may highly sensitive and proprietary, it will become more important to describe the functional and timing characteristics at the I/O's. This will drive the need for high-level description methods such as use of VHDL behavorial models, DCL, IBIS models, and dynamic timing-diagrams. Furthermore, the need to test these embedded IP blocks will mandate more use of scan-based test techniques such as JTAG Boundary Scan. Use of standards methods such as these to encapsulate IP blocks will be paramount for broad use across many designs and design systems.

There are risks, however, and reuse of IP will not cover all design needs. Grand schemes for reusable software yielded less-than-desired results. Extra effort to generalize the IP block design points for broad use, and describing its characteristics in standard formats is compounded with the ability to identify an IP block that fits a particular design need. Design and characterization of reusable IP will need to be robust in timing, power, reliability, and noise in addition to function and cost. Furthermore, the broad distribution of IP information may conflict with business objectives. Additionally, even if broadly successful, use of reusable IP will not negate the fundamental need for major EDA advances in the areas described. First, tools are needed to design the IP. Second, tools are needed to design the millions of circuits that will interconnect IP. Finally, tools and systems will require major advances to accurately design and analyse the electrical interactions between, over and under IP and application-specific design elements on the IC. Standards are essential, but they are not sufficient for success. Tools, rules, and systems will be the foundation for future IC design as they have been over the past. Nevertheless, the potential rewards are substantial, and there is an absence of any other clear EDA paradigm shift. Consequently, new standards will emerge for design and design systems, and new methods for characterization, distribution, and look-up of IP will become necessary.

78.4 Summary

Over the past three decades, EDA has become a critical science of many disciplines. Where it may have begun as a productivity enhancement, it is now a fundamental requirement for all electronic design. The criticality of EDA for IC design is the focus of much attention because of the expanding semiconductor advancements. Fundamental approaches in test, simulation, and physical design are constantly being tested by these semiconductor advancements. New EDA disciplines are opening-up. Fundamental electrical models are becoming more important and at the same time more complex. New problems in design and IC failure modes will surely surface.

The next decade of EDA should prove to be as exciting as the past three!

Algorithms and Architectures for Multimedia and Beamforming in Communications

Flavio Lorenzelli
ST Microelectronics, Inc.

Kung Yao
University of California at Los Angeles

79.1 Introduction

In recent years, we have experienced many explosions in various technologies in information processing, transmission, distribution, and storage. In this chapter, we will address two distinct but equally important algorithms and architectures of multimedia and beamforming array processings in communication systems. The first problem is motivated by our need for efficient and real-time presentation of still image, live-action video, and audio information commonly called "multimedia." To most users, multimedia presentation is easier and more natural to comprehend compared with the traditional textual form of presentation on paper. The second problem is motivated by a desire to transfer tremendous amounts of information from one location to another over limited frequency-polarization-space-time channel constraints. Beamforming array processing technologies are used to coherently transmit or receive information over these channel constraints that can significantly improve the performance of a single transmit or receive antenna system. Since both of these problems are of fundamental interest in VLSI and practical implementations of modern communication systems, we consider in detail the basic signal processing algorithmic and architectural limitations of these problems.

In Secection 79.2, we first consider the intense computational requirements for displaying images and video using a general purpose PC. The pros and cons of using a separate processor or accelerator to enhance the main CPU are also introduced. Then, "Extended Instruction Set and Multimedia Support for General Purpose Processors" discusses issues related to the extended instruction set for media support

for a general purpose PC, while "Multimedia Processors and Accelerators" considers in some detail media processors and accelerators. "Architectures and Concepts for Multimedia Processors" deals with the architectures and concepts for multimedia processors. The very long instruction word (VLIW) architecture and the SIMD and associates subword parallelism issues are presented and compared. Four tables are used in Section 79.2 to summarize some of the involved basic operations.

In Section 79.3, we discuss the use of beamforming operation originally motivated by various military and aerospace applications, but more recently in many civilian applications. In "Interface Rejecting Beamforming Antenna Arrays", we consider some early simple, sidelobe-canceller, beamforming arrays based on the LMS adaptive criterion, then we discuss in some detail various aspects of a recursive least-squares criterion QR decomposition-based beamforming array. In "Smart Antenna Beamforming Arrays", we consider the motivation and evolution of the smart antenna system and its implication.

79.2 Multimedia Support for General Purpose Computers

In any computer store, it is fairly common nowadays to see rows of computer screens running video and audio clips. Voices, sounds, and moving pictures are attracting large numbers of users who now require as basic features software applications, which include voice mail and videoconferencing. Advertisements for home computers virtually never miss the buzz words "multimedia," "interactive," and "Internet." Over time, audio and video, as well as network connectivity, have become integral parts of many user applications. This change in users' expectations has been the cause for a major shift in the operations required of a general-purpose computer. The focus of computer designers and vendors has moved to plain word processing and spreadsheet applications to highly demanding tasks, such as real-time compression and decompression of audio and video streams. CPUs are now required to process large amounts of data fast, and allow for different processes to run simultaneously. For instance, one might have different windows open at the same time, one running a streaming video, another playing an audio file, another showing an open internet connection, etc. In addition, PCs are now expected to provide high-quality graphics, 3-D moving pictures, good quality sound, and full-motion support (e.g., MPEG-2 decoders, etc.). Most computer vendors and processor designers are therefore making huge efforts to alter or enrich their products so as to be able to provide these new multimedia services.

In order to better envision the complexity required by some multimedia tasks, consider what is involved in operations such as 3-D image rotation/zooming, etc. Each 3-D object consists of hundreds or even thousands of polygons, usually triangles. The smaller the polygons — and consequently the more numerous — the more detailed the object. When an object moves on the screen (rotates or moves forward/backward), the program must recalculate every vertex of every polygon by performing a number of matrix computations. A typical 3-D object might have 1000 polygons, which means that each time it moves, at least 84,000 multiplies and adds are executed. The new MPEG-4 audio/video standard (release date November 1998) addressed, among other things, the need for high interactive functionality, i.e., interactive access to and manipulation of audio-visual data, and content-based interactivity. The standard will provide an object-layered bit-stream. Each object can be separately decoded and manipulated (scaled, rotated, translated). Even 300-MHz Pentium II's cannot supply enough coordinates for more than a million polygons per second. Accelerator cards or graphics chips are often required for high-end, graphics intensive applications, to render polygons faster than any CPU can keep up.

One of the major drives to multimedia PCs was due to Microsoft's APIs, particularly the recent DirectX interfaces. With DirectX, it is easier to replace audio and video hardware while retaining software compatibility. However, as long as older applications remain alive, multimedia PCs will have to provide compatibility with existing register level standards, e.g., superVGA and SoundBlaster. Register-level interfaces were not designed to support more advanced audio/video features, e.g., 3-D graphics. Most game programs avoid old APIs because of their poor performance. They run directly under DOS and access audio and video chips directly. Microsoft created DirectX, a new set of APIs, in order to avoid having to modify existing programs to support new graphics devices as they show up on the market.

Multimedia is likely to reach the electronics consumer market also in ways that are still unclear, for instance, in what has been dubbed home entertainment. Vendors envision gamuts of devices which combine the functions of a PC with traditional TV sets. PCs with dual-purpose monitors and set-top boxes will soon offer functionalities ranging from DVD to videophone and interactive 3-D gaming. The PC might become the basis for a living room entertainment center which includes a TV tuner, DVD, Dolby audio, 3-D graphics, etc.

Different companies have chosen different approaches to multimedia and made widely different decisions. Some companies, notably Intel and Sun Microsystems among others, have added circuitry to their new generation processor and enhanced their instruction sets in order to handle multimedia data. Other companies, e.g., Philips and Chromatics, have preferred to build whole new processors from the ground up which could work either independently or in alliance with another processor, solely in charge of audio, video, and network connectivity. There are also those who have been thinking of thoroughly new architectures and concepts, which could open entirely different perspectives and computation paradigms. In the following, we will provide a (necessarily incomplete and temporary) snapshot of the situation as it appears at the end of the 1990s, when the authors are writing.

The solutions pursued by the various companies display tradeoffs. What will be the most successful approach is open to debate and will probably be understood only in hindsight. Nonetheless, some considerations can be made now.

The main drawback of external multimedia accelerators is undoubtedly the cost.[15] The home PC market has been very sensitive to cost, and most vendors are unwilling to add expensive features which could deter possible customers and therefore reduce their market penetration. On the other hand, software developers are unlikely to generate applications tailored for multimedia processors and accelerators unless there is a sufficiently large installed based.

The alternative to a separate processor or accelerator is to enhance the main CPU to allow it to process multimedia data.[23] As of today, there are few CPUs which have enough "horsepower" to simultaneously handle the operating system, all standard applications, as well as audio decoding and mixing, video decoding, 2-D and 3-D graphics, and modem functions. A general-purpose CPU like one based on a Pentium processor Pentium is simply unable to handle digitized audio samples and pixel data. Moreover, the multimedia additions translate into larger chips with lower yield. On the other hand, if the CPU is enhanced for multimedia, no optional hardware is required to perform the multimedia tasks and the installed base can grow naturally, so to speak. Software developers will be more willing to write applications for established platforms (e.g., Pentium), whereas software vendors can target these systems with higher sales expectations. The additional hardware required for multimedia enhancement is usually only a small fraction of chip space, with minimal added cost to the overall system. As processors become faster and smaller, eventually this is the solution that most foresee prevailing, at least in low- to mid-range systems. Already, existing multimedia enhanced systems show great promise, especially when compared with the cost and performance of add-in chips and boards. What can be said in favor of separate graphics' subsystems is that the same money spent on a better graphics accelerator often buys much larger effective performance improvement (on multimedia applications) than one would get by upgrading the CPU. Users may be more willing to spend money on a system with greater multimedia performance than in a faster number-crunching CPU. In fact, graphics' subsystems have accounted for an increased percentage of the total cost of multimedia PCs, often at the expense of the central processor. Faster CPUs are still unavoidable where FP geometry calculations and rendering performance are crucial, but geometry calculations are being included in graphics chips as well.

Extended Instruction Set and Multimedia Support for General Purpose Processors

The approach of processing the multimedia data on the CPU itself has been named native signal processing (NSP). This is the approach favored by Intel, Sun, Motorola, Hewlett-Packard, and the makers of the PowerPC line. The rationale is that processors soon will be sufficiently powerful to perform tasks

such as real-time video compression and decompression, video teleconferencing, etc., without the aid of any add-in chips or cards. Tomorrow's host CPUs will be able to execute in software most if not all the tasks that today are handled by media processors and accelerators. Certainly, media processors' performance will increase over time just as much as regular CPUs. The question, though, is what is required of a media processor? Multimedia is by definition directly related to human perception. Once a multimedia algorithm reaches the limit of people's perception, there is little reason to make any further improvements. Of course, users always will be asking for more features, simultaneously running applications in real-time, etc., but it seems reasonable that eventually the drive for performance increase will level off. Both audio (including 3-D sound, up- and down-sampling, 32-channel mixing, Dolby ac-3) and 2-D graphics (GUI acceleration) have already reached the limits of human perception on any high-end Pentium system. Algorithms that still need a good deal of improvement are 3-D graphics and video compression (although in the latter, bandwidth is the key, not human perception). CPUs may soon catch up where multimedia algorithms still have not reached their limits. Intel's 233-MHz Klamath is able to execute full DVD decoding, including Dolby ac-3 audio and MPEG-2 video, and future processors will only do better. In the past, the market for hardware accelerators has been destroyed by software decoders that run on any fast CPU, i.e., MPEG-1 decoders.

NSP requires the expansion of the instruction set architecture (ISA), as well as the possible modification of the existing CPU. The additional circuitry for multimedia data processing takes advantage of the fact that most multimedia applications require calculations in lower precision (16- or 32-bit) than provided by ALUs used for standard integer and floating point (FP) data. This allows for the generation of two to eight results per clock cycle, thereby offering sufficient data rate for intensive multimedia applications. Fast computation may require additional optimized hardware: faster and possibly split buses, parallel computational units or superpipeline, larger L1 caches, small misprediction penalty, faster CPUs at lower voltage supply, etc. As an example, Cyrix has offered a chip, MediaGX,[16] that delivers Pentium-class performance and software compatibility, while adding an integrated memory controller, graphics accelerator, and a PCI interface. MediaGX improves performance by taking advantage of the tight coupling between CPU and system logic. The effects of high bandwidth demands are minimized by use of advanced compression techniques, which reduce the size of the frame buffer when stored in memory. By this technique, up to 95% of what the frame buffer reads from memory can be eliminated. MediaGX also provides full compatibility with VGA graphics and SoundBlaster audio. Later generations of this chip also include MMX support and acceleration feature for MPEG-1 video, such as pixel scaling and color scale conversion.

Intel's MMX

Intel improved its architecture's multimedia performance by extending the x86 instruction set.[13] The 57 new instructions, see Table 79.1, are referred to as MMX and are devised to accelerate calculations common in audio, 2-D and 3-D graphics, video, speech synthesis and recognition, and data communication. The overall performance improvement is estimated to be 50 to 100% for most multimedia applications (e.g., MPEG-1 decoding, pixel manipulation). Other companies, such as AMD and Cyrix, have incorporated Intel's MMX. MMX obviously has no impact on the operating system. Applications can take advantage of MMX in either of two ways: by scaling MMS-enabled drivers, or by adding MMX instructions to critical routines. One advantage of relying on drivers is that an application can automatically take advantage of a hardware accelerator for 3-D graphics, sound, or MPEG decoding if one is installed.

MMX instructions can be used in any processor mode and at any privilege level. They generate no new interrupts or exceptions. The eight new MMX registers are mapped onto the existing floating point registers, so that programs cannot use MMX and FP instructions simultaneously in the same routines. For 3-D graphics, MMX is typically used for 3-D rendering routines, while geometry calculations remain in FP.

The new instructions use a SIMD model, i.e., the same instruction operates on many values (eight bytes, four words, or two double words). On a two-way superscalar machine such as a P55C,[19] MMX

instructions can be paired with integer instructions or other MMX instructions as long as they do not use the same functional units.

One drawback of MMX is the lack of a multiply or a multiply-add for 32-bit operands; this choice is probably due to real-estate considerations. This drawback prevents routines such as 3-D geometry calculations and wavetable sound from taking advantage of MMX.

The problem of managing separate versions of each application for MMX and non-MMX systems can be solved by checking bit 23 of the CPUID to determine whether a processor implements MMX. The check can be performed via software.

While MMX can boost multimedia performance of low-end systems with no accelerators, it will probably eliminate media processors and accelerator chips from low- and mid-range systems as processor speed increases.

Intel has announced another extension, KNI, which will consist of 70 new instructions that emphasize parallel FP computations. In the meantime, AMD, Cyrix, and IDT have formally introduced a new x86 instruction set extension for speeding 3-D graphics applications. Their new set is dubbed 3DNow![4] and consists of instructions that pack two 32-bit FP values into a single MMX register and compute two results in parallel. 3DNow! provides basic add, subtract, divide, multiply, and square-root operations. The 3Dnow! single-precision FP format is IEEE-754 compatible, but results computed by 3DNow! do not comply with the IEEE standard. In particular, not all four rounding modes dictated by the IEEE standard are supported. When KNI becomes available in Intel's chips, 3DNow! is likely to be soon forgotten, since no software developer can justify supporting 3DNow! instead of KNI.

Other IS Extensions

Companies other than Intel have proposed their instruction set extensions. Sun proposed VIS for its UltraSparc. Similar to MMX, VIS includes 8-, 16-, and 32-bit parallel operations, uses FP registers, and performs saturating and unsaturating arithmetic. VIS adds some specialized instructions, which accelerate MPEG motion estimation, and video compression algorithms (MPEG-1). Some instructions are included to accelerate the discrete Fourier transform (DCT), pixel masking, and 3-D rendering. VIS instructions are encoded as three-operand and operate on 32 registers.

The PowerPC IS architecture is extended by the AltiVec instructions, which in many respects goes far beyond its 3DNow! counterparts. AltiVec offers more specialized instructions, such as 2-to-the-power, base-2 logarithm estimation, data permutation, various multiply-accumulate. Overflow and other events are more faithful to the IEEE standards than 3DNow!, a feature that helps meet requirements of advanced audio applications. The number of dedicated registers is 32.

Multimedia Processors and Accelerators

Media processors are whole new processors that can handle multimedia data efficiently.[9,12,14] By definition, they are programmable processors which can simultaneously accelerate the processing of multiple data types, including digital video, digital audio, computer animation, text, and graphics. They are required to offer high performance on these tasks, while the CPU is allowed to concentrate on other applications, be they spreadsheets or word processors, uninterrupted. Media processors combine the advantages of hardwired solutions, such as low cost and high performance, with the flexibility of software implementations. They also eliminate the need for a number of different audio/video subsystems (3-D acceleration, MPEG playback, wavetable audio, etc.)

There is no unique way to build a media processor.[26] The first ones to reach the market (NVidia NV1 and Philips TriMedia, TM-1) would combine powerful DSPs for 2-D and 3-D acceleration, audio (channels of CD-quality sound), possibly MPEG decoding, and broadband demodulation. Philips TM-1 has also units for video preprocessing (variable length decoding and image scaling and color space conversion). Other makers, notably Chromatics with its MPact Media Engine, preferred a single powerful processor that performs both audio and video tasks and telephony.[20] MPact2 also adds DVD support,

TABLE 79.1 The MMX Opcodes

Group	Mnemonic	Description
Data Transfer, Pack, Unpack	MOV[D,Q]	Move [double/quad] to/from MMX reg
	PACKUSWB	Pack W → B with unsigned sat
	PACKSS[WB,DW]	Pack W → B, D → W w/signed sat
	PUNPCKH[BW,DW,DQ]	Unpack high-order [B,W,D] from MMX reg
	PUNPCKL[BW,DW,DQ]	Unpack low-order [B,W,D] from MMX reg
Arithmetic	PADD[B,W,D]	Packed add on [B,W,D]
	PADDS[B,W]	Saturating add on [B,W]
	PADDUS[B,W]	Unsigned saturating add on [B,W]
	PSUB[B,W,D]	Packed subtraction on [B,W,D]
	PSUBS[B,W]	Saturating sub. on [B,W]
	PSUBUS[B,W]	Unsigned sat. sub. on [B,W]
	PMULHW	Multiply packed words, get high bits
	PMULLW	Multiply packed words, get low bits
	PMADDWD	Multiply packed words, add pairs of products
Shift	PSLL[W,D,Q]	Packed shift, left, logical
	PSRL[W,D,Q]	Packed shift, right, logical
	PSRA[W,D]	Packed shift, right, arithmetical
Logical	PAND	Bitwise AND
	PANDN	Bitwise AND NOT
	POR	Bitwise OR
	PXOR	Bitwise XOR
Compare	PCMPEQ[B,W,D]	Packed compare if equal
	PCMPGT[B,W,D]	Packed compare if greater than
Misc	EMMS	Empty MMX state

Brackets indicate options.
B = byte.
W = word.
D = double word.
Q = quad word.

videophone operation, as well as MMX support to reduce host processor overhead.[25] The specifics regarding clock speed, core performance, etc., are given in Tables 79.2 and 79.3.

Most media processors use VLIW and SIMD techniques to achieve high performance. These techniques are summarized in a later section. Among the issues that designers have to face are the following:

- The load balance between the media processor and the host CPU. Some of the media processors require significant preprocessing on the host CPU, which can cause a noticeable slowing of the system. For instance, MPEG-1 decoding with a high resolution display can consume as much as half the processing power of a 100-MHz Pentium when Chromatics MPact1 is used.
- Compatibility with legacy code, such as SoundBlaster and VGA emulation. Some makers guarantee some kind of compatibility, while others (e.g., Philips) do not.
- Software flexibility. Some designs are reprogrammable and thus have the advantage of being upgradable when new audio, video and graphics standards change and improve.
- Connections to outside devices. Media processor should also provide connection to PCI, external DAC, and audio codec.

The software development for the different media processors usually depends on both makers and outside vendors (with the notable exception of Chromatics, which did not make it possible for anyone else to develop software for MPact). Makers usually offer compilers and code libraries for the most common multimedia algorithms, while outside partners and OEMs develop custom software. All vendors of media processors are more or less at Microsoft's mercy for the APIs needed to run their processors under Windows.

Not all media accelerators are so ambitious as to target the complete multimedia market. Indeed, recently there has been a trend where media processors have started to specialize. Many companies have narrowed their scope to specific tasks. To name a few, C-Cube's Video RISC processor performs variable-length coding, data compression estimation, and motion estimation for use in MPEG-1 and MPEG-2 encoding by digital satellite TV broadcasters; Mitsubishi's D30V includes audio and video circuitry and a variable-length decoder; Fujitsu's multimedia assist (MMA) integrates a graphics controller and audio interfaces and can be applied to DVD; Rendition's Vérité V1000 is a 32-bit RISC processor acting as a programmable 3-D accelerator, used for antialiazing algorithms and special effects; NVidia's NV3, succeeding the unsuccessful NV1, does not support audio and programmability in favor of 3-D performance. Many makers have included special DVD playback support (Chromatic's MPact2, Digital's SA-1500, as well as Mitsubishi's D30V). Philips has focused on videoconferencing systems, which include echo cancellation, voice-tracking camera control, Web server, GUI programs.

TABLE 79.2 Comparison of Some Media Processors

	NVidia NV1	Chromatic MPact R/3000	Chromatic MPact 2/6000

Telephony	Yes	Yes	Yes

Recently, a number of companies have announced 3-D chips, among others 3DLabs, ATI, Number Nine, NVidia, S3.[10,11] 3-D chips have to face two main issues to provide the required performance levels: computational resources and memory bandwidth. The calculations necessary for 3-D consist of scene management (preparation of a 3-D object database along with information on light source and virtual camera), geometry calculations (transforms and setup), and rendering (shading and texturing applied to the pixels) (see Table 79.4). The host processor is usually in charge of scene definition, whereas rendering is handled by 3-D graphics hardware. As for geometry calculations, they are usually split equally

between host processor (transforms) and graphics chips (setup). Thanks to the evolution of 3-D chips, the host processor is often relieved of many of the tasks. The result is higher polygon throughput and better visual quality. The performance that all makers have tried to reach, and exceed, is that of a million polygons per second. The increased bandwidth demands are met by on-chip texture caches and faster, wider local memory arrays in the graphics subsystems. Memory bandwidth demands can be reduced by applying texture compression, usually based on vector quantization algorithms for still images. The bandwidth problem will also require larger internal SRAM arrays for texture caches and embedded DRAM for on-chip frame buffers. Off-chip memory will still be necessary for larger frame buffers. On-chip setup engine and motion compensation logic may be added, as in ATI's RagePro design, to accelerate MPEG-2 decoding and DVD playback.

Architectures and Concepts for Multimedia Processors

Many, if not all, multimedia applications are required to perform very computationally demanding computations. Custom architectures that support digital signal processing can satisfy the computational needs of these applications, but they are usually lacking the flexibility required in an environment where standards and algorithms change continuously. Programmable devices, such as traditional DSPs, in turn lack computing power and bandwidth necessary to perform more than a multimedia task at a time. The media processors narrow the gap between DSPs and general-purpose processors by extending the instruction-level parallelism (ILP) of traditional DSPs to a general, very long instruction word (VLIW) architecture.[24] Analogously to superscalar processors, VLIW media processors rely on hardware dispatch units to dynamically schedule the operations and evaluate data dependences, VLIW architectures rely on the compiler to statically schedule instructions at compile time. Most media processors also take advantage of SIMD concepts in order to improve computational throughput. Both VLIW and SIMD concepts are reviewed in the following.[17]

The VLIW Archictecture

Very Long Instruction Word (VLIW) architectures[3,5,7,8] are one of two categories of multiple-issue processors, the other one being referred to as superscalar architecture. Superscalar architectures issue more

than one instruction per clock, which can be either statically scheduled at compile time or dynamically scheduled using various scoreboarding techniques or Tomasulo's algorithm. VLIWs in contrast are statically scheduled by the compiler, and fixed-size instruction packets are issued at each clock cycle.

In a superscalar processor[18] the functional units are structured so that a number of instructions, typically one to eight, can be scheduled simultaneously per clock tick. An example is an architecture where one integer and one floating point instruction can be issued together. A sufficient number of read and write ports have to be provided to avoid structural hazards. Of course, simultaneously issued instructions cannot be interdependent. Moreover, no more than one memory reference can be issued per clock. Other restrictions come from latencies inherent in memory accesses or branches, e.g., it may be required that the result of a load instruction may not be used before a number of clock cycles have elapsed. When dynamic scheduling is employed, a superscalar processor requires dedicated hardware to provide for hazard detection, reservation tables, queues for loads and stores, and possibly an out-of-order scheme. Whenever the behavior is unknown or unpredictable, the architecture has to allow for conditional or predicated instructions, which can eliminate the need for certain branches altogether, and the use of speculation, whereby an instruction can be issued before knowing whether the instruction should really execute. A number of additional registers is typically required to support speculative execution and register renaming. Additionally, bits may have to be added to registers and instructions to indicate whether the instruction is speculative. In summary, a superscalar architecture may require a significant amount of additional hardware with respect to a single-issue processor, with the consequent cost of a larger die area and complex circuitry. The advantage is a low CPI (clock cycles per instruction), obtained with good efficiency (for instance, hardware-based branch prediction is usually superior to software-based prediction done at compile time). Another great advantage of superscalar architectures is compatibility to legacy code: unscheduled programs or those compiled for single-issue processors can be run on a superscalar processor.

VLIWs use multiple independent functional units. Instructions are packed into a very long instruction word. The burden for ordering the instructions and packing them together falls on the compiler, and no hardware is needed to make dynamic, run-time, scheduling and decisions. In order to keep all functional units as busy as possible, there must be enough parallelism in the application. Not all inherent parallelism is immediately available. Some has to be extracted by various software techniques, including loop unrolling and software pipelining.[1,2,21] Instructions may have to be moved even across branch boundaries, always maintaining the correct dependences among data. Some additional hardware is required also of a VLIW processor due to the increase in memory bandwidth and register file bandwidth. As the number of data ports increases, so does the complexity of the memory system. The VLIW compiler is required to perform very aggressive operations on the original code, and it generates an output code that is usually much larger than in traditional processors, e.g., due to loop unrolling. Memory size can be reduced by use of compression techniques in main memory and/or in cache. Object code compatibility is obviously the main drawback. For many types of applications, one cannot guarantee that all functional units will be used efficiently, depending on the available instruction level parallelism (ILP) of the application itself. Moreover, branch mispredictions can cause significant performance loss.[27]

Multimedia applications have characteristics which make them more suitable for VLIW processors. DSP applications as well as multimedia, display abundant amounts of available ILP, thanks to the highly regular structure of the algorithms implemented, i.e., matrix-vector manipulations or discrete cosine transforms. Not surprisingly, DSP architectures were among the first programmable devices to rely on long instruction words (LIWs) to improve parallelism.[22] Signal processing applications are characterized by

- large numbers of combination of instructions, e.g., the pair of instructions multiply and accumulate (very commonly used in filtering and linear transform algorithms)
- low-overhead counted loops, which can be supported by simple decrement-and-branch instructions
- multiple accesses to memory in a single cycle. Memory which supports multiple accesses is usually partitioned or interleaved.

Typical DSP and multimedia applications include parallel and independent computations, e.g., computations of different pixel values, which allow one to extract considerable ILP. Among the most common algorithms that may be encountered in these applications are filtering (FIR, IIR); frequency transforms (Fourier, DCT), are pixel computations.

DSP hardware has been hard to use and program through libraries and hand-tailored code. The principle was for DSPs and is for VLIWs that the processor provides some parallelism and the programmer (or compiler) must provide code that matches as much as possible the CPU's ILP. The first VLIWs were built with the intention of bridging the gap between general-purpose processors and DSPs, keeping in mind that compiler technology has to be as efficient as possible in uncovering the application's ILP. VLIWs now combine the cost/performance ratio of DSP processors with the reprogrammability of general-purpose processors. The hardware can provide parallelism in any of the following ways:

- by allowing operations to execute simultaneously on all functional units; sufficient memory and register level bandwidth are required to reduce potential structural hazards conflicts
- by replicating functional units, e.g., by having two integer units
- by pipelining longer operations, e.g., FP operations, so that one can be initiated at every clock cycle

The application's ILP can be uncovered by using any or all the following techniques:

- *Trace scheduling*. The major barrier to exposing ILP was long represented by the so-called "basic blocks," i.e., the single straight line segments of code between branches or jumps.[6] Compilers used to schedule operations of basic blocks and to stop any scheduling when it would encounter a jump or branch. The most ILP that can be gained by basic block scheduling is approximately a factor of two. More ILP can be exposed if instructions are allowed to be moved across basic blocks boundaries. Trace scheduling is based on loop-free sequences of basic blocks, i.e., paths through the program that could conceivably be taken by some set of input data. Traces are selected and scheduled according to their frequency of execution, i.e., according to how likely it is they are taken. In this scenario, the compiler can freely move operations between basic blocks, irrespective of branches. Scheduling proceeds from most to least frequently executed traces, until all the program is scheduled. Instructions can be moved only if all data dependences are guaranteed to remain unchanged. In general it may not be possible to determine all data dependences at compile time (it is actually an NP-complete problem). The compiler, with no other indications from the programmer, has to be conservative in its decisions. Trace scheduling can be successfully applied in conjunction with software pipelining and loop unrolling.[1]
- *Loop unrolling*. This is done by simply replicating the loop body a given number of times, erasing useless intermediate checks, and adjusting the loop termination code. Instructions from different loop iterations can now be scheduled together.
- *Software pipelining*. This technique reorganizes loops so that each iteration in the software-pipelined code is chosen from different iterations of the original loop. In a sense, instructions from different iterations are interleaved with one another. The loop is thus running at maximum overlap or parallelism among instructions, except for start-up and a wind-down overheads. Often it is necessary to combine software pipelining and loop unrolling, depending on the specific application.

SIMD and Subword Parallelism

Most media processors combine the VLIW architecture with another form of parallelism, usually referred to as single-interaction, multiple-data (SIMD), or subword parallelism. SIMD instructions affect multiple pieces of data, compacted in a longer word. A single SIMD instruction has the same effect as many identical instructions on as many data items. ILP can be exploited by packing many lower precision data into a large container. The ALU is set up to perform identical operations on every single subword of the input. The additional hardware required to implement SIMD operations is

- more control logic for the ALU to perform parallel operations
- more opcodes and the corresponding decoding logic

- packing, unpacking, and alignment circuitry

SIMD uses most of the existing ALU architecture to execute multiple instructions in parallel. Moreover, it uses the same register file port to read and write more distinct values. On the other hand, packing and unpacking penalties have to be paid when single items need to be accessed individually. In addition, SIMD instructions require rewriting of the application to identify the ILP and exploit it with appropriate library functions that use SIMD instructions. Many media processors try to take advantage of both approaches by implementing a VLIW architecture with some functional units supporting packed (SIMD) arithmetic.

Architecture Issues

A VLIW/SIMD processor has specific architecture characteristics, different from traditional processors.

- A larger number of registers helps when large amounts of ILP are exposed. Many registers reduce memory traffic. Moreover, the following techniques take advantage of a higher number of registers:
  - Speculative execution: speculative results must be kept until committed or discarded.
  - Loop unrolling and software pipelining: *N* iterations of the same loop, unrolled or interleaved, require more registers.
  - Predication: values computed along both paths of a branch must be kept until the branch is resolved.

  These effects are mitigated by SIMD, where a single register contains many smaller precision values.
- VLIW requires a higher number of data ports and a higher bandwidth. Data ports are costly additions because
  - the area of the register grows quadratically with the number of ports, and
  - the read access time of a register file grows linearly with the number of ports.

  Again, a SIMD approach reduces the need for ports, since a single register may contain several data items.
- The register file has to be appropriately partitioned into separate register banks. Hardware must provide for moving date from bank to bank, when needed.
- SIMD operations must be supported in the following ways:
  - The hardware must support to address individual subwords of a register. Parts of a register may be read or written without affecting the rest.
  - The hardware must support to execute lower precision operations on subwords.
  - Parts of a register may have to be shifted and realigned.
- The memory architecture has to be organized in such a way as to reduce latencies to a minimum. General-purpose processors make large use of data caches, which are very effective for locally or temporally localized data whose access pattern and size are unpredictable. Among data memory accesses, there are two categories that can be classified as follows:
  - Memory accesses with spatial locality, but little temporal locality, e.g., regular access to data structures, matrices, and vectors, which are usually traversed only once sequentially.
  - Memory accesses with temporal locality, but little spatial locality, e.g., loop-up tables, interpolation tables, etc., which are repeatedly accessed in a data-dependent, nonsequential fashion.

  Caches are usually characterized by miss penalties which are at least one order of magnitude higher than cache hits.

  DSP applications display widely different data locality characteristics. Many data streams, such as audio and video, have a high degree of spatial locality, whereas other data accesses have temporal locality. Typically large data structures with only spatial locality tend to disrupt the data items that could benefit from temporal locality. For DSP applications, the large mismatch between miss and hit penalty makes the worst-case performance unacceptable for most applications, especially if

there are real-time requirements. For these reasons VLIW, analogously to DSPs, usually makes use of local memories.

Local memories are mapped to an address space that is separate from main memory. The use of local memories requires explicit compiler support or programmer intervention in order to guarantee known and constant access time.

The programmer may help the compiler manage memory accesses by use of either of the following techniques:

– platform specific language extensions not supported by the native language, or
– compiler annotations, i.e., annotations that can be safely ignored by the compiler, but, if used, help identify which data can be accessed in local memory. These annotations can be used in high-level languages and do not affect code compatibility.

Local memories are of little use when large data structures are used a few times at most and are traversed sequentially. For these cases, it is best to use

– fast access, off-chip memory, either expensive SRAM or slower DRAM; or
– a pre-fetch butter, which works very well when the access pattern is highly predictable.

- Most DSP algorithms spend a large amount of time in simple loops, which are usually repeated a constant and predictable number of times and do not require complex control logic. Traditionally, DSPs implement very efficient and simple ways of handling the control flow of simple loops.
- VLIW code can be quite large because of the following:
  – Compilation techniques make use of loop unrolling, software pipelining, etc., which cause instructions to be replicated to allow code motion across basic block boundaries.
  – Not all VLIW instructions can be filled with useful instructions because of data dependences and because not all functional units can be continuously busy. This means that many of the VLIW instruction fields are bound to be no-operation (NOP).

  Because of the aforementioned, it is common to compress the VLIW code in order to reduce the storage space. Due to the sparse nature of VLIW instructions, there usually is room for compression. Code is kept compressed in main memory and is decompressed before execution. There are two main approaches to compression:
  – The instruction cache contains uncompressed code. In this case, decompression is not on the critical path and is crucial only during cache misses. The cache is less effective, since it must contain uncompressed instructions. Moreover, the cache cannot have synchronized instruction addresses with main memory because main memory stores variable-length instructions while the I-cache stores fixed-size instructions. The decoding scheme must therefore be more complex.
  – Main memory and the I-cache are both compressed. The cache utilization is optimal, and the address translation mechanism from main memory is simple. The disadvantage is due to having decompression on the critical path, thus affecting the hardware cost.

79.3 Beamforming Array Processing and Architecture

Beamforming array concepts were originally formulated over 40 years ago to tackle demanding defense-oriented aerospace and underwater sonar, radar, and communication system problems. These problems combine signal processing with antenna technologies. They involve the use of phase coherent transmission or reception, utilizing array sensor selectively to enhance the gain in some space-polarization-time-frequency domain to reject intentional or unintentional jamming. In recent years, there has been an explosion in civilian mobile communication usages, mainly in the form of the large number of cellular telephone users competing over a limited number of frequency bands. Proper use of beamforming arrays can increase the number of users as well as find the user's cell phone under an emergency 911 condition. The various proposed array processing systems need the availability of modern digital signal processors. These processors start from the high-end programmable DSP, the FPGA, to custom single and wafer-

integration VLSI chips. As the cost of these processors decreases rapidly while their capability increases dramatically, "smart antenna" beamforming array techniques are under serious consideration for practical communication system implementations.

Interference Rejecting Beamforming Antenna Arrays

In order to understand the rationale for beamforming antenna arrays, we briefly consider various possible types of antenna. An omnidirectional (also called isotropic) antenna has equal gains in all directions. A directional antenna has more gain at certain directions relative to other directions. Thus, it needs to be moved mechanically to point at the direction of interest for either transmission or reception. A phased antenna array uses signals from simple (and possibly omnidirectional) antennas combined appropriately to achieve a high gain in some desired direction. The direction of maximum gain is adjustable by controlling the phases among the antennas so that the voltages are coherently added in phase. An adaptive antenna array is a phased antenna array in which the gain and the phase of each antenna may be changed as a function of time depending on external conditions. As an example, a receiving adaptive antenna array not only directs a high gain toward a desired transmitter, but it may also adaptively place spatial nulls (or low gains) toward other moving co-channel interfering sources operating at the same frequency band. An antenna array is said to be optimal if it adjusts the gains and phases of the antenna elements to optimize the array performance. Typical performance of interest may be maximizing the signal-to-noise-ratio (SNR) or signal-to-interference-and-noise ratio (SINR) of the array.

A plot of the gain vs. the angle of an antenna array is called the beam pattern. The process in which signals from different antennas in an array are added coherently is called beamforming. The steering of the direction of maximum gain of an array can be achieved by mechanical means or by changing the gains and phases of the antennas to achieve electronic beam steering. Beam steering for a narrow band array only need phase-shifters, but for a wide band array, both the gain and the phase of each antenna element (typically implemented in the form of a FIR filter) need to be used. For a narrow band array, coaxial cable of different lengths can be used for phase-shifting. By switching different cable lengths, beam switching can be realized.

The earliest adaptive antenna array system is the sidelobe canceller (SLC) motivated by practical radar-jamming problems. This system consists of a high gain mainbeam dish antenna surrounded by few auxilliary low gain omnidirectional antennas. A strong jammer appears on all the auxilliary and mainbeam antennas. By using appropriate complex weights on all the antennas, the output of the auxilliary antennas consisting of the jamming signal is coherently substracted from the sidelobe of the main antenna, thus permitting desired weak signal at the mainbeam to be detected. This scheme, often called the Howells-Applebaum algorithm,[28] was first proposed in the 1960s and was implemented using analog components. It turns out the Widrow-Hoff algorithm[29] for adaptive filtering, conceived independently and at about the same time, is essentially equivalent but has broader applications. It is called the least-mean-square (LMS) algorithm. It is an approximate steepest-descent gradient search algorithm. As such, the convergence time may be slow if the system eigenvalue spread is large. However, due to its relative simplicity, most simple adaptive antenna systems are still based on variations of the LMS algorithm.

A more complex but also faster convergent adaptive antenna array is to use the least-squares (LS) method for solving the weights W of the linear system of equations $XW \approx d$. Here X is a $N \times M$ matrix with each row representing an antenna element input and M represents the time index, d is a $d \times 1$ known steering vector, and W is a $M \times 1$ unknown weights needed in the adaptive system. Various QR decomposition (QRD) methods, such as the Gram-Schmidt, Modified-Gram-Schmidt, Givens, and Householder algorithms, all can be used to solve the LS problem. In practical complex antenna systems, N can be in the low hundreds, and M can be in the thousands. Clearly, direct brute force block LS solution is not feasible. A simple form of parallel processing called systolic processing, using only small number of processing elements (PE) having adjacent neighbor connects, and operating in a synchronous manner, has been proposed to solve the QRD approach to the recursive least-squares (RLS) problem. This approach was originated by McWhirter[30] using the Givens algorithm, and variations have been proposed by Ling-

Proakis,[31] Kalson-Yao,[32] Liu-Yao,[33] and others. Issue related to the complexity of the algorithms and the practical VLSI implementation of such an array have been considered by Rader,[34] Bolstad-Neeld,[35] and Lodhtbody et al.[36]

Smart Antenna Beamforming Arrays

The explosion of cellular telephony and wireless communication services has motivated the consideration of various technologies to increase their efficiency. These systems, in order to support large number of users with increasing data rate demands and operating in difficult propagation conditions, have found "smart antenna" to be highly useful. The term "smart antenna" commonly denotes the use of a RF antenna array system with advanced signal processing techniques to perform space-time operations. While there is some similarities in smart antenna to the advanced adaptive beamforming antenna systems considered earlier for radar applications, there are also many differences. Basic issues of beamforming for signal enhancement, noise reduction, and interference rejection are still of interest. While the earlier radar systems operate in the higher X frequency band, the wireless systems operate in the lower 800-MHz and 2.4-MHz bands with significantly more multipath and fading problems. Perhaps most important is the fact that we have to deal with both up and down link communications. Various advanced modulation and coding operations not needed in radar systems are present now. With code division-multiple access (CDMA) communication, the bandwidths encountered are wider than the previously encountered systems. Furthermore, the hand-held communication devices have limited power, volume, as well as dimension for the placement of several antennas. All these harsh conditions impose demanding requirements on the smart antenna.

A smart antenna may possess adaptive beamforming capability as well as only be able to switch between small number of fixed beams. The switched beam system offers some of the advantages of a more elaborate smart antenna with reduced complexity and cost. However, for greater flexibility and performance, a smart antenna must utilize adaptivity. In an adaptive system, the weighting vector is adjusted in an adaptive manner to minimize some criteria. In the minimum mean-square error (MMSE) criteria, statistical averaging of the observed quantities are used, while in the LS criteria, the observed time samples are used directly. Variations of the stochastic gradient method are used to solve the MMSE criteria problem.

For both of the above approaches, in order to know the output of the spatial filter, training sequences known both to the transmitter and the receiver are often used. An alternative approach is to use decision directed adaptation, where the desired signal sample is estimated from the generally correctly decided sample. Still another approach uses blind adaptive algorithm, which does not require training sequences. This approach exploits various properties of the transmitted signals.

Two other approaches have been used for an adaptive antenna array system. In the maximum SNR criteria, it seeks to maximizes the ratio of the power of the desired signal to the noise power at the output of the array. In the linearly constrained minimum variance (LCMV) criteria, it minimizes the variance of the output of the array subject to linear constraints such as the directions of interferences. Both of these methods must know the direction-of-arrival (DOA) of the signal of interest. Both methods result in the solution of linear system of equations commonly termed the normal equation. Direct solution as well as various LS approximation methods and RLS methods are possible.

One important application of a smart antenna is finding the DOA and possibly the location of a source. The DOA problem has been an ongoing problem of interest in aerospace and avionics for many years. However, due to the recent FCC mandate requiring a cellular telephone system to locate each user to 125 meter accuracy, there is increasing interest in this area. There are many techniques that have been proposed to tackle the DOA and localization problem. Conventional methods use the beamforming and nulling capabilities of an array to determine the DOA of a source in the presence of noise and interference. While these techniques have been used in many practical systems, there are fundamental resolution limitations. These limitations correspond closely to frequency resolution limitations of classical DFT/FFT method in spectral analysis. Just as there are various modern parametric techniques in spectral analysis,

so too are there many parametric techniques for DOA and localization. Most of the modern techniques are based on signal subspace methods. All subspace methods exploit some signal/noise structure in the modeling of the problem and use eigenvalue decomposition (EVD) or singular value decomposition (SVD) computational tools. The earliest and most well-known subspace method is the MUltiple SIgnal Classificat (MUSIC) technique. The MUSIC method exploits the narrow band assumption of the input sources and uses an EVD of the input covariance matrix to determine the DOA of the sources. Variations and extensions of the MUSIC method have been proposed. There are also many maximum likelihood (ML) methods that have been considered to address the DOA and localization problem. These methods are all computationally costly. Most recently, various joint space-time array processing techniques based on advanced linear algebraic methods have been proposed. The goals of these techniques are to perform blind deconvolution, system identification, source separation, and equalization of the communication channels. While many technically interesting results have been discovered, there is still much work to be done before these methods can be used in practical smart antenna system. Relevant references in these areas can be found in Refs. 37–42. We also note that many of the techniques used for smart antenna are also relevant to acoustic and seismic sensor DOA and localization problems in multimedia, industrial, and military applications.[43]

Design Languages

David L. Barton
Intermetrics, Inc.

80.1 Introduction

Hardware and systems engineers are spending less and less time operating on, and manipulating, actual hardware. As the complexity of systems that fit on a single die increases, engineers are spending more of their time operating in "virtual" environments — environments that represent the systems under design at a distance, using selected abstractions, and from which the actual hardware can be created.

Central to these virtual environments are design languages. Design languages provide a structured framework within which designers can specify what their designs are to do, how they are to do them, and finally, how they are to be implemented in hardware. Design languages are becoming the primary mechanism for expressing the complex designs that are now the majority product in an increasingly large, and profitable, silicon industry.

This chapter will give a summary of the major parts of design languages, what they express, and how they may be used to design and implement digital hardware. It will begin by stating what design languages are, how they are used, and how they relate to the hardware being designed. It will then move onto the various parts of design languages, starting from the basics (values and objects that contain them), and move up through the various language structures. (Such structures are used to represent the various parts of a system, and to take those parts and compose them into a hierarchical structure that represents the entire system under design.)

There are two different ways to present design languages and languages for use by computers in general. One emphasizes use and attempts to teach design and/or programming while teaching the language. The

second emphasizes the language and language structures. We have chosen the second course in this chapter; other texts are more user-oriented and may be consulted and used for courses in design that have a language orientation. This chapter is also fairly compressed; it is oriented toward reference, not teaching or casual reading.

Two languages are undeniably more popular than others for digital systems design: VHDL and Verilog. The majority of this chapter will use VHDL in its examples and will draw from VHDL for explicit examplars of general concepts. This is being done to reduce complexity and create a single context for the discussion of general concepts. Chapter 81 will attempt to correct this imbalance in language presentation by explicitly presenting Verilog in a separate section, written by Dr. Zainalabedin Navabi, at the end of the chapter.

Uses of Design Languages

The primary use of design languages is to represent information concerning the design of a complex system. This representation serves both as documentation of the system being designed and as a guide to the instincts and practices of the designer as development progresses. The latter aspect of a design language is frequently overlooked in lists of the benefits of computer-aided design (CAD); however, it is the basis of other tool-provided benefits, since it oriented the thinking of the designer toward forms that can be used by those tools. It also provides documentation concerning the design that is far superior to descriptions written in English; the precise meaning of the description provides an unambiguous specification of just what the device under consideration is supposed to do and how it is to be constructed.

The unambiguous nature of a description written in a design language makes it a prime source of information for the various tools that make up the CAD tool suite. Of these, by far the most common and one of the most useful, is the simulator. A simulator constructs an abstract model of the device that is being developed and shows how it will operate by projecting the inputs and outputs of the device onto values that can be graphed and displayed by a computer. Simulations have value on a number of levels. First and foremost, they serve as a check on whether the device matches the customer's desired behavior. Often, requirements written in English are ambiguous. A simulation trace is the first specific representation of the behavior of the device being produced that can be shown to the customer, and which the customer can judge as either meeting or not meeting his requirements.

Beyond customer verification, a simulation is often used for assuring that the device meets the requirements imposed on it. This means feeding sufficient test cases to the simulator to gain some assurance that the device will operate across its entire range of possible inputs and conditions. The judgment of what constitutes a sufficient number of test cases is a technically complex one. This usually involves some sort of code coverage metric: each statement executed at least once, each branch taken at least once, each loop taken a certain number of times, and so on.

Beyond simulation, design languages are used as input (and output) formats for virtually every tool in the CAD toolset. Most of these work on a subset of the various languages, such as structural descriptions with respect to a given cell library. Synthesis is of particular interest. Synthesis tools work on a subset of the design languages roughly corresponding to register transfer level (RTL) descriptions. They produce structural descriptions whose leaf-level cells belong to a given ASIC cell library (see "System Hierarchy" for a discussion of leaf level cells). Synthesis is a vital arrow in the quiver of the designers of complex systems.

Beyond this are all the tools used by the practicing engineer. These include place and route, timing analysis, layout production, and so on. The end product is a working piece of silicon that is fully documented in the design language used to produce it. This aids in reproducing the part later and in reusing the design in other circumstances. Reuse is of particular interest as the complexity of systems increases. Designs that take advantage of the full capability of existing and future silicon foundries will need to make extensive use of existing designs. Design reuse is the key to effective utilization of the full capability of silicon production facilities.

Syntax and Semantics

Any language, including any design language, has two parts that give it meaning. Syntax controls what a description in the language looks like, and semantics control what the description means. More formally, the syntax of a language specifies what character strings (or, more generally, what strings of binary data, where that data may be strings, graphical representations, or other data formats) constitute legal descriptions in the language. Such descriptions may or may not be meaningful; however, any description that is not syntactically correct is dismissed out of hand.

The syntax of a design language is usually defined by a formal description in one of a small set of standardized formats. Most common is a description in a dialect of the Backus-Naur Form (BNF) that has been used to define syntax for software languages for decades. Such formats can be used as input to compiler building tools such as YACC to produce parsers and other language tools.

The semantics of a design language gives meaning to the descriptions written in the language. While there are formal mechanisms for defining the semantics of a language, at present the most common mechanism for semantic definition is carefully worded English descriptions. The wording of these English documents is carefully structure to avoid ambiguity wherever possible. This tends to make the document difficult to read; language definitions are infamously soporific to those who try to read and understand them.

The syntactic and semantic definitions for a design language are usually combined into a single document called a language reference manual (LRM). LRMs are available from standards organizations if the design languages are standardized; VHDL and Verilog are both standardized by the IEEE. The LRM is the document that is voted on by members of the standards organizations, and the LRM (and not any particular implementation or textbook) is the official definition of the design language that it describes.

Models

A description of a silicon-based system is useful only to the extent that it reflects the actual system once it is implemented. For this reason, a description of a system written in a design language is commonly called a model. The model is a representation of reality that, like any other model, abstracts the real system in various ways.

The semantics of a design language limits the models that can practically be written in the language. This range of models is often called the operational model of the language itself. VHDL and Verilog are both discrete event systems. This means that they both view time, and the actions of a system in time, as a series of discrete events that happen at specific points in time. Other languages have different operational models. VHDL-AMS, for example, integrates a continuous time model with the discrete time model of VHDL so that analog systems, and mixed signal digital/analog systems, can be described.

The usefulness of any language is constrained by its operational model (do not think that software languages are exempt from this). It is a serious error to attempt to apply a design language outside its operational model. The operational model is made up of the values and objects that the language can use to represent real processes, the kinds of actions that can be taken on those objects and values, and how the various actions can be combined into a single model representing a digital design.

The engineering process using a design language is a process of refining the model to become closer and closer to reality. This normally requires more and more detail and a lower level of abstraction on the part of the leaf level nodes in the hierarchy that corresponds to the model (see "System Hierarchy" for a definition of leaf nodes). This may or may not be a product of the top-down hierarchical decomposition process that is so beloved of textbooks; in many cases, the design will work up from libraries of available cells to functions that seem to the designer to be of use in the design before working to-down from the overall device specification. In either case, the produced model must agree with the real device to a given level of accuracy for it to be of use.

80.2 Objects and Data Types

Values, the data types to which they belong, and the objects that contain them are the basic units of the models that are created within a description language. The models are mapped to reality by taking values that are created, manipulated, and displayed by the model and mapping them to measurable phenomena associated with the corresponding device. The model is correct, and faithful to reality, to the extent that the values produced by simulation and defined by the semantics of the language correspond to the measured values of the device as it is implemented by the synthesis, place and route, layout, and other tools that operate on the description.

We will describe the values associated with description languages, the types to which they belong, and the objects that contain them in turn.

Values

Values in a description language are used to represent real phenomena. Since physical phenomena are complex and varied in their manifestation, we need a variety of values to represent them. It is more important for these values to be intuitively meaningful than for them to be precisely correct; a meaningless correct value is useless, while a meaningful but somewhat inaccurate value may have some use in dealing with a device being designed. The kinds of values available in the language are thus important to its ability to flexibility and faithfully reflect reality.

This section reflects more differences between VHDL and Verilog than other sections in this chapter; the values available in VHDL are considerably richer than Verilog. Please refer to Chapter 81 for the restrictions on Verilog values.

Basic Values

Basic values are those values that are defined by the language itself. No user action is necessary to make these values available. They are, in some sense, the ground that the language stands on. There is a surprisingly small number of basic values in most languages; mechanisms for creating user defined values can build a larger number of complex values from the basic values.

Description languages define the following basic kinds of values:

Bits All description languages define some kind of logical value, and some provide several. Indeed, VHDL allows the user to define any logical value it likes, as we shall discuss later. The decision concerning which logical value to use is an important one for a complex description. Entire IEEE standards are devoted to logical types and the operations available on them.[3]

Integers Integers represent the mathematical integer values. Languages differ concerning the size of the integer values provided and the protection from overflow that the user can depend on.

Reals Some form of floating point representation of real numbers is provided by all description languages. Floating point numbers are subject to all the restrictions and numerical analysis issues that are found in software languages providing floating point values. Values provided by description languages tend to be IEEE-compliant.[2]

The different kinds of values, including both basic values and user-defined values, are given by their types. We therefore move on to a discussion of types before addressing user-defined values.

Types

A type is a bunch (collection) of values. Each object is assigned a type, which identifies what values the object may contain. User-defined values are identified by creating user-defined types. All description languages have types corresponding to integer values, floating point values, and bit (logical) values. Just what a type is, and how it is defined, is the subject of the following subsections.

Bunches and Types

A type is a bunch of values, where a bunch is a set that is not containerized, i.e., a bunch may not contain other bunches as sets may contain sets. Bunch theory avoids the potential paradoxes of set theory; see Ref. 1 for an exposition of the theory of bunches. The integer type corresponds to the bunch of all floating point values available in the design language. Values that are members of a given bunch are said to be values of the type that is associated with the bunch.

Bunches have the same kinds of operations defined on them as sets: union, intersection, membership, difference, and subsetting (subbunching). These become important in type definitions, which can often be given in terms of these operations.

Type Definitions and User-Defined Types

A type definition defines a bunch of values that can be manipulated, saved in objects, and which represent phenomena in real systems. In a design language, a type definition is a marker that a specific kind of phenomenon is going to be represented in the model. Thus, type definitions are important pieces to the understanding of a complex model.

Basic types need no explicit type definitions; they are assumed to be predefined (in VHDL, these types are presumed to be defined in a package called package STANDARD). Other type definitions construct different kinds of values; they are called user-defined types. Each type definition for a user-defined type identifies the bunch of values that make up the type. There are a number of ways for a user to define a type.

The first way for a user to define a type is for the user to name the values that make up the bunch corresponding to the type. This is called an enumeration type; the values in the type's bunch are enumerated, or explicitly named. An example of an enumeration type is:

type `COLOR` is (`Red`, `Yellow`, `Green`, `Blue`, `Orange`, `Violet`);

This type definition creates a bunch of six values: `Red`, `Yellow`, `Green`, `Blue`, `Orange`, and `Violet`, corresponding to the colors in the rainbow. There is an implicit order imposed on the values in the bunch that corresponds to the order in which the values are named; `Red` is less than `Green`, which is greater than `Yellow`.

Enumeration types are the only mechanism of creating new scalar values. There are two mechanisms for combining values together to create new values. These combinations take one of two forms: a collection of same typed values which are indexed by number (an array), and a collection of heterogeneously typed values which are indexed by name (a record).

Arrays in design languages are similar to arrays in software languages. Arrays are sequences values of the same type which are indexed either by an integer or by an enumeration value. An example of such a type definition:

type `VECTOR` is array (`Red` to `Violet`) of `BIT`;

This definition creates an array type called `VECTOR` which is indexed by `COLOR` rather than by a number. The values of the array — one for each color — are all of type `BIT`. They are accessed by stating which member is desired, by color: my_vector(`RED`) returns the first bit in the array my_vector of type `VECTOR` (since `Red` is the first element of type `COLOR`). Arrays may be sliced; my_vector (`Red` to `Green`) results in an array value which is three elements long.

Records in design language are also similar to records in software languages. Records are divided into fields. Each field has a specific type and a name by which the value corresponding to the field is accessed. An example is

```
type STOPLIGHT is record
current_color: COLOR;
horizontal_grid, vertical_grid: INTEGER;
end record;
```

This creates a record with three fields. If the user has declared a `STOPLIGHT` called stop, then the current color of that stoplight is given by `stop.current.color`.

Design languages thus give the user the ability to create new basic values via enumeration types, and to combine different values into other values (by combining different types into other types) using arrays and records. As we will see, there are other ways to create types from other types.

Subtypes

A subtype bears the same relation to a given type (called the base type) as a subbunch does to a bunch of which it is a subbunch; in fact, the values that are members of the subbunch are the same as the values that are of the subtype. A subtype is defined by giving a restriction on the values of a type. For example,

```
subtype NATURAL is INTEGER range 0 to INTEGER'HIGH;
```

This defines the subtype of natural numbers. All natural numbers are integers; only integers in the given range are natural numbers. The notation `INTEGER'HIGH` is the largest value in type `INTEGER`. This is called an attribute, and it is used in VHDL to give information about something in the language (such as a type). This may be used with any type that has a range; for example,

```
subtype STOP_COLOR is COLOR range Red to Green;
```

This type definition defines the colors that appear in stoplight as a range of the colors of the rainbow.

User-defined types and subtypes create a powerful and flexible mechanism for specifying the types of a system. If used properly, user-defined types can make a description much more readable and understandable for the user reading the model (and therefore much more easy to debug).

Objects and State

Objects are containers of values. A value may be stored in an object and then referenced later in the simulation of the description. The sum total of all the values in all the objects in the description, along with the system time and the internal objects used to keep track of the simulation cycle, is called the system state. The system state, at a given simulation time, should map to measurable phenomena of the system being modeled at the time corresponding to the given simulation time. To the extent that the mapped system state differs from the measured values, the model is inaccurate.

The semantics of a design language define two things:

1. How each object in the description gets an initial value (what the initial value is for each object in the system).
2. Given a system state and a description, how the values contained by the objects change at the next "step" (where "step" is also defined by the language semantics).

The objects of the model, and the values they contain, are thus the link to the behavior of the modeled device. Proper display of these values (in particular, using familiar graphical concepts like waveforms and user interface devices) allows the user to make sense of the simulation.

Object Kinds

Objects change values as a result of the execution of language statements. Description languages have a much wider range of action than software languages. Different statements affect objects in different ways, and in general they may or may not affect the values in the objects immediately. The way that an object changes value is determined by the kind of the object. The kinds of objects available in VHDL and its analog extension, VHDL-AMS, are

Constant Objects of kind constant never change value; they keep their initial value throughout all time.

Variable Objects of kind variable change their value immediately on the execution of an assignment statement (specifically, a variable assignment statement).

Signal Objects of kind signal change their value during the simulation cycle. A signal assignment statement records its action; in VHDL, this is recorded in a driver for the signal. During the simulation cycle the values of the drivers are combined to determine the new value of the signal. Signals that are assigned to in more than one part of the model (in more than one process) are said to have multiple drivers; in this case, the drivers need to be resolved. This is done by providing a function that takes an array of values and produces a single value of the same type as a result; this function is attached to the subtype of the signal. Such signals are said to be resolved signals, and subtypes that have function names attached to them are called resolved subtypes.

Quantity Objects of kind quantity get values as a result of the solution of a set of simultaneous equations that are derived from the description in the description language. As time progresses, an analog equation solver assigns each quantity a value that is in agreement with the entire system of equations.

Terminal Objects of kind terminal are composed of two related quantities that are of related types, one across quantity and one through quantity. Terminals, and their connections, are governed by conservation equations determined by Kirchhoff's Voltage Law and Kirchhoff's Current Law. The quantities that make up the terminal get their value in the same manner as other quantities. Terminals do not have types per se. Instead, a terminal is said to belong to a nature which specifies the types of the across and through quantities of the terminal.

Object declarations specify the kind and type of the objects being declared. In VHDL, this takes the following form:

```
constant pi: REAL = 3.14159;
variable x, y, z: INTEGER;
signal in1, in2, in3: BIT;
quantity bias_voltage: VOLTAGE;
terminal c1, c2: ELECTRICAL.
```

80.3 Standard Logic Types

All description languages have one or more representations of electrical signals, called standard logic types. Some, such as VHDL, allow the user to define other logic types as well; however, simulator vendors often have specialized features that allow simulations of descriptions expressed in terms of one of the standard logic types to run faster than simulations of descriptions expressed in terms of user-defined types.

Simulator vendors may choose to optimize any logic types that they wish; however, in the case of VHDL there are a number of types that are standardized and are therefore available for optimization by simulator vendors. At the time this chapter was written, these standard logic types derive from two specific sources.

The first is package STANDARD itself. This defines the type BIT, which consists of two values: '0' and '1'. Because this is defined in the package STANDARD, every implementation of VHDL must provide it (although it may not be optimized on all systems).

The second source is the standard utility library called std_logic_1164. It defines a logic type called std_ulogic (and a corresponding resolved type called std_logic) with the following values:

'U' Uninitialized
'X' Forcing Unknown
'0' Forcing 0
'1' Forcing 1
'Z' High Impedance
'W' Weak Unknown
'L' Weak 0
'H' Weak 1
'-' Don't care

These values are also provided by Verilog, and are optimized for various timing optimizations as a part of those simulator vendors that support the VITAL standard. In addition to this standard logic type, there are four subtypes of this type that are defined:

X01 This subtype contains only these three values: 'X', '0', and '1'.
X01Z This subtype adds 'Z' to X01.
UX01 This subtype adds 'U' to X01.
UX01Z This subtype adds 'Z' to UX01.

In addition to these two types, there is a proposed extension to the standard that adds three values to std_logic:

'C' Capacitive unknown.
'D' Discharge 0.
'P' Precharge 1.

This type is not as widely supported across the universe of vendors; therefore, counting on these last three values being provided by a given vendor may not be wise.

Logical Operations

In addition to the standard logic types, there are a number of standard logical operations defined on values of these types. These are defined on all standard logic types. They are

- Logical and (conjunction).
- Logical or (disjunction).
- Logical not.
- Logical nand (not and)
- Logical nor (not or).
- Logical xor (inequality).

These operations may be used on vectors of logical types as well.

Other Standard Operations

In addition to the standard logic types and logical operations, there are a number of standard numeric operations that are provided by VHDL and most VHDL implementations. These are either provided in package STANDARD, or in a standard mathematical package called MATH_REAL. These include

Additive operations Addition, subtraction, and inverse.
Multiplicative operations Multiplication, division, modulus.
Exponentiation Exponent, log.
Transcendental functions Sine, cosine, tangent, arcsine, arccosine, arctangent.
Hyperbolic functions Hyperbolic sine, cosine, and tangent.
Boolean operations And, or, and not. Note that these are separate from the logical operations above.

These operations may be used to build up expressions that appear in assignment statements, sequential statements, simultaneous statements, and statements where expressions are appropriate such as if, loop, and return statements.

80.4 Concurrent Statements

Concurrent statements are the basic units of cooperating action. Hardware involves a number of devices — whether modeled at the gate level, the transistor level, or at a high behavioral level — working simultaneously and exchanging information. Concurrent statements specify the actions that execute in

isolation from one another, exchanging information using signals and shared variables. The basic unit of concurrent action is the process.

Processes

Processes are units of action in a simulation. Processes affect the system state, and therefore affect the model of the device under development, by assigning to signals. These signals are in turn read by other processes and used to determine the signals they assign in turn.

In general, processes may be thought of as tasks or co-routines in a software language. Processes may declare variables which serve as internal state, call procedures, and read from and write to files. Processes also suspend their own execution via wait statements. Processes are composed of sequential statements (see Section 80.5 for a discussion of sequential statements).

Processes begin execution at the beginning of simulation, and also at some combination of the following three conditions:

- when one of a given set of signals changes value
- after a certain period of time
- when a Boolean condition becomes true

When suspending execution, each process states the conditions under which it will next resume execution. Consider the following simple example:

```
process
begin
  a <= b nand c after 50 ns;
  wait on b,c;
end process;
```

The signal assignment statement specifies the value of the signal **a** based on the values of signals **b** and **c**. The following statement specifies that whenever the values of either **b** or **c** change, the process will resume execution. Note that processes always inherently loop; after the wait statement, the process will resume execution at the first statement of the process.

There are several other kinds of concurrent statements; however, all of them that execute are equivalent to processes of one or another. We will consider these subsequently.

Other Concurrent Statements

Concurrent statements may be divided into two categories: those that affect the system state during execution (and which are therefore equivalent to some concurrent process) and those that define the structure of the model being built. We will cover the first category in this section; the second category will be dealt with in other sections below.

Signal Assignment Statements

Signal assignment statements may be expressed directly, without embedding them inside a process statement. Such signal assignment statements are equivalent to a process that contains them, and a wait statement containing the signal names of the signals on the right hand side of the assignment statement. For example, the process statement given above is equivalent to the signal assignment statement:

```
a <= b nand c after 50 ns;
```

The b and c for the wait statement in the process statement are taken from the **nand** expression on the right side of the signal assignment statement.

There are two other forms of the signal assignment statement, each with an equivalent process. The following conditional signal assignment statement

```
output <=in1 after 10ns when cntl == '1' else
         in2 after 10ns
```

is equivalent to the following process:

```
process
begin
  if cntl = = '1' then
    output <= in1 after 10ns;
  else
    output <= in2 after 10ns;
  end if;
  wait on cntl, in1, in2;
end process;
```

which contains an if statement derived from the choices. Note that the list of signals in the wait statement is the union of those found in the assignment statements, along with the expression in the when clause. Similarly, the following selected signal assignment

```
with cntl select
output <= in1 after 10 ns when '1',
           in2 after 10 ns when '0';
```

is equivalent to the following process:

```
process
begin
case cntl is
  '1' => output <= in1 after 10ns;
  '0' => output <= in2 after 10ns;
end case;
wait on cntl, in1, in2;
end process;
```

Again, the list of signals in the wait statement is equivalent to the union of the lists provided by each signal assignment statement, along with the name in the case expression.

Behavior that is defined totally by concurrent signal assignment statements (and particularly by simple signal assignment statements) is often referred to as a register transfer level, or RTL, description. Such descriptions are particularly useful in conjunction with synthesis tools; there are standardized subsets of both VHDL and Verilog for use by synthesis tools.

Concurrent Procedure Calls

The concurrent procedure call is a procedure call that is executed as a process itself. This is useful if a more complex piece of behavior is used repeatedly as a concurrent "chunk," and embedding the single procedure call is confusing and wasteful. The following procedure call

```
select_signal (cntl, in1, in2, output);
```

is equivalent to the following process statement:

```
process
begin
  select_signal (cntl, in1, in2, output);
  wait on cntl, in1, in2, output;
end process;
```

The signals for the wait statement are gathered from those parameters of mode **in** or **inout**.

Concurrent Assertion Statement

Like the concurrent procedure call, the concurrent assertion statement allows the designer to express invariants about his design without having to embed the statement in a process. Unlike some of the other concurrent statements, it is perhaps more common to find the concurrent form of the assertion statement used than the sequential form. The following concurrent assertion statement

```
assert not (in1 == '1' and in2 == '1')
  report "Illegal input combination on flip flop."
  severity WARNING;
```

is equivalent to the following process:

```
process
begin
  assert not (in1 == '1' and in2 == '1')
    report "Illegal input combination on flip flop."
    severity WARNING;
  wait on in1, in2;
end process;
```

Concurrent Break Statement

The concurrent break statement signals a discontinuity to the analog solver, which must then reinitialize the values it is calculating for all quantities and terminals based on information given by the break statement. The following break statement

```
break vel => –vel on ypos'ABOVE(10);
```

is equivalent to the process statement:

```
process
begin
  break vel => –vel;
  wait on ypos'ABOVE(10);
end process;
```

Note that the use of the form ypos'ABOVE(10) creates a signal that changes value when the expression ypos—10 becomes above zero; in other words, when ypos crosses the value 10.

80.5 Sequential Statements

Sequential statements appear in process statements or in subprograms (procedures and functions) which are called by process statements. They are the statements that change the program state and that control execution flow through the process. Statements that change the program state are assignment statements.

Many of the sequential statements in description languages should be familiar to software programmers. Indeed, it may be said that in many ways, designing hardware with a design language is similar to programming. We will summarize constructs similar to software languages here without a tremendous amount of discussion. More time will be spent on those constructs that are unique to, or more common in, description languages.

Assignments

An assignment calculates an expression and assigns it to an object that is part of the system state. There are two kinds of assignment statements: variable assignment statements and signal assignment statements. In both cases, the expression on the right side of the statement is evaluated and then the action specified

by the statement takes place. The two kinds of statements are distinguished by the sign used to mark the assignment:

```
x: = y + z
a <= b nand c;
```

The first statement is a variable assignment, and the second is a signal assignment statement.

A variable assignment statement takes effect immediately; the statement directly following it can read the new value. A signal assignment statement takes effect more indirectly in the following fashion. Consider the following signal assignment statement:

```
clock <= 'X' after 10 ns, '1' after 20 ns;
```

The right-hand side consists of a potentially unbounded number of pairs (two in this case), separated by commas, consisting of an expression and a time (which can also be an expression). The times must be nondecreasing. Each process has an object called a driver for each signal for which it has a signal assignment statement. The update to the driver takes place immediately; the value of the signal does not change until all processes have been executed and the simulation cycle updates the signal values (see 80.8 for a description of the simulation cycle).

Updating the driver is a complex operation. The driver may already contain a number of time value pairs. The time value pairs in the signal assignment statement are overlaid on top of the time value pairs in the driver in one of two ways. The first, called transport delay, takes the first time in the signal assignment statement and eliminates all pairs in the driver with a time equal to or later to the first time. The second, called inertial delay, also reflects the first value back to the first occurrence of that value in the driver, eliminating all pairs in between. For a fuller explanation of this process, see the VHDL LRM; the process in Verilog is considerably simpler.

Control Flow

Within a process statement, control transfers from statement to statement in a sequential fashion, one after another, unless this is interrupted or changed by one or another control flow statement. Most of these are familiar to programmers; however, there is one that is used in description languages. This is the wait statement, which has been mentioned previously. Other statements will be mentioned more briefly.

Wait Statement

The wait statement suspends the execution of a process and specifies the conditions under which the process will resume execution. We have already seen examples of a wait statement; its most general form is

```
wait on <signals> until <condition> for time;
```

The user can leave out any of the parts if he wishes. In this case, these are automatic defaults. The meaning of each of these parts is

on <signals> The process will resume when any of the signals in the list of signals given changes value. If none is given, the list is derived from the signals in the condition; if there is no condition, the list is empty;

until <condition> The process will resume when the condition is true; it is checked only if one of the signals in the list above changes value. If no condition is given, it defaults to TRUE.

for <time> The process will resume execution after the given amount of simulation time has elapsed. If no time is given, it defaults to the highest time in the system (minus the current time; the process will restart "at the end of time," or never).

Thus, the process will resume when one of the signals in the list changes value or when the given time has elapsed, whichever is first. If one of the signals changes value and the condition is false, the process does not resume.

Assertions

An assertion states a condition that must be true at a point in the simulation of the system. If the statement is not true, the message in the report clause is printed out and execution either halts or continues depending on the value in the severity clause. An example is:

```
assert not (in1 == '1' and in2 == '1')
  report "Illegal input combination on flip flop."
  severity WARNING;
```

This statement works just as well inside a process as outside a process; inside a process it is a sequential statement, and outside a process it is a concurrent assertion statement with an equivalent process as described in "Concurrent Assertion Statement."

Often we need no condition for an assertion statement; the simple fact that we have reached a point in the execution flow is enough. In this case, we need only specify the report and the severity clauses in a report statement. The previous assertion statement is equivalent to

```
if in1 == '1' and in2 == '1' then
  report "Illegal input combination on flip flop."
    severity WARNING;
end if;
```

Conditionals

As with most software languages, there are two forms of conditionals: the if statement and the case statement. The following are equivalent

```
if cntl == '1' then
  output <= in1 after 50 ns;
else
  output <= in2 after 50 ns;
end if;
```

```
case cntl is
  '1' => output <= in1 after 50 ns;
  others => output <= in2 after 50 ns;
end case;
```

Loops

There are two forms of loops: for loops and while loops. Associates with loops are two statements for loop control: the next statement, which immediately jumps to the beginning of the loop (when used with a label, to the loop with the label given), and the exit statement, which jumps to the statement following the end of the loop (if labeled, the loop with the label given). Three loops that do the same thing–initialize an array–are

```
for i in 1 to 10 loop
  for j in 1 to 10 loop
    a (i,j): = 0;
  end loop;
end loop;
```

```
i: = 0;
iloop: while i < 10 loop
  i: = i + 1; j: = 1;
  jloop: loop
    a (i,j) = 0;
```

```
    if j == 10 then
      exit jloop;
    else
      j: = j + 1;
    end if;
  end loop;
end loop;
```

```
i: = 0;
iloop: while i < 10 loop
  i: = i + 1; j: = 1;
  jloop: loop
    a (i,j) = 0;
    if j == 10 then
      next iloop;
    else
      j: = j + 1;
    end if;
  end loop;
end loop;
```

Obviously, the second and third are for purposes of illustration only.

Procedure Calls and Returns

A procedure call is an invocation of a given procedure, giving values for all the parameters. The statement simply gives the name of the procedure and the parameter values:

```
fetch_memory (1024);
```

The return statement returns control from a subprogram. If inside a procedure, it consists of the single keyword return; if inside a function, it consists of the keyword return followed by an expression that, when evaluated, becomes the value of the function call.

Null Statement

The null statement consists of the single keyword null and does nothing at all.

Break Statement

The break statement is not a control flow statement per se; control continues with the immediately following statement. The break statement signals that a discontinuity has occurred and that the analog solver must re-initialize its set of solutions before proceeding. An example is

```
break vel => -vel when ypos == 0;
```

The expression gives the new value for the quantity during reinitialization, and the condition denotes when the break is signaled. If the expression evaluates to false, no break occurs.

80.6 Simultaneous Statements

Simultaneous statements determine the value of quantities and terminals. They do not take effect directly; instead, they are used to determine the values of the objects involved via a mathematical process of determining the solution of a system of simultaneous equations. To explain this further, we consider modeling analog circuits in general.

Analog circuits are modeled by specifying, via a series of different algebraic equations (DAEs), the relationship between the values of the quantities involved. These equations are characteristic for each

analog device. It becomes the responsibility of the simulator to assign values such that these mathematical relationships are maintained.

In addition to the relationships specified by the DAEs in a model, the analog system also uses two laws — Kirchhoff's Current Law, which states that the sum of all currents into a single terminal must be zero, and Kirchhoff's Voltage Law, which states that the sum of all voltages in any loop of connected terminals must be zero — to create any additional mathematical relationships needed to solve the system.

Given that these DAEs exist and are specified in the description language, the job of the analog solver is to

1. Collect the DAEs and create a system of simultaneous equations out of them.
2. Determine a set of initial values for the system.
3. Solve the system in increasing time steps, synchronizing with the fixed event simulator of the digital system as needed.

Within this general description there is a great deal of room for differences in specific algorithms. The important task is to maintain the mathematical relationships defined in the model whenever the values of the quantities and terminals are read.

Specifying DAEs is the job of the simultaneous statements. These are not part of VHDL, but are specified as part of the analog extensions to VHDL; the entire language is referred to as VHDL-AMS.

Forms of Simultaneous Statements

The basic form of a simultaneous statement is an equation. It simply sets up the relationship involved. The equation is written identically to a Boolean condition that could be checked in a conditional statement. An example is

```
brvolts == L * brcurr'DOT;
```

where the use of the form `brcurr'DOT` signifies the time derivative of the branch current.

As with the signal assignment statement, there are alternative forms of the simultaneous statement. These select the equation to be used by the analog solver depending on the values of the surrounding objects. One is analogous to a conditional statement:

```
if v> 0.0 use
  v'dot == -g – v ** 2 * resis;
else use
  v'dot == -g + v ** 2 * resis;
end use;
```

The second is analogous to a case statement:

```
case cntl use
  when '1' => outv = 10 * inv;
  when '0' => outv = 2 * inv;
end case;
```

There is a third form which is considerably more complex, and effectively allows the user to insert a function that is called each time a given quantity value is determined. This is the simultaneous procedural statement. It allows the same quantity names to be used as variables and for them to be assigned to as necessary. For example, the procedural equivalent of the conditional example above is

```
procedural is
begin
  if v > 0.0 then
    v'dot: = -g – v ** 2 * resis;
  else
```

```
        v'dot: = -g + v ** 2 * resis;
    end it;
end procedural;
```

Any number of quantities may be assigned to by the procedural statement; the procedural statement then acts as the DAE for all of them.

80.7 Modular Designs

Modern systems that are implemented on a single silicon chip can be incredibly complex. They can include millions of lines of software, millions of gates of digital logic, and thousands of active analog devices. The only mechanism for controlling this kind of complexity is modularity. This means splitting up a very complex design into small pieces that can be understood and controlled. This section begins with some discussion of general issues in modularity, then moves on to mechanisms for creating and enforcing modularity.

General Issues

In dividing a system up into pieces, there are several concerns that must be addressed. Each one of these is important to the ability of the user to understand and use in individual pieces. To a large extent, this differs depending on what can be legitimately divided and separated from other pieces of the system, and this varies between digital and analog descriptions.

Description languages have the task of providing the user with the ability to split up the system in a manner that conforms to engineering and design practice. In general, this means separating interface from implementation and making sure that the interface is uniquely defined. Different mechanisms of partitioning and separation are used, depending on the effect that is desired. Decomposition is a powerful tool, and sometimes a two-edged one. Great attention is needed to partition a design effectively and efficiently.

Forms of Partitioning

There are several forms of partitioning that are made available by description languages:

Algorithmic partitioning This entails the ability to use an algorithm, or rule, without necessarily knowing how it is implemented. This kind of partitioning is used by software languages, as well, and is implemented in general with some sort of packaging and subprogram mechanism.

Physical partitioning A design can be partitioned according to the physical packages that appear within it. This means if a given device has a physical realization — it is placed in a separate package with pins and soldered connections, for example (other physical packaging is possible) — it has a separate definition in the description language.

Design partitioning A designer normally begins his design with a block diagram which shows, in conceptually separate blocks, a number of functions and the connections between them. These blocks may or may not implement identifiable algorithms, and they may or may not have specific physical packages associated with them.

Implementational partitioning During the design of a complex system, multiple implementations (or models) of a given part will be used during the system lifetime. These may include a bus functional model (a model that attempts to give timing of messages flowing through the device at a very high level), a behavioral model, an RTL model, and a detailed structural model.

Description languages must be able to provide each of these partitioning mechanisms.

Name Space Control

In a large design where objects, models, devices, and other parts of the system under development all have their separate names, name space control is a tremendous problem. In general, having unique names

for each of these named things is not possible. Name space control is an important part of the definition of any description language.

Name space control is a problem shared by software languages as well. In general, it consists of importing various sets of names — libraries and packages — into a given description unit and using those names just as any locally defined name.

There are usually two options for importing names:

1. Import all the names defined in a given package or library.
2. Import a list of a selected list of names defined in a given package or library.

Designers often use method 1, which requires less writing. One reason for this discussion is to urge more use of method 2, which is more trouble but provides a great deal more control over the names and more visibility over where they are defined.

Another mechanism of name space control used by many languages is to mark off a section of the description where names may be declared that are not visible outside that section. The general name for such a section, both in software languages and in description languages, is the block. In VHDL, there is an explicit formulation of a block that is called the block statement. The basic format of a block statement is:

```
block
  <declarations>
begin
  <statements>
end block;
```

where the declarations and statements can be anything that may occur in a concurrent declaration or statement context, respectively. Names declared in the block are not visible outside the block.

In fact, it is possible to use a block like a component (see "Interfaces and Implementations" for more discussion) by defining an interface consisting of ports and generics and connecting these to objects outside the block. This is a rather advanced use of the block statement, and we will not discuss it further here.

System Hierarachy

Each unit in a description has two choices concerning how to define the behavior of that unit:

1. It can link together other components — a structural definition.
2. It can define the unit with code specifying how it behaves — a behavioral definition.

Units can mix behavioral and structural definitions.

Given that a description has been split up into a large number of pieces, the pieces must be recombined in order to form a complete system description. This combined description is composed of three kinds of units:

1. Units with only behavioral descriptions. These are called leaf level units; they use no other devices.
2. Units which refer to other units in their definition. These units are called the parents of the units to which they refer, which are called children. Units which have both parents and children are called internal units.
3. Units which refer to other units in their definition but have no parents. These are called roots.

While it is possible for a given design to have multiple roots, in practice there is a single root for each design. The transitive closure — parents using children, who in turn, use their children until nothing but leaf units are left — of the root is called the design hierarchy of the system. The design hierarchy represents the entire system being designed. It almost always represents a testable unit, with a separate physical interface. Test benches and testing occur on design hierarchies and refer to the entire design hierarchy through its root.

Interfaces and Implementations

The first mechanism for partitioning provided by description languages is a separation between interfaces and implementations. In VHDL, this occurs at several levels. This section will cover physical and design partitioning and leave algorithmic partitioning to "Packages and Subprograms."

Any interface must define the interface points, or points where information may be exchanged. These are often divided into two kinds of exchange:

1. interfaces where a physical package itself would be connected, or where actual information is exchanged during system operation (perhaps by coupling);
2. interfaces where information concerning system modification and adaptation is exchanged.

In VHDL, the former is accomplished by ports, which are signal objects, and the latter is accomplished by generics, which are constant objects. The interface is called an entity. An example is

```
entity multiplexor is
  generic (delay: TIME);
  port (cntl, in1, in2: in BIT;
        output: out BIT);
end entity multiplexor;
```

This section of VHDL code gives all the information necessary for a user to understand how to use the device, including setting its delay time and how it is to be connected into a system. It says absolutely nothing about how the device behaves. This is left to the specification of the implementation of the device. In VHDL, this is done by the architecture:

```
architecture behavioral of multiplexor is
begin
  with cntl select
    output <= in1 after delay when '1',
              in2 after delay when '0';
end behavioral;
```

Together, the entity and the architecture define the entire device; each is incomplete without the other. There may be many architectures for a given entity. The appropriate architecture is chosen by a configuration, as seen in "Configuration."

Instances and Instantiations

Given units created by entities and architectures, we must be able to use them. Using an entity architecture pair (or component) is called creating an instance of that component, and the statement that does so is a component instantiation statement. Creating an instance of a component means creating all of the objects defined by that component (which means all of the objects defined by the design hierarchy rooted at that computer) and connecting them appropriately, as shown in the component instantiation statement.
VHDL has an additional level of indirection between the component instantiation statement and the component: the component declaration. If the name in the component declaration is the same as the name of the entity in the library, then no further action is needed. If the designer wishes to change the device used later, then a configuration can be used, as in the following section.

All of these are combined into the (rather stupid) implementation of a nand gate:

```
entity my_nand is
  port (in1, in2: in BIT;
    output: out BIT);
end my_nand;
```

```
architecture sample of my_nand is
  component my_and
    port (in1, in2; in BIT;
      output: out BIT);
    end component;
  component my_not
    port (input: in BIT;
      output: out BIT);
    end component;
  signal t: BIT;
begin
  and1: my_and port map (in1, in2, t);
  not1: my_not port map (t, output);
end sample;
```

This implementation defines two components, my_and and my_not, and uses them to build up the implementation of the nand gate by creating one instance of each. The form of the component instantiation statement begins with a required label, and then names the component. The port map follows, which gives an object of kind signal for each port in the component definition. A generic map clause would be used to provide values for any generics in an entity definition.

Configuration

As stated in the previous section, VHDL provides an extra level of indirection between the component instantiation statement and the component to which it refers in the form of a component declaration. If the name of the component matches the name in the library and if the port and generic lists match as well, then nothing more need be done; a default connection will occur between the component declaration and the component in the library.

In some cases, it is desirable to override this default matching. Indeed, it may be desirable to override this matching all up and down the entire design hierarchy. In VHDL, this is done with a configuration declaration. The configuration intuitively "follows the design hierarchy," specifying which component is used for each component declaration. The configuration allows the user to "step into" the different parts of the design hierarchy. An example is

```
configuration my_config of my_nand is
  for sample
    for my_and use and_123(struct); end for;
    for my_not use not_456(struct); end for;
  end for;
end configuration my_config;
```

Note that the various for statements follow the design hierarchy down; each time the user "steps into" a component, a new for statement is written. The for statement specifies which entity and architecture (the architecture name appears in the parentheses) is to be used for each component, along with configuring any components below it in the design hierarchy.

The configuration declaration is the only unit in VHDL that can "dip into" different units and get visibility over the names in those units as it progresses down in the hierarchy. This makes the configuration declaration potentially the most complex single unit in the description.

Packages and Subprograms

Algorithmic partitioning is accomplished by the use of packages and subprograms. Packages are collections of declarations, including type and subprogram declarations. Packages allow the user to take a

number of related declarations and place them together, using them in many different models. Subprograms allow the user to take a portion of an algorithm and separate it, invoking it in a number of processes. There are two different kinds of subprograms: procedures (which act like sequential statements) and functions (which act like expressions).

Both packages and subprograms maintain the VHDL practice of separating interfaces from implementations. In all cases, the interfaces are called declarations (package declaration, subprogram declaration) and the implementations are called bodies. The bodies may repeat part of the declaration and then give values to the declaration by giving more details.

Since packages are collections of declarations and therefore do not execute per se, they have no interface points, and therefore no parameters. Subprograms do execute and therefore have interface points. These parameters are specified by name, type, and direction; the direction specifies whether the parameter is being used as input to the subprogram or output from the subprogram. Functions cannot use parameters as outputs; they can only return values in an expression.

Subprograms can be overloaded; i.e., different subprograms can share the same name. In this case, the types of the parameters to the subprogram are used to determine which subprogram is to be called. This is useful where the same essential function is defined on a number of different types, thus allowing the user to state the definition for each of the types and therefore avoid using different names for what is the same basic operation.

Consider the following example:

```
package sample_inc is
  constant factor: INTEGER;
  procedure inc (x, y: in INTEGER;
                 z: out INTEGER);
  function inc (x, y: INTEGER) return INTEGER;
end package sample_inc;

package body sample_inc is
  constant factor: INTEGER: = 2;
  procedure inc (x, y: in INTEGER;
                   z: out INTEGER) is
  begin
    z = (x + y) * factor;
  end procedure;
  function inc (x, y: INTEGER) return INTEGER is
  begin
    return (x + y) * factor;
  end function inc;
end package body sample_inc;
```

In the context of this package, the following two statements

```
inc (a, b, c);
c: = inc (a, b);
```

do precisely the same thing. Note that the value of constants as well as subprograms can be deferred to the implementation; it is possible to name constants without giving their value.

80.8 Simulation

Although details vary, each description language determines object values and executes statements in a manner determined by what is called the simulation cycle. The simulation cycle has responsibility for the following tasks:

- initialization of all objects;
- initial execution and resumption of processes;
- determination and advancement of simulation time;
- solving systems of simultaneous DAEs, and setting the values of quantity and terminal objects; and
- determination and propagation of values in signal objects.

In general, while some interleaving may take place, these operations are done in separate steps that make up what is called the simulation cycle.

Initialization of objects is performed prior to the beginning of simulation. This is a one-time operation and has the effect of setting the system to a known state before simulation begins.

The processes to be executed are determined by a combination of three things: the simulation time, changes on various signals, and the conditions set in wait statements. In general, models do not depend on the execution order of processes. Indeed, VHDL models that do depend on this order are deemed to be in error.

Simulation time is determined based on the drivers of all the signals in the model. Each driver has an earliest transition; the minimum of these earliest transitions determines the next simulation time. In some cases, simulation time may not advance at all, but remain at its present value. In VHDL, this is called a delta cycle.

The system of simultaneous equations is determined each time the analog solver is invoked. Because of the action of conditional and selected signal assignment statements, that system may change at any time. The analog solver has the task of determining the time steps it will take (although this may be limited in VHDL by a predefined procedure call). In addition, if a discontinuity has been signaled by a break statement, the analog solver has the task of determining a new set of initial values before continuing to update its own simulation time steps.

Determining the value of signal objects means taking the contribution to that signal value from each process that assigns to it (contained in the driver) and combining them appropriately. If there is only one driver, then the driver value is the value of the signal. If there are multiple driver values, then the values must be resolved. This is the purpose of the resolution function which is specified by the subtype (not the type) of the signal. This resolution function takes an array of values in the type of the signal, and produces a signal value of that type. The values of each of the drivers is invoked, and the result becomes the value of the signal.

The extent to which these operations can be interleaved, and executed in parallel, is determined by the exact definition of the language as contained in the LRM. Simulators are not confined to doing these functions separately, or serially, as long as the results they produce are identical to those defined by the abstract simulation mechanism defined by the LRM. Study groups and standard practices for parallel simulation are a continuing field of research in VHDL and Verilog language development.

80.9 Test Benches

Given a model of a device under development, the designer next has the task of simulating that device. Simulation, and the definition of test vectors to the simulation, is very tool dependent; however, there are two basic approaches:

- The toolset can provide inputs to the simulation and graph (or check) outputs outside the model itself. This approach is totally dependent on the tool features, and we do not deal with it further here.
- The toolset can assist in the construction of a component called a test bench, which instantiates the design to be tested, feeds data to the input pins, collects data from the output pins, and checks it in various ways. The test bench becomes the root of the design hierarchy that is simulated.

Writing a test bench is like writing any other component in the description language; the same language constructs are used and the same principles apply. A test bench does two things. First, it generates

behavior; it causes the device to simulate. In some development methodologies, this is a vital function. The initial checking of the device consists of generating random inputs and visually inspecting the outputs (as waveforms or as more comprehensible outputs) to see if they match those inputs. Such methodologies can go even further, using this mechanism to produce actual test vectors for the resulting device from the simulation itself (and thus using the model as the specification of the device).

Second, a test bench can be used to check that the device actually fulfills its function. This means both generating the behavior and checking that the behavior is correct. Such checking requires an outside specification of that behavior. There are two approaches to writing this kind of test bench: algorithmic, where the specification is provided by an algorithm, and vector-based, where the specification is provided by a set of test vectors.

Algorithmic Test Benches

An algorithmic test bench tests a device by implementing the algorithm that the device is intended to embody. For example, if a multiplier is being designed, an algorithmic test bench would feed two numbers to the input of the device, capture the output, then multiply the numbers together and check that the output matches the result of the multiplication.

Algorithmic test benches can fit in very nicely with a top-down design methodology where each entity has at least two architectures: one behavioral and one structural. If the algorithm in the behavioral architecture is encapsulated in a procedure, the test bench can call the procedure in parallel with the provision of inputs to the structural device. The outputs of the two can then be compared. This can apply to quite complex devices, even to ISP-level simulations of complex microprocessors.

While the function of the device is provided by the algorithm, the exact inputs are not. There are three approaches to choosing inputs. First, the designer may decide (particularly in a memoryless device such as a multiplier) to exhaustively simulate the entire input space. This is implemented using a nested loop, with one level for each input. Second, the designer may choose to select inputs randomly and run the simulation for as long as time allows. This is implemented with a random number generator. Finally, the designer may attempt to provide some level of fault or algorithmic code coverage. This must be accomplished with a test tool that measures such coverage metrics.

Vector-Based Test Benches

Vector-based test benches use a series of inputs and outputs that are, in some sense, defined outside the model itself. The only task of the test bench is to obtain the test vectors (usually from a file), provide the inputs to the input ports, read the outputs from the output ports, and check them against the output values provided by the test vectors.

Vector-based test benches are thus very simple to write, and indeed there are tools that write them automatically based on a list of input pins, output pins, and a matching between the pins and the bits in the test vectors. From this, the code to read the vectors, apply them to the device, and check the output values can be derived automatically.

In vector-based test benches, the complexity is contained in the vectors themselves. Indeed, it could be said that the test vectors are a specification of the behavior that the device must meet. The production of the test vectors therefore becomes of vital importance. Often, the test vectors are produced by simulation as discussed above. In this case, the specification contained in the test vectors can be said to develop iteratively, first by inspection of initial outputs and later by running further inputs and expanding test cases as necessary.

The adequacy of vector-based test benches is usually measured by fault coverage. Fault coverage entails the deliberate introduction of faults into the model, either by altering the actual model code or (more commonly) by having the simulator introduce faults into the model automatically without changing the code and recompiling. Faults are usually simple in nature, the most common being setting the value of a specific object to a given value regardless of the actions of the surrounding devices (a “stuck at” fault).

A set of vectors is said to achieve a certain percentage of fault coverage for a device if that percentage of generated faults are detected by the test bench using the given set of test vectors.

The use of vector-based test benches is sufficiently important that the standardization activities have been devoted to it. In particular, the waveform and vector exchange specification (WAVES) is a standard test vector specification language that is designed to both work with a VHDL model and to provide input to various automatic test equipment (ATE) systems. Tools exist to create test benches from a WAVES description as described previously, making the simulation of a VHDL mode with a set of WAVES specified test vectors easy and convenient. These tools are vendor-independent in the sense that they produce standard VHDL code that runs on any compliant simulator.

Hardware Description in Verilog: An Overview

Zainalabedin Navabi
Northeastern University/University of Tehran

This chapter presents an overview of the Verilog hardware description language (VHDL) and the way it may be used in a design environment. Many details of the language will not be discussed in this introduction. However, this chapter will cover the general concepts of Verilog that enable the reader to understand Verilog code and develop simple hardware descriptions in this language. This chapter also facilitates the learning of the full language as presented in the IEEE standards document or any of the available texts on this topic.

In the sections that follow we will first present an overview of Verilog and elements of this language. We will then describe basic component descriptions such as flip-flops and small combinational circuits. Using the coding styles presented, we will then describe more complex hardware component descriptions such as counters and shift registers. The section that follows part descriptions will show a complete component-based design using components from the earlier sections.

Describing complete systems at the RT (Register Transfer) level requires use of data units such as registers, busses, and logic units as well as controller circuitry. While data units facilitate storage, movement, and processing of data, controllers control flow of data and times at which each of the data units handles its given data. Sections 81.2 and 81.3 of this chapter discuss Verilog coding styles for basic components. These styles apply to describing data units and their interconnections. In Section 81.4, we will present Verilog code of a state machine representing a coding style for description of controller circuitry. Together, material in Sections 81.2, 81.3, and 81.4 present coding styles for describing a complete system at register transfer level.

Finally, in Section 581., we will discuss the use of Verilog primitives and the way they can be used for describing basic gate and switch level components. System designers usually deal with more abstract

descriptions than those at the gate or switch level. However, being able to read machine generated gate level descriptions, and being able to develop glue logic at this level of abstraction is necessary for a VLSI designer using Verilog in his or her design environment.

81.1 Elements of Verilog

Constructs of the Verilog language are designed for describing hardware modules and primitives. This section presents language features related to these applications. We will show the general outline of a Verilog code for describing a hardware part and will discuss the use of various coding styles in a design.

Describing Hardware Modules

The Verilog HDL is used to describe hardware components of a system and complete systems. The main component of the language, which is a module, is the main body for describing parts and systems. As shown in Fig. 81.1, a module description consists of the keyword **module**, followed by list of ports of the hardware module, module functionality specification, and the keyword **endmodule**. Following the list of ports of a module, a semicolon separates this part from the next part in which declarations of parameters, ports, and signals of a module are specified. After the declarations, statements in a module specify its functionality. This part defines how output ports react to changes on input ports.

```
module module_name
        list of ports;

        declarations;
        specification of the
        functionality of module;
endmodule
```

FIGURE 81.1 Module specifications.

As in software languages, there is usually more than one way a component or a module may be described. Various descriptions of a component may correspond to descriptions at various levels of abstraction or various levels of detail of functionality of a module. As shown in Fig. 81.2, a module description may be at the behavioral level of abstraction with no timing details, while another description for the same component may include transistor level timing details. A module may be part of a library or predesigned library components and include detailed timing and loading information, while a different description of the same module may be at the behavioral level for input to a synthesis tool. It must be noted that not all descriptions of the same module must necessarily behave exactly the same way, nor, is it required that all descriptions behave correctly. In a fault simulation environment, faulty modules may be developed to study various forms of failure of a component.

```
module module_i
        (ports, ...);
        declarations, ...;

        behavioral
        specification
        of module_i
        with no timing
        specification;
        . . .
        . . .
endmodule
```

```

and	buf	bufif0	pulldown	cmos	Rtran
nand	not	bufif1	pullup	nmos	rtranif0
or		notif0		pmos	rtranif1
xnor		notif1		rcmos	tran
xor				rnmos	tranif0
				rpmos	tranif1

As shown in Fig. 81.2, a module begins with a module header that includes a listing of the ports of the module. Although there may be many module descriptions for a hardware component, the same port specification is used in all such modules. Initially in a design process, a behavioral description of a system helps the designer understand the general functionality of the system under design. After the initial phase of the design process and when a design is partitioned into its subcomponents, a structural specification specifying wiring of subcomponents is used. In the last stage of design of a component, RTL (Register Transfer Level) descriptions for manual design, or synthesizable descriptions for automatic design are used. After a design is synthesized, the synthesized output is generated in form of a structural description specifying wiring of primitive components.

Often in a design process various forms of a module are created manually or automatically. These descriptions are analyzed and simulated, and their results are compared for verifying the synthesized circuit functionality or for timing verification. The Verilog hardware description language also provides constructs for generation of test benches. A test bench is a Verilog behavioral module in which a design module is instantiated and test data is applied to it. Test benches can also instantiate several modules describing the same design for functional and timing comparisons.

Primitives

Generally, hardware components are described as modules. Often, however, in a design environment certain bit level functions exist that are used as primitive gates or memory elements. These primitives are used for formation of glue logic in large designs or for complete netlist descriptions of a system. A description based on primitive structures is useful for timing analysis, test applications, and other applications where exact hardware correspondence is important. Verilog provides a set of 25 logic primitives as shown in Table 81.1. These primitives have a fixed interface with output port being listed first, and can be used in a design much the same way as a user-defined module is used. Verilog descriptions that are primarily based on gate and transistor primitives have the same properties as netlist formats used in many CAD tools as intermediate database. Because of this, many commercial Verilog synthesis tools have an option to generate their netlist output in Verilog. This, in effect, translates an abstract description in Verilog to another less abstract form.

In addition to predefined primitives, Verilog allows definition of bit level sequential or combinational user primitives. Figure 81.3 shows the basic structure of a user defined primitive in Verilog. Defining a multiplexer, a special function flip-flop or a CMOS complex gate can be done by user-defined primitives. Generating functional models for a specific ASIC library can take advantage of this Verilog utility.

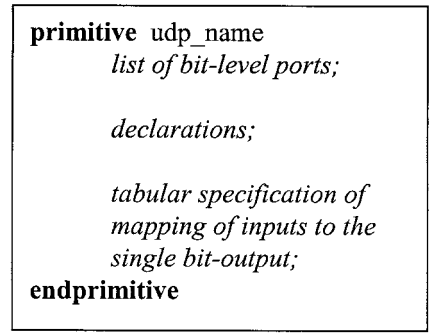

FIGURE 81.3 Verilog user-defined primitives.

81.2 Basic Component Descriptions

To demonstrate basic language features, we will show descriptions of several components in this section. Language features enable a designer to describe a component at the structural, dataflow, or behavioral levels of abstraction, which will be utilized in the descriptions that follow.

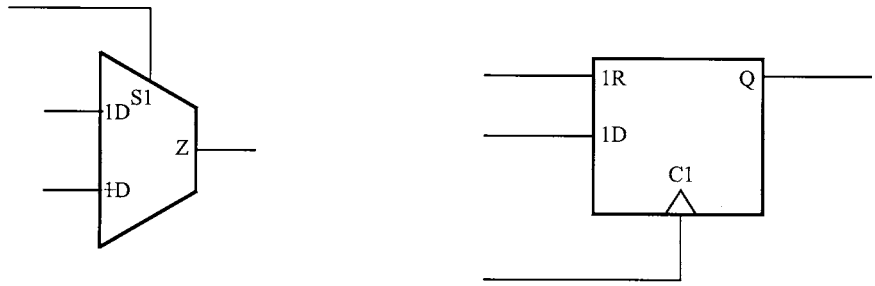
We will show Verilog code for a multiplexer, a D-type flip-flop, a full-adder, a counter, and a shift-register with enable and reset. These examples are chosen such that a wide range of behavioral and dataflow language constructs for combinational and sequential circuits are covered. For each example, the functionality will be described and a corresponding Verilog code will be presented; language constructs used in example codes will be explained. A complete design in the next section uses components of this section in a hierarchical structural description.

Small-Scale Part Descriptions

The components described in Fig. 81.4 are a multiplexer and a flip-flop. The multiplexer will be described at the dataflow level and the flip-flop at the behavioral level. The coding styles used here will be used as models for more complex hardware units. A shift-register and a counter that will be described next use the general format of the multiplexer and the flip-flop with added functionality and expanded number of bits.

The multiplexer is a 2-to-1 multiplexer with active high inputs and outputs. The flip-flop is synchronous D-type with synchronous, active, high reset input. With a delay after the rising edge of the clock if the reset is not active, the input value is clocked into the output. If the reset is active, the output becomes **0** with the falling edge of the clock.

Figure 81.5 shows the Verilog code for the 2-to-1 multiplexer of Fig. 81.4a. The code shown describes the *mux2_1* module. Following the *timescale*, which defines time unit of 1 ns and time precision of 100 ps, the first line of code specifies the name of module and its ports. Four input and output ports of *mux2-1* are named *sel*, *data1*, *data0*, and *z*. The line following this header line specifies that the first three ports are inputs, and the following line declares *z* as an output. This subsection ends declarations



(a) Multiplexer (b) Flip-flop

FIGURE 81.4 Symbolic notations for a multiplexer and a flip-flop.

```
`timescale 1ns/100ps

module mux2_1 (sel, data1, data0, z);
input sel, data1, data0;
output z;
  assign #6 z = (sel == 1'b1) ? data1 : data0;
endmodule
```

FIGURE 81.5 Verilog code for the multiplexer.

of inputs and outputs. If other signals were necessary for describing the operation of *mux2-1*, they would be declared here or anywhere in the code before they are used. It is usually best to put all the declarations at the top after the module header. All declared signals in this description, and in general, in Verilog, are of the bit type. This data type takes four logic values of **0**, **1**, **Z**, and **X**.

Following the declarations, the main body of a Verilog module describes the operation of the module. In this part, a module may be described in terms of its subcomponents, its register, and bus structure, or its behavior. In the *mux2_1* example, a continuous assign statement is used to specify output values for various input combinations. This statement specifies a 6 ns delay for all values assigned to *z*. The right-hand side of this statement selects *data1* or *data0* depending on *sel* value being binary **1** or **0**. Signals, such as *z*, to which assign is done, are presumed to be driven by their right-hand side at all times. Such signals are considered wires that do not need to hold any value. The description of the multiplexer presented here is at the dataflow level of abstraction. In this level, flow of data between buses and registers under control of the control signals is specified.

Figure 81.4.b shows schematic diagram for a flip-flop with synchronous reset and data inputs. Figure 81.6 shows the Verilog code for this small-scale part.

As in Fig. 81.5, the first line in Fig. 81.6 specifies time unit and its precision. Also, as in the description of *mux2-1*, the header line of the *flop* module specifies input and output ports of the flip-flop. Declarations following this header specify which ports are inputs and which are considered outputs of the module. An additional declaration specifies *qout* to be a signal that has capability of holding its values. This becomes clearer in the following paragraph.

```
`timescale 1ns/100ps

module flop (reset, din, clk, qout);
input reset, din, clk;
output qout;
reg qout;
  always @(negedge clk)
  begin
    if (reset) qout = #8 1'd0;
    else qout = #8 din;
  end
endmodule
```

FIGURE 81.6 Verilog code for a D-type flip-flop.

The part of the code in Fig. 81.6 that begins with the **always** keyword specifies values assigned to *qout* in response to *clk* and input changes. As specified by the statement following the at-sign, the body of this always statement is executed at the negative edge of the *clk* signal. At such times, if *reset* is true, *qout* receives 1′d0 (1-bit decimal 0), otherwise *qout* receives *din*. Value assignments to *qout* take place only on the negative edge of the clock. Therefore, in order for this output to hold its value between clock edges, it has been declared as a **reg**. A **reg** declaration is used for variables that hold values, while a net declaration that uses the **wire** keyword is used for continuous assignments and module interconnections.

In all Verilog descriptions a delay value is specified by an integer following a pound sign. In Fig. 81.6, 8 ns delay values specified on the right-hand sides of assignments to *qout* specify time delay between evaluation of the right-hand side expression and assigning them to *qout*.

A software-like, sequential coding style is used for describing the flip-flop model. A modeler writing such a behavioral description is concerned only with assigning appropriate values to circuit outputs. Neither the structure of the circuit nor the details of hardware in which data flows is of any concern. Behavioral constructs of Verilog enable designers or modelers to concentrate on *what* the hardware is supposed to do rather than *how* the task is to be done.

Medium-Scale Part Descriptions

In this section, coding styles described previously will be used to describe more complex hardware structures. A counter will be described at the behavioral level and a shift-register at the dataflow level of abstraction. We will also describe a full-adder circuit that demonstrates the use of functions in Verilog.

```
`timescale 1ns/100ps

module counter (reset, clk, counting);
input reset, clk;
output counting;
reg counting;
integer count;
parameter limit = 8;
  always @(negedge clk)
  begin
    if (reset) count = 0;
    else
    begin
      if (count < limit) count = count + 1;
    end
    if (count == limit) #8 counting = 0;
    else #8 counting = 1;
  end
endmodule
```

FIGURE 81.7 Divide-by 8, counter.

Procedural Coding

The behavioral description of the flip-flop uses procedural statements of Verilog. In general, in a procedural body of Verilog if-then-else, case and various loop constructs may be used. The example that follows shows a more general procedural coding than that of Fig. 81.6.

Figure 81.7 shows Verilog code for a counter with a synchronous *reset* input and a *counting* output. While counting falling clock edges to 8, the *counting* output stays high. When the circuit is reset or when 8 clock edges are counted, *counting* becomes **0**.

The Verilog code of the counter begins with module name and port list. Input and output declarations as well as declaration of *counting* as a **reg** follow the module heading. The *counting* variable is to hold values between activations of assignment of values to this signal, and, therefore, it is declared as **reg** to have the value holding property.

The declared integer *count* to keep the count and parameter limit to set the count limit. As in the description of *flop*, an **always** statement that becomes active on the negative edge of *clk* encloses the statements specifying behavior of the counter. Following the keyword **begin**, an if-then-else statement increments *count* if *reset* is not active and if *count* has not reached the limit. Another if-then-else statement sets the *counting* output of the counter to **1** if the count limit of 8 has been reached. Assignments to *counting* are delayed by 8 ns, specified by integers following pound signs.

User-Defined Functions

In the dataflow description of the multiplexer, continuous assignment statements were used to assign right-hand side expressions to net outputs. Use of functions can eliminate the need for complex right-hand side expressions in behavioral and dataflow descriptions. An example here will demonstrate definition and use of functions.

Figure 81.8 shows Verilog codes for a full-adder. The *fulladder* module describes a combinatorial circuit with three inputs and two outputs. A continuous assign-statement assigns the two-bit output of the *fadd* user-defined function to concatenation of *sum* and *cout*. The *sum* output receives the left-most output of *fadd* and *cout* receives bit 0 of this function. The *fadd* function is defined in the module of Fig. 81.8 as a function with a two-bit output. An expression concatenating two Boolean expressions for the two outputs of the function forms the right-hand assignment to function identifier, *fadd*. On the right-hand side of *fadd*, the symbol ^ is used for exclusive-or, & is used for anding, and the vertical bar is used for Boolean or operation.

```
`timescale 1ns/100ps

module fulladder (a, b, cin, sum, cout);
input a, b, cin;
output sum, cout;
  assign {sum , cout} = fadd (a, b, cin);

  function [1:0] fadd;
  input a, b, c;
    fadd = {(a ^ b ^ c) , ((a & b) | (a & c) | (b & c))};
  endfunction
endmodule
```

FIGURE 81.8 Full-adder description.

```
`timescale 1ns/100ps

module shifter (sin, reset, enable, clk, parout);
input sin, reset, enable, clk;
output [7:0] parout;
reg [7:0] parout;
  always @(negedge clk)
    parout = (reset) ? 8'd0 : ((enable) ? {sin, parout [7:1]} : parout);
endmodule
```

FIGURE 81.9 Shifter Verilog code.

Conditional Operator

In the dataflow description of the multiplexer, conditional operator was used on the right-hand side of a continious assignment. The example that follows will show the use of condition operator in sequential blocks. We will also show how clock control can be incorporated into an assignment statement with complex right-hand side operations.

For this part, a shift-register as shown in Fig. 81.9 is described in Verilog. Following module header and declarations, an always block, the flow into which is controlled by the falling edge of the clock (determined by *negedge clk*), encloses a sequential assignment to *parout* shifter parallel output. The value assigned to *parout* is determined by nested expressions using Verilog conditional operator (?:).

On the falling edge of the clock if *reset* is **1**, an 8-bit decimal 0 is placed on parout. If reset is **0**, a second conditional operator checks for *enable* being **1**. If *enable* is **1**, then *sin* is left concatenated with previous value of parout and will be assigned to parout as its new value. This concatenation causes *parout* to be shifted to the right by one bit. On the other hand, if *enable* is **0**, the second conditional operator in Fig. 81.9 will place the previous value of *parout* back on itself, causing the shift register state to remain unchanged.

81.3 A Complete Design

The previous section presented several styles for describing small- and medium-scale parts. In a complete design, these parts are wired to form a functional unit. Verilog provides constructs for wiring primitives and modules. This form of describing hardware is most often referred to as structural, in which components to be wired are instantiated and their connections are specified by **nets** that may be explicitly declared. The example that illustrates this style of coding is a sequential adder that is implemented using parts described in Section 81.2.

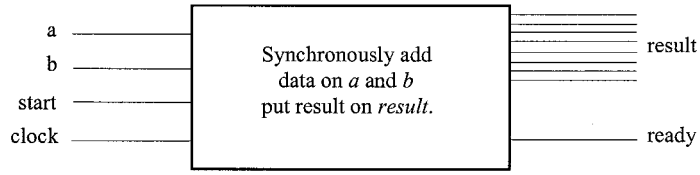


FIGURE 81.10 Serial adder.

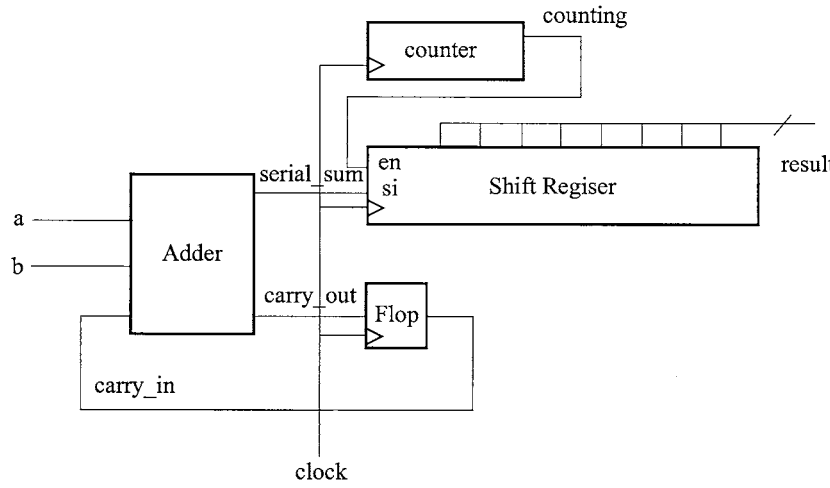

FIGURE 81.11 Implementing the serial adder.

The design we have selected is a sequential adder shown in Fig. 81.10. The circuit has two data inputs *a* and *b*, and a *start* input. The outputs of the circuit are *ready* and *result*. The circuit is a synchronous sequential circuit that uses the *clock* signal for the synchronization clock.

Serial data are synchronized with *clock* and appear on *a* and *b* inputs. Valid data bits on these inputs design after a pulse on start, and the ordering of these bits is from least to most. After eight clock pulses, the *result* output of the circuit will have the add result of the serial data are *a* and *b*. The *ready* output becomes **1** to indicate that one data set has been collected and add result is ready. This output remains **1** until another synchronous *start* pulse is observed.

Figure 81.11 shows an implementation of the serial adder using parts described in Section 81.2. An adder is used for adding serial bits, a flip-flop saves the value of carry for a next add stage, a shift-register stores bit results, and a counter keeps count of bits that are added. When the *counting* output becomes **0**, add result is ready of the *result* output.

Figure 81.12 shows the structural description of *serial_adder* consisting of interconnection of its four subcomponents. The module declaration consists of port list describing inputs and outputs of the serial adder. Declarations in the structural description of Fig. 81.12 declare inputs and outputs of *serial_adder* as well as wires for interconnection of components of which the serial adder is composed. Following the declarations, the *serial_adder* module includes instantiation of *fulladder*, *flop*, *counter*, and *shifter* modules. Instantiation refers to naming a module within another module for use as a subcomponent. Every instantiation begins with the name of module that is being instantiated, followed by an arbitrary label and a list of module port connections.

The format used here for module port connections is according to an ordered list. Signals in port connections of an instantiated module, e.g., *fulladder* instantiation in Fig. 81.12, connect to actual ports of the module, e.g., *fulladder* module in Fig. 81.8, in the order that ports appear in port-list of the module.

```
`timescale 1ns/100ps

module serial_adder (a, b, start, clock, ready, result);
input a, b, start, clock;
output ready;
output [7:0] result;
wire serial_sum, carry_in, carry_out, counting;
  fulladder u1 (a, b, carry_in, serial_sum, carry_out);
  flop u2 (start, carry_out, clock, carry_in);
  counter u3 (start, clock, counting);
  shifter u4 (serial_sum, start, counting, clock, result);
  assign ready = ~ counting;
endmodule
```

FIGURE 81.12 Shifter Verilog code.

Within a module, variables in the port list of the module as well as wires that can be explicitly declared in the module may be connected to ports of an instantiated module. For example, signals *a*, *b*, *start*, *clock*, *ready*, and *result* that appear in port list of *serial_adder* in Fig. 81.12, as well as declared wires in this module, i.e., *serial_sum*, *carry_in*, *carry_out*, and *counting*, can be used for connections to ports of *fulladder*, *flop*, *counter*, and *shifter*. Through instantiation of full-adder, wires visible in *serial_adder* module are connected to ports of the *fulladder*. Elaborating on this connection mechanism, consider the *carry_in* signal that connects to the *cin* input of *fulladder* and at the same time is used in the port map of *flop* to connect to its second port. The *carry_in* wire causes the *cout* output of *fulladder* to connect to *din* of *flop*.

81.4 Controller Description

The main purpose of this introductory tutorial has been the presentation of an overview of Verilog. A complete design usually consists of a data unit and a controller. Because of the size of our design examples, we were not able to discuss controllers and Verilog coding styles for them. A sequence detector is a state machine that represents a simplified controller and represents most characteristics of complex controller circuits.

This section shows Verilog coding style for describing a simple synchronous Moore sequence detector. A sequence detector has several states the transitions between which are decided by input values. Outputs of a detector are issued when one of its states becomes active. All state transitions in a sequence detector are synchronized with a main clock. Verilog code for the simple sequence detector in Fig. 81.13 will be presented here.

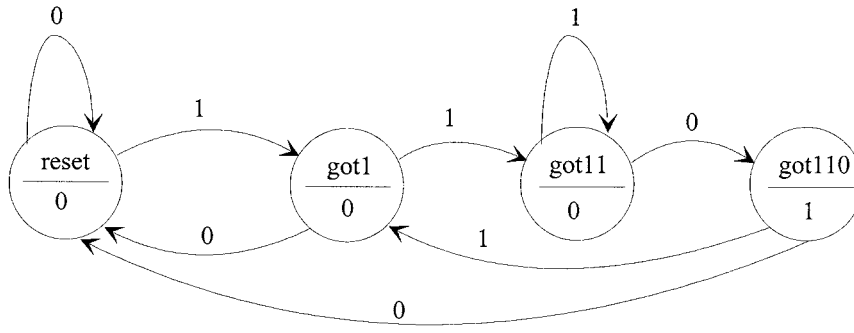

FIGURE 81.13 Moore machine state diagram.

```
module moore_110_detector (x, clk, z);
input x, clk;
output z;
reg [1:0] current;
parameter [1:0] reset = 0, got1 = 1, got11 = 2, got110 = 3;
  initial current = reset;
  always @(posedge clk)
  begin
    if     (current == reset) current = x ? got1 : reset;
    else if (current == got1) current = x ? got11 : reset;
    else if (current == got11) current = x ? got11 : got110;
    else if (current == got110) current = x ? got1 : reset;
  end
  assign z = (current == got110) ? 1'b1 : 1'b0;
endmodule
```

FIGURE 81.14 Moore machine Verilog description.

```
always @(posedge clk)
  begin
    . . .
    else if (current == got1)
        begin
            if (x) current = got11;
            else current = reset;
        end
    . . .
endmodule
```

FIGURE 81.15 Alternative coding style for Moore detector.

The Moore machine in Fig. 81.13 searches on its *x* input for the 110 sequence. When this sequence is detected in three consecutive clock pulses, the output (*z*) becomes **1** and stays **1** for a complete clock cycle. States are named according to bits detected on the *x* input. Starting in the *reset* state, it takes at least three clock pulses for the state machine to get to the *got110* state, in which output becomes **1**.

The Verilog behavioral description for this machine is shown in Fig. 81.14. The list of ports contain *x*, *clk*, and *z*, which match those in the state diagram of Fig. 81.13. A two-bit variable is declared as **reg** to hold the current state of the machine. Four two-bit parameters define state names and their binary assignments. In an **initial** block, the present state is set to the *reset* state. The main flow of the state machine is implemented by an **always** block the flow into which is controlled by the positive edge of the clock. In this statement, **if-else** statements are used to check for each of the four cases of the *current* state. For each state that matches the current state a conditional operator is used to set the current state to the next active state of the machine depending on the value of the *x* input. The condition operators can be expanded to **if-else** statements. For example, code corresponding to state *got1* of the machine could be written as shown in Fig. 81.15. Functionality of the code in Fig. 81.14 would be no different if codes for all four states were replaced with style used in Fig. 81.15.

81.5 Gate and Switch Level Description

As discussed in the previous sections, system designers are mostly concerned with high-level descriptions that can be easily developed, understood, and synthesized. Gate and switch level descriptions are also part of Verilog and are used for cell modeling, glue logic, and machine generated codes. At this level,

```
`timescale 1ns/100ps

module aoi (a, b, c, z);
//
input a, b, c;
output z;
wire w;
  and #(3, 4) n1 (z, ~a, w);
  nand #(3, 4) n2 (w, b, c);
endmodule
```

FIGURE 81.16 A gate level logic function using predefined primitives.

primitives shown in Table 181. are used in a design. These primitive structures are instantiated in a module describing a gate-level circuit or they may be used along side with other coding styles presented in the previous sections of this chapter. In this section we will show modules that consist of pure gate and switch level codes using Verilog primitives.

A Gate Level AOI

Figure 81.16 shows description of an and-or-invert gate using **and** and **nand** primitives. As in all the descriptions we have presented, the module begins with a list of inputs and outputs followed by declaration of these ports. The *aoi* module in this figure has 3 inputs and one output. The **nand** output of *b* and *c* inputs is used by the **and** structure to produce the circuit output. The declared wire, *w*, connects the output of the **nand** gate to the input of the **and** gate. Declaring such intermediate wires is not mandatory in Verilog. Instantiations of these two primitives are done much the same way as modules are instantiated with a few differences that will be discussed here.

Unlike module instantiations, the names used with instantiation of primitives are not required. In our *aoi* module, gate names *n1* and *n2* are optional. Another difference between primitive instantiations and module instantiations is the way ports are ordered. Module ports are determined according the module definition. A user can order inputs and outputs of a module in any order that he or she prefers. In predefined primitives (the same also applies to user-defined primitives), the output of the gate is always first in the port list followed by the inputs. In the primitives we have used in this design any number of inputs can be used. Another feature of primitive instantiations is the specification of delay values. In our *aoi* example a **0** to **1** propagation delay of 3 ns and a **1** to **0** propagation delay of 4 ns are used for each of the gates used in this design. Basic gate primitives take two delay values, while gates with three-state outputs take three delay parameters.

A Switch Level NAND

Shown in Fig 81.17 is a CMOS NAND using n-type and p-type transistors. Although the complete functionality of this circuit is available in a **nand** primitive, there may be cases that the two timing parameters allowed by this primitive do not provide the necessary timing accuracy required in a design. Furthermore, the **nand** predefined primitive only produces **0** and **1** output values that may not be sufficient for designers interested in charge sharing issues and three-state values. In such instances, Verilog allows description of a system at the switch level using switch primitives shown in Table 1. Simulation at the switch level provides detailed information but is slow. In large designs switch level simulation is avoided as much as possible. This level of modeling and simulation is useful when designing cells and evaluating their detailed functionality.

Figure 81.18 shows *cmos_nand* module that corresponds to diagram of Fig. 81.17. Built-in structures **nmos** and **pmos** are used with three delay values. Switches in Verilog can use up to three delay values.

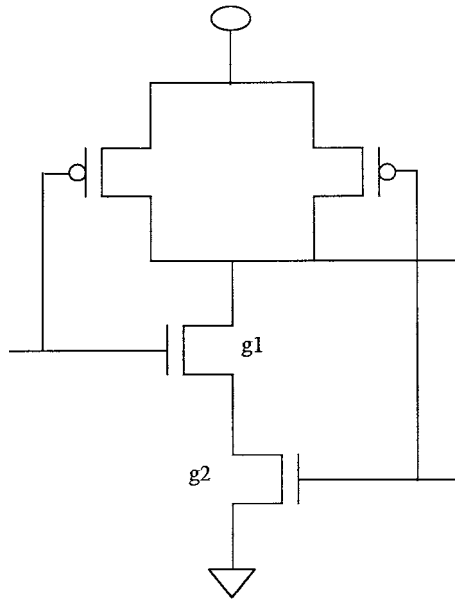

FIGURE 81.17 Switch level CMOS NAND.

```
`timescale 1ns/100ps

module cmos_nand (a, b, z);
//
input a, b;
output z;
supply1 vdd;
supply0 gnd;
wire im1;
  nmos #(0, 0, 4)
    g1 (z, im1, a),
    g2 (im1, gnd, b);
  pmos #(0, 0, 5)
    g4 (z, vdd, a),
    g5 (z, vdd, b);
endmodule
```

FIGURE 81.18 Verilog code for a switch level CMOS NAND.

The first two parameters are for **0** to **1** and **1** to **0** transitions, while the third timing parameter is the delay when the switch opens. Labels *g1*, *g2*, *g4*, and *g5* are optional, and we have used them for making a better correspondence between diagram of Fig. 81.17 and code of Fig. 81.18. The last field of switch instantiations in Fig. 81.18 lists output, input, and control terminal connections, respectively. Because switches are unidirectional, the output-input connections are based on the direction of flow of data out of the switches. For n-type transistors, gnd terminal is input pushing 0 into the switch, and for p-type transistors, vdd terminal is considered as input pushing 1 into the switch. Control connections (transistor gate terminals) are the last of the three terminal connections.

```
`timescale 100 ns/1ns

// Verilog test bench and stimulus for
cmos_nand
module test_cmos_nand;
reg a, b;
wire z;
  cmos_nand n (a, b, z);
  initial  begin
    a = 0; b = 1;
    #25 a = 1; #11 b = 0;
    #10 a = 0; #10 b = 1;
    #11 a = 1; #11 b = 0;
    #30 $stop;
  end
endmodule
```

FIGURE 81.19 Verilog code for a test bench for testing cmos_nand module,

81.6 Test Bench Descriptions

Verilog provides constructs that can be used for applying data to a design module and monitoring its response. A module in which this is done is referred to as a test bench. To show how a test bench is developed and the tasks performed by such modules, a simple test bench is developed for the CMOS NAND gate of Fig. 81.18. The test bench is shown in Fig. 81.19. This is a Verilog module that instantiates the module corresponding to the circuit under test and uses behavioral Verilog constructs to generate data for the inputs of the circuit. In our simple example, an **initial** block applies values to the inputs of cmos_nand module. Assignment of values is timed to allow for the internal propagation delays of the NAND gate. The time control statements that begin with a number sign, e.g., #25, suspend the flow of program for the amount of time given before the next statement is executed. An **initial** block is similar to an **always** block but only runs once and terminates when program flow reaches its last statement. The **$stop** statement is a Verilog system task that stops the simulation when it is reached. Simulation of test_cmos_nand module ends after 108 ns from the start of simulation.

81.7 Summary

This overview introduced the main concepts of the Verilog Hardware Description Language. Entities needed for description of designs were presented. We have shown ways of describing small components, medium-size parts, complete systems, and controller descriptions. In addition we have presented gate and switch level descriptions in Verilog that make this language a very effective tool for modeling and design of VLSI circuits. Descriptions shown here are general in style and represent most coding styles required in a large design environment.
